The configuration of choice for most EDS systems places the magnets on board and the electrical conductors on the guideway. One disadvantage of the EDS system is that, because the lift force depends on the speed, mechanical support must be used at rest and at low speeds until the lift-off speed where the magnetic suspension force exceeds the force of gravity is reached. Pneumatic tires mounted on retractable landing gears can provide suitable mechanical support. Support at rest or at low speed can also be achieved with repulsive magnetic forces. This can be accomplished using AC-excited coils interacting with eddy currents induced in reaction rails or coils. However, this method tends to be rather energy-intensive.

A variety of combinations of vehicle-borne magnets and guideway-mounted electrical conductor configurations have been devised for EDS systems. These include the use of continuous-sheet and discrete-coil guideways. Three configurations are illustrated in Fig. 2. In all cases, the guideway-mounted conductors are completely passive. The null-flux coil configurations have high lift efficiency and can produce forces in two opposing directions (up and down or left and right).

Both permanent and superconducting magnets (SCMs) can be used as the magnetic field sources. Designs utilizing permanent magnets have been investigated by both American Maglev Technology, Inc. and by Lawrence Livermore National Laboratory. The latter group has incorporated permanent magnets in Halbach arrays, which provide greater field strength at the pole faces per unit weight and substantially reduced stray fields behind the arrays.

The principal advantage of SCMs is greater force per unit weight. This is due to the strong magnetic fields that can be produced over large volumes of space and because the SCMs do not use iron cores. Air gaps on the order of 10 to 20 cm are possible with SCMs. Such large air gaps help ensure against contacting the guideway surfaces when guideway irregularities or disturbances including wind gusts and seismic activity are encountered. However, in practical designs, component parts tend to take up at least some of that space, reducing the actual clearance between the outer vehicle and guideway surfaces to 6–8 cm. The major disadvantage is that the superconducting windings must be kept below their critical temperatures to maintain their superconducting states. This requires the use of specially designed cryostats and cryogenic refrigeration systems. Superconducting magnets used in transportation applications are of the "low-temperature" type, which are operated at liquid-helium temperatures. The Japanese have successfully developed efficient cryogenic systems for use with SCMs on their high-speed "linear motor cars." The newer "high-temperature" superconductors, which can be cooled with liquid nitrogen, are not yet ready for such applications.

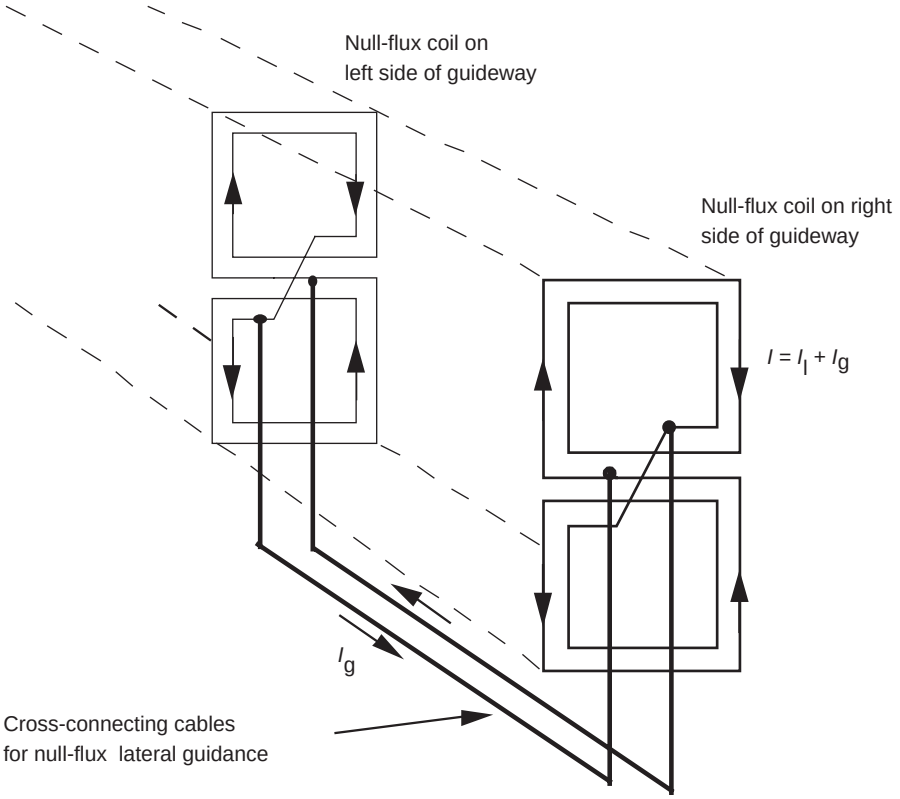

FIGURE 6 Connections of null-flux coil system for null-flux lift and guidance.

EDS systems use eddy current repulsion for guidance as well as lift. Depending on the type of lift and propulsion system being used, and the guideway configuration, either separate magnets or the same magnets can be used for lift and guidance. In the Japanese linear motor car system, the same onboard SCMs provide the magnetic field for lift and lateral guidance and serve as the field sources for the secondary side of the LSMs. Eddy currents induced in the null-flux coils mounted on the guideway sidewalls in this system interact with the magnetic fields of the SCMs to produce both lift and guidance forces. The guidance forces are enhanced by cross-connecting the null-flux coils on opposite sides of the guideway (Fig. 6). Null-flux lift and guidance rely on the same operating principle. That is, the two loops of a null-flux coil are wound in opposite directions so that when a magnet is in the neutral position, an equal amount of magnetic flux links both loops so that no net current flows in the two connected loops and hence, no force is generated. When the magnet is displaced relative to the neutral position, then one loop links more flux than the other, a net current flows in both loops, and a restoring force is produced.

4. MAGLEV DEVELOPMENT HISTORY

One of the earliest known mentions of the concept of high-speed ground transportation using maglev technology appeared in a fictional story written by Robert Goddard, father of the rocket, in 1907. By 1911, two patents were awarded to Graeminger for attractive force suspension systems. He proposed several methods, involving mechanical contact between the electromagnets and the reaction rail, for overcoming the inherent instability in attractive force systems. In the October 18, 1912 edition of *The Engineer*, the article "Foucault and Eddy Currents Put to Service" began with the line: "There was demonstrated some months ago at Mount Vernon, which is really a suburb of New York City, a levitating transmitting apparatus invented by Mr. Emile Bachelet." Bachelet actually conducted a series of experiments in which he levitated plates of various metals above a coil excited with 60 Hz single-phase current. The eddy currents induced in the plates by the time-varying magnetic field reacted against that field to produce the resultant lift force. He designed a test vehicle consisting of aluminum reaction plates

for lift and iron framing pieces that served as the reaction rails for the sequentially excited coils of a simple type of LIM. The energy requirements, though large, were minimized by the clever use of limit switches that turned the levitating and propelling coils on and off as the vehicle passed. Little further development was reported until the 1930s, when Hermann Kemper, a German inventor, demonstrated the first noncontact method for stably suspending an object with attractive magnetic force. His inventions, for which he was awarded patents in 1934 and 1935, were the basis for modern attractive-force-based systems.

Following a long hiatus, widespread interest in maglev technology suitable for intercity and urban applications was renewed in the late 1960s and early 1970s. After a decade of experimentation and analysis in Germany, it was decided in 1978 to use EMS technology with separate lift and guidance electromagnets and long stator LSMs with iron cores for propulsion (see Fig. 1). By 1985, the first 20 km section of the Emsland test track, which included a closed loop at the north end, was completed and the first high-speed prototype commercial vehicle (the TR06) reached a speed of 355 km/h. A second 10 km long closed loop was added to the south end, permitting continuous running in 1987. Continued technical refinements resulted in the TR07 200-passenger vehicle prototype, which reached speeds in excess of 450 km/h in the early 1990s. Visitors could purchase rides, for 20 Deutsch Marks, on the TR07, which reaches speeds near 450 km/h. Construction of the first commercial route is completed in China and is expected to begin revenue service in early 2004.

At the same time that the Germans were developing the high-speed EMS maglev system, several countries including Germany, Japan, and the United Kingdom undertook the development of EMS technology for low-speed applications. Japan Airlines initiated a long-term program in the early 1970s to develop and commercialize an EMS maglev system using the same "U"-shaped magnets and reaction rails for both lift and guidance and short-stator LIMs for propulsion (see Fig. 3). Commercialization was taken over by the Chubu HSST Development Corporation in 1991. Various versions of the HSST family of vehicles have been demonstrated in public venues since the early 1980s, but thus far no systems have been put in revenue service. Developments continued in the 1990s on a 1.6 km test track in Nagoya. The M-Bahn system, which used permanent magnets stabilized by a mechanical contact system and propelled by a LSM, was developed in Germany in the early 1980s and placed in demonstration service in Berlin in the late 1980s but was never operated in revenue service. The first commercial EMS maglev system in the world was installed at the Birmingham Airport in the United Kingdom in 1984. Based on experiments at the British Rail Research and Development Division, lift and guidance were provided by the same controlled DC electromagnets reacting against laminated iron rails in the longitudinal flux configuration and a LIM provided the propulsion. The system shuttled passengers from the air terminal to an adjacent railway station until it was retired in 1995. Short-stator EMS systems are also under development in other countries including Korea and the United States. A consortium of organizations, including American Maglev Technology Corporation, is building a people-mover system at the Old Dominion University in Virginia. Additional efforts at urban maglev technology development, under Federal Transit Administration sponsorship, are in progress at Sandia National Laboratory and at General Atomics Corporation.

Development of the EDS system technology commenced with U.S. scientists Powell and Danby, who received a patent in 1969 for the design of the first SCM-based suspension and stabilization system. It utilized the same set of vehicle-borne SCMs for null-flux lift and guidance. The use of SCMs greatly reduced the energy requirements that stymied further development of repulsive-force, eddy-current-based suspension concepts first demonstrated by Bachelet in 1912. They also allowed large air gaps on the order of 10 to 20 cm. In the early 1970s, researchers around the world, including those in the United States, Canada, the United Kingdom, Germany, and Japan, subsequently picked up on some of Powell and Danby's ideas and began developing their own versions of EDS systems using SCMs. North American participants included researchers at Massachusetts Institute of Technology, Stanford Research Institute, Ford Motor Co., and the Canadian Institute of Guided Ground Transport at Queen's University. Government support for maglev research in the United States stopped in the mid-1970s but work continued in other countries, including Canada, the United Kingdom, and, most notably, in Japan, where development has proceeded to the stage of commercial readiness on the high-speed Japanese linear motor car.

Following several years of basic development and testing of their superconducting maglev concept at the Japanese Railway Technical Research Institute,

construction of the 7.1 km long test track at Miyazaki on Kyushu Island was initiated in 1977. The guideway was of the inverted "T" type with levitation coils (called ground coils) placed horizontally on the floor and LSM stator windings mounted vertically on either side of the stem of the inverted "T." In 1979, the unmanned MLU-500 test vehicle incorporating SCMs reached a speed of 517 km/h. Shortly thereafter, the superstructure of the guideway was converted to a "U" shape and a long program of developmental and testing of the MLU family of vehicles commenced. In the late 1980s, the ground coils were replaced with null-flux lift coils mounted on the vertical sidewalls of the guideway. Up to that period, separate coils were used on the guideway for lift and combined propulsion and null-flux guidance. In the late 1980s and early 1990s, sections of the guideway coils were replaced with a new set of coils that served all three functions of lift, guidance, and propulsion. Meanwhile, the construction of a new 42.8 km test track began in the Yamanashi Prefecture approximately 70 km west of Tokyo. Originally planned so that it could be extended to form a commercial route from Tokyo to Osaka, the first phase consisted of an 18.4 km "priority section" that was completed in 1995. Due to the mountainous terrain, approximately 87% of its length is in tunnels. A 12.8 km portion of the priority section was double-tracked to permit tests of passing vehicles. The first test vehicle delivered to the test track in July 1995 consisted of a full-scale prototype commercial three-car train set referred to as the MLX01. Following preliminary trials, the test speed was gradually increased to 550 km/h in March 1998. After a second prototype vehicle arrived, tests were conducted with trains passing each other at relative speeds as high as 1000 km/h. A new system under development in Switzerland is the SwissMetro. It is a high-speed EDS system designed for operation in partially evacuated tunnels. Such a system is motivated by the mountainous terrain and the desire to reduce the propulsion power required to overcome the large aerodynamic drag force present at high speed in tunnels.

In the United States, the National Maglev Deployment Program, under the auspices of the Transportation Equity Act for the 21st Century, is in its second phase. Two consortia are competing for final approval of their proposed high-speed maglev projects. One connects Baltimore to Washington, DC and the other connects the Pittsburgh Airport to the city and its eastern suburbs. Another project, under the sponsorship of the state of Florida, and the direction of Powell and Danby, will link the Titusville Airport to the Kennedy Space Center and the cruise terminals at Port Canaveral. In addition, the development of low-speed maglev systems for urban mass transit applications is being sponsored by the Federal Transit Administration.

5. ADVANTAGES OF MAGLEV TECHNOLOGY FOR HIGH-SPEED TRANSPORTATION

High-speed maglev technology offers four main advantages: noncontact operation; low-mass vehicles (on a per seat basis, maglev vehicles weigh approximately one-third to three-quarters as much as high-speed trains); high speed; and wayside system control and self-propelled vehicles (each car contains its own secondary part of a LSM).

Noncontact operation means that vehicle traction does not depend on adhesion between contact surfaces, e.g., wheels and rails. Combined with lower mass, vehicles can accelerate and brake faster and can climb steeper grades independent of whether the surfaces are wet or dry. Noncontact also means lower noise levels than for conventional trains in urbanized areas, permitting higher urban and suburban speeds or, alternatively, reduced or eliminated noise abatement costs. In addition, maintenance costs associated with routine wheel, rail, and bearing wear are eliminated. (However, if the specific maglev system design requires a landing gear for low-speed operation, some maintenance costs will be incurred for landing gear wear.) The combination of noncontact operation and reduced vehicle weight translates into reduced stress on guideway support structures and construction costs. At grade, guideway costs have been estimated to be more for maglev systems than for conventional trains, but approximately the same as or even less than that for elevated guideways, depending on the specific technology. A technology assessment conducted by the U.S. Army Corps of Engineers in the mid-1990s estimated that the technology cost (omitting profits and land acquisition costs) for elevated maglev system concepts would range from $18 to $28 million/double-track mile and at grade systems from approximately $11 to $25 million/double-track mile (all in terms of 1993 U.S. dollars). Estimates place the total cost for the elevated German Transrapid system at approximately $35 million/double-track mile. Total costs for existing high-speed rail systems range widely

depending on country, terrain, and percentage of elevated track and tunnels used. In terms of 1993 U.S. dollars, costs range from $7.3 to $21.5 million/double-track mile in France and from $32 to $50 million/double-track mile in Germany.

High speed translates into reduced trip times. Existing maglev systems have demonstrated operating speeds of passenger-carrying vehicles in the range of 450 to 550 km/h. Higher speeds are possible in open air but become increasingly energy-intensive due to the rapidly increasing aerodynamic drag force with speed. However, higher speeds are practical in partially evacuated tunnels. Figure 7 shows a comparison of line haul times versus trip length for commercial jet aircraft and high-speed ground transportation (HSGT) modes. Line haul time refers to time spent in the vehicle from terminal to terminal and does not include terminal access or egress times or times spent in the terminals. Time spent on the ground by aircraft in major airports is clearly a disadvantage that is only compensated for by higher speeds at flight altitude at flight distances greater than approximately 400 to 500 miles. Figure 8 shows a more realistic comparison of the total trip times, including access and egress time and times spent in the origin and destination terminals for maglev and jet aircraft. The maglev makes two additional urban stops to pick up and discharge passengers (reducing access and egress times); the aircraft makes no additional stops. The maglev is the clear winner even for distances greater than 900 miles.

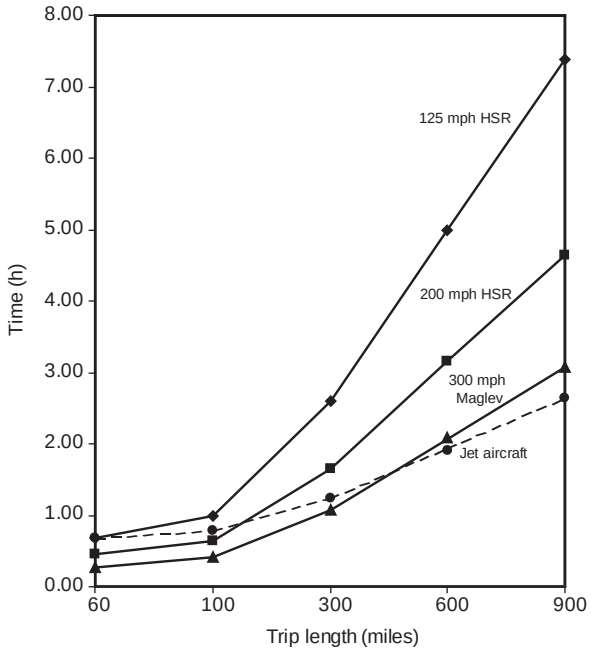

FIGURE 7 Line-haul trip times versus trip length for various high-speed modes.

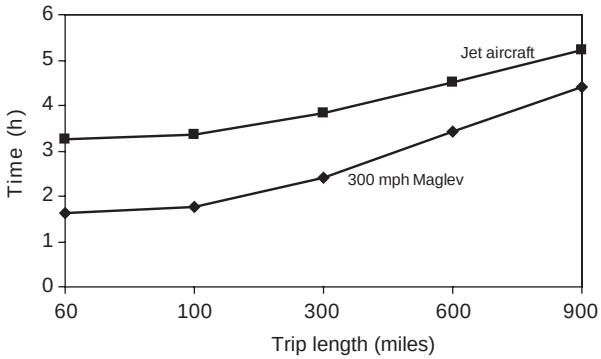

FIGURE 8 Total trip times versus trip length. Maglev makes two urban stops. Jet aircraft makes no stops.

Since maglev cars are self-propelled, they can be operated as individual cars (each carrying 50 to 100 passengers) or as linked cars, depending on travel demand. Furthermore, since each car or set of linked cars is controlled by the wayside control system, headways (times between vehicles) can be reduced to less than 30 s, if necessary, to accommodate travel demand. In contrast, most high-speed trains are operated as standard train sets consisting of one or two locomotives and 8 or 10 coaches. Consequently, the technology provides considerable flexibility to meet a wide range of passenger demand and still maintain a very high-frequency service.

Two public benefits of maglev vehicle systems are reduced dependence on petroleum-based fuels and reduced emissions of air pollutants. The energy used by a maglev system comes from the electric utility grid. Consequently, the emissions produced and energy consumed are strongly dependent on the mix of electricity-generating technologies that supply the grid. To the extent that renewable energy sources, such as hydroelectric, wind, solar, and nuclear technologies, are used, the emissions can be greatly reduced. Furthermore, new fossil-fuel-generating technologies, including combined-cycle gas turbines and fuel cells, that are substantially more efficient than traditional technologies are coming into the mix. In addition, nationally, less than 4% of the electricity is generated by combustion of petroleum-based fuels. Hence, to the extent that trips are diverted from conventional modes to maglev vehicles, the United States moves closer to energy independence and a cleaner environment. The reduction in emissions and energy use comes about for a variety of reasons including the high efficiency

of the maglev technology itself, the efficiency of the generating plants, and the manner in which the maglev vehicles are operated. The efficiencies are somewhat design-specific, e.g., systems incorporating SCM technology are more efficient than those that use conventional electromagnets. Generally, SCMs are operated in the "persistent current" mode, whereby once energized, the winding is disconnected from the power source and the current in the winding continues to flow without loss. Power is then required only to keep the SCM below its critical temperature. Propulsion energy is used only when the vehicles are moving (there is no need for idling). Maglev vehicle systems have the added advantage that they utilize three-phase power, which provides a more balanced load to the utility grid than catenary-based systems, which can use only single-phase power. In addition, the use of smaller coaches with shorter headways tends to distribute the load to the utility system more evenly over time. Finally, since maglev guideways are connected together electrically, there is a greater opportunity to convert the power derived from regenerative braking of some vehicles into propulsion power of other vehicles.

Figure 9 shows a comparison of energy used per seat · mile for jet aircraft and HSGT modes as a function of trip length. Aircraft consume the greatest amount of energy except for distances greater than approximately 700 miles. Figure 10 shows a similar comparison for which the HSGT modes make two additional urban stops and one in-route stop, whereas the aircraft makes only one in-route stop. In this case, the aircraft uses more energy for distances further than 900 miles.

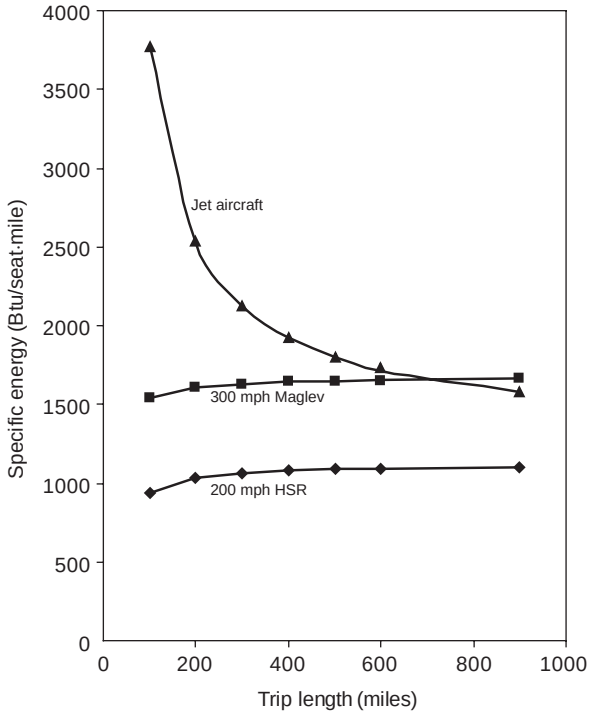

FIGURE 9 Energy per seat · mile used by HSGT and short-haul jet aircraft (no stops).

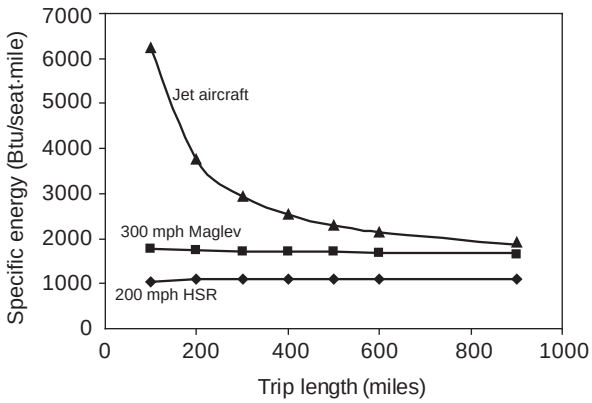

FIGURE 10 Same as for Fig. 9, but includes energy for two urban in-route stops and one in-route stop for HSGT and one in-route stop for jet aircraft.

Glossary

Alfvén wave A wave that propagates along magnetic lines of force because of the tension of the field lines; also called a hydromagnetic wave.

Ampère's law The law that, in pre-Maxwell theory, determines the magnetic field created when electric current flows.

beta The name given to the ratio of the gas pressure to the magnetic pressure in a conducting fluid; plasma β is one of the figures of merit awarded to a magnetostatic equilibrium.

dynamo The process whereby a magnetofluid self-excites and amplifies a magnetic field.

electromotive force The electric field created by a changing magnetic field. Motive refers to its ability to move charge in a conductor (i.e., generate current).

Faraday's law The law that determines the electromotive force created by a changing magnetic field.

field line A curve that is everywhere parallel to the direction of the prevailing magnetic field; also called a line of (magnetic) force, it is part of a family of such lines, one of which passes through each point of space.

field line tension Part of the stress that a magnetic field **B** exerts on a medium and interpreted as a tension in a flux tube of B^2/μ_0, per unit cross-sectional area of the tube; μ_0 is the permeability of the medium.

figure of merit A number that quantifies the susceptibility of a plasma equilibrium to a certain type of magnetohydrodynamics instability.

flux tube See magnetic flux surface.

force-free field The field in a particular type of magnetostatic equilibrium in which the Lorentz force vanishes and in which field and current are parallel.

gradient A term used to indicate how rapidly a scalar or vector field changes with position. In the case of a scalar field, Φ, it is used to describe the vector field that is parallel to the direction in which Φ increases most rapidly; it is equal to the spatial rate of change of the scalar in that direction and is denoted by $\nabla\Phi$.

interchange-ballooning mode An instability driven by the combined effects of pressure gradient and average, or locally, unfavorable curvature of the field lines.

International Thermonuclear Experimental Reactor (ITER) a large-scale experiment, run by an international consortium, designed to study the physics of burning plasma.

kink safety factor A figure of merit quantifying the susceptibility of a plasma equilibrium to kink instability.

kink-tearing mode An instability driven by current gradients.

line of force A curve that is everywhere parallel to the direction of the prevailing magnetic field; also called a (magnetic) field line, it is part of a family of such lines, one of which passes through each point of space.

Lorentz force The force per unit volume on a fluid conductor that carries an electric current (density **J**) and lying in a magnetic field **B**; mathematically, it is the vector product of **J** and **B** and can also be represented by magnetic stresses.

magnetic helicity A property of a magnetic field that is preserved in the motion of a fluid that is a perfect electrical conductor.

magnetic pressure Part of the stress that a magnetic field **B** exerts on a medium and interpreted as an isotropic pressure $B^2/2\mu_0$, where μ_0 is the permeability of the medium.

magnetic reconnection The process by which a magnetofluid forms thin current layers that change the field line topology and dissipate magnetic energy.

magnetic relaxation The process by which a magnetofluid relaxes to its minimum energy state subject to certain constraints.

 © 2004 Elsevier Inc. All rights reserved.

magnetic shear The rate at which the direction of a magnetic field changes with position **x**; a special case is used in plasma physics as a figure of merit.

magnetic stresses Stresses that are equivalent in their dynamical effect to the Lorentz force.

magnetic surface, also called a flux tube or a magnetic flux surface A surface composed of field lines so that the magnetic field, **B**, is everywhere tangential to it. The flux of **B** contained within the surface is the same everywhere along its length.

Ohm's law The law that states that the electric current density, **J**, produced in a motionless conducting medium by an electric field **E** is proportional to **E**. The constant of proportionality is the electrical conductivity of the medium.

pre-Maxwell theory The approximate form of electromagnetic theory that existed prior to Maxwell's discovery of displacement currents.

scalar product A convenient mathematical abbreviation used to describe a quantity derived from two vectors, **F** and **G**, and in magnitude is equal to the product of their magnitudes, |**F**| and |**G**|, and the cosine of the angle between them; it is written as $\mathbf{F} \cdot \mathbf{G}$.

Taylor relaxation The process proposed by J. B. Taylor whereby a magnetofluid relaxes to its minimum energy state subject to the constraint of constant global magnetic helicity.

toroidal Alfvén eigenmode (**TAE**) A particular type of Alfvén wave appropriate to toroidal geometry.

vector product A convenient mathematical abbreviation used to describe a vector that is perpendicular to two other vectors, **F** and **G**, and that in magnitude is equal to the product of their magnitudes, |**F**| and |**G**|, and the sine of the angle between them; it is written $\mathbf{F} \times \mathbf{G}$, where **F**, **G**, and $\mathbf{F} \times \mathbf{G}$ form a right-handed triad.

Magnetohydrodynamics (*MHD*) is the study of the movement of electrically conducting fluids in the presence of magnetic fields. The magnetic field influences the fluid motion through the Lorentz force, which is proportional and perpendicular to the magnetic field and the electric current flowing through the conductor: The magnetic field is affected by the electric current created by an electromotive force which is proportional and perpendicular to the magnetic field and the fluid velocity. It is this duality between magnetic field and fluid flow that defines the subject of MHD and explains much of its fascination (and complexity).

1. INTRODUCTION

Magnetohydrodynamics (MHD) is the marriage of hydrodynamics to electromagnetism. Its most famous offspring is the Alfvén wave, a phenomenon absent from the two subjects separately. In fact, many consider the discovery of this wave by Alfvén in 1942 to mark the birth of MHD. Initially, MHD was often known as hydromagnetics, but this term has largely fallen into disuse. Like MHD, it conveys the unfortunate impression that the working fluid is water. In reality, the electrical conductivity of water is so small that MHD effects are essentially absent. Moreover, many fluids used in MHD experiments are antipathetical to water. Even as fluid mechanics is now more widely employed than hydrodynamics the terms magnetofluid mechanics or magnetofluid dynamics, which are already sometimes employed, may ultimately displace MHD. Magnetofluid is already widely used in MHD contexts.

Since electric and magnetic fields are on an equal footing in electromagnetism (EM), it may seem strange that the acronym EMHD was not preferred over MHD. There are two reasons for this. First, to invoke EM theory in its full, unapproximated form would, in most contexts, add complexity without compensating enlightenment. It usually suffices to apply the form of EM theory that existed in the 19th century before Maxwell, by introducing displacement currents, cast the theory into its present-day form. In this pre-Maxwell theory of EM, there are no displacement currents and the electric and magnetic fields are not on an equal footing; the magnetic field is the master and the electric field the slave. Consequently, MHD is an appropriate acronym, but EMHD is not. Situations in which this is untrue and in which full EM theory is needed involve relativistically moving fluids and are too seldom encountered to be described here; in this article, the pre-Maxwell approximation is used throughout. The second reason why EMHD cannot be used is that the acronym is generally understood to mean electron MHD, which studies the MHD of the electron fluid in a two-fluid description of a plasma, the ions forming the other fluid. This topic is also outside the scope of this article.

A significant branch of MHD is the study of Magnetostatic equilibria (MSE). This subject is the MHD analogue of hydrostatics, the branch of fluid mechanics that deals with fluids at rest, with the pressure gradient in the fluid balancing external forces such as gravity. Similarly, in MSE the fluid is motionless and the pressure gradient balances the Lorentz force (and any other forces present).

The two main applications of MHD are technological—to liquid metals and to plasmas. There is little doubt that the former has had the greater

impact on society. It includes the casting and stirring of liquid metals, levitation melting, vacuum-arc remelting, induction furnaces, electromagnetic valves, and aluminum reduction cells. Another application, the flow of a liquid metal in the blanket surrounding a thermonuclear reaction chamber, touches on the other main area: plasma MHD. The reactor contains a rarefied plasma of deuterium/tritium (DT) that is raised to a high enough temperature for these nuclei to fuse and release energy. The economic promise of such a device in generating magnetic fusion energy (MFE) has provided a powerful incentive for studying plasma MHD and has led to significant new insights, particularly into the structure and stability of MSE. In addition to these practical applications, the elucidation of a wide variety of magnetic phenomena in nature depends on an understanding of MHD. Astrophysics and geophysics provide abundant examples, including the magnetism of the earth, planets, and satellites, that of the sun and other stars, and that of galaxies.

This article describes the simplest form of MHD theory, in which the working fluid is a homogeneous, continuous medium. This may or may not (depending on context) be a satisfactory description of a plasma. In general, a plasma and its dynamics are described by kinetic equations that govern distribution functions for electrons, ions, and (if the plasma is incompletely ionized) neutral atoms. The distribution function, $f(\mathbf{x}, \mathbf{v}, t)$, of any of these species is proportional to the probablility that a particle of that species at position $\mathbf{x}$ is moving with velocity $\mathbf{v}$ at time t. In certain cases, such a description can be greatly simplified by replacing the kinetic equations for the functions f by a closed set of fluid equations. This happens when the dependence of each f on $\mathbf{v}$ is close to what it would be if the plasma were in local thermodynamic equilbrium, as seen by an observer moving with the mean velocity, $\mathbf{V}(\mathbf{x}, t)$, of the species at $\mathbf{x}$ and t. Such a distribution is termed Maxwellian. The distribution functions are then replaced by ion, electron, and neutral densities, n_i, n_e, and n_n, respectively, that give the total numbers of each species per unit volume at $\mathbf{x}$ and t, with each fluid having its own (mean) velocity. Although this may seem (and is) very complicated, it is far less forbidding than the alternative (i.e., solving for the evolution of the distribution functions).

The method of closure described previously necessarily involves an approximation of restricted validity. Single-fluid MHD also assumes that the characteristic length scale, $\mathscr{L}$, is large compared with the Debye length, $\mathscr{L}_{\text{debye}}$. This length quantifies the distance over which n_e and n_i can differ substantially from one another. When $\mathscr{L} \gg \mathscr{L}_{\text{debye}}$, these densities are closely equal and the plasma is very nearly electrically neutral. A second requirement for simple one-fluid MHD to hold is that $\mathscr{L}$ be large compared with the mean free path between particle collisions in the plasma and in comparison with the gyroradii. (A charged particle in a magnetic field would, in the absence of collisions with other particles, orbit about a field line in a spiral having a certain gyroradius that depends on its mass and charge and on the field strength.) These demands are more easily satisfied in many astrophysical contexts than in a thermonuclear reactor chamber. Nevertheless, one-fluid MHD can provide useful qualitative insights into the structure and stability of plasmas relevant to MFE.

To simplify the following discussion, the abbreviations shown in Table I will usually be employed. In particular, velocity means fluid velocity, density stands for the mass density of the fluid, field means magnetic field, current is short for electric current density, conductor means conductor of electricity, and potential means electric potential. Script letters—$\mathscr{L}$, $\mathscr{T}$, $\mathscr{V}$, $\mathscr{B}$, $\mathscr{J}$, $\mathscr{E}$, etc.—are used to indicate typical magnitudes of length, time, velocity, field, current, electric field, etc.

The aim of this article is to provide as simple an account of MHD as possible—one that is slanted toward the MFE field but one that involves a minimum of mathematics. Some familiarity with vector fields is necessary, however.

TABLE I

Abbreviations

Quantity	Symbol	Magnitude	SI unit
Time	t	$\mathscr{T}$	Seconds (s)
Position	$\mathbf{x}$	$\mathscr{L}$	Meters (m)
Velocity	$\mathbf{V}$	$\mathscr{V}$	m/s
Density	ρ	—	Kilogram/m^3 (kg/m^3)
Pressure	p	—	Newton/m^2 (N/m^2)
Temperature	T	—	Kelvin (K)
Field	$\mathbf{B}$	$\mathscr{B}$	Tesla (T)
Current	$\mathbf{J}$	$\mathscr{J}$	Amp/m^2 (A/m^2)
Charge density	ν	—	Coulomb/m^3 (C/m^3)
Potential	Φ	—	Volt (V)

2. PRE-MAXWELL APPROXIMATION

Some readers may value a brief review of the relevant concepts in EM theory that underpin MHD; others may prefer to skim this section and move ahead to Section 3.

Under discussion are systems having characteristic length, time, and velocity scales, $\mathscr{L}$, $\mathscr{T}$, and $\mathscr{V}$, respectively, for which $\mathscr{L} \ll c\mathscr{T}$ and $\mathscr{V} \ll c$, where c is the speed of light. In these circumstances, EM phenomena are well described by an approximation that was in use before Maxwell introduced displacement currents and his famous equations into EM theory. This approximation, which is also called the nonrelativistic approximation (since it implies that c is infinite), is summarized.

Electrostatics is the study of static electricity. Each positive (negative) electric charge experiences an attraction toward every negative (positive) charge and a repulsion from every other positive (negative) charge. The sum, **f**, of all these forces on a charge e is proportional to e and is conveniently represented by an electric field, $\mathbf{E} = \mathbf{f}/e$. Suppose that, in steady conditions, a test charge is carried around a closed curve Γ, where by test charge is meant a charge so small that it does not have any effect on the other charges. As the charge describes Γ, the agency that moves it will sometimes do work against the force $\mathbf{f} = e\mathbf{E}$ and will sometimes receive energy from it but, when the circuit is complete the net gain or loss of energy is zero. Such forces are termed conservative and this fact is expressed mathematically by the statement that $\mathbf{E} = -\nabla\Phi$, where Φ is the electric potential. (Here, $\nabla\Phi$ denotes the gradient of Φ, a vector that has Cartesian components $\partial\Phi/\partial x$, $\partial\Phi/\partial y$, $\partial\Phi/\partial z$.) If positive, $\Phi_1 - \Phi_2$ is the energy received from the electric field when a unit positive charge moves from a location where the potential is Φ_1 to one where the potential is Φ_2; if negative, it is the work that must be done to move the charge from the first location to the second. The force $\mathbf{f} = -e\nabla\Phi$ acts to move a positive charge in the direction of **E** from a region of higher potential to one of lower potential.

If a conductor carries a net charge, the mutual repulsion between charges quickly drives them to the surface of the conductor, where they arrange themselves with a surface charge density such that the surface is at a uniform potential Φ. The electric field is then normal to the surface and cannot move charges along the surface. The charge distribution is therefore static. Beneath the surface charge layer, **E** is identically zero, as is the volumetric charge density ϑ. If different areas of the surface are held at different potentials, as at the two ends of a straight wire, **E** is no longer zero in the conductor and a charge e experiences the force $\mathbf{f} = e\mathbf{E}$. If $e > 0$ (< 0) this moves it from (to) the area at the higher potential to (from) the area at the lower potential. The resulting flow of charge is called an electric current. Its density, **J**, is proportional to the force **f** and, according to Ohm's law, it is given by $\mathbf{J} = \sigma\mathbf{E}$, where σ is the electrical conductivity of the conductor in siemens/meter (S/m). To relate this to the more familiar form of Ohm's law, consider again the example of the straight wire. If its length is L meters, a potential difference of Φ volts between its ends creates an electric field of strength Φ/L (V/m) and therefore a current of density $J = \sigma\Phi/L$ A/m^2. If the cross-sectional area of the wire is A, the total current is $I = JA = \sigma A\Phi/L = \Phi/R$, where $R = L/\sigma A$ is the electrical resistance of the wire in ohms (Ω). This result, $I = \Phi/R$, is the form of Ohm's law encountered in elementary texts on electricity and magnetism.

In pre-Maxwell theory, the flow of charge resembles the flow of a constant density fluid, for which mass conservation requires that the net flow of mass into any closed volume is equal to the net flow out of that volume. In the same way, charge conservation requires that the inward flow of electric current into the volume balances its outward flow.

Whenever current flows, a magnetic field, **B**, attends it. This is shown in Fig. 1, again for a straight wire C having a circular cross section of radius a. In this case, **B** is in the θ direction, where θ is the azimuthal angle around the wire. Some lines of (magnetic) force are shown. A line of force, also called a field line, is actually not a line but a continuous curve whose tangent is everywhere

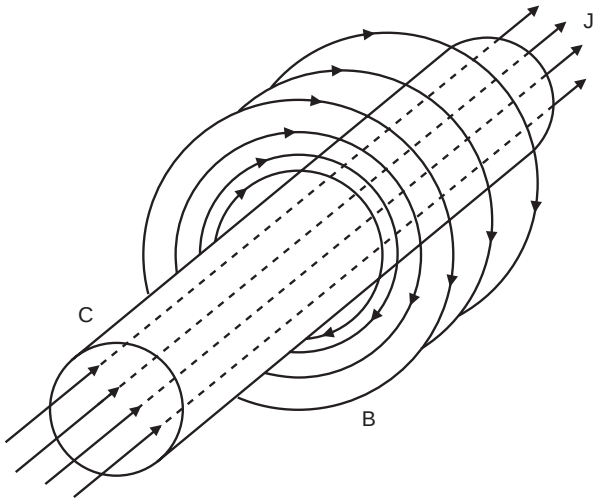

FIGURE 1 Lines of force created by a current-carrying wire C.

parallel to **B**. Although lines of force pass through every point in space, sketches such as Fig. 1 can only show a finite number. The density of lines indicates the strength of the field. Where lines bunch together (spread apart) the field is stronger (weaker). Magnetic charges, analogous to electric charges, do not exist. This means that a line of force may close on itself or cover a magnetic surface ergodically (i.e., without closing; Fig. 2), or it may continue to infinity, but it cannot terminate. It also means that (as for **J**) the net flow of **B** into any closed volume is equal to the net flow of **B** emerging from the volume. A bundle of lines of force contained in a magnetic surface form a flux tube (Fig. 3). The net flow of **B** into one end of a volume of the tube bounded by two of its cross sections is the same as the net flow that emerges from the other end. This is called the strength of the tube.

To determine **B** from **J** in a situation such as that sketched in Fig. 1, Ampère's law is required. This states that the component of **B** along any closed curve Γ is, when integrated around that curve, proportional to the net flux, I, of current through Γ. In a uniform medium, the constant of proportionality is its permeability, which in this article is always assumed to be the permeability of free space, $\mu_0 = 4\pi \times 10^{-7}$ H/m. (The fact that this value is exact is a quirk of the SI system of units, which makes use of one more quantity than is strictly necessary.) Taking the closed curve to be the (circular) line of force of radius r surrounding the wire, the required integral is $2\pi r B_\theta$, which by Ampère's law is also $\mu_0 I$, so that $B_\theta = \mu_0 I/2\pi r$; the field decreases with distance r from the wire as $1/r$. The field outside the wire does not depend on whether the current is uniform across the cross section of the wire ($J = I/\pi a^2$) or whether, as in a case considered in Section 3, it flows only along the surface of the wire with density $I/2\pi a$.

Faraday's law provides the final link between **B** and the electric field. This law applies to any closed curve Γ that is the periphery of a surface S. It states that the component of **E** along Γ, when integrated around Γ, is equal to the rate of decrease of the flux of **B** through S. This statement depends on a sign convention that can be understood from Fig. 4. If **E** is integrated around Γ in the direction of the arrows, then the flux of **B** through S is taken into the plane of the paper. (This right-handed rule also applies to Ampère's law; see Fig. 1.) Faraday's law shows that in unsteady EM states, **E** is not conservative (i.e., it cannot be expressed as $-\nabla\Phi$).

Faraday's law applies even when Γ is moving and changing shape, but in such cases **E** must be reinterpreted. To see why this is necessary, consider again Fig. 4. Suppose that **E** is zero and that **B** is uniform, constant in time and directed out of the plane of the paper. Now suppose that the sides *ad* and *bc* start to lengthen at speed U so that the area

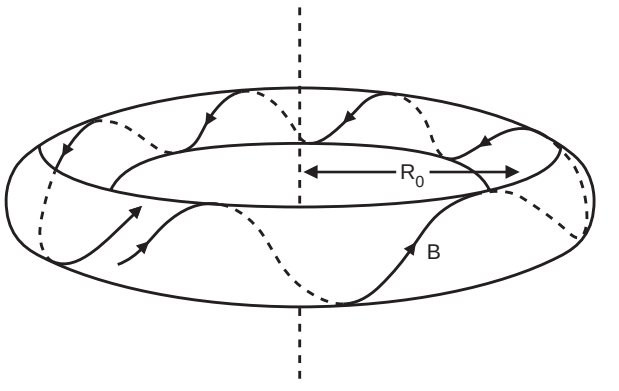

FIGURE 2 An axisymmetric magnetic surface filled ergodically by one line of force that does not close. The dashed line is the symmetry axis of the "donut"; it is also called the magnetic axis.

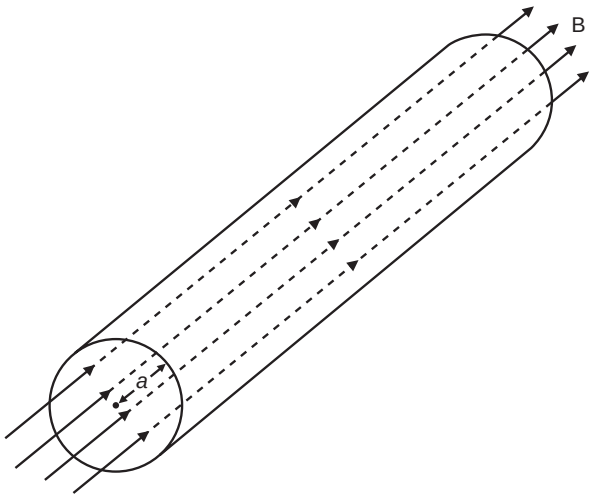

FIGURE 3 A straight flux tube. Its surface is composed of field lines.

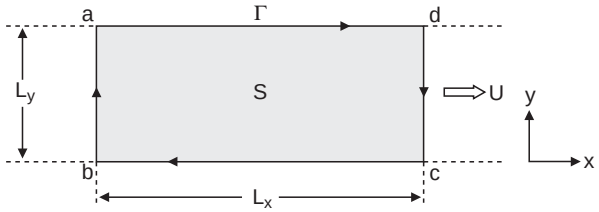

FIGURE 4 Application of Faraday's law to a growing rectangle S with periphery Γ. The sides *da, ab,* and *bc* are fixed. The side *cd* moves with speed U in the x direction. The sides *ad* and *bc* lengthen at the same rate.

S of the rectangle increases at the rate UL_y. The flux of $\mathbf{B}$ out of the plane of the paper increases at the rate BUL_y; in the positive sense defined previously, it decreases at the rate BUL_y. By Faraday's law, this must also be the integral of the component of the electric field along the sides of the integral. However, $\mathbf{E}$ is clearly zero on all sides of Γ, particularly on the stationary sides da, ab, and bc. One must conclude that when integrating the electric field around Γ, one is not integrating E_y on the moving side cd but some other electric field, E_y'. The required integral is then $E_y'L_y$ and Faraday's law gives $E_y' = -UB$.

This argument has uncovered a very significant fact: Although $\mathbf{B}$ (and $\mathbf{J}$) are the same in all reference frames, the electric field is not. In the current example, $E_y' = -UB$ in the reference frame moving with speed U in the x direction. It is convenient here to make use of a shorthand notation: $\mathbf{U} \times \mathbf{B}$ is called the vector product of $\mathbf{U}$ and $\mathbf{B}$. It is proportional and perpendicular to $\mathbf{U}$ and $\mathbf{B}$; its Cartesian components are $U_yB_z - U_zB_y$, $U_zB_x - U_xB_z$, and $U_xB_y - U_yB_x$. In this notation, the electric field in the frame moving with the side cd is $\mathbf{E}' = \mathbf{U} \times \mathbf{B}$. More generally, when the electric field in one reference frame $\mathscr{F}$ is $\mathbf{E}$, then it is $\mathbf{E}' = \mathbf{E} + \mathbf{U} \times \mathbf{B}$ in the reference frame $\mathscr{F}'$ moving with velocity $\mathbf{U}$ relative to $\mathscr{F}$. Returning to Faraday's law in the case in which Γ moves or changes shape, it is $\mathbf{E}'$ and not $\mathbf{E}$ that is integrated around Γ, where $\mathbf{E}'$ is evaluated at each point P of Γ using the velocity $\mathbf{U}$ at P.

The force on a charge e that is stationary in $\mathscr{F}'$ is $\mathbf{f} = e\mathbf{E}'$, which in $\mathscr{F}$ is more conveniently written as $\mathbf{f} = e(\mathbf{E} + \mathbf{U} \times \mathbf{B})$. Analogously, Ohm's law in a solid conductor moving with velocity $\mathbf{U}$ is $\mathbf{J} = \sigma(\mathbf{E} + \mathbf{U} \times \mathbf{B})$. To illustrate this modification of Ohm's law, suppose that the rectangle sketched in Fig. 4 is electrically conducting, with ad and bc being parallel rails along which cd slides, the electrical contact between cd and the rails being perfect. In general, a current I will flow around Γ in the direction indicated by the arrows. This current is driven through $cb + ba + ad$ by a potential difference Φ created by charges that accumulate at the sliding contacts c and d. At one extreme, when the resistance R_1 of $cb + ba + ad$ is large, $I = \Phi/R_1$ is small. By charge conservation, I is also the current flowing in cd and it is small because the electric field $E_y = (\Phi_c - \Phi_d)/L_y$ in cd created by the charges at c and d cancels out almost completely the electric field $-UB$ induced by the motion of cd; i.e., $|E_y'|$ is small. At the other extreme, when R_1 is small, the path $cd \to ba \to ad$ is almost a short-circuit, the contact charges at c and d are small, and these points are at nearly the same potential; E_y is small, $E_y' \approx -UB$, and the current $I = UBL_y/R_2$ flows around Γ in the direction indicated, where R_2 is the resistance of cd. In the general case between these two extremes, $I = UBL_y/R$, where $R = R_1 + R_2$ is the total resistance of Γ.

The modified Ohm's law also applies when the conductor is a fluid, but now $\mathbf{U}$ is replaced by the fluid velocity $\mathbf{V}$, which is usually not the same everywhere. At a point at which the fluid velocity is $\mathbf{V}$, the current density is $\mathbf{J} = \sigma(\mathbf{E} + \mathbf{V} \times \mathbf{B})$. By Ampère's law, this current will influence $\mathbf{B}$. This fact exposes one half of the relationship between $\mathbf{V}$ and $\mathbf{B}$, alluded to in Section 1, that characterizes the subject of MHD: Flow alters field in a fluid conductor. The other half of the relationship is a consequence of a force that a conductor experiences when $\mathbf{J}$ and $\mathbf{B}$ are nonzero. The force is proportional to, and perpendicular to, both $\mathbf{J}$ and $\mathbf{B}$. This is the Lorentz force, $\mathbf{J} \times \mathbf{B}$ per unit volume. Through this force, field alters the flow of a fluid conductor.

To illustrate the action of the Lorentz force, consider the conducting rectangle Γ sketched in Fig. 4. The sides ab and cd experience equal and opposite forces in the x direction, IBL_y and $-IBL_y$ respectively. These oppose the continual expansion of the rectangle (an example of Lenz's law). To maintain the expansion, forces must be applied to the sides ab and cd, and these do work at the rate $UIBL_y = (UBL_y)^2/R = I^2R$, which is precisely the rate at which electrical energy is converted into heat in the circuit Γ by its electrical resistance R. In this way, mechanical energy is converted into electrical energy and then "ohmically" into heat.

To state this result more generally, it is convenient to introduce a second shorthand notation: $\mathbf{F} \cdot \mathbf{G}$ is the scalar product of two vectors $\mathbf{F}$ and $\mathbf{G}$. In terms of their Cartesian components, it is $F_xG_x + F_yG_y + F_zG_z$. If $-\mathbf{V} \cdot (\mathbf{J} \times \mathbf{B})$ is positive at a point P, it quantifies the rate at which fluid loses its kinetic energy at P. This energy goes partially to increasing the magnetic energy density at P but some is radiated away from P through a "Poynting" energy flux $\mathbf{E} \times \mathbf{B}/\mu_0$. The remainder offsets the ohmic losses, J^2/σ per unit volume, at P. When $-\mathbf{V} \cdot (\mathbf{J} \times \mathbf{B}) > 0$ at P, the loss of kinetic energy provides a brake on the motion, which would cease even in the absence of viscous friction, unless maintained by some other force. When $-\mathbf{V} \cdot (\mathbf{J} \times \mathbf{B}) < 0$ at P, the reverse process occurs; field passes energy to motion, as in an electric motor.

The volumetric charge density ϑ in a moving fluid conductor is generally nonzero so that the fluid experiences a body force $\vartheta\mathbf{E}$ per unit volume. In the pre-Maxwell approximation, this is negligible in comparison with $\mathbf{J} \times \mathbf{B}$. These forces can be

reinterpreted in terms of stresses on the fluid and, not surprisingly, the electric stresses are negligible in comparison with the magnetic stresses. It is also found that the energy density of the electric field is insignificant compared with the energy density, $B^2/2\mu_0$, of the magnetic field. This highlights the unimportance of **E** relative to **B** in pre-Maxwell theory.

The magnetic stresses alluded to previously have two parts. One is an isotropic magnetic pressure, $p_M = B^2/2\mu_0$; the other is nonisotropic and can be interpreted as a field line tension of B^2/μ_0 per unit area, or AB^2/μ_0 for a flux tube of cross-sectional area A. Both parts increase quadratically with B. The magnetic pressure, which is already approximately 4 atm for a field of 1 T, is 10,000 times greater for $B = 100$ T.

The action of the field on the flow is recognized by including the Lorentz force $\mathbf{J} \times \mathbf{B}$ in the equation of motion that governs the fluid velocity **V**. The remaining forces affecting the motion include the gradient of the (kinetic) pressure p and a term, proportional to the (kinematic) viscosity ν, that describes frictional effects. When the Lorentz force is equivalently represented by magnetic stresses, the magnetic pressure p_M joins p in a "total" pressure $P = p + p_M$. The ratio $\beta = p/p_M = 2\mu_0 p/B^2$ is usually called beta. It is a significant quantity in plasma physics, where it is a figure of merit—one of several used to quantify the excellence or otherwise of a plasma containment device.

3. IDEAL MAGNETOHYDRODYNAMICS AND MAGNETOSTATICS

A fluid is termed ideal if it has zero viscosity and zero thermal conductivity but infinite electrical conductivity. Since **J** must be finite even though $\sigma = \infty$, Ohm's law $\mathbf{J} = \sigma(\mathbf{E} + \mathbf{V} \times \mathbf{B})$ implies that $\mathbf{E} = -\mathbf{V} \times \mathbf{B}$. Consequently, Alfvén's theorem holds: Lines of force move with the fluid as though frozen to it.

To establish this important result, let Γ be the periphery of a surface element S that moves with the fluid. Since $\mathbf{E}'$ vanishes everywhere on Γ, Faraday's law shows that the flux of **B** through S is unchanging. Suppose S is part of the curved surface C of a flux tube (Fig. 5A). The flux of **B** through S is zero because **B** is tangential to it; by Faraday's law, it remains zero as the contents of the flux tube are carried to a new location by the fluid motion **V**. Since this applies to every such S drawn on C, **B** remains tangential to C everywhere. Thus, it is still a flux tube at its new location. On shrinking the cross section of the tube to a single line of force, it is seen that this line of force moves with the fluid, as though frozen to it. A stronger statement can be made. Let Γ encircle the tube so that S becomes a cross section of the tube (Fig. 5B). The flux of **B** through S is the strength of the tube, as defined in Section 2. By Faraday's law, it is the same at its new location. This applies to every cross section. The fluid motion therefore preserves the strength of flux tubes and the integrity of the magnetic surfaces that contain them.

Alfvén's theorem provides a useful way of envisioning MHD processes in highly conducting fluids. For example, consider the eruption of a flux tube from the relatively dense region below the solar photosphere and into the more tenuous solar atmosphere (Fig. 6). Gravity drains the material in the ejected flux loop back to the solar surface, leaving the flux loop at low density and pressure, where it is in approximate equilibrium with its new surroundings. Such processes are responsible for expelling from the sun the field created within it.

Next, consider the way in which fluid motions can exchange energy with the field. Imagine a straight flux tube, initially of cross-sectional area A_0, lying in

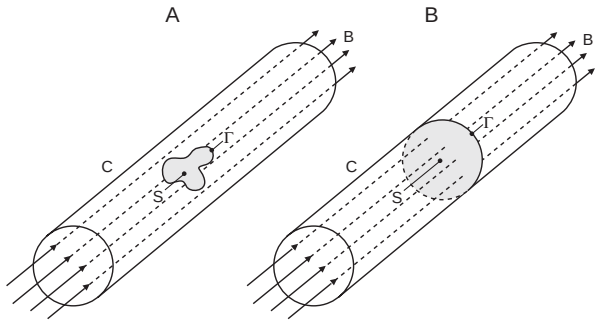

FIGURE 5 (A) An element S of surface area lying on the surface of a flux tube with periphery Γ. (B) A cross-section S of the flux tube with periphery Γ.

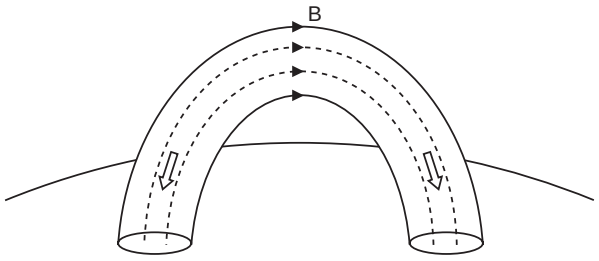

FIGURE 6 Fluid pulled by gravity down a flux tube that has erupted from the surface of the sun. Field directions are indicated by single arrows and fluid motion by arrowheads.

a compressible fluid. Suppose a motion compresses the tube uniformly so that, while remaining straight, its cross-sectional area is reduced to $A(<A_0)$. The density of the fluid it contains increases from its initial value of ρ_0 to $\rho = \rho_0(A_0/A)$. Since (by assumption) the fluid does not conduct heat, the tube compresses adiabatically, and its internal energy (i.e., the energy of the random molecular motions within it) increases so that its temperature rises. Because the strength of the tube cannot change, the field B_0 initially within the tube increases to $B = B_0A_0/A$ (i.e., by the same factor as ρ_0); thus, B/ρ remains at its initial value, B_0/ρ_0. The magnetic energy per unit length contained by the tube, however, increases from $A_0(B_0^2/2\mu_0)$ to $A(B^2/2\mu_0) = [A_0(B_0^2/2\mu_0)](A_0/A)$. In short, the kinetic energy of the compressing motion has been transformed into internal energy and magnetic energy. The reverse happens if $A > A_0$; the flux trapped in an intense tube tends to expand into surroundings where the field is weaker. For these reasons, sound traveling across a field moves faster (and much faster when β is small) than it would in the absence of the field; the magnetic pressure created by the field intensifies the restoring force in the compressions and rarefactions of the wave.

The transformation of kinetic energy into magnetic energy also occurs in an incompressible fluid when motions stretch field lines against their tension. The process may be likened to the storing of elastic energy in a stretched rubber band or to the energy transmitted to a violin string by plucking it. If the flux tube of cross-sectional area A_0 containing field B_0 considered previously is lengthened from L_0 to L, its cross section will decrease by the same factor ($A = A_0L_0/L$) and the field within it will increase by the same amount ($B = B_0L/L_0$). The magnetic energy it contains, which is proportional to B^2, is enhanced by a factor of $(L/L_0)^2$ from $(B_0^2/2\mu_0)L_0A_0$ to $(B^2/2\mu_0)LA = (B^2/2\mu_0)L_0A_0 = [(B_0^2/2\mu_0)L_0A_0](L/L_0)^2$. If $L = L_0 + \delta$, where $\delta \ll L_0$, the increase in magnetic energy is $(B_0^2/\mu_0)A_0\delta$. This is the work that the applied force had to do against the magnetic tension $(B_0^2/\mu_0)A_0$ of the field lines in stretching the tube by δ.

Tension has other important effects. Consider again the system shown in Fig. 1, but suppose now that the cylinder C is a compressible fluid or plasma surrounded by a vacuum. Suppose that the current I flows along the surface of C so that $I/2\pi a$ is the surface current density. The current I produces a field of strength $B_\theta = \mu_0 I/2\pi a$ on C. Because of their curvature, the field lines exert a "hoop stress" on C of $B_\theta^2/2\mu_0$ per unit area and directed radially inward. This compresses the fluid in C. Since $\mathbf{B}$ is zero in C, only (kinetic) pressure p can oppose the hoop stress. If $p = B_\theta^2/2\mu_0$, the forces are in balance, and the configuration is in *MSE*.

One may imagine that this MSE is brought about in the following way. Initially, A is large and p is small. After the current I and its associated field B have been set up, the forces on C are not in balance and the hoop stresses exerted by the field lines encircling C pinch the plasma column in much the same way as a stretched elastic band squeezes what it encircles. As these lines of force shorten and A becomes smaller, magnetic energy is converted into internal energy. The interior of C becomes hotter and its pressure p increases to oppose the further contraction of the field lines. Plausibly, the final result is an MSE of the kind envisaged previously, in which a plasma column has been strongly heated and prevented from expanding by the encircling field. Hot plasma is then confined within a magnetic bottle and away from solid walls. The possibility of this kind of magnetic confinement is of considerable interest in the MFE field. A hot reacting plasma must be prevented from leaching impurities from the solid walls of the reactor because these would greatly enhance the radiative losses, cooling the plasma and quenching the reactions.

In an MSE, the Lorentz force $\mathbf{J} \times \mathbf{B}$ balances the pressure gradient ∇p. This means that $\mathbf{B}$, being perpendicular to ∇p, is tangential to the constant–p surfaces, which are therefore magnetic surfaces, as defined in Section 2, and can be labeled by their value of p. Current lines (curves drawn parallel to $\mathbf{J}$) also lie on these surfaces and, like the field lines, they may close or traverse the surfaces ergodically. The total pressure P is continuous across the special magnetic surface that is the boundary of a plasma; if the exterior is a vacuum, P must balance the magnetic pressure, $B^2/2\mu_0$, in the vacuum.

If a region exists in which $\mathbf{J} \times \mathbf{B} = 0$, the field within it is termed force-free. Since $\nabla p = 0$, the pressure p is constant in the region, and p is no longer available to label surfaces on which the field and current lines are constrained to lie. Since $\mathbf{J}$ and $\mathbf{B}$ are parallel in a force-free field, $\mathbf{J} = \lambda\mathbf{B}$, where λ is constant on each field line, this being the component $J_\parallel = \mathbf{J} \cdot \mathbf{B}/B$ of $\mathbf{J}$ parallel to $\mathbf{B}$ on that line. The parameter λ may act as a surrogate for p in labeling the magnetic surfaces and constraining the field and current lines. If, however, λ is also constant, the field and current lines become unconstrained. A single field line and a single current line may fill the region. These are termed stochastic lines. They magnetically connect every part of the region to

every other part. Particular cases of this are presented in Sections 4.6 and 5.3.2.

The MSE just described is called the Z pinch because the current flows parallel to the axis of C, a direction usually labeled by z. The Z pinch is shown in Fig. 7A, together with two other MSEs. In Fig. 7B, the θ pinch, the current flows around the plasma column, a direction often denoted by θ. Between these extremes is the screw pinch (Fig. 7C). Here, the current flows in helices around C. The pitch $q_J = J_z/J_\theta$ of the helices depends on r, the radius of the cylindrical magnetic surface on which they lie. The field lines are also helices with a different pitch, q. The way that q varies with r is a significant factor for the stability of the equilibrium, and dq/dr is another figure of merit, called magnetic shear (see Section 5.3). It quantifies how rapidly the direction of the magnetic field changes as a function of r.

As applied to plasma devices, an obvious shortcoming of the linear or one-dimensional pinches shown in Fig. 7 is that, in practice, they must have ends, and these are sources of contamination. Greater interest therefore centers on toroidal or two-dimensional pinches. One may visualize a toroidal MSE as a linear pinch whose ends are joined together by bending it around on itself to form a donut of radius R_0, similar to that sketched in Fig. 2; R_0 is called the major radius and a the minor radius of the torus. The axis of symmetry is called the magnetic axis and distance from it is denoted by R. The z coordinate of the linear pinch is replaced by the angle ϕ around the magnetic axis, and increasing ϕ is called the toroidal direction. The coordinates r and θ of the linear pinch are approximately the same for both the linear and toroidal systems, r now being the distance from the axis running through the center of the donut and θ being the angle around that axis. Increasing θ is now called the poloidal direction. There is no toroidal MSE analogous to the θ pinch; in the absence of current flow in the toroidal direction, the Lorentz force cannot be balanced by a pressure gradient. Main interest centers on the toroidal screw pinch. The quantity $q = rB_\phi/R_0B_\theta$ is another figure of merit called the kink safety factor (see Section 5.3.2).

In addition to the one- and two-dimensional MSEs, there are also interesting three-dimensional configurations, so-called because they have no symmetry. Of fundamental concern in all these MSEs is the stability of the equilibria. This topic is discussed in Section 5.

Alfvén's theorem leads to a new phenomenon, the Alfvén wave. Consider again the straight flux tube of cross-sectional area A. Suppose first that the fluid is incompressible, and imagine that a transverse displacement bends the tube, carrying its contents with it, in obedience to the theorem (Fig. 8). The tension $\tau = AB^2/\mu_0$ of the tube acts, as in a stretched string, to shorten the tube. A wave results that moves in each direction along the tube with speed $V_A = \sqrt{(\tau/\Sigma)}$, where $\Sigma = \rho A$ is the mass per unit length of the string, with ρ being the fluid density. The wave velocity is therefore $\mathbf{V}_A = \mathbf{B}/(\mu_0\rho)^{1/2}$, which is usually called the Alfvén velocity. It is also the velocity with which energy can be transmitted along the field lines. In a compressible fluid, the situation is more complex because the presence of the field and its associated Lorentz force make sound propagation anisotropic. For example, the speed s of sound waves traveling parallel or antiparallel to the field $\mathbf{B}$ is unaffected by it: $s = \sqrt{\gamma p/\rho}$, where γ is the ratio of specific heats. For sound traveling perpendicular to the field, $s = \sqrt{(\gamma p + B^2/\mu_0)/\rho}$. For small β this is approximately V_A.

The MHD or Alfvénic timescale, $\tau_A = \mathscr{L}/V_A$, is very significant in many MHD contexts. It provides an estimate of how quickly a system responds to changes in its state. Such changes generate acoustic and Alfvén waves, the former crossing the system in a time of order $\tau_s = \mathscr{L}/s$, which for $\beta \ll 1$ is indistinguishable from τ_A. Thus, τ_A is the time required for the initial change to permeate the system. In particular, it is the dynamic timescale on which an MSE responds to a perturbation, and it is usually the timescale on which that equilibrium will, if unstable, be disrupted. It should be noted, however, that even if an equilibrium is stable according to ideal MHD, it

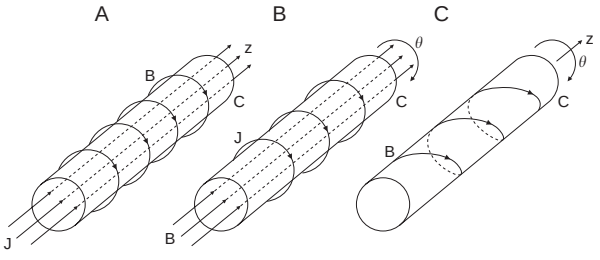

FIGURE 7 (A) Z pinch; (B) θ pinch; (C) screw pinch.

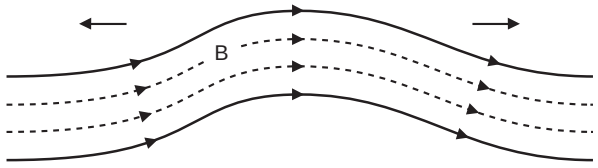

FIGURE 8 Alfvén wave propagation down a straight flux tube. The arrows indicate the directions of wave propagation.

may be unstable through diffusive effects ignored in ideal MHD. Such resistive instabilities are discussed in Section 5.

4. NONIDEAL MAGNETOHYDRODYNAMICS

4.1 Quantifying Deviations from the Frozen in Law

Alfvén's theorem poses a paradox: If field and fluid are inseparable, how did the fluid acquire its field in the first place? The answer is by diffusion, by which is meant, by diffusion of magnetic field. This happens because every real fluid has a finite conductivity.

In the reference frame $\mathscr{F}'$ moving with a particular point P of the fluid, Ohm's law is $\mathscr{J} = \sigma\mathscr{E}'$, in order of magnitude. Ampère's law shows that $\mathscr{J} = \mathscr{B}/\mu_0\mathscr{L}$, whereas Faraday's law implies that $\mathscr{E}' = \mathscr{B}\mathscr{L}/\mathscr{T}$. The timescale $\mathscr{T}$ on which **B** at P can change as P moves around is therefore the magnetic diffusion time, defined as $\tau_\eta = \mu_0\sigma\mathscr{L}^2 = \mathscr{L}^2/\eta$, where $\eta = 1/\mu_0\sigma$ is the magnetic diffusivity. On timescales $\mathscr{T}$ short compared with τ_η, the field is frozen to the fluid; for $\mathscr{T} \gg \tau_\eta$, it is not. Unless a field of scale $\mathscr{L}$ at P is maintained in some way, its lifetime is τ_η; also, a field of this scale cannot be implanted at P in a lesser time. One may consider these phenomenon as a type of EM memory that sets a minimum timescale for change, in the frame moving with the conductor.

Consider again the Z pinch described previously. After the potential difference has been applied between the ends of C at time $t = 0$, the current it creates initially flows only over the surface of C because, over short times, the plasma behaves as an ideal conductor in which **B** in the bulk of C cannot change from its initial zero value. Thereafter, the current sheet penetrates into C by diffusion, its thickness being of order $\delta_\eta = \sqrt{(\eta t)}$ at time t. After a magnetic diffusion time of $\tau_\eta = a^2/\eta$, the current will be distributed almost uniformly across the cross section of the column. As a digression, in practice the process may take rather longer since the diffusion of field into C is hampered by the increasing conductivity of the plasma as its temperature T rises through its adiabatic compression or heating. Similarly, the $z-$directed field initially trapped in a screw pinch grows as the column C collapses, whereas B_z in the surrounding vacuum does not. The tendency for the flux in C to diffuse out of the column is hampered by the diminishment of η that accompanies the compressional increase in T.

As another example, suppose that a plasma column C, such as the screw pinch shown in Fig. 7C, is contained within, but is not in contact with, a surrounding metallic wall. The field created outside C after the pinch has been initiated at time $t = 0$ cannot at first penetrate the walls because, over short times, they behave as perfect conductors in which **B** cannot change. The field is excluded from the walls by currents that flow in a thin skin on their surfaces, and these create their own field, which (when the walls are planar) is the mirror image of that of the plasma column (Fig. 9). The plasma column is repelled by its image (another example of Lenz's law), thus, preventing it from striking the wall. This stabilizing effect weakens in time because the thickness $\delta_\eta = \sqrt{(\eta t)}$ of the skin increases with t until ultimately the field completely penetrates the walls.

In a moving fluid, the advective timescale, $\tau_v = \mathscr{L}/\mathscr{V}$, quantifies the time taken (according to Alfvén's theorem) for a field of scale $\mathscr{L}$ to be carried over that distance. However, electrical resistance diffuses the field on a timescale of τ_η. If the magnetic Reynolds number, $Rm = \tau_\eta/\tau_v = \mathscr{L}\mathscr{V}/\eta$, is large, advection is more rapid than diffusion and Alfvén's theorem is useful in visualizing MHD processes. When $Rm \ll 1$, as is usually the case in technological applications of MHD involving liquid metals, the concept of frozen fields is not very useful. The prevailing field then provides an anisotropic friction that attempts to damp out motions perpendicular to itself on a timescale of $\tau_d = \rho/\sigma V_A^2 = \eta/V_A^2$, often called the magnetic damping time or the Joule damping time.

Energy can also be transmitted in a fluid by waves, and particularly significant for MHD systems is

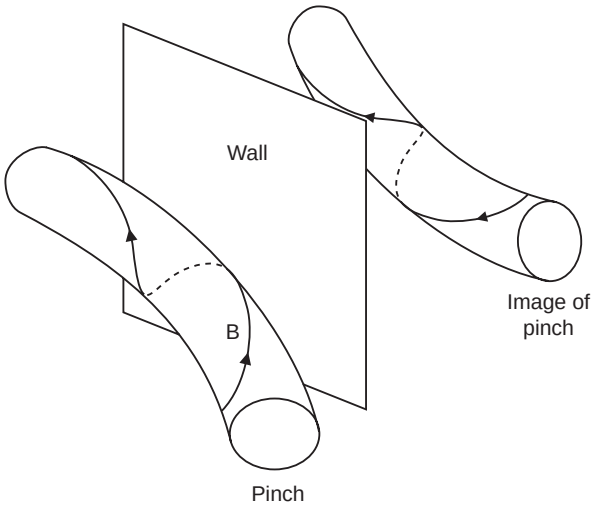

FIGURE 9 Image of a screw pinch in a conducting wall.

Alfvén radiation. This introduces a second way of quantifying diffusive effects: the Lundquist number, Lu. Alfvén waves are damped both by electrical conduction and by the viscosity ν of the fluid. The timescale over which this occurs is a combination $\tau_c = \mathscr{L}^2/(\eta + \nu)$ of τ_η and the viscous diffusion time, $\tau_\nu = \mathscr{L}^2/\nu$. For a liquid metal ($\nu \ll \eta$), $\tau_c \approx \tau_\eta$, and we shall now use τ_η in place of τ_c. During a time τ_η, the Alfvén waves travel a distance, $V_A\tau_\eta$. If the Lundquist number, $Lu = V_A\tau_\eta/\mathscr{L} = V_A\mathscr{L}/\eta$, is large, this distance greatly exceeds the characteristic length scale $\mathscr{L}$, and Alfvén radiation is significant. If $Lu \ll 1$, this is not the case since the time $\tau_d (= \eta/V_A^2)$ taken for the wave to damp out is small compared with the time $\tau_A (= \mathscr{L}/V_A)$ that the Alfvén wave requires to traverse the distance $\mathscr{L}$. The Lundquist number can be thought of as a magnetic Reynolds number, with the wave speed V_A replacing the advection speed $\mathscr{V}$.

4.2 Magnetic Reconnection

According to Alfvén's theorem, the topology of field lines cannot change in ideal MHD, but in a finitely conducting fluid ($\eta > 0$), field lines can sever and reconnect. This can happen fastest where scales are smallest (i.e., where the gradients of **B** are greatest). Magnetic reconnection is the process that forms thin current layers that change field topology and dissipate magnetic energy, even though the resistivity is modest and smoothly varying. Indeed, it is very important to distinguish magnetic reconnection, a process in which very thin (nearly singular) current sheets form in otherwise smoothly varying systems, from simple diffusive dissipation of magnetic energy when sharp profiles are built in *ab initio*. In magnetic reconnection, resistive diffusion and the magnetofluid dynamics combine to release energy stored in the magnetic fields and to reconfigure the magnetic topology of the system. Reconnection phenomena are usually subdivided into two classes, namely driven magnetic reconnection (discussed here) and spontaneous magnetic reconnection (described in Section 5 in the context of the tearing instability).

Perhaps the simplest and most fundamental model of magnetic reconnection is that of Sweet and Parker, hereafter referred to as the Sweet–Parker reconnection (SPR) model. This is a two-dimensional machine that steadily reconnects field lines. A cross section is sketched at successive times in Fig. 10. Resistivity acts everywhere but is most effective near a segment of the x axis. To simplify the argument, it is supposed that $\eta = 0$ everywhere except in reconnection region (shown

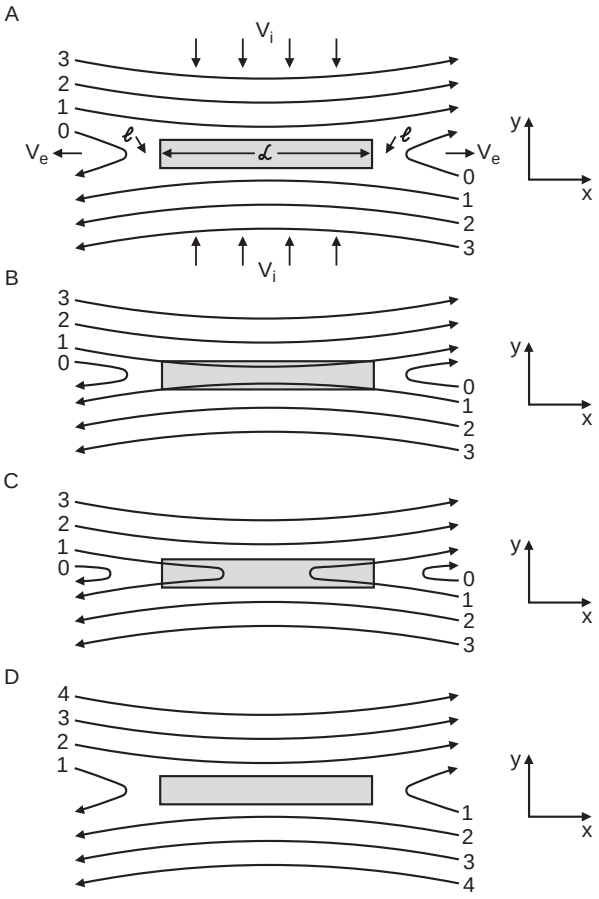

FIGURE 10 The Sweet–Parker reconnection mechanism. (A) Reconnection occurs when fluid motion brings slabs of oppositely directed magnetic fields together. The slabs have length $\mathscr{L}$ and velocity V_i. Pushing the slabs of field together creates a current sheet of thickness ℓ and ejects fluid at velocity V_e. The field lines labeled 1–3 approach the current sheet and field line 0 leaves it. (B) Field lines 1 enter the current sheet. (C) Field lines 1 are reconnected in the current sheet. (D) Field lines 1 leave the current sheet and move away in the $\pm x$ directions with velocity V_e. The configuration of field lines is now identical to that in A, but field lines n take the place of field lines n–1. Reconnection has changed the field line topology and dissipated magnetic energy.

shaded) of x width $\mathscr{L}$ and y width ℓ; it is assumed that ℓ is so much smaller than $\mathscr{L}$ that it is almost a current sheet. A steady inflow, V_i, in the $\pm y$ directions forces together two slabs of oppositely directed field $\pm B$ (Fig. 10A). The fluid is incompressible so that fluid must be ejected, with velocity V_e in the $\pm x$ directions. Figure 10B shows the field lines, labeled 1, moving into the reconnection region, and Fig. 10C shows them moving out after they have been reconnected. Their curvature implies a tension that assists the ejection of fluid in the $\pm x$ directions.

The object now is to determine V_i, V_e, and ℓ, assuming that the configuration is in a steady state

and that the Lundquist number $Lu = V_A\mathscr{L}/\eta$ is large. The argument rests on three simple balance laws:

1. Balance of fluid mass flowing into the reconnection layer with that flowing out: This gives $V\mathscr{L} = V_e\ell$.
2. Balance of fluid momentum in the reconnection layer. Since the flow in the reconnection layer is approximately one dimensional, it is governed by Bernoulli's law, which states that the sum of the total pressure P and the dynamic pressure $\frac{1}{2}\rho\ V^2$ is constant. Furthermore, the total pressure P is, in turn, the sum of the thermal pressure p and the magnetic pressure $p_M = \mathbf{B}^2/2\mu_0$. The sum, $S \equiv p + \mathbf{B}^2/2\mu_0 + \frac{1}{2}\rho\ V^2$, is therefore constant throughout the layer. By symmetry, the center of the configuration is a stagnation point ($\mathbf{V} = 0$), and at the midpoints on the long sides of the reconnection layer $\mathbf{V}$ is negligibly small so that $S \approx p + B^2/2\mu_0$. Outside the layer (i.e., for $|x| \gg \mathscr{L}$), the magnetic field is small so that at the ends of the layer where fluid is ejected in the $\pm x$ directions, $S \approx p + \frac{1}{2}\rho\ V_e^2$. Equating these two expressions for S shows that the ejection velocity is simply the Alfvén velocity: $V_e = V_A$.
3. Balance of magnetic energy: In the steady state, the influx of magnetic energy to the layer must equal the rate of ohmic dissipation in the layer. The influx rate is simply $(2V\mathscr{L})B^2/2\mu_0$ since the efflux from the narrow side edges of the reconnection region is negligible. The rate of ohmic dissipation is $(\mathscr{L}\ell)J^2/\sigma$, where by Ampère's law, $J = B/\mu_0\ell$. Since $\eta = 1/\mu_0\sigma$, the inflow velocity is related to the layer thickness by $V = \eta/\ell$.

Taken together, these three demands imply that

1. Since $Lu \gg 1$, the reconnection velocity, $V = V_A/\sqrt{Lu}$, is much smaller than V_A. It is proportional to a fractional power of the resistivity of the system; the growth rate of the tearing mode (discussed in Section 5) shows a similar fractional dependence.
2. The aspect ratio, $\ell/\mathscr{L}$, of the reconnection region is small, of order $Lu^{-1/2} \ll 1$. The direction of the merging fields imposes this anisotropy. It is consistent with the idea that magnetic energy is dissipated in a thin current sheet. Of course, the simultaneous smallness of V/V_A and the aspect ratio $\ell/\mathscr{L}$ is a consequence of their equality, by the balance law, and of the assumption $Lu \gg 1$.

Although conceptually simple and plausible, SPR tells a rather pessimistic story, namely that reconnection is a relatively slow process (i.e., $V = V_A/\sqrt{Lu} \ll V_A$, where $Lu \gg 1$ in cases of greatest interest). Many physical phenomena appear to require, for their explanation, fast reconnection (i.e., reconnection on ideal timescales or, equivalently, at Alfvénic velocities $V \sim V_A$). This is especially true of many solar and astrophysical phenomena, such as solar flares. The physics of fast reconnection is an active area of research in MHD and plasma physics.

Two main routes to fast reconnection have been proposed. Within the framework of MHD, one originally proposed by Petschek suggests that shock waves carry energy away from the reconnection layer. This rapid process of energy removal is thought to increase both the aspect ratio of the reconnection region and the reconnection rate. The Petschek mechanism predicts a reconnection velocity of order V_A, with only a weak logarithmic dependence on Lu [i.e., $V \sim V_A/\ln(Lu)$]. The alternate route to fast reconnection appeals to small-scale, non ideal, or kinetic processes that cannot be studied using the one-fluid model of MHD. All models of fast reconnection are controversial and they will evolve considerably in the years ahead.

4.3 MHD Turbulence

Many fluid systems are turbulent. This fact presents formidable obstacles to theorists and is likely to embarrass them for the foreseeable future. The motions and fields of a turbulent fluid have many length and timescales. In the classical picture of turbulence, these range from macroscales, $\mathscr{L}_{\text{macro}}$ and $\mathscr{T}_{\text{macro}}$, corresponding to scales on which the fluid is stirred, to dissipation scales, $\mathscr{L}_{\text{diss}}$ and $\mathscr{T}_{\text{diss}}$, which are dominated by viscosity. It is argued that $\mathscr{L}_{\text{macro}}/\mathscr{L}_{\text{diss}} \sim (Re)^{3/4}$, where $Re = \mathscr{V}_{\text{macro}}\mathscr{L}_{\text{macro}}/\nu$ is the Reynolds number. This is typically greater than 10^4, so the range of scales spans many decades and cannot be adequately resolved even by modern, high-speed computers.

In classic turbulence, interscale interaction occurs via a process of cascade in which larger eddies (i.e., fluctuations that have the appearance of vortical whorls) fragment into smaller eddies, thus producing a range of fluctuations on scales from $\mathscr{L}_{\text{macro}}$ to $\mathscr{L}_{\text{diss}}$. This process is encapsulated by a well-known parody by Louis Fry Richardson of a verse of Jonathan Swift:

> *Big whorls have little whorls, that feed on their velocity.*
> *And little whorls have lesser whorls, and so on to viscosity.*

In contrast to ordinary fluid turbulence, which can be thought of as a soup of eddies, MHD turbulence consists of a mixture of eddies and small-scale Alfvén

waves and is controlled by viscosity and resistivity. Thus, although the idea of a cascade remains useful for describing MHD turbulence, the interaction processes in MHD are considerably more complex than in nonmagnetic fluids. Perhaps the most important difference is that, since MHD turbulence involves Alfvén waves, it necessarily retains an element of memory or reversibility. Here, Alfvénic memory refers to the tendency of even small-scale magnetic fields (which are always present when Rm is large) to convert the energy in eddies (which cascades irreversibly) to reversible nondiffusive Alfvén wave motion. This is a consequence of the fact that wave motion is necessarily periodic and involves a restoring force.

Despite the difficulties discussed previously, there is considerable effort in the research community directed at numerical simulation of MHD turbulence. The large scales can be resolved numerically in so-called large eddy simulations (LES), but only if the effects of the unresolvable or subgrid scales (SGS) on the large scales are parameterized in some way. One popular, although controversial, expedient originated from an idea by Osborne Reynolds in the 19th century. He drew an analogy between the diffusive effects of the small-scale eddies and collisional diffusion processes at the molecular level. This suggested that the SGS similarly spread out the large-scale motions and fields diffusively, but on timescales $\tau_{\nu/\mathrm{turb}} = \mathscr{L}^2/\nu_{\mathrm{turb}}$ and $\tau_{\eta/\mathrm{turb}} = \mathscr{L}^2/\eta_{\mathrm{turb}}$ determined by turbulent diffusivities, ν_{turb} and η_{turb}, of order $\mathscr{L}_{\mathrm{eddy}}\mathscr{V}_{\mathrm{eddy}}$ that might be very large compared with the corresponding molecular values, ν_{mol} and η_{mol}.

Reynolds's idea is not totally satisfactory but is qualitatively useful. For example, the fact that $\eta_{\mathrm{turb}} \gg \eta_{\mathrm{mol}}$ in the solar convection zone explains, in a rough and ready way, why the timescale $\mathscr{T}$ of magnetic activity on the sun, as estimated by the period of the solar cycle, is on the order of a decade, even though $\tau_{\eta/\mathrm{mol}}$ exceeds the age of the sun: $\mathscr{T}$ is determined by η_{turb} and not η_{mol} so that $\mathscr{T} \approx \tau_{\eta/\mathrm{turb}}$.

Reynolds's idea also correctly implies that turbulence enhances viscous and ohmic dissipation. Although the magnetic Reynolds number Rm may be large when defined from $\mathscr{L}_{\mathrm{macro}}$ and $\mathscr{V}_{\mathrm{macro}}$, it may be small when $\mathscr{L}_{\mathrm{eddy}}$ and $\mathscr{V}_{\mathrm{eddy}}$ are used instead. Even if the characteristic macroscale field, $\mathscr{B}_{\mathrm{macro}}$, is large compared with the typical eddy field, $\mathscr{B}_{\mathrm{eddy}}$, so that the magnetic energy resides mostly in the macroscales, the magnetic energy may be dissipated mainly by the eddies. This is because $\mathscr{L}_{\mathrm{eddy}} \ll \mathscr{L}_{\mathrm{macro}}$ so that $\mathscr{J}_{\mathrm{macro}} = \mathrm{O}(\mathscr{B}_{\mathrm{macro}}/\mu_0\mathscr{L}_{\mathrm{macro}})$ may be smaller than $\mathscr{J}_{\mathrm{eddy}} = \mathrm{O}(\mathscr{B}_{\mathrm{eddy}}/\mu_0\mathscr{L}_{\mathrm{eddy}})$, even though $\mathscr{B}_{\mathrm{eddy}} \ll \mathscr{B}_{\mathrm{macro}}$. In many situations however, $\mathscr{B}_{\mathrm{eddy}} \gg \mathscr{B}_{\mathrm{macro}}$ so that the eddies contain most of the magnetic energy and are mainly responsible for its dissipation. Similarly, they may contain the majority of the kinetic energy and be the main cause of its viscous dissipation. The reader is cautioned, however, that the expressions for ν_{turb} and η_{turb} given here are estimates only. In particular, it has been appreciated that the Alfvénic memory intrinsic to MHD turbulence may cause significant reductions in ν_{turb} and η_{turb} in comparison with the estimates given here. The self-consistent calculations of ν_{turb} and η_{turb} are active topics of current research in MHD.

MHD propulsion and drag reduction are topics of considerable interest and usually concern systems for which $Rm \gg 1$ and in which MHD turbulence occurs. An extensive discussion of these topics is beyond the scope of this article.

4.4 Buoyancy in MHD

A real (nonideal) fluid has a nonzero thermal conductivity, K. The appropriate measure of the resulting conduction of heat is the thermal diffusivity, $\kappa = K/\rho C_p$, where C_p is the specific heat at constant pressure; the thermal diffusion time is $\tau_\kappa = \mathscr{L}^2/\kappa$. The finiteness of κ gives rise to the magnetic buoyancy of flux tubes. Such tubes are created by, for example, the turbulent motions in a stellar convection zone, such as that of the sun. These cause the prevailing magnetic field to become intermittent, with regions of strong field (i.e., flux ropes) being surrounded by regions of comparatively weak field. During a time $t \ll \tau_\eta$ after its formation, flux loss from a tube can be ignored. Radiative transport of heat, however, is very effective in a star and $\tau_\kappa \ll \tau_\eta$. Any difference in temperature between the rope and its surroundings diffuses away in a time of order τ_κ. It is reasonable to suppose that in the time interval $\tau_\kappa \ll t \ll \tau_\eta$, the temperature of the rope is the same as its surroundings but that the field B in the interior of the rope differs from the field $B_0 (< B)$ outside it. Magnetostatic balance requires that the total pressure exerted by the rope on its surroundings is approximately the same as the total pressure the surroundings exert on it: $p + B^2/2\mu_0 = p_0 + B_0^2/2\mu_0$. This means that the kinetic pressure p of the gas in the tube is less than that of its surroundings, p_0. However, since its temperature is the same, its density must be less. The tube is therefore buoyant and rises toward the stellar surface.

When the tube breaks through the stellar surface, dark regions occur that are called starspots (or sunspots in the case of the sun). That these spots are dark is another illustration of the constraining effects of the field. Near the stellar surface, heat is carried outward mainly by convective overturning, which within a tube is coupled to Alfvén waves that radiate energy and therefore tend to suppress the convective motions. The emerging heat therefore has to find a route that goes around the spots rather than through them. The spots are thus cooler and darker than their surroundings.

4.5 Amplification of Magnetic Fields in MHD

A magnetic field threading a sphere of solid iron of radius 1 m would disappear in approximately 1 s unless maintained by external current-carrying coils. Since $\tau_\eta \propto \mathscr{L}^2$, larger bodies can retain their fields longer, but many celestial bodies (planets, stars, galaxies, etc.) are magnetic and are believed to have been magnetic for times long compared with their magnetic diffusion times. The age of the geomagnetic field, for instance, exceeds 3×10^9 years, even though τ_η is less than 10^5 years. A process must exist that replenishes these fields as they diffuse from the conductor. This process is the same as that operating in commercial power stations: self-excited dynamo action. From a field **B**, fluid motion creates the electromotive force (emf) $\mathbf{V} \times \mathbf{B}$ that generates the electric currents **J** necessary to create, by Ampère's law, **B**.

Although it was stated previously that in turbulent flow eddies may be responsible for greatly enhancing diffusion of the large-scale part, $\mathbf{B}_{\text{macro}}$, of **B**, these small-scale motions can, if they lack mirror symmetry, also act to replace the lost flux. The simplest manifestations of such symmetry breaking are helical motions. Helicity is defined as $\mathbf{V} \cdot \boldsymbol{\omega}$ where $\boldsymbol{\omega}$ is the vorticity of the flow, a vector that has Cartesian components $\partial V_z/\partial y - \partial V_y/\partial z$, $\partial V_x/\partial z - \partial V_z/\partial x$, $\partial V_y/\partial x - \partial V_x/\partial y$ and that is often written as curl**V** or $\nabla \times \mathbf{V}$. Helicity is a measure of how mirror symmetric the flow is; like a common carpenter's screw, a helical flow does not look the same when viewed in a mirror. Helicity is created naturally by the rotation of large systems such as the solar convection zone, where the rising and falling motions created by buoyancy acquire vertical vorticity through the action of the Coriolis force. Small-scale helical motions create a large-scale emf that, in the simplest case, is proportional to $\mathbf{B}_{\text{macro}}$ and is conventionally written $\alpha \mathbf{B}_{\text{macro}}$. This α effect may suffice to maintain $\mathbf{B}_{\text{macro}}$ and hence $\mathbf{B}_{\text{turb}}$ as well, thus creating a turbulent dynamo. The α effect is the cornerstone of a subject now called mean field electrodynamics. (Confusingly, this is often known by the acronym MFE, which we reserved as an abbreviation for magnetic fusion energy.)

The α effect illustrates the danger, mentioned previously, of adopting the Reynolds ansatz too uncritically; through their anisotropy and lack of mirror symmetry, small-scale motions can create large-scale emfs that are not recognized when η_{mol} is merely replaced by η_{turb}. It should also be mentioned that the issue of Alfvénic memory appears once again in the context of the dynamo and the α effect. Recent research has suggested that because of memory effects and constraints on the rate of magnetic reconnection, the α effect at large Rm may be much weaker than it would be were the dynamical effects of the small-scale eddies ignored, as was done in the early days of mean field theory. Further developments in this important research area may be expected in the near future.

The interested reader can get an intuitive, hands-on perspective on a particular type of dynamo process by the following home demonstration, which also illustrates several of the processes described in this section and the last. Obtain an elastic (rubber) band. This loosely corresponds to the flux tube in Fig. 11A, its tension being the sum of the tensions in the magnetic field lines it contains (i.e., it is proportional to the energy of the field within it).

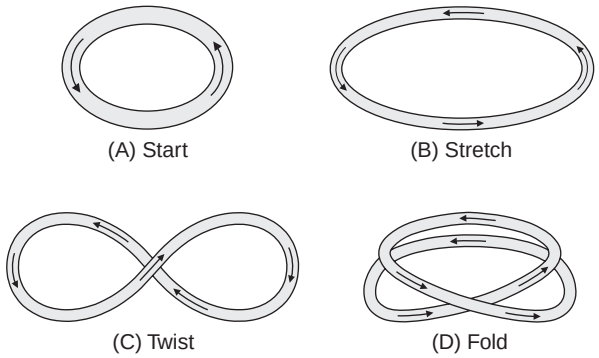

FIGURE 11 The stretch–twist–fold dynamo. (A) The initial undeformed flux tube; (B) the result of stretching it to twice its length; (C) the stretched tube is twisted into the shape of an infinity sign ∞; and (D) the result of folding one loop of the ∞ over onto the other. Reconnection in D can produce two loops of the same size as the initial tube.

The tension in the band may be systematically increased by a three-step, stretch–twist–fold process:

1. Stretch the rubber band to double its length.
2. Twist it into the shape of an infinity sign, ∞.
3. Fold the loops on top of one another to form two linked loops of the same size as the original band.

These steps are illustrated in Fig. 11B–D. In a similar way to the rubber band, the energy within and the tension of the flux tube are increased by a factor of 4. This is the essence of a dynamo, the creation of magnetic energy by helical motion.

In principle, these steps can be repeated over and over again, with the sense of twist in step 2 being always the same. This gives the band the sense of handedness of a screw motion and the broken reflection symmetry and helical motion that are crucial to the success of the dynamo. The tension in the band (analogous to the magnetic tension) increases progressively as the steps are repeated, and at some stage the reader's hands will tire, making it impossible to increase the tension further. This illustrates the end of the kinematic regime (in which fluid motion is prescribed *a priori* and the field grows) and the beginning of the dynamic regime (in which the field quenches its own further growth). If the reader lets go of the band at any stage, it will immediately relax back to its initial state. This illustrates the crucial importance of magnetic reconnection as a means of locking in the amplified magnetic field. In other words, magnetic reconnection provides the crucial element of irreversibility in the dynamo. The analogue of magnetic reconnection in the case of the rubber band could be achieved by fusing the two loops together after the stretch–twist–fold process.

In recent years, much effort has been expended on the study of fast dynamos, which are defined as processes of field amplification that operates on timescales independent of τ_η in systems with $Rm \gg 1$. It should be apparent to the reader that a fast dynamo necessarily requires fast reconnection in order to lock in the dynamo-generated field. Thus, the problems of fast reconnection and those of the fast dynamo are intimately linked.

4.6 Magnetic Helicity and Relaxation in MHD

No doubt the reader has noticed that the past three sections, which discuss magnetic reconnection, turbulent transport of magnetic fields, and the dynamo process, all concern the following broader question: Given certain initial conditions, what magnetic configuration does the magnetofluid ultimately adopt? This question seeks to identify the final state when some very complex dynamical processes, involving the dissipative phenomena mentioned previously (as well others, some unknown), are at work.

Apart from a very few simple, exactly soluble cases (that nearly always have an unrealistically high degree of symmetry built in), there are two main ways of finding the final state.

The first is to integrate the MHD equations directly using a computer. This approach forces the researcher to confront all the thorny issues of MHD turbulence, SGS modeling, etc. described previously. Moreover, such brute force tactics are often expensive and inefficient. One is naturally motivated to seek other approaches that are bolder but simpler. Foremost among these is constrained relaxation. This variational method seeks to identify the final state as one that minimizes the magnetic energy, subject to certain constraints. The central issue then becomes the identification and inclusion of the most important constraint or constraints.

A natural candidate for consideration as a constraint is the magnetic helicity. This is the analogue of the (kinetic) helicity, which was previously defined as $\mathbf{V} \cdot \boldsymbol{\omega}$, where $\boldsymbol{\omega} = \mathrm{curl}\mathbf{V}$. Conversely, $\mathbf{V}$ can be derived from $\boldsymbol{\omega}$ by integration in an uncurling operation. Likewise, a vector $\mathbf{A}$ can be obtained from $\mathbf{B}$ by a similar uncurling operation. This defines a vector potential, $\mathbf{A}$. The scalar product $K = \mathbf{A} \cdot \mathbf{B}$ is the magnetic helicity. It is conserved in the motion of an ideal fluid, and this is why it is significant in MHD. Physically, magnetic helicity quantifies the self-linkage or knottedness of the magnetic field lines and is thus a measure of the topological complexity of the field. Indeed, the invariance of field line topology in ideal MHD is the origin of the conservation of magnetic helicity.

If an MSE is analyzed using ideal MHD, it is found that magnetic helicity is conserved in detail in the sense that if we regard the MSE as an assembly of infinitesimally thin flux tubes of volume Δv and labeled by parameters α and β, their individual magnetic helicities, $K_{\alpha,\beta} = (\mathbf{A} \cdot \mathbf{B})_{\alpha,\beta} \Delta v$, are conserved, although they are not the same for each tube. If instead nonideal MHD is used in analyzing the MSE, the configuration will relax toward its final state on a timescale determined by the resistivity and other slow diffusion mechanisms. In this process,

individual flux tubes lose their identity through magnetic diffusion and turbulent cascade. Thus, the local magnetic helicity, $K_{\alpha,\beta}$, associated with a given thin flux tube, is *not* conserved. However, J. B. Taylor made the insightful conjecture that the global magnetic helicity (i.e., the sum of $K_{\alpha,\beta}$ over the system) would be approximately conserved on the timescale of the relaxation.

Global helicity is the integral of K over the entire system. It is, in some sense, a coarse-grained topological invariant that is also related to the self-inductance of the plasma. Taylor relaxation theory proposes to determine relaxed states by minimizing magnetic energy subject to the constraint of constant global magnetic helicity. The resulting Taylor states have the property that the current is linearly proportional to the field (i.e., $\mathbf{J} = \lambda \mathbf{B}$, where λ is a constant). This, is a force-free field of the special type described in Section 3 for which the component, $J_{\|}$, of $\mathbf{J}$ parallel to $\mathbf{B}$ is everywhere the same. In Section 5.3.2, we discuss kink-tearing instabilities of toroidal MSE. These instabilities are current driven (i.e., they exist only because $\nabla J_{\|}$ is nonzero). Since $\nabla J_{\|} = 0$ in the Taylor relaxed state, it is stable to kink-tearing modes.

Taylor relaxation theory has been very successful in explaining the relaxed mean field profiles of low β confined plasmas, especially the reversed field pinch (RFP) and spheromak. Of particular note is Taylor's successful prediction of the F–Θ curve for the RFP. The F–Θ curve relates the degree of field reversal to the poloidal field at the edge of the RFP and is an experimentally derived signature of the final RFP state. In relation to Section 4.4, it is worth noting that the relaxed state is maintained by a cyclic dynamo process in which dissipative excursions from the Taylor state trigger instabilities that drive the plasma back to relaxed state.

The main mystery of Taylor relaxation theory is why it works so well. In other words, why is the global helicity the most important constraint on turbulent relaxation? There are at least three plausible answers:

1. *Enhanced dissipation:* Turbulence and dissipation drive magnetic reconnection, which destroys domains of local magnetic helicity on all but the largest scale. Thus, as the system evolves, the global magnetic helicity is the only surviving topological invariant.
2. *Field line stochasticity:* In the initial state of the configuration, the field lines lie on magnetic surfaces, each labeled by its hydrostatic pressure p. However, as the configuration relaxes to the force-free state of constant p, the identity of the surfaces evanesces, and field lines become increasingly stochastic. Ultimately, as the turbulent relaxation proceeds, the entire MSE is threaded by a single field line. Since magnetic helicity is calculated by volume integration over a region enclosed by a magnetic surface, and all other magnetic surfaces are destroyed, only global magnetic helicity is relevant to a stochastic state.
3. *Selective decay:* In three-dimensional MHD turbulence, energy cascades to small scales. It can be shown, however, that magnetic helicity cascades inversely to large scales. As a result, magnetic helicity accumulates on the largest scales of the system, with minimal coupling to dissipation. Thus, magnetic helicity is dynamically rugged, whereas energy decays.

It should be noted that these are only plausibility arguments, and that a rigorous justification of the Taylor hypothesis remains an elusive goal of current research.

5. STABILITY OF MAGNETICALLY CONFINED PLASMAS

5.1 Generic Issues

Configurations of MHD fluids are analyzed using the concepts of equilibrium and stability. These are used to classify a variety of possible configurations according to their intrinsic interest, potential utility, importance for science and technology, and so forth. They are vital in the context of magnetic plasma confinement for the success of controlled fusion (hereafter referred to as MFE). This is the only application considered here, but there are many others in astrophysics, geophysics, space plasma dynamics, and MHD power generation.

MHD equilibria are configurations in which the plasma pressure gradient, ∇p, balances the $\mathbf{J} \times \mathbf{B}$ force (Lorentz force) and any other body forces acting on the magnetofluid. An equilibrium in which the balance is dominated by the pressure gradient and the Lorentz force is referred to as a *MSE*. All equilibria of interest in the context of MFE are MSEs. In general, the magnetic fields in MSEs are produced in part by external coils and in part by plasma currents. They are characterized by the pressure and current profiles $p(r, \theta, \phi)$ and $\mathbf{J}(r, \theta, \phi)$. In toroidal MSEs, these are independent of ϕ, the angle around the torus in the toroidal

direction, but still depend on θ, the angle that increases in the so-called poloidal direction.

Interesting MSEs almost always have closed magnetic flux surfaces (i.e., surfaces that enclose a specified amount of magnetic flux). These are labeled by an effective radius r, and because they are so significant, we generally suppress the dependence of p and $\mathbf{J}$ on θ and ϕ. Charged particles in a plasma cannot readily cross a flux surface and are therefore confined. For this reason, an MSE is sometimes called a magnetic bottle.

MSEs have a high degree of symmetry, corresponding to closed toroidal, spheroidal, or helical configurations. Toroidal MSEs of interest in the context of MFE include the tokamak (based on a Russian acronym for maximum current) and the RFP. Together, these two configurations are referred to as toroidal pinches since plasma is confined by a toroidal current that produces a magnetic field, which in turn acts to pinch the plasma column. A tokamak has a strong, externally applied toroidal magnetic field, whereas a RFP plasma generates its own toroidal field by a process of constrained relaxation, whereby some of the toroidal current is dynamically twisted into the poloidal direction. This relaxation process is closely related to that of the dynamo described previously. RFPs are intrinsically dynamic (i.e., not quiescent) in nature. Spheroidal MSEs include the spheromak and the spherical torus, whereas helical MSEs include the heliac, a type of stellarator. Stellarator MSEs do not rely on inductively driven currents as do toroidal pinches, but they sacrifice the virtues of toroidal symmetry. In this section, the discussion is limited for reasons of brevity and clarity to toroidal pinches in general, and tokamaks in particular. The MSE of a tokamak is particularly simple in that the pressure and toroidal current profiles, $p = p(R)$ and $J_\phi = J_\phi(R)$, can be parameterized by a single coordinate, R, that may be thought of as a (generalized) distance from the symmetry axis.

Once the existence of a closed MSE is established, the next question is whether it is magnetohydrodynamically stable—that is, whether initial, small perturbations that break the symmetry of the equilibrium tend to reinforce themselves and grow. This growth is due to the release of potential energy stored in the initial MSE and is accompanied by a relaxation of the pressure and/or current profiles $p(r)$ and $J_\phi(r)$, which tends to lower the initial potential energy and degrade the quality of the nascent MSE. Instability is a linear concept and is relevant for only a few growth times (at most), until the dynamics enter the nonlinear regime, characterized by finite (i.e., not small) amplitude perturbations. Instabilities saturate (i.e., cease growing) either when the plasma arrives at a new secondary equilibrium, which is a MSE with lower potential energy than the initial equilibrium, in which the symmetry is usually broken as well, or when the kinetic energy of the plasma motion is lost through dissipation (e.g., through viscosity). The latter often occurs as a consequence of the cascade to small scales characteristic of MHD turbulence.

MHD instabilities are usually classified as either pressure driven [when they are associated with relaxation of $p(r)$] or current driven [when associated with relaxation of $J_\phi(r)$]. They are either ideal or resistive. Ideal instabilities occur without a violation of Alfvén's frozen flux constraint, whereas resistive instabilities require some decoupling of field and fluid, usually by collisional resistivity, to trigger the energy-release process. MHD instabilities are of great interest in the context of MFE, because they limit the class of viable MSEs and thus severely constrain the performance of magnetic fusion devices.

Entire books have been devoted to the MHD stability of confinement devices for MFE. There is space here to describe only a few of the basic concepts and their application to MFE. One way of investigating dynamical stability makes use of the fact that ideal MHD conserves the total energy E of the system. This is the sum of the kinetic energy E_K, the magnetic energy E_M, and the internal energy of the plasma, E_I. Before perturbation, $\mathbf{V} = 0$ and therefore $E_K = 0$ so that $E = E_M + E_I$. The perturbation creates a small initial E_K and this may grow at the expense of $E_M + E_I$, indicating that the initial state is unstable; if the initial state is linearly stable, E_K remains small.

The situation may be described conceptually by analogy with a ball rolling under gravity on a surface S. Then E_K is the kinetic energy of the ball and its height z above some reference level plays the role of $E_M + E_I$. A magnetostatic equilibrium is analogous to the ball being at rest at some point P where the surface is level (i.e., where the tangent plane at P to S is horizontal, as at the points indicated in Fig. 12). In Fig. 12A, the ball rests at a global minimum of z, and the system is not only linearly stable but also globally stable (i.e., stable to all perturbations no matter how large they are or in which horizontal direction they occur). In Fig. 12B, the ball is at an unstable equilibrium that is destroyed if perturbed in any horizontal direction. Figure 12C also illustrates an unstable state; although it is true that some

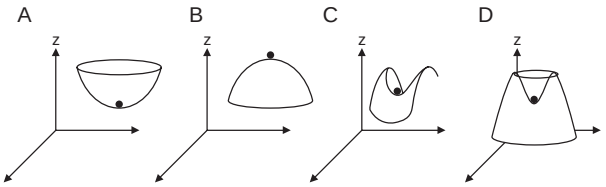

FIGURE 12 Equilibrium points (•) of a ball rolling on a surface. (A) global stability; (B) instability at a maximum of z; (C) instability at a saddle point of z; (D) stability for small perturbations but not large.

perturbations increase z (suggesting stability), other directions of perturbation exist that will cause the ball to descend permanently from the saddle point. In Fig. 12D, a sufficiently large perturbation will take the ball over an adjacent hill, after which it descends permanently to a state remote from its starting point (i.e., the initial state is linearly stable but unstable to finite amplitude perturbations).

Similarly, if $E_M + E_I$ increases for every small perturbation of a MSE, it is linearly stable, as in Figs 12A and 12D. The MSE is unstable if any perturbation exists that reduces $E_M + E_I$, as in Figs 12B and 12C. Figure 12C is the better analogue for a MSE since many directions of perturbation do not threaten a MSE; perturbations that bend field lines increase E_M and those that compress the plasma increase both E_M and E_I. Other directions of perturbation, however, may exist that reduce $E_M + E_I$, and these are the perturbations that should be understood and, as far as possible, eliminated. These directions are usually associated with perturbations that relax the current or pressure gradients.

5.2 Magnetically Confined Plasmas and MFE

The hope of controlling the release of thermonuclear energy by the fusion of light nuclei provides a very powerful incentive for the study of plasma physics and MHD. To make light nuclei react and release energy, they must be forced together against their mutual electrostatic repulsion. This happens naturally at the enormous pressures characteristic of the interiors of stars, such as the sun. The aim of MFE, of course, is to create high plasma pressure MSEs using magnetic fields. The efficiency of the MSE is determined (in part) by the dimensionless parameter β, (which is the ratio of the plasma pressure p to the magnetic pressure $B^2/2\mu_0$. For fusion to occur, high pressure must be sustained long enough for the ignited plasma to replace its energy, via the fusion burn, faster than it loses it through leakage of energy across the confining fields. Thus, both high plasma pressure and a sufficiently long plasma energy confinement time, τ_E, are necessary for the success of MFE. The Lawson criteria for ignition of a fusion burn are that the ion temperature T_i exceeds $4.5 \times 10^7 K$ and that the product of density and energy confinement time $n\tau_E \geq 10^{20}\,\mathrm{m}^{-3}\,\mathrm{s}$. These two conditions can be combined into a single criterion often referred to as the Lawson triple product. This requires that $nT\tau_E > 4.5 \times 10^{27}\,\mathrm{m}^{-3}\,\mathrm{Ks}$. This product is proportional to $\beta B^2 \tau_E$, indicating that high beta and large fields are desirable for fusion, assuming that τ_E does not degrade rapidly with either. In addition, high β is intrinsically desirable for economic reasons.

The required Lawson number is lower for a DT plasma than for a D plasma. Tritium, which is virtually nonexistent in nature, may be bred in a lithium blanket surrounding the ignited plasma in which alpha particles escaping from the burning DT plasma react to create T, which can subsequently be extracted to fuel the fusion reactions. Of course, the commercial viability of MFE demands even better performance. The fusion reactions occurring during confinement must recoup the cost of creating and heating the plasma and all other overheads of the system, such as collecting T from the lithium blanket and extracting the spent fuel from the reaction chamber. This necessarily raises the required Lawson triple product in comparison with the value needed for ignition. In practice, Lawson triple products in excess of $2.4 \times 10^{28}\,\mathrm{m}^{-3}\,\mathrm{K\,s}$ are thought to be required for a fusion power plant producing 1 GW of power.

The performance of a magnetic confinement device is determined by

1. *The magnetic configuration*: the external magnetic fields and plasma currents that together define the geometry of the MSE and the strength of the magnetic bottle. Today's tokamaks rely heavily on optimization of the magnetic geometry by shaping of the cross section to achieve peak performance.
2. *Heating power and method*: the means by which the plasma is heated. These include ohmic heating, neutral beam injection, radiofrequency heating, and self-heating by the slowing down of fusion-generated alpha particles. Most scenarios for achieving ignition require auxiliary (i.e., non-ohmic) heating, usually via injection of radiofrequency waves that resonate with a characteristic frequency (known as the cyclotron frequency) of a class of plasma particles.

3. *Fueling*: the means by which fuel is injected. These include gas-puffing, pellet injection, and beam fueling.

4. *Boundary control*: the means by which the deleterious effects of impurity accumulation and other undesirable consequences of plasma–wall interaction are minimized by control of the plasma boundary. This is usually accomplished by a special magnetic configuration called a divertor. This diverts plasma outside the confinement region to a separate chamber, where interaction with walls occurs.

5. *Momentum input*: the means, usually via neutral beam injection, whereby plasma rotation is generated. Toroidal rotation is desirable for optimizing energy confinement and controlling certain types of MHD instabilities.

The principal limitations on fusion plasma performance are

1. *Collisional transport*: There is an irreducible minimum to the cross-field losses, that is, for a given magnetic geometry, *some* losses through diffusion are due to collisions between charged particles (analogous to, but dynamically different from, molecular diffusion in fluids) and these are unavoidable.

2. *Radiative losses*, especially due to *impurities* in the plasma.

3. *Macroscopic MHD instabilities*: MHD instabilities are large-scale perturbations that constrain possible pressure and current profiles. Robust ideal instabilities set hard limits on $p(r)$, $\mathbf{J}(r)$, β, etc. that place an upper bound on the possible Lawson number. Resistive instabilities may set soft limits (i.e., bounds that can be exceeded but only at unacceptably high cost in, for example, heating power). Both ideal and resistive instabilities can lead to disruptions, which are catastrophic events that result in termination of the plasma discharge and may also damage the confinement vessel.

4. *Microinstabilities*: These are small-scale instabilities, driven by local temperature and density gradients, leading to small-scale turbulence that degrades energy and particle confinement through turbulent transport. Microinstabilities typically require a description in terms of two (or more) fluids or one using kinetic equations. Discussion of these is beyond the scope of this article. Microinstabilities typically produce cross-field leakage of energy and particles that far exceeds that due to collisions. They essentially control τ_E, which enters the Lawson triple product.

Instabilities are the key players that limit achievable Lawson numbers. MHD phenomena typically determine β and the plasma pressure p, whereas microinstabilities determine τ_E. Thus, the interplay of macro- and microinstabilities is a recurring theme in the design of MFE devices.

MHD instabilities have played a prominent role in the history of MFE, especially in elucidating the behavior of tokamaks. The early predictions of rapid progress in MFE relied on naive expectations based only on considerations of collisional and radiative losses. Fusion researchers soon learned, however, that an evil genie named instabilities lurked in the magnetic bottle and was only too anxious to escape. The instabilities it created were difficult to control. Thus, the hopes of the MFE pioneers were dashed by the struggle against unexpected, premature termination of discharges by disruptions created by MHD instabilities. The genie had to be persuaded to remain in the bottle. The instabilities had to be understood and minimized or eliminated.

Much, indeed most, research on tokamaks in the late 1960s and 1970s focused on current-driven instabilities called kink-tearing modes, which can disrupt the current profile and thus the discharge. The output of this phase of fusion research was a greatly improved understanding of the parameter space of viable tokamak operations, particularly with respect to current profile and magnetic field configurations. The emphasis of tokamak research in the 1980s and early to mid-1990s shifted to microinstabilities and the turbulent transport associated with them. The aim here, simply stated, was to understand and predict the parameter scaling of τ_E. Great progress was made.

A watershed in this line of research was reached with the discovery of spontaneously formed transport barriers at the edge of, and within, the plasma. A transport barrier is a localized region in which turbulence due to microinstabilities is greatly reduced or extinguished so that cross-field leakage declines to very low, collisional levels. This, in turn, results in the formation of regions of steep pressure gradient. Transport barriers usually form via a spontaneous transition to a state of strongly sheared poloidal and/or toroidal flow, which tears apart the eddies driven by microinstabilites before they can cause significant leakage. Present-day transport barriers can sustain temperature gradients that seem almost incredibly large, in excess of 1 million degrees per inch. Profiles with and without transport barriers are shown in Fig. 13.

The discovery and exploitation of transport barriers stimulated a renewed interest in MHD stability in the late 1990s, a trend that continues to

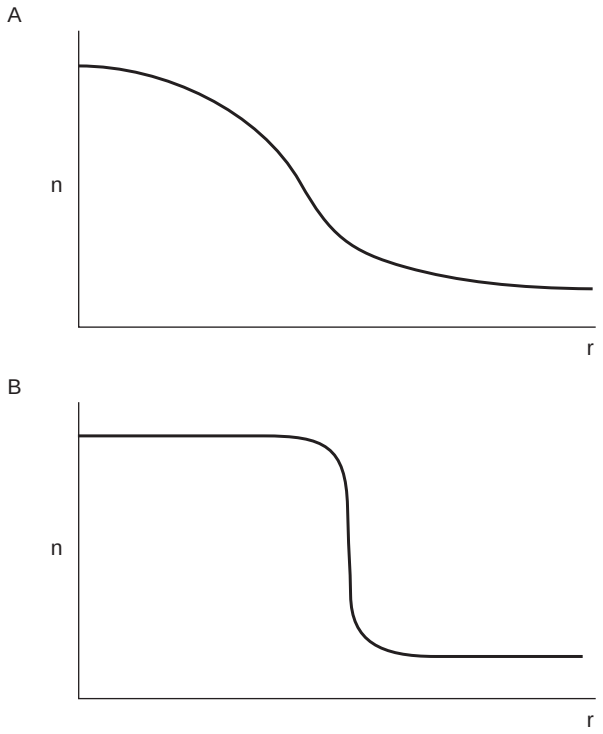

FIGURE 13 Profiles with and without transport barrier. (A) Normal profile; low confinement. (B) Profile with transport barrier; high confinement. Particle density is denoted by n.

this day. In confining the plasma better, a transport barrier also creates a larger pressure gradient in the plasma column that brings it closer to the verge of ideal MHD instability. In the jargon of MFE, enhanced confinement is necessary to reach the β limit. Thus, much of the current research on MFE is devoted to avoiding or mitigating the effects of pressure-driven ideal MHD instabilities via cross-section shaping, active feedback techniques, and profile control. Paradoxically, after 40 years of research on how to exterminate microinstabilities, effort is now being expended on finding ways to stimulate them at opportune times. The aim is to reap the full benefits of transport barriers by avoiding disruptions while at the same time controlling impurity accumulation.

5.3 Examples of MHD Instabilities in MFE Plasmas

As mentioned previously, the MHD instability of MFE plasmas is an exceptionally complex topic but is the subject of several excellent monographs. Here, we give only an introduction to the major pressure gradient and current gradient instability

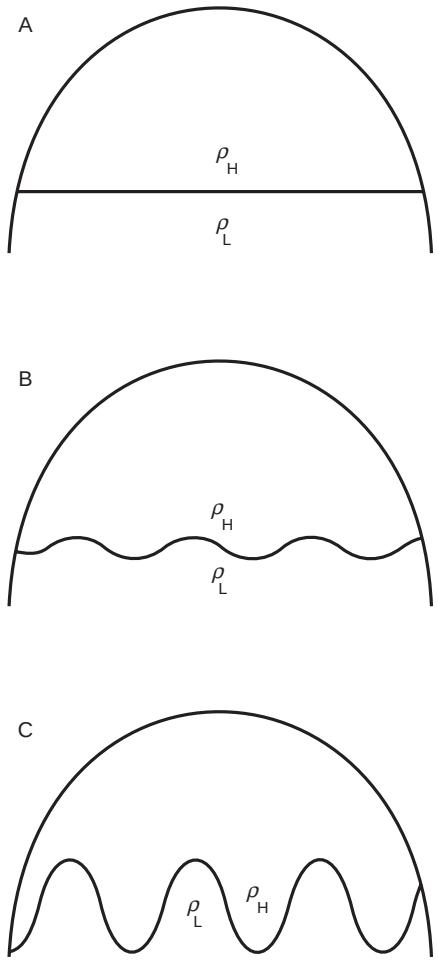

FIGURE 14 Development of Rayleigh–Taylor instability. (A) Initial equilibrium, with heavy fluid (density ρ_H) on top of light fluid (density ρ_L). (B) Ripples form on the interface. (C) Ripples are amplified by Rayleigh–Taylor instability.

mechanisms; interchange-ballooning modes and kink-tearing modes, respectively.

5.3.1 Interchange-Ballooning Modes

These modes, like all ideal MHD instabilities driven by the pressure gradient, are related to Rayleigh–Taylor instability, familiar from classical (nonmagnetic) fluid dynamics. Rayleigh–Taylor instability occurs when ripples are excited on the interface between a heavy fluid (e.g., water) sitting atop a lighter fluid (e.g., air) in a gravitational field, as shown in Fig. 14. Everyone knows what happens: The water falls out of the glass. What is not so apparent is that the initial configuration of the water and air is in equilibrium, but that the equilibrium is unstable to the growth of ripple perturbations. The experimentally inclined reader (with inexpensive carpeting) may easily convince himself or herself of

this by filling a glass to the brim, placing a strong piece of cardboard (preferably two-ply) over the surface of the water and in contact with the rim of the glass, and then inverting the glass. Because the presence of the cardboard prevents the formation of surface ripples, the water will not fall, so long as the integrity of the cardboard is maintained. Of course, the free energy source for this instability is simply the gravitational potential energy stored in the initial configuration (i.e., the elevated heavy fluid); the gradient that relaxes is simply the density gradient.

The analogue of the Rayleigh–Taylor instability in the MHD of magnetically confined plasmas is the interchange instability. Interchange instability relaxes the gradient in density, or more generally in the pressure gradient, by lowering the effective gravitational potential energy of the system. It does this by interchanging a tube of high-pressure fluid with a tube of low-pressure fluid, as shown in Fig. 15. In a magnetically confined plasma, the role of gravity is played by the centrifugal force exerted on the plasma particles as they traverse curved field lines. This results in a net body force that resembles a gravitational force. Thus, if field lines curve or sag away from regions of higher pressure, the system is interchange unstable, whereas if they curve or sag toward regions of higher pressure, the system is interchange stable (Fig. 16). Equivalently, an interchange stable system is said to have favorable curvature, whereas one that is unstable is said to have unfavorable curvature. Also, it is important to realize that the conceptual image of an interchange of two plasma tubes is motivated by the fact that potential energy release will be maximal when the perturbation does not spend any portion of its energy budget on bending field lines. In other words, a pure interchange instability does not couple to Alfvén waves. In reality, the physical appearance of an interchange instability resembles that of a convection roll (Fig. 17).

In magnetic confinement devices of practical interest (including tokamaks), the magnetic curvature is not constant but, rather, varies along the field lines. Interchange stability is then determined by an average of the magnetic curvature over the extent of the field line. One key virtue of the tokamak is that its configuration has favorable average curvature and thus is interchange stable. However, as one follows a field line around the tokamak, one traverses regions of locally unfavorable curvature on the outboard side of the torus and locally favorable curvature on the inboard side. Thus, if perturbations are larger and stronger in regions of locally unfavorable curvature

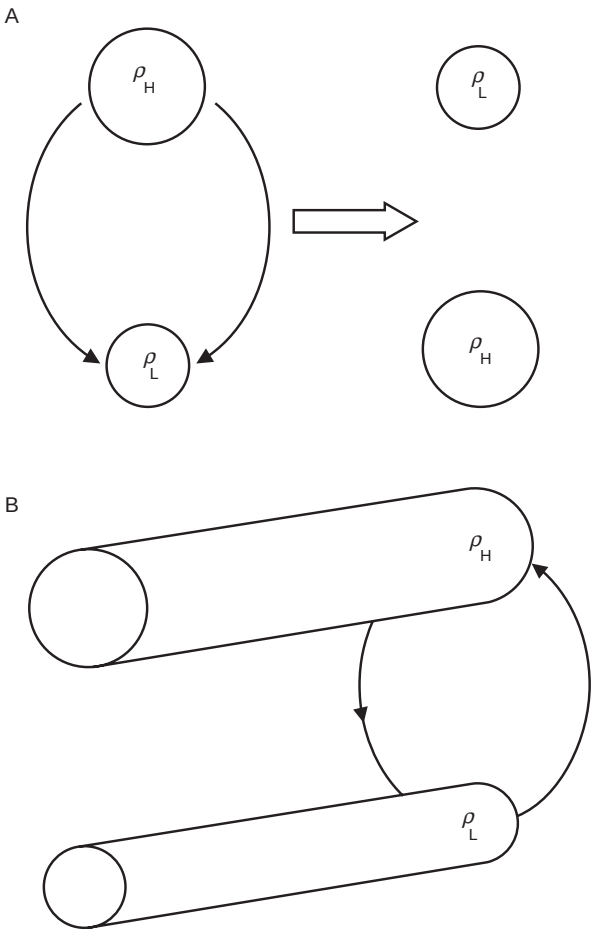

FIGURE 15 Interchange instability. (A) Interchange instability switches tubes of heavy and light fluid (densities ρ_H and ρ_L, respectively. (B) Oblique view of tube interchange; note that tubes, which are aligned with field lines, are not bent.

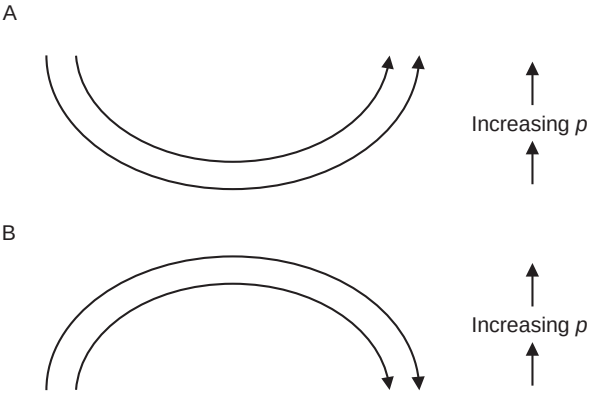

FIGURE 16 Favorable and unfavorable curvature. (A) Unfavorable curvature: Field lines sag away from the region of high pressure p. (B) Favorable curvature: Field lines curve toward the high-pressure region.

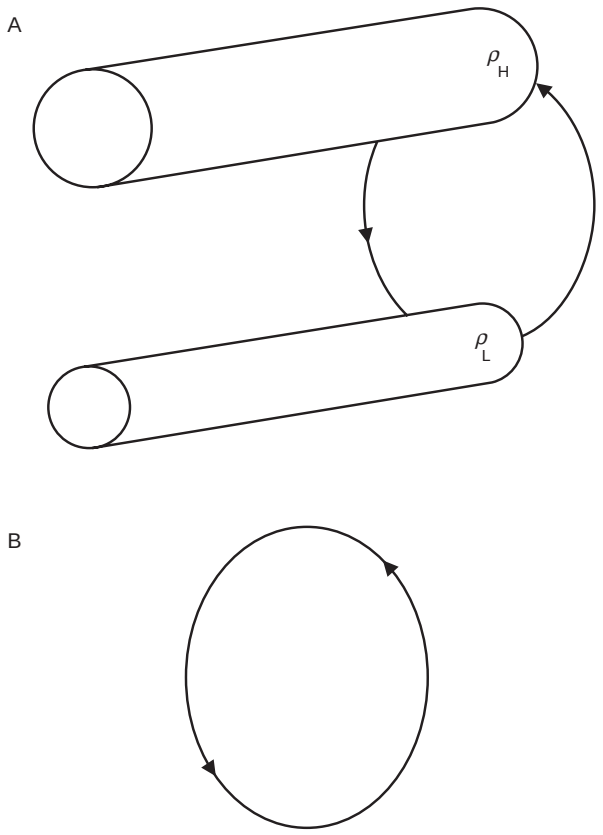

FIGURE 17 Depiction of an interchange convection roll; see legend to Fig. 15.

than they are in the locally favorable regions, instability is possible. These are called ballooning instabilities because the perturbation in the plasma pressure balloons the plasma outward in regions of unfavorable curvature. A physical picture of a ballooning instability may be gained by thinking of what happens when one overinflates a bicycle tire. Of course, the tire eventually ruptures. If there is no flaw in the tire material, the rupture will be likely to occur on the outboard portion of the wheel because the inboard portion is supported by the structural frame of the wheel and is thus mechanically more resilient. Indeed, sometimes an aneurysm will form in the tire. Finite-amplitude ballooning may be thought of as a kind of aneurysm in the magnetic surface that is driven by high plasma pressure interior to that surface. Finite-amplitude ballooning-kink instabilities are shown in Figs 18 and 19. Figure 18 shows development of the instability in a poloidal cross-section. Notice how fingers form on the outboard side of the torus. Figure 19 shows the magnetic flux surfaces. Notice how the ballooning instability produces crenelations in these.

Although ballooning instabilities are closely related to interchange instabilities, they differ crucially in that the perturbations vary along the field lines and therefore must bend the field lines. Thus, ballooning instabilities couple localized interchange motions to Alfvén waves. For ballooning instability to occur, the energy released by interchange motions in the unfavorable regions must exceed the energy expended in bending the magnetic field lines. Thus, there is a minimal or critical pressure gradient required for ballooning instability to occur. This is in sharp contrast to the interchange mode (in a system with a curvature that is on average unfavorable), which, in ideal MHD, can occur for any pressure gradient. The critical pressure gradient for ballooning instability plays a central role in the ultimate determination of the maximum achievable β for a specific configuration (i.e., its beta limit). In practice, the magnetic geometry and magnetic field strength determine the critical pressure gradient for ballooning instability. One important feature of magnetic geometry is the magnetic shear, which parameterizes how rapidly the direction of field lines changes as a function of radius r. Magnetic shear plays an important and subtle role in the detailed dynamics of ballooning instabilities. A complete discussion of this is beyond the scope of this article.

5.3.2 Kink-Tearing Modes

Kink-tearing modes are all driven by the current gradient, although the symptom of instability is often related to the pitch of the magnetic field lines. The physical nature of the modes is best illustrated by a sequential discussion of sausage instabilities, kink instabilities, and tearing instabilities.

Consider the Z pinch (Fig. 7A). Figure 20 illustrates a type of perturbation, sometimes called a sausage mode, which is axisymmetric around the axis of the pinch. The existence of the sausage mode of instability can be explained rather simply. As discussed in Section 2, the field B_θ outside the plasma column, created by a current I flowing down it, is azimuthal in direction and of strength $\mu_0 I/2\pi r$. On the surface of the column, the field strength is therefore $\mu_0 I/2\pi a$, where a is the local radius of the column, which varies when the tube is pinched. The pinched column then resembles a tube of sausage meat that has been compressed to create a chain of links. The surface field and the associated field line tension are greater where the column necks and smaller where it bulges. This is the field that confines the plasma column, and since I is constant, the tension it exerts on the necks of the chain further

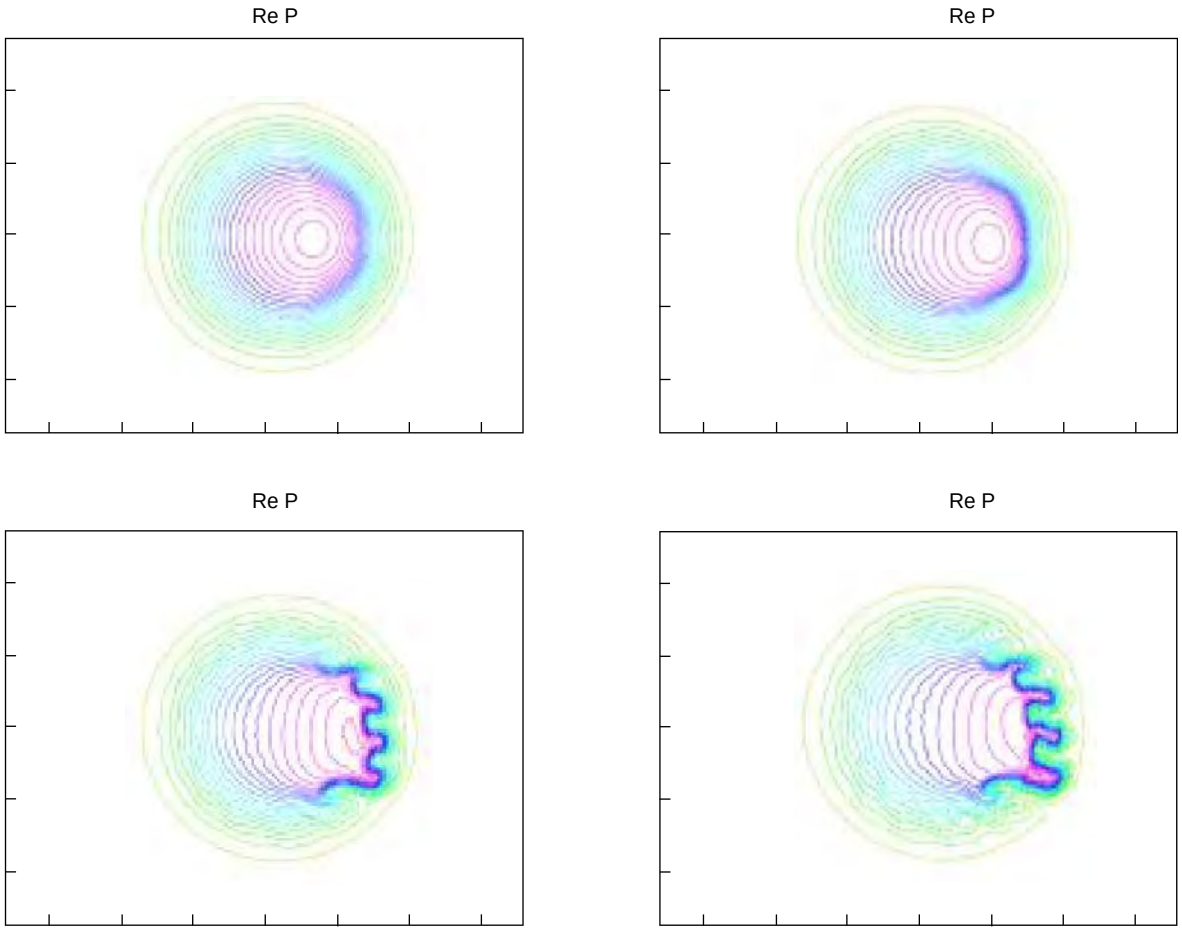

FIGURE 18 Development of a ballooning mode as seen in a poloidal cross section of the torus. The magnetic axis is on the left of each panel. The sequence of panels is as follows: top left, top right, bottom left, and bottom right. Note that perturbations are larger on the outboard midplane regions (on the right). Also note that as the perturbation grows, it evolves to form fingers or spikes. Courtesy of S. C. Jardin and the Center for Extended MHD Modeling, Princeton Plasma Physics Laboratory.

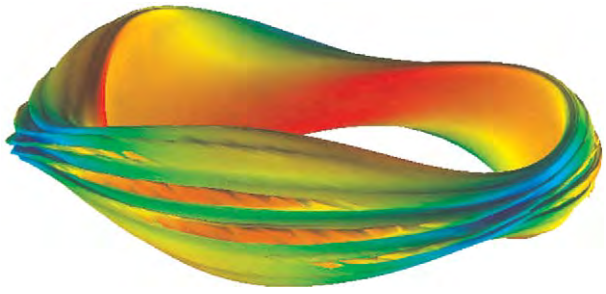

FIGURE 19 Development of a ballooning-kink mode in a torus. Note how a side view of the finger formation reveals the tendency of the ballooning mode to crenelate the plasma and break it into ribbons. FIGURE 20 The sausage mode of instability of a Z pinch; lines of force encircling a current-carrying plasma column are shown. J_z indicates the cross section through which the current enters.

increases the initial deformation of the column. This self-reinforcing, positive feedback loop is indicative of an instability process that tends to break up the column into a chain of plasmoids (i.e., plasma droplets). For obvious reasons, the instability is called the sausage instability. The mechanism of sausage instability is closely related to that causing a thin stream of water from a faucet to break up into a

line of spheroidal droplets. In this case, surface tension plays the role of field line tension.

The sausage instability may be stabilized by an axial field B_z of sufficient strength within the column, which provides a tension that opposes the formation of necks. The critical strength of B_z necessary for stabilization can be estimated by comparing the field energy released by necking of the column with the energetic costs of deforming the axial field B_z. Because necking motions must conserve axial magnetic flux, the change, $\Delta(B_z^2/2\mu_0)$, in energy density of the axial field is $-B_z^2\Delta a/\mu_0 a$, where $\Delta a/a<0$. The corresponding change, $\Delta(B_\theta^2/2\mu_0)$, in the azimuthal field energy density is $B_\theta^2\Delta a/2\mu_0 a$. It follows that the net change in magnetic energy is positive if $B_z^2>\frac{1}{2}B_\theta^2$. This gives the required axial field strength necessary to stabilize the instability, as depicted in Fig. 21. Note that when the plasma tube is bent into a torus, one arrives at a simple model of the tokamak configuration.

The dual presence of both a poloidal field and a strong, vacuum toroidal field greatly improves the MHD stability of a toroidal pinch by eliminating both the sausage instability and the related bending instability shown in Fig. 22 and by introducing magnetic shear, which is useful in controlling pressure-driven instabilities. Indeed, the tokamak

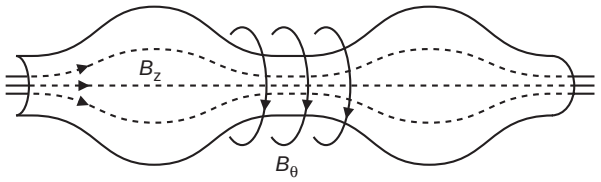

FIGURE 21 Stiffening of the *Z* pinch against sausage modes of instability by the addition of a field B_z along the plasma column (creating a screw pinch).

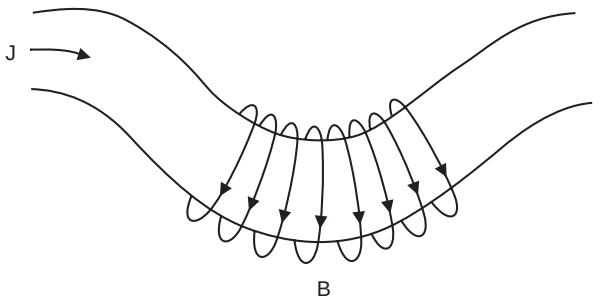

FIGURE 22 The bending mode of instability of the *Z* pinch. Note how the lines of force are crowded together on the inside of the bend and are moved apart on the outside of the bend; the concomitant difference in magnetic pressure acts to reenforce the displacement.

magnetic configuration is de facto defined by the pitch of its magnetic field lines, which is given by $q(r)=rB_\phi/R_0B_\theta$. With the (possible) exception of a finite region around the magnetic axis, the $q(r)$ of standard tokamaks exceeds 1 and increases with r so that the magnetic shear is positive. The maximum $q(r)$ in most standard tokamaks is between 2 and 4. The intrinsic dual periodicity of toroidal configurations means that perturbations also have their own effective pitch. This is a rational number, m/n, where m and n are positive integers, with m being the number of times the perturbation circles the torus in the poloidal direction while completing n turns in the toroidal direction. Thus, it is possible for the field line pitch $q(r)$ to equal (or resonate with) the perturbation pitch m/n at certain radii, $r_{m,n}$, where $q(r_{m,n})=m/n$. These special radii define magnetic surfaces that are called rational or resonant surfaces.

Resonant surfaces, and more generally field line pitch, are crucial to an important class of instabilities called kink-tearing instabilities. The onset of these instabilities is determined by $q(r)$ and by the radial gradient of the current profile. Since $q(r)$ is determined primarily by $B_\theta(r)$, kink-tearing instabilities are also conveniently described as current-driven instabilities. When the perturbation pitch m/n exceeds $q(a)$ for $r<a$, the instability does not involve magnetic reconnection and is called an external kink. It may then be described by ideal MHD. The effects of boundaries, particularly conducting walls, are vitally important to external kink dynamics and stability (see Section 4 and Fig. 9). When the perturbation is resonant [i.e., when $m/n=q(r)$ for $r<a$], reconnection is usually involved and the instability is called a tearing mode since magnetic field lines tear and reconnect. Tearing modes involve the formation of current filaments. In certain cases, the instability dynamics of a resonant kink (usually with $m=1$) can be described, at least in its initial phases, by ideal MHD. Such instabilities are called ideal internal kinks.

Ideal kink instabilities are current driven, but it is really the pitch of the magnetic field lines that signals the onset of the instability. Kink instabilities have long wavelength in the toroidal direction and cause the plasma column to snake helically around its equilibrium position in the manner shown in Fig. 23. Before the column is perturbed, the current flows parallel to the magnetic field. After perturbation, it follows the helical path shown and produces a magnetic field resembling that shown in Fig. 23. This is only part of the total field; to obtain the total field, one must imagine augmenting the **B** shown in the

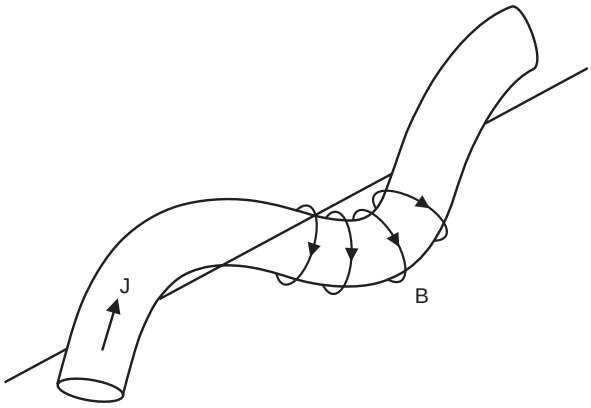

FIGURE 23 Kink instability of a toroidal equilibrium. In the initial state, the current flows along field lines. In the perturbed state (shown here), the current follows a helical path and creates a field, **B**, of the type shown. The remainder of the field (not shown) is along the helically distorted column. The net result is a field that has a component perpendicular to **J** that creates a Lorentz force enhancing the perturbation.

figure by the field along the column. The net result is a field, **B**, that has a component orthogonal to **J**. This creates a $\mathbf{J} \times \mathbf{B}$ force that reenforces the initial perturbation, thus promoting instability.

Kink instabilities are similar to the helical deformations of an elastic tube or band that occur when it is twisted beyond a critical value. An example of such kinks is sometimes seen on a wire connecting a telephone handset to its cradle. The twist of the band is clearly analogous to the initial pitch (or twist) of field lines, as given by $q(r)$. Kink instabilities reflect the tendency of the plasma to lower its energy by assuming a secondary, helical equilibrium that replaces the initial configuration with one of helical symmetry. The ultimate radial extent of the helical deformation is determined by several factors, including the amount of plasma current, the toroidal field strength, and the size of the gap between the plasma boundary and the conducting walls of the containment vessel. Since the plasma current channel expands during kink instabilities, these constitute a simple but very direct route to an undesirable disruption of the discharge, should the current column come into contact with a wall of the containment vessel.

In practice, external kink instabilities can be avoided by not operating the discharge with $q(a)$ close to a low-order rational number, such as, $\frac{3}{2}$, 2, or 3, and/or by having a conducting wall sufficiently close to the plasma column. Kink instabilities are also predicted to occur when $q(r) < 1$. For this reason, internal kinks are ubiquitous in tokamaks and are thought to be related to the sawtooth phenomenon. This refers to quasi-periodic relaxation oscillations of the central temperature of the tokamak that, in diagnostic recordings, produce a jagged trace reminiscent of the teeth on a saw.

Since internal kink perturbations usually do not pierce the plasma boundary or bring the current channel into contact with the vessel wall, they are usually not directly associated with disruptions. Internal kinks do, however, affect the performance of tokamaks by limiting the central plasma pressure that can be achieved.

The dynamics of energy release in resonant kinks or tearing modes are determined by nonideal effects (i.e., by effects that break the Alfvén frozen flux constraint). Typical of such nonideal effects is plasma resistivity η. However, it is important to keep in mind that the free energy source for tearing modes is the same as that for kinks, namely the current gradient. Nonideal effects, such as resistivity, are only the triggers of the instability and are significant only in a narrow diffusion layer, surrounding the resonant surface, in which reconnection occurs. Just as kinks tend to form helical secondary equilibria, so do tearing modes. However, since tearing modes are resonant, reconnection occurs, resulting in the formation of magnetic islands in the region near the resonant surface, as shown in Fig. 24. These islands may be thought of as consequences of current filamentation and concomitant reconnection. Magnetic islands are MHD analogues of Kelvin cat's eyes or nonlinear critical layers, which form as a consequence of certain hydrodynamic shear flow instabilities. When magnetic islands grow to a size at which they touch the wall, or when magnetic islands at neighboring resonant surfaces overlap (resulting in stochastic field lines in a region that pierces the surface of the plasma), MHD turbulence is generated, resulting in turbulent transport, rapid heat loss, and a sudden expansion of the current channel. When the current strikes the wall, a large impurity influx commences, and this raises the effective

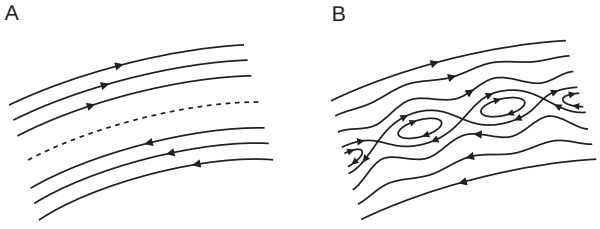

FIGURE 24 The formation of magnetic islands. (A) Initial state; the neutral line is shown dashed. (B) Field configuration after magnetic islands have formed around the neutral line.

plasma resistivity, which in turn quenches the current, creating a disruption. For this reason, tearing mode dynamics and stability are of great interest to MFE.

A final comment on tearing instabilities concerns their rate of growth. Ideal MHD instabilities grow exponentially, on Alfvénic (e.g., kink) or sonic (e.g., ballooning) timescales. Tearing modes initially grow at a rate proportional to $(\tau_A^{-2}\tau_\eta^{-3})^{1/5}$, where τ_A and τ_η are the Alfvén and (global) resistive diffusion times defined in Sections 3 and 4. Since $\tau_A \ll \tau_\eta$, tearing modes grow more slowly than ideal MHD modes. However, linear growth rates are of little relevance to the dynamics of the tearing mode since magnetic islands rapidly enter a nonlinear phase of algebraic growth. This occurs when the width of the magnetic island exceeds the width of the (narrow) reconnection layer of the linear theory. A major current research topic in tokamak MHD concerns the nonlinear growth and saturation of magnetic islands.

5.4 Interplay of MHD Instabilities and Tokamak Operation

Considerations of turbulent transport and MHD stability define the possible viable operating space of present-day tokamaks. The MFE program has sought to exploit understanding of MHD stability limits, etc. in order to expand and optimize the tokamak operating space. The tactics and tricks used include

1. *Shaping the cross section* to increase β limits: The goal here is to design a shape that increases the relative fraction of a magnetic field line that lies in the region of favorable curvature.
2. *Programming current and heating evolution* in order to avoid conditions that are prone to the onset of disruptions (i.e., in order to improve ideal stability limits).
3. *Controlling current profiles* by driving currents locally through the injection of radiofrequency waves.
4. *Using active feedback*, including current drive, to mitigate or retard the growth of undesirable perturbations.
5. *Driving plasma rotation* by neutral beam injection in order to stabilize certain MHD instabilities.

A recurrent theme in fusion research is the often rather diabolical ways in which various instabilities conspire to limit the operating space and tokamak performance. As mentioned previously, eliminating microinstabilities using transport barriers enhances confinement times but opens the door to pressure-driven instabilities (i.e., interchange ballooning modes). Operating at high current is good for energy confinement and helps limit pressure-driven ballooning modes, but it increases the possibility of disruption due to kink-tearing modes. Employing low currents improves stability but often degrades confinement and fails to achieve maximal machine performance. The list is long and continues to grow. These numerous and accumulating questions and concerns ensure that both the theoretical and experimental MHD of tokamaks and other MFE devices will remain vital and vibrant research areas well into the 21st century.

5.5 The Future of MHD in MFE

There is little doubt that in the near future the focus of the world MFE program will be the International Thermonuclear Experimental Reactor (ITER), a tokamak shown schematically in Fig. 25. The ITER program is an international project involving the collaboration of many countries. Its primary mission is to study plasma dynamics under conditions of a fusion burn, in which the main source of plasma heating is from collisional friction between the alpha particles produced by the thermonuclear reactions and the electrons.

A burning plasma is different from the standard electron–ion plasma discussed so far in (at least) two very important respects. First, a burning plasma contains a very substantial population of high-energy alpha particles. This situation is inconsistent with the foundations of MHD, which treats both ions and electrons together as a single fluid. The absolutely minimal viable theory of the dynamics of a burning plasma is a two-component description involving an MHD-like model of the bulk plasma and a kinetic equation for the energetic alphas; these have a velocity distribution that is far from Maxwellian and cannot therefore be adequately modeled by fluid equations. The two components of the model couple to each other electrodynamically.

The second important distinction between a burning plasma and a standard plasma is that high-energy alpha particles can resonate with plasma waves of higher frequency than can bulk particles, thus encouraging a new class of instabilities. Of particular importance among these are toroidal Alfvén eigenmodes (TAEs), which can be destabilized by resonance with alphas and so relax the alpha particle density and temperature gradients. TAEs are

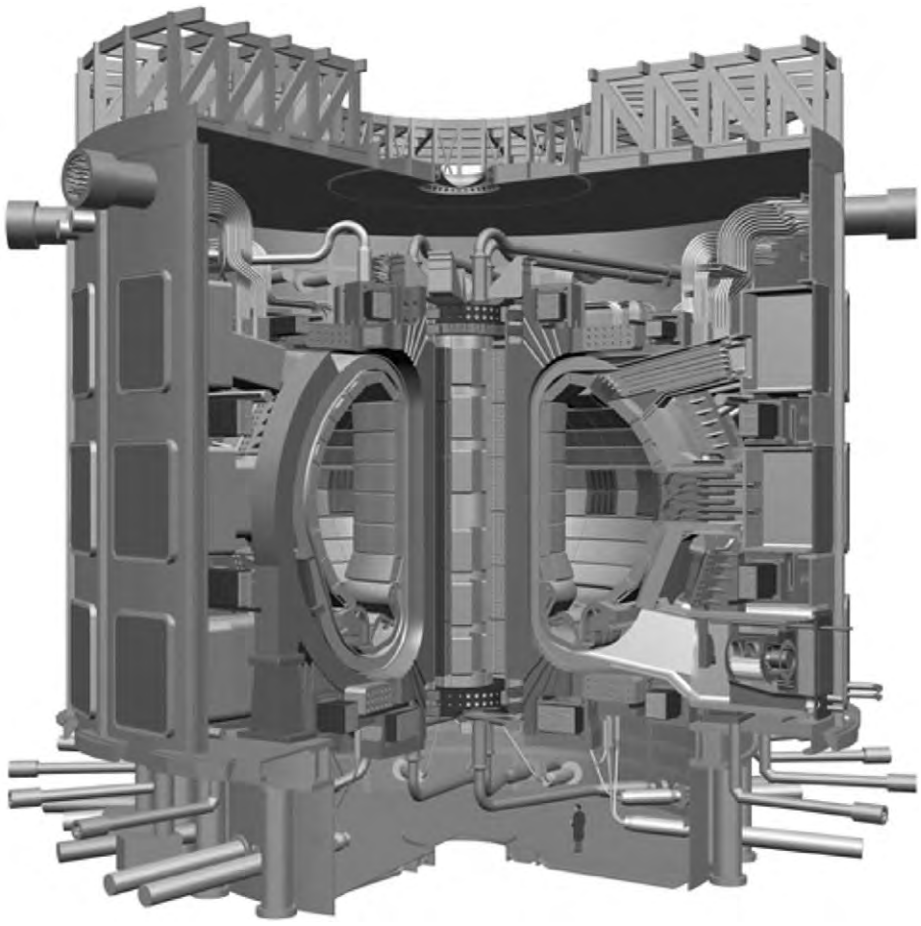

FIGURE 25 The tokamak ITER. To appreciate the scale of the device, see the figure of a person near the bottom.

critical to MFE since excessive instability-induced alpha losses can prevent, or prematurely quench, ignition. TAEs and other energetic particle-driven instabilities have been a topic of great interest in theoretical, computational, and experimental MFE research, with beams of externally injected high-energy particles used to simulate the effects of the alphas. Clearly, research in alpha particle-driven instabilities will be a major part of the ITER program.

Traditional MHD problems will be major foci of the ITER program as well. A key topic will certainly be feedback stabilization of instabilities, with the aim of avoiding or mitigating disruptions. Note that the disruption of a burning plasma could cause very significant damage to the ITER confinement vessel. Also, any successful fusion power plant must be effectively disruption free. Because the ITER plasma will be very hot, with concomitantly infrequent collisions between particles in the plasma, the traditional MHD model will need extension in order to include dynamical effects relevant to the ITER plasma. Such effects include possible nonideal, kinetic modifications to MHD as well as transport coefficients that describe dissipation due to micro-turbulence rather than collisions. Theoretical and computational research on such extended MHD models is being pursued vigorously throughout the world today. In addition, it is anticipated that subgrid scale models of turbulent transport will be an integral component of extended MHD models in the future.

Glossary

carbureted water gas Gas produced by spraying blue gas (water gas) with liquid hydrocarbons and thermally cracking it to form carbureted water gas and tars.
coal gas A method of heating bituminous coal in a retort to destructively distill volatiles from the coal in order to produce fuel gas for illuminating and heating purposes.
water gas A fuel gas composed primarily of hydrogen and carbon monoxide produced through the interaction of steam with incandescent carbon, usually from anthracite coal or coke.
Welsbach mantle A mantle made of cotton fabric impregnated with rare earth that becomes incandescent when exposed to a gas flame.

This article examines the development of the manufactured gas industry in the United States from its origins early in the 19th century to its demise in the post-World War II period. It discusses the production technologies of coal gas, water gas, and oil gas and their methods of distribution. It also discusses industry innovations, such as the development of carbureted water gas and of the Welsbach mantle, and their effect on regulatory standards. It explores the shift from the use of manufactured gas to natural gas in the period from the 1920s through the 1950s, with the consequent demise of the industry. Finally, the article examines the environmental effects of the industry and the issues of the cleanup of former MGP sites.

1. ORIGINS AND CHARACTERISTICS OF THE INDUSTRY

Manufactured gas was one of the most critical energy sources and fuels that provided American cities, as well as other cities throughout the world, with light and energy during much of the century from 1850 to 1950. Manufactured gas is produced by heating coal or other organic substances such as wood, pitch, or petroleum, driving off a flammable gas made primarily of carbon monoxide and hydrogen as well as other gases. The discovery that flammable gas could be produced in this manner was first made in Great Britain by John Clayton in the late seventeenth century followed by the work of Frenchmen Jean Pierre Minckelers and Philippe Lebon in the late 18th and early 19th centuries. At the turn of the century, the British engineer William Murdock developed methods of gas lighting that were used in cotton mills.

Demonstrations and applications of gas lighting began in the United States in 1802, based on European developments. Gasworks were installed to provide better illumination for cotton mills and lighthouses during the first decade of the century. In 1817, the Baltimore municipality granted the Gas Light Company a franchise to lay gas pipe in the city streets and to light them. Others cities quickly followed: New York, 1825; Boston, 1829; New Orleans, 1835; Philadelphia, the first municipally owned plant, 1836; and San Francisco, the first western plant, 1854. The U.S. Census reported 30 manufactured gas plants in 1850, 221 in 1859, 390 in 1869, 742 in 1889, 877 in 1904, and 1296 in 1909, but the actual number was probably much larger.

The manufactured gas utilities that emerged ranged in size from very small plants in small towns (cf. 5000 population) that served a limited number of consumers (200–300) to very large plants with extensive distribution systems that served thousands

of customers with gas for home lighting, cooking, and heating, served municipalities by illuminating city streets, and provided gas for a number of industries. Urban gas utilities were systems that generated fuel for their customers from a central plant (or plants in the case of the very large utilities) and distributed it through a piped system. By far, it was most widely used for lighting purposes. Individual gas production units were also manufactured and were used for isolated factories and homes (spirit gas lamps). From the late 19th century onward, various industries in need of low-Btu (British thermal unit) gas frequently installed coal-using producer gas units in their factories.

Municipal and state governments regarded gas manufacturing plants as public utilities and required that they acquire franchises to use the city streets for their distribution lines. In order to profitably survive, gas manufacturing utilities required long rather than short franchises—the exact term, however, produced many heated political battles. Franchises were originally local but frequently became the concern of state authorities because the natural monopoly characteristics of the utilities were resistant to market forces. Battles over issues such as price, luminosity and energy ratings, and technology, as well as price and duration, frequently took place between utility firms and municipal and state authorities. Although some municipally owned gas works existed, the industry remained largely private.

2. THE PERIOD OF COAL GAS DOMINATION, 1816–1875

In the period from 1816 to 1875, the number of centralized gas works grew to between 300 and 400, primarily using technology developed in Great Britain. The most important innovations during these years concerned fuel, distillation technology, distribution, and metering technology.

Although most firms eventually used coal as their feedstock for gas production, other substances were also initially used. The Baltimore Gas-Light Company, for instance, used pine tar as the feedstock for its initial gas production, the New York Gas Works used rosin, the Brooklyn Gas Works consumed British coals, and the Wilmington, North Carolina Gas Works used wood from the Carolina Pine Barrens. Several small eastern cities used distillate of turpentine to manufacture rosin gas and Philadelphia experimented with wood as late as the 1850s. Utility managers originally avoided coal because of its impurities, but in the period from 1815 to 1820, British gas manufacturers developed methods to remove such impurities. In 1822, Baltimore became the first American city to consume coal to produce gas, using bituminous coal from Virginia mines for its feedstock.

Since bituminous coal mines were not easily accessible for most cities, the cost of the fuel kept prices relatively high or forced the use of organic materials such as wood. Expensive fuel, therefore, provided a reverse salient (a concept originated by historian of technology Thomas Hughes), in terms of extending the size of the market for improved lighting. Whereas bituminous coal, considered "the best in the world for gas light," existed in western Pennsylvania and was used in Pittsburgh for gas production and for home heating, transportation costs over the Allegheny Mountains were extremely high, limiting its use in eastern markets.

The major transportation breakthroughs came in the late 1840s and 1850s with the slack watering of the Pittsburgh area rivers and the completion of railroad connections from Philadelphia to Pittsburgh in 1852. These transport improvements facilitated the shipping of high-quality bituminous gas coal from western Pennsylvania to gas works in eastern cities at greatly reduced transportation costs. By the late 1850s, for instance, the Westmoreland Coal Company, a large western Pennsylvania producer of gas coal, was supplying 58 gas works.

Responding to the lower fuel costs and the anticipation of a larger market for cheaper light, a number of gas works were founded in the 1850s and 1860s. Between 1850 and 1860, the U.S. Census reported that the number of manufactured gas establishments jumped from 30 to 221, a rise of over 600%—an increase much greater than that of urban population growth. By 1870, the total number of manufactured gas plants reported was 390, another large jump.

The manufacture of coal gas consisted of three operations: distillation, condensation, and purification. Although there were many different processes patented for the production of coal gas, by the 1850s those most widely used operated by heating bituminous coal in a retort to destructively distill volatiles from the coal. The leading types of coal-carbonization retorts were the horizontal, inclined, and vertical. Horizontal retorts were most commonly used; until approximately 1850, they were made of cast iron, when superior clay refractories were substituted. A typical horizontal bench consisted of six

retorts and a producer gas furnace that used coke or coal for heating the retorts. Coal tar condensed from the gas was also used as a retort fuel. Wet and dry lime processes were used in purification methods, as was iron oxide, beginning in 1870.

Proper modes of metering, gas storage, and distribution were critical to the successful operation of a gas firm. Gas holders, or gasometers, as they were called, were essentially inverted iron bells in a tub of water. The early gas holders were usually made of masonry and often set in the ground, with iron plates for the bell. A number of firms initially used wooden mains for distribution, but in ~1820, cast iron pipes manufactured in British foundries were introduced into the United States; however, some wooden mains of tamarack logs lasted into the late 19th century. By the 1830s, American foundries were producing their own cast iron pipe, reducing dependence on the British. From ~1820 through 1850, pipe was made in horizontally cast sections (4–5 ft in length). These were subject to considerable core sagging and slag accumulations but in 1850 foundries shifted to casting in vertical molds, producing a much stronger and longer (12 ft) pipe product. Nineteenth century cast iron gas mains often lasted 50 to 75 years.

The distribution system was another major cost for the gas companies. Firms occasionally used smaller diameter mains than was ideal, causing problems and poor service as the system expanded. In Philadelphia, for instance, the city-owned utility used pumps to force gas through mains too small to accommodate the demand, often resulting in customers receiving gas under excess pressure. Though the gas utilities seldom extended conduits to undeveloped streets, they quickly installed pipe on streets in growing areas in order to benefit from rises in real estate prices.

Cities initially used gas primarily for street illumination but cost reductions plus innovations such as improved burners and fixtures and metering led to a broader market. Gas companies originally charged flat rates per burner, leading to expansion limits for street lights and domestic sales. Meters were essential for price reduction for both municipalities and domestic consumers but were fought in many city councils. The original meters were "wet" meters, using water, but in the 1850s firms began replacing them with more accurate dry meters.

The manufacture of coal gas provided the potential for firms to recover and sell by-products such as coke, tar, light oil, and ammonia. However, unlike Great Britain, there was no market for such products in the United States (aside from the coke) before the late 19th century. The United States lacked a coal-based chemical industry and was almost completely dependent on imports for dyestuffs, drugs, and explosives and other products of coal tar and light oil origin. Ammonia was regarded as a nuisance until after the Civil War, when ammonium sulfate was used for fertilizer. Gasworks themselves burned by-product coke under their retorts and sold some on the open market, but it had limited appeal.

By the 1870s, over 400 manufactured gas utilities existed and the industry had spread throughout the country. Over half of the firms, with over 50% of the labor and capital, were located in just four states: New York (71), Massachusetts (52), Pennsylvania (43), and Ohio (32). Price, however, still limited home gas service to a relatively affluent segment of the market. Gas companies had originally hoped to make large profits from street lights, but municipal franchises applied stringent regulations as to the numbers of public street lights and rates paid, and many firms defaulted on this part of the contract or were continually petitioning city councils for rate increases. Because costs were high and margins low, gas companies were reluctant to expand to lower income markets, putting the industry at risk from lower priced fuels. In the 1850s, coal oil lamps provided much of the lighting needs of those who could not afford gas, the fuel supplied from refineries concentrated in Pittsburgh and Ohio. These lamps furnished up to 14 cp and were quite flexible to use. In the post-Civil War period, however, two new competitors for manufactured gas emerged to challenge the industry for the lighting market—kerosene and electricity.

3. INNOVATIONS AND CHALLENGES FROM COMPETING FUELS, 1875–1927

Substantial competition for urban lighting markets developed in the half century from 1875 to 1927. Municipalities and states also subjected the industry to increased regulation. The first competitor for the lighting market was the kerosene lamp, an outcome of the discovery of oil in Pennsylvania in 1859, which largely captured the low end of the illumination market. Improvements in petroleum refining and transportation techniques and the discovery of new sources of supply resulted in reduced oil prices. By the 1870s and 1880s, most of the urban working

class, as well as a substantial part of the middle class, used kerosene lamps for domestic illumination.

Electric arc lamps began competing with manufactured gas for the street lighting market in the 1880s. Since gas companies found these lighting contracts unprofitable, it was a limited loss. By the 1880s, domestic lighting accounted for 90% of gas revenues and arc lamps posed no threat in this market because their intensity made them unusable in the home. In 1881, however, Thomas Edison, the inventor of the incandescent lamp, developed a central power station in New York City that supplied power for home lighting that directly competed with interior gas light. Edison had wisely based his distribution system on that of the gas industry, constructing an "electrical analogue to the gas system."

The manufactured gas industry responded to this challenge with the development of carbureted water gas. The concept behind water gas, which was first observed in 1780 and patented in France in 1834, involved the action of steam on incandescent carbon, usually anthracite coal or coke. When the steam, composed of oxygen and hydrogen, came into contact with the incandescent carbon, it produced a fuel gas composed of hydrogen and carbon monoxide, as well as other products. The gas had a heating value of approximately 300 Btu/ft^3, burned with a blue flame, and had little illuminating power. The last characteristic diminished the utility of water gas for commercial use, because the market for manufactured gas in most of the 19th century was almost entirely in lighting.

In 1875, however, Thaddeous S. C. Lowe, a Pennsylvania inventor, patented a process to enrich the blue gas by spraying it with liquid hydrocarbons and thermally cracking the gas to form carbureted water gas and tars. The Lowe process was acquired by the United Gas Improvement Company (UGI) of Philadelphia, formed in 1882. Before this time, utilities had been slow to adopt the water gas process and the states of Massachusetts and New Jersey actually outlawed water gas because of gas poisoning incidents. UGI, however, aggressively pushed the technology and the rapid growth of the petroleum industry made oil available at a relatively cheap price. The gas industry proceeded to shift a substantial amount of its manufacturing processes from the production of coal gas to carbureted water gas. Originally carbureted water gas manufacturers used naphtha as the process oil because it was relatively inexpensive, but after 1895, as rising demand caused the price of naphtha to rise, gas manufacturers switched to the petroleum fraction known as gas oil. The invention and adoption of the automobile increased the demand for the higher petroleum fractions even further and in ~1930 the carbureted water gas industry switched to a yet cruder grade of petroleum.

The use of oil rather than coal as the feedstock for gas production was another major step by the manufactured gas industry. Oil gas was made by the thermal decomposition or cracking of petroleum. Whale oil had been used in several gas plants early in the 19th century, but it was not until 1889 that a modern refractory process to use petroleum was invented. L. P. Lowe, the son of the discoverer of carbureted water gas, was the inventor. The first oil gas plant was constructed in California and in 1902 an oil gas plant was erected in Oakland, California for lighting purposes. The so-called Pacific Coast oil gas process was used mostly in Pacific coast cities—an area that was poor in coal but rich in petroleum.

The number of carbureted water gas plants in the United States grew steadily. In 1890, the census reported returns from 742 gas manufacturing firms, probably approximately 75% of the total. In this census, coal gas represented 46.7% of the total product, whereas water gas made up 38% of the total. Between 1890 and 1904, coal gas production dropped precipitously to 11.2% of total gas produced, straight water gas rose to 48.6%, and a new category, mixed coal and water gas, absorbed 36.4% of the market. Between 1904 and 1914, coal gas declined even further, from 11.2 to 5.2% of total gas production; carbureted water gas also declined from 48.6 to 44.2% and mixed gas advanced from 36.4 to 42.4%. Because Great Britain (the first water gas plant was built in 1890) and other European nations did not have access to inexpensive petroleum, they did not adopt carbureted water gas to the same extent as did the United States. The U.S. gas industry, therefore, became increasingly dependent on oil, whereas the European industry remained largely based on coal.

Carbureted water gas had a number of advantages over coal gas. Its production required less space, less capital, and less labor, as well as a smaller storage capacity, because plants could be started up in a relatively short time. Many coal gas plants installed auxiliary carbureted water gas machines to increase their flexibility in regard to load, mixing the two gases. Without the auxiliary water gas equipment, firms would have had to add additional storage or construct additional retorts, which would have been idle for many hours in the day. Carbureted water gas

also had a higher illuminating value and a flexible heating value; a plant could produce gas varying in heating value from 300 to 800 Btu/ft^3. Utility operators could produce carbureted water gas with widely varying Btu contents by changing the amount of oil cracked into the blue gas. Higher Btu carbureted water gas could be mixed with gas with a lower Btu grade from blue gas or coal gas retorts, thereby increasing the available gas volume without the necessity of increasing the number of water gas sets.

The addition of petroleum hydrocarbons to water gas provided a gas that had illumination values equal to those of coal gas but at a lower cost. Most municipal franchises to gas companies required illuminating power of between 15 and 17 cp. The manufactured gas burners most commonly used before 1886 were the bat-wing, the fish-tail, and the Argand burners. These burners depended on the luminosity of the flame in order to fulfill legal candlepower requirements. Therefore, when carbureted water gas was burned as a fuel, the burners produced an equal or better flame at a lower cost. The lamps, however, still depended on the incandescence of the carbon particles in the flame itself for their illuminating power.

In 1885, Carl Auer von Welsbach of Germany, working in the laboratories of Robert Wilhelm von Bunsen, produced another major innovation in the consumption of manufactured gas. Welsbach patented a gas mantle made of cotton fabric impregnated with rare earth. When the mantle was placed near a gas flame from a Bunsen burner, it "became incandescent," producing a steady white light of 30–50 cp. This increased the light that could be obtained from a given quantity of gas approximately six times, utilizing the principle of incandescence rather than the direct illuminating properties of the gas. Thus, it mirrored the innovation of the gas industry's chief competitor, the incandescent electrical lamp. The Welsbach mantle provided an inexpensive and superior incandescent lamp to meet the competition of the electric light and helped modernize an industry whose existence was under severe competitive threat.

Although carbureted water gas was necessary for the older burners in order to meet existing legal candlepower and calorific requirements, it did not have to be used with the Welsbach mantle, which produced an equally brilliant light with cheaper blue water gas. Yet, legal candlepower requirements for manufactured gas required that higher priced carbureted water gas rather than blue gas had to be used with the Welsbach mantle. At the time of the mantle's introduction, municipal franchises usually stipulated a candlepower standard for gas ranging from approximately 14 to 16 for coal gas and 18 to 36 for water gas. The illuminating power of the Welsbach Mantle, however, which was not dependent on a higher candlepower gas rating, made these standards obsolete.

Statutory change to accommodate the new technology occurred slowly and some utilities actually opposed shifting to a different standard because they feared a possible profit decline. Beginning with the Wisconsin Public Utilities Commission in 1908, however, states and municipalities began requiring that gas be measured in Btu or heat units per cubic foot of gas (as was done in Great Britain) rather than lighting units. Of the 1284 gas firms reporting in the 1914 Manufacturing Census, 1055 reported candlepower standards and 811 reported standards expressed in Btu heating values. By 1919, there had been a substantial change. Of 1022 establishments reporting, only 389 reported candlepower standards, whereas 737 reported Btu heating value standards.

The use of gas solely for lighting resulted in poor load factors for gasworks. Although they needed generating, storage, and distribution equipment capable of handling demand during peak lighting periods, their capital equipment was often utilized for only 10–12 h per day. The use of larger gasholders (gasometers) was one way utilities could reduce investment in gas-producing equipment. Smaller plants frequently ran their equipment during part of the day and relied on their gasholders to supply gas at night. Larger companies could not risk supply cutoffs and had to run separate units of gas producers, even though they too used gas holders for reserve. From the 1870s through the 1890s, several important improvements were made in gasholders, including the use of iron and steel tanks and the installation of the first three-lift holder tank. Because of limited capacity, however, gas holders were not a satisfactory solution to the load factor.

Competition from electricity, despite the success of the Welsbach mantle, consistently ate into the gas industry's market share. Utilities could attempt to spread their loads as a way to meet competition and to use their technology more efficiently. The gas industry moved increasingly into markets outside of lighting, such as cooking stoves, water heating, and house heating, although firm aggressiveness varied from place to place. In both Baltimore and Philadelphia, for instance, both large markets, the gas companies only gradually moved away from lighting as their only product. In other cities, however, such as Denver and Los Angeles, utilities introduced gas-consuming

appliances more rapidly. Two technical innovations aided in the expansion of these markets: the Bunsen burner (1885), which premixed gas with air, and thermostatic controls, initially applied to water heating in 1899. This movement away from light and into household appliances reflected the recognition that manufactured gas was a fuel or energy source. It was also a "technical mimicry" of electricity and an attempt by an older technology to survive by copying a more recent technology, in this case electricity.

Even though the gas industry developed a substantial market share in the home utility domain, it still faced excess productive capacity. In ~1900, gas firms began to try to capture industrial customers to absorb this capacity. Efforts were made to market gas engines as well as to sell gas for heating purposes. Potential industrial customers, however, often found it more economical to use low-Btu gas to meet their energy requirements rather than high-Btu carbureted water gas. Frequently they used producer gas, a low-grade but inexpensive gas made on the firm's site from coal. Gas companies also found it difficult to enter industrial markets because of state requirements for a fixed number of Btu per cubic foot (usually 450–550 Btu) in their gas, which raised gas prices. This Btu rating was higher than many industries desired or would pay for, limiting the number of industrial customers. The gas industry, therefore, began to push for the sale of gas with Btu as a standard and sold by the therm (100,000 Btu), as was done in Great Britain, rather than by the cubic foot. Industries could then obtain less costly low-Btu gas to supply the heat they needed in their processes. Changes in this regard were reported in the 1920 Census of Manufacturers. The census noted that the prevailing Btu standard was lower in 1919 than it had been in 1914, as the number of gas firms providing high-Btu gas dropped sharply. Between 1919 and 1927, the industrial use of manufactured gas increased from 70.4 billion to 136.4 billion ft^3.

Gas utilities could also compete with electricity by investing in electrical generating equipment or by acquiring electrical companies. In 1887, approximately 40 gas companies supplied electric lighting, usually arc lights; by 1889, the number was 266, or approximately 25% of U.S. gas companies, and in 1899, 362 or nearly 40% of gas companies provided electric lighting. A counter trend was for electrical utilities to acquire gas utilities, and large electric firms or holding companies made acquisitions of small gas companies increasingly in the 20th century.

Water gas possessed another disadvantage compared to coal gas in terms of potential profits—the character of its by-products. Markets had developed in the late 19th century for coal gas by-products such as tar for creosote in railway tie preservation, pitch for roofing and waterproofing, and refined tar for road surfacing. The carbureting process produced gaseous, liquid, and solid by-products, but they were not as salable as those from coal gas. The liquid was "water-gas tar," which was lighter and contained less valuable constituents than coal tar. The solid was coke, the sale of which could substantially affect the profit position of plants. Water gas coke, however, was lower in thermal efficiency than coal gas coke. In addition, water gas firms, rather than entering the coke markets, consumed the coke they produced as water gas fuel. Finally, unlike coal gas, the water gas process did not produce ammonia, cyanides, or phenolic compounds as by-products. The ammonia was especially valuable and could constitute 6–10% of the cost of the coal used. Before the invention of the Haber process for the synthetic production of ammonia, coal carbonization was the main source of fixed nitrogen, and coal carbonization processes found increasing favor in the 1920s among some gas producers.

Between 1914 and 1929, the amount of manufactured gas distributed expanded from approximately 204 billion to over 450 billion ft^3. A little more than 50% of the gas produced in 1929 was water gas, approximately 40% was classified as coal gas, although the sum also included gas from by-product ovens, and oil gas was 6.2%. The most significant new addition to the census categories was gas from by-product coke operations.

Between approximately 1916 and 1929, a revolution occurred in the technology used by the iron and steel industry to make coke. From 1850 through 1910, most of the coke manufactured for use in blast furnaces was carbonized in beehive coke ovens. These ovens produced a high-quality coke from bituminous coal, but wasted all of the coal by-products. The by-product coke oven had originally been developed in Europe, and beginning in the 1890s several by-product coke plants were constructed in the United States. The real expansion of the United States industry, however, occurred just before World War I and in the following decade. The by-product coke oven captured the valuable coal chemicals for use and also produced a gas surplus. That is, by-product ovens could be heated by 35 to 40% of the coal gas produced in the oven, leaving approximately 60% to be marketed. Coke oven gas had a heating value of approximately 560 Btu and could be easily sold to other customers. By 1932, by-product coke firms

produced 25% of the manufactured gas distributed by utilities to domestic, commercial, and industrial customers in the United States.

During the 1920s, the manufactured gas utilities themselves moved into the by-product industry. In order to meet peak period requirements, utilities with carbureted water gas technology had to manufacture large amounts of coke. By utilizing by-product ovens rather than retorts, utilities could combine gas manufacture with coke manufacture to meet peak load requirements and to produce a higher quality of coke for sale than that produced in retorts. During the 1920s, construction firms such as Koppers Company and Semet-Solvay built coke oven batteries for a number of large utilities, including Brooklyn Union Gas, Consolidated Gas Company of New York, New Jersey Public Service Gas & Electric, Rochester Gas & Electric Company, and People's Gas & Coke Company of Chicago. In addition, entrepreneurs built a number of merchant plants that had as their chief products foundry coke, domestic coke, and coke for making water gas, as well as producing gas to sell under contract to public utilities. These plants had the advantage of flexibility in meeting demand peaks for either gas or for coke as well as lowering the cost of gas generation. By the end of the decade, a clear trend existed for manufactured gas utilities to adopt carbonization equipment that produced both high-quality gas and high-quality coke, and by 1932, 18.7% of the manufactured gas produced by gas utilities was coke oven gas. Thus, as a 1926 text on fuels noted, "the gas and the coke industry gradually are merging as far as equipment requirements are concerned, and…the tendency is toward the same type of plant for both branches."

4. THE TRANSITION TO NATURAL GAS, 1927–1954

Natural gas is a substance that occurs in nature under three conditions: in porous domes that form a gas field (nonassociated gas), in association with petroleum deposits (casinghead or associated gas), and mixed with the oil so that it must be trapped out of it. Chemically, there is no difference between natural gas and manufactured gas—each is composed of hydrocarbons—but they differ in heating value. Manufactured gas usually averages between 550 and 600 Btu, whereas natural gas is approximately 1000 Btu. Natural gas is not distributed evenly throughout the environment. In the late 19th and early 20th centuries, there were four regions where natural gas was piped in for use in cities and industries: western Pennsylvania and West Virginia, northern and central Indiana, locations around Los Angeles including the San Joaquin Valley, and eastern Kansas. Towns and cities close to these fields utilized the natural gas until it was exhausted.

In the first decades of the 20th century, additional natural gas discoveries were made in the Southwest, but gas from these fields was initially wasted because of the absence of nearby markets and because the technology to produce pipelines long enough to reach markets was nonexistent. In the 1920s, however, significant breakthroughs occurred in the making and laying of welded pipe technology. In addition, the mathematical understanding of the role of tensile steel strength, pipe thickness and diameter, pipeline capacity, gas pressure, and compressor station spacing to pipeline capacity greatly increased. Pipeline construction passed beyond the craft stage into the stage where decisions were made by mathematical analysis.

From 1925 to 1935, pipeline companies and utilities constructed a number of pipelines ranging from 200 to over 1000 miles in length, connecting southwestern and California gas fields to urban markets. Cities such as Houston and Beaumont (1925), Wichita (1927), Denver (1928), St. Louis (1928), Atlanta (1929), San Francisco (1929), Minneapolis (1930), Chicago (1931) and Washington, DC (1931) were supplied with natural gas, driving out manufactured gas. The depression and the war slowed pipeline construction, but in 1944 the Tennessee Gas Transmission Company completed a 1265-mile pipeline from the Texas Gulf Coast to West Virginia as part of a wartime push to replace diminished Appalachian supplies.

The last major regions to be linked by pipeline with natural gas fields were the Middle Atlantic States and New England. New York City and Philadelphia were considered especially prized markets, since New York City alone consumed 40% of the nation's manufactured gas. These cities were supplied with natural gas in 1947 through the conversion of Big Inch and Little Inch, wartime government-constructed petroleum pipelines, to natural gas and the sale of these pipelines to private enterprise. New England was the last major region to receive natural gas, with Boston being the most distant urban market to draw from the southwestern gas fields. The postwar period also saw a boom in the construction of pipelines serving California and Florida, as well as new major pipelines to the midwest.

In these new markets for natural gas, the logistics of conversion of manufactured gas distribution systems into natural gas distribution systems was a major undertaking. Manufactured gas utilities did not always view conversion with favor, even though there seemed to be many advantages to the change. Some utility managers worried that natural gas supplies would prove insufficient to maintain their service commitments. Corporations were also reluctant to abandon their substantial investments in gas manufacturing plants and equipment.

In the conversion to natural gas as a fuel, the gas could be circulated in the same distribution system and consumed by the same appliances used by manufactured gas. However, because of the different Btu ratings of the gases, conversion required gas main and appliance adjustments. In addition, engineers and managers had to decide whether to use natural gas or natural gas mixed with manufactured gas after conversion. Occasionally regulatory commissions overturned the decisions made by utility managers.

The 1946 Federal Natural Gas Investigating Committee recommended that natural gas be used primarily for enrichment purposes. This strategy would expand the production capacity of existing plants, provide backup in case of supply interruptions, and furnish peak load shaving abilities. A number of firms followed the recommendation for mixed gas. In 1945, for instance, 301.4 million therms of manufactured gas and 988.5 millions therms of natural gas were used to produce mixed gas; by 1954, this total had reached 936 million therms of manufactured gas and 2012.7 million therms of natural gas. Other utilities, especially after World War II, went directly to natural gas, usually to avoid the costly necessity of adjusting gas appliances twice. In many cases, utilities kept their gas-making equipment for emergencies and for peak shaving purposes.

Once the decision concerning the type of gas to be used had been made, utilities faced major organizational tasks of conversion and adjustment, regardless of whether mixed or natural gas had been chosen. In 1931, an American Gas Association Subcommittee issued a report on "The Study of Factors Involved in Change-over from Manufactured to Natural Gas." The committee made four major recommendations: (1) that cities be divided into districts for conversion purposes and that each district be converted to natural gas separately; (2) that those handling the conversion task be thoroughly trained and that the work force be large enough so that the largest district could be covered in 1 week; (3) that customers be kept fully informed at all times of the conversion process; and (4) that a universal adapter be used to adjust orifices. The committee also warned of the drying-out effects of the natural gas on joints and valves in a system that had formerly only carried wet manufactured gas, with resultant leaks. The committee concluded, however, that compared to manufactured gas, natural gas presented fewer hazards. In approaching the conversion process, utilities communicated extensively with one another regarding the pitfalls to be avoided.

The largest single task facing a utility converting to natural gas was adjusting domestic and commercial appliances to the new gas. All gas-using appliances had to be adjusted at the orifice because of natural gas' higher Btu rating and its slower rate of flame propagation compared to 550–600 Btu for manufactured gas. Management of conversion could involve thousands of specially trained workers. In order to carry out the conversion tasks, the larger utilities hired engineering management firms. Some utilities, however, managed their own transitions rather than hiring outside contractors, forming schools and training men specifically for the job and relying on experience from other utilities.

With the transformation in the gas industry, the fuel flow now originated from a distant source rather than traveling a relatively short distance from gasworks to customer. From a regulatory point of view, this shifted responsibility to the federal government because pipelines often crossed state boundaries. Pipeline companies became subject, after the Natural Gas Act of 1938, to federal control, which had a constraining and shaping effect on the industry.

5. ENVIRONMENTAL IMPACTS OF THE MANUFACTURED GAS INDUSTRY

The various by-products produced by the manufactured gas industry, if not captured and disposed of in a safe manner or sold, could become environmental externalities, damaging surface and groundwater quality, poisoning soils with toxic substances, and producing odors and smoke. British gas engineers were aware during the industry's early years of the potential for environmental pollution. In London, for instance, in 1821, effluents from gasworks killed fish and eels in the Thames. In 1841, in his *Practical*

Treatise on the Manufacture of Gas, published in London, engineer Thomas Peckston warned of the possible escape of "tar and ammonical liquor" from the "tar cistern" because it could "percolate through the ground" and render water in springs and wells "unfit for use."

Americans also became aware of the injurious environmental effects of manufactured gas effluents on the environment as the industry expanded. New York State, for instance, passed a statute in 1845 restricting the disposal of gas house wastes in streams in the New York City area; Pittsburgh, Pennsylvania passed a similar statute in 1869 and New Jersey approved legislation limiting the disposal of gas house wastes in streams in 1903 and 1911. Plaintiffs filed numerous nuisance suits against manufactured gas companies in the late 19th and early 20th centuries for offenses such as odors, pollution of wells, damage to trees, and the killing of finfish and shellfish. Various city councils and state bodies undertook investigations of the environmental effects of manufactured gas wastes as well as their pricing policies beginning in the middle of the 19th century. Warnings about the pollution potential of gas house wastes appeared with increasing frequency in the professional literature during the first decades of the 20th century.

Because of the potential costs of nuisance suits as well as the damage to the industry's reputation, in 1919 the American Gas Association established a committee on the "Disposal of Waste from Gas Plants." The 1920 report of the committee noted that gas plant wastes could drive "away fish and damage oyster beds," create "damage to paint on pleasure boats," cause "objectionable odors," result in "pollution of wells [by] contaminating ground water," create "deposits in sewerage systems," and cause "pollution of drinking water supplies where water is chlorinated." The committee provided numerous recommendations to help manufactured gas plant operators to deal with pollution disposal questions and even volunteered to visit sites with problems. The committee continued to meet throughout the 1920s and to explore these issues.

The gradual phasing out of the manufactured gas industry in the 1950s and 1960s because of the conversion to natural gas resulted in the elimination of many plants and a gradual loss of institutional memory concerning their operations. The renewed interest in land and groundwater pollution that developed after Love Canal in 1978 and the subsequent passage of the Superfund Acts, however, focused renewed attention on the sites of former manufactured gas plants (MGPs), many of which had been stripped of gas-making technology and structures. Investigation of these sites by state and federal environmental officials identified a number of toxic by-products remaining in the soil and in groundwater from past MGP operations. Some of the MGPs had operated for a century or so and most sites contained accumulated wastes from the gas-making processes. Thus, an industry largely of the past that had operated approximately 2000 plants in towns and cities throughout the nation and provided it with fuel for light and heat for over a century was discovered to have left a heavy environmental burden for the future.

6. CONCLUSIONS

This article has focused on the evolution of the manufactured gas industry in the United States and the transition to natural gas as well as its environmental legacy. Manufactured gas systems were urban public utilities that, because they utilized city streets for their distribution systems, required first municipal and later state approval for their operations and rates.

Manufactured gas systems shared a number of characteristics with other urban networks, such as water supply, sewerage, and district heating. These were "grid-based systems" that required a special physical network devoted to supplying users. They were also centralized rather than decentralized and had natural monopoly characteristics, a factor that affected their rate-making and consumer relations and, at times, resulted in their becoming deeply involved in politics.

The substitution of natural gas for manufactured gas resulted in the gradual death of the manufactured gas industry as an entity that produced a product rather than merely distributing it. However, much of the original industry's grid remained in the form of inner-city distribution systems. The substitution of natural gas for manufactured gas did not require network reconfiguration but only adjustments because the delivery system and appliances from the first system were retained for use with the natural fuel.

The industry had large environmental effects, both during its period of operation and after, because of wastes discarded during its processing of coal and oil for purposes of producing a fuel for illumination and energy. As an industry it furnished both illumination and energy to American cities for many decades, but its significance today is measured primarily in terms of the environmental burdens it has left to contemporary society.

Marine Transportation and Energy Use

JAMES J. CORBETT
University of Delaware
Newark, Delaware, United States

1. Introduction
2. Overview of Marine Transportation
3. Energy Choice and Marine Propulsion Development
4. Trends, Opportunities, and Challenges

Glossary

bunker Marine fuel, typically for international shipping. The term is adapted from the days of coal-fired steam boilers; fuel was stored aboard ship in coal bunkers and was shoveled into the boiler; when oil replaced coal, the bunkers became fuel tanks, but the name stuck.

deadweight ton (dwt) The weight of cargo, fuel, and supplies needed to make a vessel fully loaded; in other words, it is the weight difference between a completely empty and a fully loaded vessel.

gross registered ton (grt) The capacity on a ship, in cubic feet, of all spaces within the hull (body of the ship) and the enclosed spaces above the deck available for passengers, crew, and cargo, divided by 100; simply, 100 cubic feet of capacity is equal to 1 gross registered ton; the equivalent term, gross ton (gt), is also used.

marine distillate oil (MDO) A group of distillate oils that can be burned in auto-ignited engines (typically called diesel fuels). MDO can be specified with a range of properties such as density, flashpoint, and maximum sulfur content. Sulfur contents may not exceed 2% by weight. This fuel requires very little pretreatment for proper combustion in marine engines.

marine gas oil (MGO) A group of distillate oils that are typically clean and clear, used for emergency diesel engines, lifeboat diesel engines, etc. Marine gas oil is comparable to No. 2 fuel grade (onroad diesel fuel) used commercially ashore. MGO can be specified with a range of properties, such as density, flashpoint, and maximum sulfur content.

residual fuel (heavy fuel oil) (HFO) A group of residual fuels that can be burned in auto-ignited engines (typically called diesel fuels). HFO can be specified with a range of properties such as density, flashpoint, and maximum sulfur content. This fuel typically requires heating and filtering for proper combustion in marine engines. The maximum sulfur content allowed is 5% by weight, but the world average is much lower ($\sim$2.7% sulfur).

tonne-kilometer (tonne-km) The transport of 1 tonne of cargo over a distance of 1 km.

More than any other transportation mode, most modern shipping activity is designed to minimize fuel consumption because it helps minimize operating costs. As a result, waterborne commerce generally is considered an energy-conserving mode of transportation. On average, ships and barge tows accomplish the work of moving cargo on oceans and inland rivers at much less energy per tonne-kilometer, compared to trucking, rail, or air modes. This is especially true for cargoes shipped in bulk, such as oil or grain (see Table I). Published data suggest that there are important exceptions to this effort: (1) naval ships are designed for power and performance for military readiness and warfare and (2) some passenger ships (e.g., fast ferries) need to meet high-speed service requirements as a condition of high-value passenger service. The focus in this article is on the characteristics of the marine transportation system, the role of energy conservation in marine propulsion development, and trends in energy use for marine transportation as ships meet increased demand for cargo trade worldwide.

1. INTRODUCTION

Conservation of energy in marine transportation has been important since before the classical times of the Greeks and Romans. Shipping has been an important

TABLE I

Comparison of Modal Energy Intensities[a]

Mode	National averages of energy intensity[b] (MJ/tonne-km)	Modeled ranges of energy intensity[c] (MJ/tonne-km)
Average road freight	1.8–4.5	
Heavy-duty trucks	0.60–1.0	
Rail (freight trains)	0.40–1.0	0.25–0.50
Marine freight (average)	0.10–0.40	
General cargo		0.20–0.50
Container ship		0.20–0.30
Bulk carrier		0.10–0.25
Oil tanker		0.10–0.20
Air freight	7–15	

[a] As the data show, marine transportation is less energy intensive, on average, compared to other transport modes. Specific energy intensities depend strongly on individual vehicle load factors and patterns of use.

[b] Data from United Nations Framework Convention on Climate Change Working Paper No. 1, Appendix A, Table 21.

[c] Data from International Maritime Study of Greenhouse Gas Emissions from Ships, Appendix A4, Figure 4.9.

human activity throughout history, particularly where prosperity depended primarily on commerce with colonies and interregional trade with other nations. From ancient times, when ships sailed mostly in sight of land using wind-driven sails or slave-driven oars, to today's oceangoing fleet of steel ships powered by the world's largest internal combustion engines, the history of shipping includes many examples of technical innovations designed to increase ship performance while conserving energy, capital, and labor. Whether the primary energy for ship propulsion has been wind and sail or engines and petroleum, all major innovations in marine transportation throughout history have involved balancing these factors. Since the 1800s, when industrialization made combustion power available to shipping, marine propulsion technology development has focused on ways to move a ship using less fuel and smaller crews (See Table I).

2. OVERVIEW OF MARINE TRANSPORTATION

The role of marine transportation in today's commerce and society must be considered to understand energy use practices and trends. Marine transportation in the 21st century is an integral, if sometimes less publicly visible, part of the global economy. The marine transportation system is a network of specialized vessels, the ports they visit, and transportation infrastructure from factories to terminals to distribution centers to markets. On a worldwide basis, some 44,000 oceangoing vessels move cargo more than 33 billion tonne-km annually (see Table II). In the European Union, marine transportation moves more than 70% (by volume) of all cargo traded with the rest of the world; in the United States, more than 95% of imports and exports is carried by ships. This work is accomplished by ships using 2 to 4% of the world's fossil fuels.

Maritime transportation is a necessary complement to and occasional substitute for other modes of freight transportation (see Fig. 1). For many commodities and trade routes, there is no direct substitute for waterborne commerce. (Air transportation has replaced most ocean liner passenger transportation, but carries only a small fraction of the highest value and lightest cargoes.) On other routes, such as some coastwise or short-sea shipping or within-inland river systems, marine transportation may provide a substitute for roads and rail, depending on cost, time, and infrastructure constraints. Other important marine transportation activities include passenger transportation (ferries and cruise ships), national defense (naval vessels), fishing and resource extraction, and navigational service (vessel-assist tugs, harbor maintenance vessels, etc.).

2.1 Marine Transportation System Complexity

The marine transportation system is a complex element of global trade. From an energy consumption perspective, the most important elements are the vessels; complexity of the marine transportation may be seen most easily by examining the complex mix of ships and boats that comprise the system's vehicles.

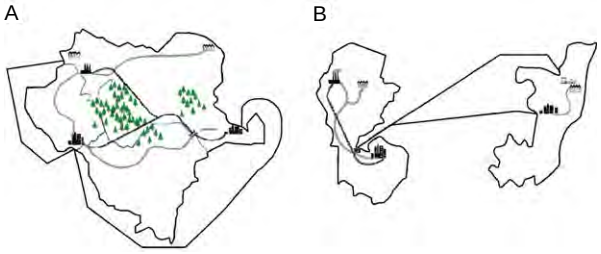

FIGURE 1 The marine transportation system as (A) a substitute for and (B) a complement to land modes.

TABLE II

Profile of World Commercial Fleet, Number of Main Engines, and Main Engine Power

Ship type	Number of ships	Percent of fleet	Number of main engines	Percent of main engines	Installed power (MW)	Percent of total power	Percent of energy demand[a]
Cargo fleet							
Container vessels	2662	2	2755	2	43,764	10	13
General cargo vessels	23,739	22	31,331	21	72,314	16	22
Tankers	9098	8	10,258	7	48,386	11	15
Bulk/combined carriers	8353	8	8781	6	51,251	11	16
Noncargo fleet							
Passenger	8370	8	15,646	10	19,523	4	6
Fishing vessels	23,371	22	24,009	16	18,474	4	6
Tugboats	9348	9	16,000	11	16,116	4	5
Other (research, supply)	3719	3	7500	5	10,265	2	3
Registered fleet total	88,660	82	116,280	77	280,093	62	86
Military vessels[b]	19,646	18	34,633	23	172,478	38	14
World fleet total	108,306	100	150,913	100	452,571	100	100

[a] Percent of energy demand is not directly proportional to installed power because military vessels typically use much less than their installed power, except during battle. The average military deployment rate is 50 underway time per year; studies indicate that when underway, naval vessels operate below 50% power for 90% of the time. Therefore, energy demand was adjusted in this table to reflect these facts.

[b] The data on which military vessel power was estimated specified the number of engines aboard ship associated with propulsion systems.

Ships, barges, ferries, towboats, and tugboats are among the most recognized and romanticized parts of the marine transportation system, perhaps second only to the water. Unlike automobiles, of which many thousands of each model are built and sold each year and a popular car design may remain largely the same for years, each ship design is unique to only one or a few vessels.

Because of different service requirements, ship vary greatly in terms of hull designs, power plants, cargo loading/discharge equipment, and other features. Inland-river and coastal towboats range in power from 0.5 to 4 megawatts (MW), or 600 to ~5000 horsepower (hp), and can push between 1 and more than 30 barges in a tow. Passenger ferries often have capacity to carry 150 to 300 passengers and range in power from 2 to 4 MW (~2600 to ~5000 hp), depending on speed requirements; some ferries, such as the Staten Island ferries in New York, have capacity for 6000 passengers. Roll-on, roll-off ships (or RoRos, so called because vehicles and other rolling cargo are driven onto the vessel rather than loaded by crane) can carry between 200 and 600 automobiles and have installed power between 15 and 25 MW (~20,000 and ~33,000 hp). Tankers and dry bulk carriers can carry more than 250,000 tons of cargo, with installed power often in the range of 25 to 35 MW (~33,000 to ~46,000 hp). Although container ships are not often as large as tankers, they have much larger power plants to accommodate greater vessel speeds. Average container ships carrying between 1750 and 2000 standard shipping containers have installed power of 20 to 25 MW (~26,000 to ~33,000 hp); larger container ships with capacity for more than 4000 containers can have installed power of 35 to 45 MW (46,000 to 60,000 hp), and the largest container ships can carry more than 6000 standard containers with engines rated as high as 65 MW (86,000 hp).

To accommodate complexity in geography, cargoes, and vessels, ports and terminals also vary greatly. The primary common goals at ports and terminals are to achieve rapid vessel loading and unloading and to maximize the rate of cargo transport

through the port facilities. Many ports are designed to facilitate container movements between ship, truck, and rail. Transportation planners and engineers have been working to speed this port transfer with on-dock rail, larger cranes, and improved queuing schedules for trucks. Some ports are megahubs that attract much of the world trade (by value and volume), whereas other ports are networked ports that handle much of the niche cargoes or serve as feeders for megaports. Each of the world's ports is unique by location (proximity to market), waterway configuration, and ecosystem, making general characterizations difficult. (Although each of these developments affects the overall energy consumption required to move cargo, the land-side energy demands of industrial port terminals are not addressed herein.)

In terms of the work performed, measured in tonne-kilometers or ton-miles, the marine transportation system rivals the other modes. The relative share of cargo moved by water, compared with truck and rail modes, varies from year to year, but U.S. waterborne commerce represents between 22 and 24% of the total tonne-kilometer of cargo movements in recent years. Truck and rail modes in the United States each account for about 25–29% of annual cargo tonne-kilometer. In Europe, the European Commission reports that waterborne commerce between nations (called shortsea shipping) accounts for nearly 41% of the goods transport market, compared to 44% for trucking and only 8% for rail and 4% for inland rivers.

One of the reasons that marine transportation moves so many tonne-kilometers of cargo is cost efficiency. Choice of mode is a function of cost (shipping is usually cheaper), time (shipping is often slower), and other quality-of-service factors. Only pipelines move goods at lower average cost than shipping, because of their fixed capital and ability to move fluids (liquids and gases), at very low energy requirements. Bulk shipment of liquid and dry goods such as oil and grain costs about two to three times as much per tonne-kilometer as pipelines, averaging between 2.5 and 3.5¢/tonne-km according to U.S. national transportation statistics. These average costs are generally less than but similar to rail, whereas marine transportation of bulk goods can cost much less than trucking. Except for high-value containerized goods that are shipped intermodally, the cost per tonne-kilometer for trucking can be more than an order of magnitude greater than the cost of marine transportation.

In energy conservation terms, shipping is not only among the least costly modes of transportation but efforts to keep down costs focus operators directly on fuel savings. Fuel costs can be the first or second largest cost of operating a vessel (not considering vessel capitalization); labor is generally the other largest cost and may vary with crew nationality. Fuel costs can range between 20 and 60% of operating costs, depending on vessel design and route factors. In order to be competitive, shipping companies try to reduce costs and/or add value to their service. These economic motivators have been very strong in the shipping industry and motivated much of the progress in energy conservation on ships.

2.2 International Fleet Propulsion Profile and Vessel Energy Use

The world's ships are primarily powered by diesel engine systems, consisting of one or more diesel engines in one of three typical propulsion configurations. Diesel direct-drive engines are typically large, slow-speed diesel engines directly connected to the propeller; they rotate at exactly the same revolutions per minute (rpm) as the propeller (0–130 rpm), except when connected to controllable-pitch propellers. Diesel gear engines drive the propeller indirectly through a set of gears, allowing the engine speed to be selected independently of the propeller. Diesel electric engines drive generator systems that turn the propeller; these engines typically operate at a constant speed, with electric power providing variable power to the propeller shaft. Diesel electric and diesel gear engines can operate at speeds greater than propeller revolutions per minute; in the international fleet, these are generally medium-speed engine designs operating between 130 and 2000 rpm. A fourth major category of engine, steam turbine systems, relies on conventional steam generation to drive a turbine geared to the propeller shaft; these marine systems typically have thermal and fuel efficiencies lower than modern marine diesel efficiencies and are rarely installed on new vessels. Other propulsion systems, not in wide use today, include combustion turbines (gas turbines) and older or nontraditional designs such as wind-powered vessels, reciprocating steam pistons, and nuclear power (for some military vessels). The evolution of engine technologies is discussed further in Section 3.

Most of the energy required by marine transportation is used on cargo or passenger transport vessels (ships that move cargo or passengers from one place to another in trade). A profile of the internationally registered fleet of ships greater than 100 gross tons is

shown in Table II. Transport vessels account for almost 60% of the ships and nearly 80% of the energy demand of the internationally registered fleet (not including military ships); considered along with military ships, cargo ships account for 40% of the world fleet and 66% of world fleet fuel use. Cargo ships are analogous to on-road vehicles because they generally navigate well-defined (if unmarked) trade routes, similar to a highway network. Other vessels are primarily engaged in extraction of resources (e.g., fishing, oil, or other minerals), or are primarily engaged as support vessels (vessel-assist tugs, supply vessels). Fishing vessels are the largest category of nontransport vessels and account for more than one-quarter of the total fleet. Fishing vessels and other nontransport ships are more analogous to off-road vehicles, in that they do not generally operate along the waterway network of trade routes. Rather, they sail to fishing regions and operate within that region, often at low power, to extract the ocean resources. As a result, fishing vessels require much less energy.

The exception to energy conservation designs in shipping would be the nearly 20,000 military vessels worldwide, which are sized for power and performance by their military mission, not for plant fuel economy. The naval ship is designed for sustained speeds in excess of their endurance (cruise) speed; as a result, the installed power in the world Navy is nearly 40% of the total installed power of the entire commercial fleet. However, the world's Navy ships use less energy than their installed power would suggest, because most of the time they operate in peaceful conditions at endurance speeds, partly to achieve fuel/cost savings. Average engine power characteristics for the U.S. Navy show that military ships operate below 50% power for 90% of the time that they are underway. Moreover, military vessels spend greater time in port than do modern commercial ships. Whereas commercial ships cannot effectively earn profits unless underway, Navy studies claim that military ships typically spend as much as 60–70% of their time in port; this is confirmed by public records of Naval ship activity, which show that typical deployment rates range between 40 and 55% of the fleet. This means that, in practice, military ships would demand some 14% of total energy required by the world fleet (commercial plus military fleets), much less than their installed power implies (Table II).

Fuel consumption is generally proportional to installed power on commercial vessels, and this power is concentrated in the larger commercial ships. About two-thirds of commercial ships are powered by four-stroke compression-ignition engines (operating on the compression-ignition, or diesel, cycle, and therefore referred to as diesel engines). More than one-quarter are powered by two-stroke diesel engines. Recent fleet statistics report that 6% of the ships have "unknown" diesel engines (i.e., either two- or four-stroke engines) and only 1% are turbine-driven. Most turbine-driven vessels (80%) are steam turbines with oil-fired boilers; the number of aero-derivative gas turbine engines in the commercial fleet is very low.

When estimating fuel consumption from commercial ships, the installed engine power rather than the number of engines or vessel size provides the most direct indication of energy requirements. The registered fleet has approximately 84,000 four-stroke engines with total installed power of 109,000 MW and some 27,000 two-stroke engines with total installed power of 164,000 MW. Engines with "unknown" cycle types and "turbines" together make up only about 2.5% of total installed power for main engines. This suggests that 27,000 two-stroke marine prime movers account for almost 60% of the commercial fleet's total energy output and fuel consumption, and more than half of the energy demanded by the world oceangoing fleet (including military ships). A majority of these engines are large-bore, low-speed diesel engines with above 10 MW rated output. Two-stroke engines are the main consumers of bunker fuel and therefore are the major sources of oceangoing ship emissions, followed by four-stroke engines.

The fuel types used in marine transportation are different from most transportation fuels. Marine fuels, or bunkers, used in today's fleet, can be generally classified into two categories: residual fuels and other fuels. Residual fuels, also known as heavy fuel oil (HFO), are a blend of various oils obtained from the highly viscous residue of distillation or cracking after the lighter (and more valuable) hydrocarbon fractions have been removed. Since the 1973 fuel crisis, refineries have used secondary refining technologies (known as thermal cracking) to extract the maximum quantity of refined products (distillates) from crude oil. As a consequence, the concentration of contaminants such as sulfur, ash, asphaltenes, and metals has increased in residual fuels. Residual fuel has been described by industry professionals as "black, thick as molasses, and has an odor that's pungent, to put it politely." By contrast, "other" bunkers used in international shipping include marine distillate oils of higher grade; however, these fuels often consist of a blend of heavier

fractions (residuals) with distillate oils and are not to be confused with the more highly refined fuels used in motor vehicles. Domestically, ferry vessels and harbor craft may use a more familiar diesel fuel that currently meets less stringent standards for maximum contaminant concentrations; however, in the United States, at least much of the marine fuel used by inland towboats, workboats, and ferries is rebranded on-road diesel. Few commercial ships, but many recreational vessels (not addressed here), use spark-ignited engines and marine gasoline oils (MGOs).

To reduce fuel costs, marine engines have been designed to burn the least costly of petroleum products. Residual fuels are preferred if ship engines can accommodate its poorer quality, unless there are other reasons (such as environmental compliance) to use more expensive fuels. Of the two-stroke, low-speed engines, 95% use heavy fuel oil and 5% are powered by marine distillate oil (MDO). Fuel consumed by 70% of the four-stroke, medium-speed engines is HFO, with the remainder burning either MDO or marine gas oil. Four-stroke, high-speed engines all operate on MDO or MGO. The remaining engine types are small, high-speed diesel engines all operating on MDO or MGO, steam turbines powered by boilers fueled by HFO, or gas turbines powered by MGO.

2.3 National and International Energy Statistics for Ships

The world's fleet operates internationally, but individual ships are registered under national authorities. Understanding which nations have maritime and trade interests is important to understanding which nations provide fuel for these ships. In terms of fuel sales, the nations providing the most fuel for ships are typically nations with strong interests in the cargoes or services those ships provide. Table III presents a summary of the top nations selling international marine fuels during the 1990s, according to the World Energy Database. The United States provides most of the world's marine fuels by far, and together the top 20 nations selling international marine fuels (shown in Table III) account for more than 80% of total marine fuel sales.

According to the Energy Information Administration's World Energy Database, some 140 million tonnes of fuel has been recorded as sold for international marine fuel consumption in recent years. At least 70% of these fuel sales has been identified as residual fuel, although recent work by Jos Olivier and co-workers at the National Institute for Public Health and the Environment in The Netherlands [Rijksinstituut voor Volksgezondheid & Milieu (RIVM)] suggests that residual fuel probably accounts for more than 80% or more of oceangoing fleet energy. (Typically, statistics for international "other" bunkers include international fuel sold to aircraft, which are excluded from the quantities discussed here.) This lack of clarity in the definitions makes the statistic somewhat uncertain, but the general trends are well documented.

Organization for Economic Cooperation and Development (OECD) nations account for roughly half of these fuel sales and provide a good illustration of historical consumption trends in the overall fleet, according to the International Energy Agency. Detailed fuel statistics for OECD nations over the past several decades (Fig. 2) show that marine fuel consumption has increased gradually, along with a growth in global trade and transportation. Over the entire period shown, the increase in marine fuel sales

TABLE III

International Marine Fuel Sales by Nation

Percent of total sales (1990–1999, inclusive)	Nations selling residual bunkers	Nations selling other bunkers
>15%	United States (18%)	United States (22%)
6–15%	Singapore (9%), Russia (9%), Netherlands (8%), United Arab Emirates (8%)	Saudi Arabia (12%)
2–5%	Japan, Saudi Arabia, Belgium, South Korea, Spain, South Africa, Greece	Hong Kong, Singapore, Netherlands, South Korea, United Kingdom, Spain, Russia
~1%	France, Taiwan, China, Italy, Egypt, Netherlands Antilles, Hong Kong, United Kingdom, Germany	Thailand, Greece, India, Belgium, Italy, Brazil, Indonesia, Denmark, Egypt, Venezuela, Germany
<1%	47 other countries	92 other countries

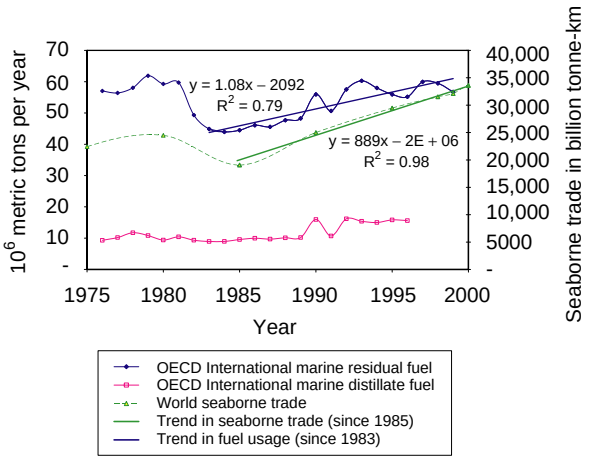

FIGURE 2 International marine fuel sales for Organization of Economic Development and Cooperation (OECD) nations and world seaborne trade, according to the International Energy Agency, Energy Information Agency, and United Nations data. The regression equations represent a simple linear statistical annual growth relationship. For residual fuels, the slope (1.08) suggests that, on average, an additional 1.08 million metric tons of residual marine fuel is sold each year by OECD nations; this represents an annual growth rate of about 2% for all international marine residual fuel sold. Note that there was significant variability in residual fuel sales during the 1990s and that the trend for international marine distillate furl is much flatter. For seaborne trade, the slope suggests that each year, ships move cargo an additional ~900 tonne-km; this represents an annual growth rate of about 3.5% in seaborne trade.

averages only about 0.2%/year, but since 1983 (i.e., after the recession in the early 1980s), these data show about a 2% annual average growth in residual fuel use. This growth in fuel consumption is about the same as recent annual growth rates in the fleet of ships, according to United Nations statistics. In other words, the fuel economy per ship may be roughly constant. However, over the long term, the fleet may be performing more useful work (i.e., transporting more cargo over longer distances) with a less-than-proportionate increase in energy demand. During a similar period (1985–2000), as shown in Fig. 2, seaborne trade increased slightly faster (~3.5%/year on average) than fuel sales; this could indicate that economies of scale and/or improved cargo logistics may work to reduce the energy consumed per cargo tonne-kilometer of work performed by the fleet.

An important caveat to consider is that these international fuel statistics do not represent the total fuel consumed by the international fleet of ships. Even making simplistic and conservative assumptions about the number of hours that vessels operate main engines and applying general fuel consumption rates for marine diesel engines, the international fleet of ships presented in Table II would require more fuel than reported as international marine bunkers. Recent estimates based on ship activity and installed engine power suggest that the world fleet of ships (including cargo, noncargo, and military vessels) consumes some 284 million metric tonnes of fuel per year, with more than 200 million metric tonnes required for cargo ships alone. This represents nearly 4% of all fossil fuel use.

Clearly, internationally registered vessels must be consuming domestic supplies of marine fuels. However, fuel statistics are generally well understood, especially for the OECD nations that sell most of the world's marine fuels. There are two reasons for the discrepancy. First, not all statistical sources for marine fuels have defined international marine fuels the same way. Original International Energy Agency (IEA) definitions have been reworded to be more consistent with reporting guidance under the *Revised 1996 IPCC Guidelines for National Greenhouse Gases*. The IEA defines "international marine bunkers (fuel) [to] cover those quantities delivered to seagoing ships of all flags, including warships. Consumption by ships engaged in transport in inland and coastal waters is not included." The IEA defines national navigation to be "internal and coastal navigation (including small craft and coastal vessels not purchasing their bunker requirements under international marine bunker contracts). Fuel used for ocean, coastal and inland fishing should be included in agriculture." Second, domestic fuel consumption inventories include fuel provided to oceangoing ships, at least during voyages that do not meet the definition criteria for international marine fuels.

Reconciling fleet fuel consumption between international and domestic fuel supplies is not simple. To get agreement with international fuel statistics and with the definitions, about 31% of the fuel consumed by transport vessels must occur while operating in shortsea or coastwise service using domestic fuels, and all of the nontransport ships (fishing, research, tugs, etc.) operate on fuel included in domestic inventories. This appears to be the case. The U.S. Energy Information Administration publishes state-by-state consumption statistics by fuel type and by end-use sector for the United States, the world's largest provider of marine fuels over the past 10 years at least (accounting for some 21% of marine residual sold by OECD nations). These Combined State Energy Data System (CSEDS) statistics identify residual fuel consumption in the transportation

sector in the United States domestic inventory, which represents marine residual fuels primarily because no other mobile source category consumes residual fuel.

A comparison of marine residual fuels on a state-by-state basis, alongside state-by-state waterborne commerce statistics, shows good agreement. First, total residual fuel consumption reported in the CSEDS agrees exactly with domestic residual consumption statistics in the World Energy Database, providing a consistency check. Second, the 10-year average residual consumption by marine transportation in the United States equals more than 40% of total residual consumption, more than enough to accommodate the difference between fleet energy requirements and international residual fuel statistics. Third, the top states for waterborne commerce (measured by total cargo volume) are also the top states for marine fuel sales. This suggests that most of domestic marine fuel consumption is going to cargo transport ships, and to vessels that directly support commerce. In terms of energy conservation, it is also worth noting that, although domestic land-based consumption of residual fuel has decreased significantly over the past two decades, marine transportation fuel consumption has not changed much, either internationally (Fig. 3) or domestically (Fig. 4).

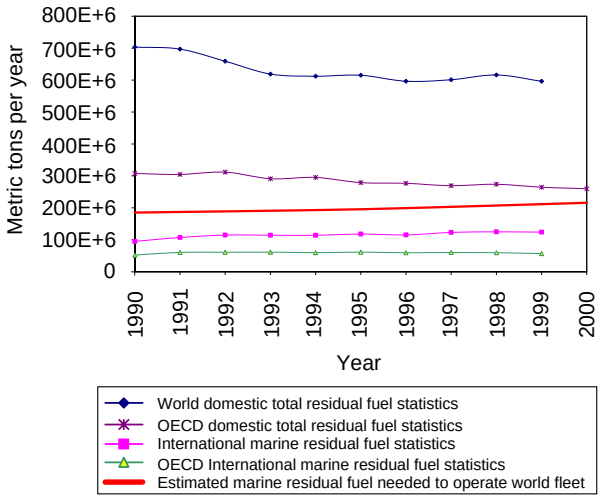

FIGURE 3 Comparison of domestic residual fuel consumption and international marine residual fuels worldwide and by Organization for Economic Cooperation and Development (OECD) members.

3. ENERGY CHOICE AND MARINE PROPULSION DEVELOPMENT

Aside from the shift of human labor (oars) to wind-driven sails, the first modern energy conversion in marine transportation was the shift from sails to combustion. Two primary motivators for energy

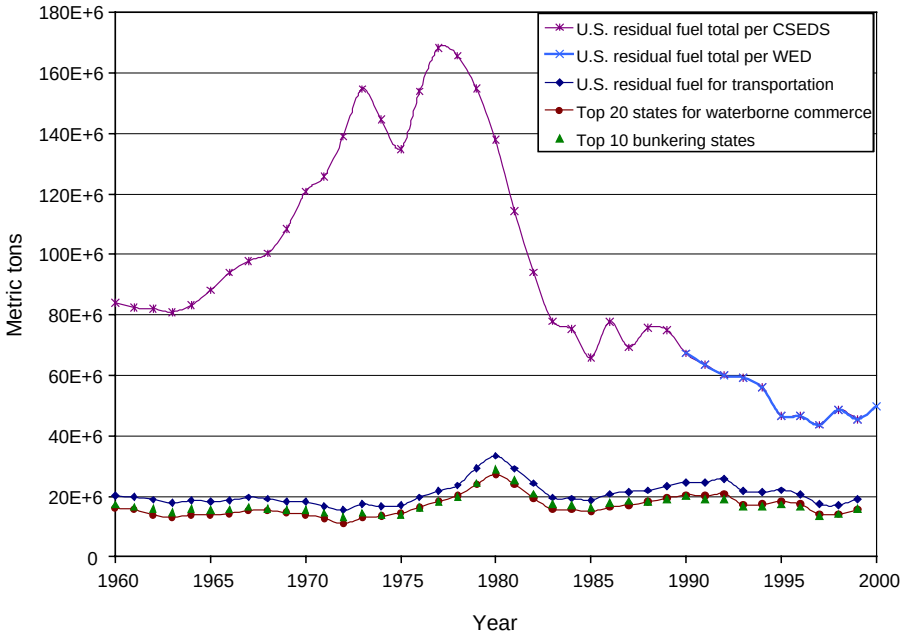

FIGURE 4 United States domestic residual fuel statistics, including residual fuel for transportation. Nearly 100% of residual fuel used in transportation is used by oceangoing marine vessels; nearly all inland vessels, harbor craft, and small commercial workboats use diesel fuel. CSEDS, Combined State Energy Data System; WED, World Energy Database.

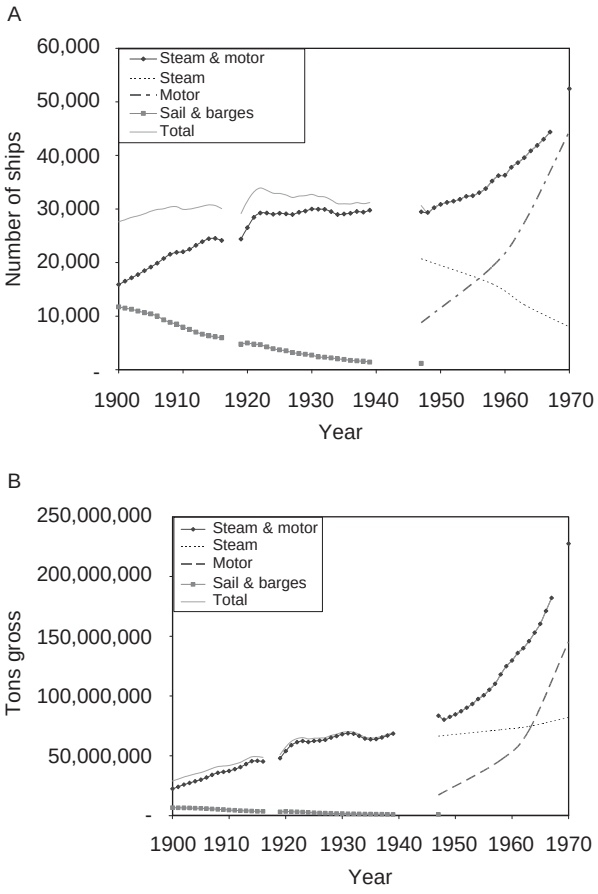

FIGURE 5 Conversion of ship propulsion, from sail to combustion propulsion, for internationally registered ships greater than 100 gross tons. (A) The conversion from sail as measured by number of ships took approximately 50 years to complete. (B) The effective fleet conversion of vessel tonnage to higher performing combustion systems took less than 20 years. During the shift from steam to motor, after 1948, the number of steamships decreased steadily. Economies of scale meant that ships with steam plants were still being built (mostly tankers) and that they were among the largest ships in the fleet. Note that ship registry data were not published during major world wars. Data from Lloyd's Register of Shipping Statistical Tables for various years.

technology innovation—greater performance at lower cost—caused this conversion. Figure 5 illustrates how this shift was completed during the first half of the 20th century, using data from Lloyd's Register Merchant Shipping Return for various years. Essentially, newer and larger ships adopted combustion technologies as part of an economy of scale. These technologies enabled trade routes to emerge, regardless of the latitudes, without consistent winds (referred to as the doldrums) supporting both international industrialization and modern political superpower expansion. As shown in Fig. 5, the conversion of fleet

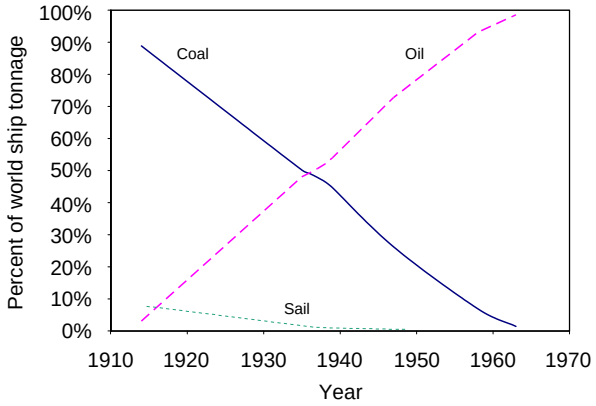

FIGURE 6 First major shift of world shipping to alternative fuel (coal to oil). Note that due to sparse data, particularly during world wars, these curves may misrepresent how smooth the transition was; the switch to oil was likely accelerated during periods of heavy shipbuilding (e.g., during the war periods and times of rapid economic growth). Data from Lloyd's Register of Shipping Statistical Tables for 1914, 1935–1939, 1947, 1958, and 1963.

tonnage to the preferred technology was achieved much more rapidly than was the phaseout of smaller ships using the outdated technology; this lead in conversion by tonnage was because the new technology was installed on the larger and newer vessels. Initially, these ships were powered by coal-fired boilers that provided steam first to reciprocating steam engines and later to high-speed steam turbines that drove the propellers. Later, the introduction of the industry's first alternative fuel, petroleum oil, enabled the introduction of modern marine engines. This pattern is repeated in many technology changes for marine transportation: some ship operators continue to use long-lived vessels purchased on the secondhand market while industry leaders replace their fleets to achieve new markets or realize economies of scale.

The switch from coal to oil was clearly motivated by a desire to conserve fuel. Switching fuels was both a direct means of conservation and a technology enabler during the introduction of internal combustion engines that ultimately replaced steam turbines and boilers. Of course, the reasons were economic: According to British Admiral Fisher's remarks to Winston Churchill in 1911 (quoted in Yergin's 1991 book, *The Prize*, page 155), a cargo steamer could "save 78 percent in fuel and gain 30 percent in cargo space by the adoption of the internal combustion propulsion and practically get rid of stokers and engineers." Essentially, the commercial sector was converting to oil-fired boilers powering marine turbines and introducing

oil-fueled internal-combustion, compression-ignition engines, commonly known as the diesel engine.

Figure 6 illustrates how international shipping switched from coal to oil over five decades. It is worth emphasizing that energy conservation was not the primary purpose for this conversion to "alternative fuel" in the early 1900s. Oil-powered commercial ships required fewer crew members and enjoyed a greater range of operations between fueling. This was not only of commercial interest; military vessels appreciated these advantages and the fact that refueling at sea could be accomplished more quickly and easily. Oil-powered ships also accelerated more quickly than did coal-powered systems, and could achieve higher speeds. When Churchill converted the British Navy to oil, despite the fact that this conversion made the British fleet dependent on a fuel not found within the British islands, the industry conversion was irreversible. After the fuel conversion was implemented, the next big shift was to more fuel-efficient marine diesel engines. A historical overview by Joe Evangelista in the American Bureau of Shipping's *Surveyor* describes how marine diesels came to dominate marine propulsion:

> *The first oceangoing diesel ship, the 370-ft Selandia, was delivered to the East Asiatic Company in 1912 by Burmeister & Wain (B&W) shipyard, Copenhagen, Denmark. In the 20 years since the first commercial diesel motor was proven, through the collaboration of Rudolph Diesel and Maschinenfabrik Augsburg-Nürnberg (MAN), the new type engine had been the subject of intense development and speculation. It promised industry a revolutionary new power source, and in so doing threatened the world's coal producers. So Selandia's sailing was one of the biggest news items of the time. Winston Churchill, Britain's First Lord of the Admiralty, visited the vessel and hailed it as an achievement of world proportion.*
>
> *Selandia was powered by twin B&W eight cylinder, four-stroke diesels, each developing 1,250 hp. Within the year, competitors like MAN, Sulzer, Vickers and Krupp were working to develop two-stroke engines with an output near 2,000 hp per cylinder—beginning a power competition that has not paused since. Observing these early efforts, Rudolph Diesel commented, "If, as seems probable, these tests give satisfactory results, the era of very large diesel engines has come."*
>
> *The king of propulsion for the biggest commercial vessels—tankers, bulkers, and containerships—is the large, slow-speed, two-stroke diesel engine. It became a market force during the late 1920s, as growing ship size and power requirements began slipping beyond the capabilities of four-stroke engines. By making the intake and exhaust phases occupy a fraction of a stroke, instead of a full stroke each, the two-stroke conferred several advantages. It doubled the power output per unit size over four-strokes, and made higher power outputs accessible through bigger piston sizes and longer strokes. In addition, the low speed two-stroke allowed direct coupling to the propeller. Over time, two-stroke manufacturers would also come to claim—as they do today—higher efficiency and greater overall reliability for these engines.*
>
> *The two-stroke diesel's 50-year battle against steam for supremacy of the seas was settled amid the skyrocketing fuel prices of the 1970s. In 1975, for example, of 614 engines delivered for the biggest commercial ships, 78 percent (482) were low-speed diesels, and the remaining 123 were steam turbines. In 2000, of the 1,059 main engines delivered to vessels over 2,000 dwt, 60 percent were low-speed two-strokes. Most of the remainder was medium-speed four-strokes.*
>
> *Four-stroke marine diesels are applied everywhere from racing boats and motor yachts to cruise ships, {freight and passenger} vessels and shuttle tankers (and in a large number of stationary power plants). Their higher speed requires some intermediary between engine and propeller (reduction gearing or diesel-electric drive), a setup offering advantages of quieter operation, lower vibration, and highly flexible engine room layout and location. Competition for this variety of business is divided among a large field of manufacturers, led by Wärtsilä (51 percent of the market in 2000) and MAN B&W Diesel.*
>
> *In their competition for higher performance [and fuel economy], diesel designers focused most of their efforts on raising power while controlling engine weight. To gage their success, consider just the power increase between two 420 mm-bore, 12-cylinder two-stroke engines, separated by 30 years. In 1968, B&W's 1242-VTBF-90 delivered a total output of 6,600 bhp on a stroke of 900 mm at a speed of 220 rpm. In 2001, MAN B&W's 12S42-MC delivered 17,640 bhp on a stroke of 1,764 mm at a speed of 136 rpm—a power increase of about 2.5 times within nearly the same engine silhouette. Such power increases were realized across the diesel spectrum. Top engine power jumped in that time from some 40,000 to 100,000 bhp. Average piston speeds increased from about 6.6 m/s to about 8.5 m/s.*
>
> *The tremendous increase in internal forces and pressures that accompanied this power rise was handled not by doubling the physical size of the engine, but through advanced materials, forging, and structural technologies. There have also been great gains in thermal efficiency, the measure of an engine's ability to get mechanical work out of the energy potential of the fuel. Efficiency has been raised from roughly 40 percent in 1975 to 50 percent today, with hybrid systems pushing 55 percent. In the orderly, high-tech workshops of today's diesel designers, the massive components of even the biggest engines—like piston crowns nearly a meter in diameter and fuel injectors 600 mm long—are hand-machined to watchworks precision in order to coax every fraction of power from the combustion process. New methods of fuel treatment, computerized injection and cylinder controls, and new exhaust handling technologies optimize power while lowering the pollutant content of engine emissions. And now, the last bastion of steam propulsion, the LNG carrier, is under assault from compact, attractively-priced diesels that burn a combination of oil and natural gas.*
>
> *—Joe Evangelista, in the American Bureau of Shipping's Surveyor (Spring 2002), pp. 14–20*

Although the introduction of motor ships dominated new construction, the phaseout of existing sail and steam vessels still took many decades. For example, in 1948, steam ships accounted for 68% of the ships in the fleet and 79% of the fleet tonnage, whereas motor ships accounted for 29% of ships and only 20% of the tonnage; sail still powered 4% of vessels but only 1% of registered ship tonnage. By 1959, motor ships accounted for 52% of vessels and 39% of registered tonnage in the fleet, and in 1963, motor ships represented 69% of vessels and 49% of registered tonnage. By 1970, motor ships dominated the fleet both in terms of ships and cargo tonnage, with 85 and 64%, respectively.

For maritime nations, this rapid modernization of the world fleet was anything but shared. In fact, a nation's fleet modernizes according to economic and political motivators within each country. This means that some large merchant fleets simply age while some of the latest technologies go to emerging maritime nations. For example, after World War II, the United States had the second largest fleet by number and the largest fleet by tonnage capacity; its fleet was populated by ships built during the war to carry supplies. These ships were nearly all steam turbine powered, and they would last at least two decades. As a result, the U.S. merchant fleet of ships did not invest significantly in newer motor-driven vessels; moreover, despite stated intentions to promote a modern and competitive fleet, policymakers continued a practice of industry subsidy and protection that discouraged domestic shipbuilding and subsidized older, costlier ships that burned more fuel and required larger crews. Even as late as the 1990s, when the world merchant fleet was more than 97% diesel powered, the U.S. oceangoing fleet was more than 50% steam-powered.

4. TRENDS, OPPORTUNITIES, AND CHALLENGES

The marine transportation system has clearly considered the importance of energy conservation in its technological and economic development. However, whether these achievements continue will depend on how marine energy systems respond to growth in trade (increased demand to perform work), emerging environmental regulations (competing constraints on power system design), and increased attention to CO_2 reductions to mitigate climate change (higher expectations for energy conservation improvements). Consideration of each of these in terms of the global fleet of ships that will continue to provide a primary transportation and trade service worldwide is the focus of this final section.

4.1 Increasing Trade Volumes

Global trade has increased dramatically over the past century, and projections continue to forecast a doubling of trade volume for major nations, and as much as tripling in cargo volumes to major world ports. Carriage of these increasing trade volumes will by necessity include water transportation, and energy conservation will be a factor. There exist three possible ways for the marine transportation system to accommodate these forecasted cargoes. First, the existing fleet might simply carry more through better logistics and more fully loaded ships to maximize efficiency. Second, additional ships may be added to carry the additional cargoes, resulting in an increase in ship traffic overall. Third, the fleet might transition to larger vessels without increasing the overall number of ships in service in order to provide greater capacity within the same network of routes. In practice, each of these alternatives may be applied in some combination.

First, on certain routes and for certain cargoes, it may be possible to carry more cargo with the current fleet. However, there is an upper bound to this alternative. Most shipping routes are practically unidirectional, meaning that most of the cargo flows in one direction. For example, oil is primarily imported into the United States, and grain is primarily exported. Bulk carriers typically transit empty (or under ballast) in one direction and return with a load of cargo; this results in a practical upper bound of 50% capacity overall on routes for bulk carriers (e.g., averaging 100% one way and 0% the other, or more realistically, averaging 80–90% one way and 10–20% on the return). For container and general cargoes, some routes are able to secure a backhaul; however, there is limited ability for ships to realize this idealized goal. Where a strong backhaul market can be established, the backhaul freight rates usually are much lower and may not directly cover the costs of the voyage; here, as for bulk carriers, the freight rate for "inbound" cargoes must cover most of the cost of the round-trip voyage. For inland-river and shortsea shipping, backhauls are more practical, because vessel capacities are smaller. In fact, the industry appears to behave as though there is an upper bound. Most ships carry loads that average 50–65% capacity or less. When cargo capacities exceed 70%, it can be an indication that

too few ships are available for the route; under these conditions, ships are added to the route. Where possible, this may help reduce growth in energy consumption by the fleet.

Second, adding ships to increase route capacity is easier than it might be for on-road vehicles in the current transportation system. This is primarily because ocean routes are "unconstrained" highways. For most route distances, few modifications will be needed to enable more vessel traffic. However, in and near port regions, this may not hold. The number of berths at terminals and cargo handling rates provide at least two important limits on how many vessels a port can accommodate in a given period. No consistent metric to evaluate port capacity exists, but clearly, the capacity of the marine transportation system will be limited if ships have to wait for a berth at a port. This may involve increased energy demand for waterborne transportation, and unless these added ships divert cargoes from land-based modes, the overall energy consumption will likely increase.

The third alternative is to continue increasing economies of scale for shipping with larger ships, better cargo stowage technologies, and improved cargo logistics planning. Examples of this include the 6000-tonne equivalent unit (TEU) containerized "megaships" and supertankers. Very large ships are being employed on some routes where the cargo volumes are strong, and this practice is projected to grow. However, trade logistics may limit the cost-effectiveness of applying this option across the fleet. There will continue to be important niche routes and specialty cargoes that require vessels smaller than the megaships. This alternative may allow for even greater growth in trade while minimizing increases in energy consumption.

In general, the challenge of decoupling energy requirements from a growing global trade will be significant. The cost motivation of carriers to reduce fuel consumption will continue to promote conservation research and innovation; however, cheaper fossil-based fuels may limit the conservation progress in shipping. This is an important consideration, because many of the alternative energy sources are much more expensive than residual fuels and will require matching engine technology to the fuel.

4.2 Environmental Constraints and Continuing Conservation Efforts

Environmental impacts from shipping have been the focus of increasing attention over the past decades, primarily focused on waterborne discharges and spills of oil, chemical, and sewage pollution. A number of international treaties and national laws have been adopted, along with industry best practices, to prevent these pollution releases through accident or substandard operation. However, the shipping industry is seen as an important hybrid between land-based transportation and large stationary power systems. On the one hand, these are non-point-source vehicles operating on a transportation network of waterways; on the other hand, these vehicles operate ship systems that compare to small power-generating plants or factories. As industry leaders and policymakers at state, federal, and international levels recognize these facts, environmental and energy performance is being measured and regulated. Recent efforts to mitigate environmental impacts from shipping (for example, invasive species in ballast water, toxic hull coatings, and air emissions) are relatively new for the industry and will take decades to address.

Environmental regulation of the shipping industry typically lags behind regulation of similar industrial processes (engines, etc.) on land. At the international level, the International Maritime Organization has effectively developed a set of treaties addressing much of these ship pollution issues. Under the International Convention for the Prevention of Pollution from Ships, these regulations (MARPOL 73/78, a combination of two treaties from 1973 and 1978) apply global standards to environmental protection practices aboard ship. However, national and state jurisdictions can apply stricter regulations to certain vessel operations and to the ports that receive these ships. For example, the U.S. Environmental Protection Agency recently regulated shipping under mandated authority in the Clean Air Act. Another example includes efforts by port states in Sweden and Norway, and by individual ports in California, to apply market-based or voluntary regulations to reduce air pollution from ships entering their ports.

Environmental regulation may make some energy conservation efforts more difficult, by introducing environmental trade-offs. For example, hull coatings are specialized for marine conditions to prevent hull fouling; some of these coatings have been shown to affect the marine environment, particularly in ports and harbors, by releasing toxic chemicals or metals. These compounds slowly "leach" into the seawater, killing barnacles and other marine life that have attached to the ship. But the studies have shown that these compounds persist in the water, killing sea life,

harming the environment and possibly entering the food chain. Toxic hull coatings are being banned by national and international regulations, and this may threaten to increase energy consumption by shipping. Replacing these coatings with less toxic alternatives may result in increased rates of hull fouling and increased fuel requirements.

4.3 Future Alternative Fuels and Energy Conservation

Future energy conservation efforts in shipping are increasingly considering factors other than cost. Certainly, energy independence and fossil fuel resource availability continue to play a factor. Traditional pollution mitigation also plays a role. And most recently, climate change concerns are motivating reductions in CO_2 emissions that are directly proportional to fossil fuel combustion. Marine fuels, like all petroleum products, are about 86% carbon. If achieving greater reductions in CO_2 from marine transportation is to be achieved through means other than cost-driven fuel economy, then alternative fuels will likely be introduced.

It is worth noting that alternative fuels for energy conservation were the focus of significant attention during the energy crisis in the 1970s. In fact, the National Research Council conducted a large study, Alternative Fuels for Maritime Use, motivated explicitly by President Carter's national energy policy. That report proposed a 20-year plan to conduct research and development toward conversion of fleet to alternative energy sources; however, very little marine transportation research was pursued because energy independence descended from the top of the public policy agenda after the crisis. To a large extent, this work is being updated by current policy efforts to achieve CO_2 reductions to mitigate climate change impacts. Whether the political attention will sustain such a long-term research and development effort remains to be seen; after all, it took nearly five decades to switch the industry from coal to oil even with the performance advantages.

The current focus on alternative fuels in maritime applications involves various types of fuel, including biofuels such as biodiesel, clean diesel products, natural gas, and hydrogen. Solar, wind, and other noncombustion sources (e.g., nuclear) are sometimes identified but do not appear to be particularly suited for modern ships or global seaborne trade. Hydrogen is attracting increasing attention as a long-term goal among alternative fuels; for that reason it will be the main example for this discussion, although the issues discussed generally apply to other fuels as well.

There are challenges to the successful introduction of alternative fuel in any transportation mode. Five factors that may favor marine transportation as a cost-minimizing mode for hydrogen (or other alternative fuel) introduction have been discussed by Farrell et al. in a 2003 *Energy Policy* article. In general, converting to hydrogen fuel in freight modes first may offer certain cost-saving advantages over passenger-only modes of transportation. Some factors may apply equally or better to nonmarine modes as well, but here they are discussed only in context with marine transportation.

First, vehicle design and performance factors are important constraints on less dense fuels such as hydrogen. When the fuel-storage:payload ratio is high, switching to hydrogen will involve greater cost trade-offs. For smaller ferries, this may mean carrying significantly fewer passengers; for large cargo ships, the loss of cargo capacity may be less. Also, if the alternative fuel (hydrogen) has less energy density, then there may be impacts on acceleration, which would matter less to slower, oceangoing vessels than to high-speed harbor craft.

Second, ship operations and management may be well suited to adopting alternative fuels. Ship crews are generally well trained and licensed, and requirements for shipboard qualifications are becoming stricter. This means that commercial vessels with professional crews may be able to adopt innovative technologies more safely and at lower cost than the general public can accomplish. Moreover, if there is an increased risk of accident from the alternative fuel (which may not be strictly true for hydrogen versus petroleum fuels), then introducing a new fuel into marine cargo transportation may be accomplished through crew training that minimizes exposure to the general public. Also, fueling operations for marine vessels occur at commercial docks or by fuel barges in a commercial port harbor. Furthermore, because most commercial vessels are operated around the clock and throughout the year, investments to convert to alternative fuel may be spread across a greater period of operation than, say, is the case for passenger vehicles, which are typically driven only a few hours each day.

Third, one of the most important factors in alternative fuels is the cost of energy infrastructure. Larger, more centralized refueling locations tend to reduce the cost of delivering the alternative fuel. In the case of marine transportation, about 30 major

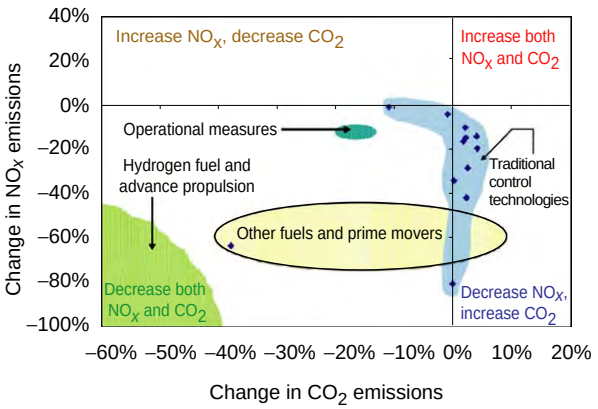

FIGURE 7 Potential trade-off between technologies to achieve reductions in traditional pollutants (NO_x) and fuel economy (in terms of CO_2).

fuel providers (refiners) in the United States supply most of the marine fuel, and most of that fuel is delivered in the top 20 ports for waterborne commerce.

Fourth, reduced air emissions are one of the benefits offered by many alternative fuels, and improved environmental performance may be greater in less regulated industries such as international and domestic shipping, compared to passenger cars, for which emissions standards have been applied increasingly for more than three decades. Converting ships to hydrogen will reduce emissions of traditional pollutants significantly, depending on the prime mover used. Figure 7 illustrates the potential trade-offs between different technologies and fuels aimed at reducing ship air emissions versus achieving greater energy conservation. It appears likely that any of the trade-offs will not be motivated by a reduction in vessel operating cost.

Fifth, shipbuilding and marine engine production rates will also be important to any fuel conversion. On the one hand, the facts that ships use tailored designs with generally similar power systems and that they are built one at a time make the process of innovation more effective than for massed-produced vehicles such as passenger cars. On the other hand, the few number of ships that are built annually and their long operating lifetimes make economies of scale for new propulsion systems difficult to achieve. However, marine engines are currently available that operate on gaseous fuels, and the long tradition of engine designs that can handle a wide range of fuel properties may contribute to successful demonstration efforts.

1. Types of Instruments
2. Principles and Applications to Energy-Related Environmental Management

Glossary

command-and-control A regulatory method by which acceptable activities are tightly prescribed, such as designating the permissible technologies for pollution control.
double dividend The claim that environmental taxes not only benefit the environment, but the collected revenues can be beneficially used to reduce other tax distortions.
emissions allowances Certifiable permits to emit pollutants.
emissions reduction credits Certifiable credits received for reducing emissions below allowance levels or beyond required reductions.
externalities Inadvertent effects on persons, such as adverse health effects of pollution, from activities of production or consumption.
marginal control cost Additional costs of controlling emissions by one more unit (ton, pound, etc.).
market-based instruments Regulatory tools that use market-like forces to provide flexibility and incentives to meet regulatory objectives.
performance bonds A financial obligation to pay when performance criteria are not met.
pigovian taxes Levies that reflect the social costs of activities, such as pollution, that are not typically accounted for in traditional markets.
tradable permits Quantified permits to engage in an action, such as emissions, whose ownership can be transferred among parties.

Market-based instruments (MBI) are proposed as one of several types of regulatory tools for attaining environmental, ecological, and resource management objectives. MBI mimic processes found in traditional markets, such as price signals, trading, and information. They allow behavioral flexibility by entities acting in their own self-interest. MBI include the following specific instruments: prices, marketable rights, subsidies, liability, and information. They contrast with command-and-control (CAC) instruments, which stipulate with varying degrees of specificity what actors must do and how they must do it, for example, establishing a technology standard for pollution control or specifying allowable emissions. MBI are also referred to as incentive-based instruments, although the latter term is a bit misleading as CAC instruments with fines for violations create incentives. Each of these MBI create circumstances where some activities critical to regulatory objectives are not fully prescribed, leaving varying degrees of discretion open to the regulated parties. Interest in MBI reflects concerns for cost-effective management and the need to persuade regulated parties to buy into regulation. They provide more flexibility in the achievement of environmental goals than CAC. Whereas CAC instruments have been successful in moving toward these goals, their typical "one size fits all" rigidity and centralized specification of behavior standards have led to concerns of overly costly regulations, as actors are allowed little flexibility and have minimal incentives for developing new control technologies. Cost savings obtained by shifting from CAC to MBI may be a prerequisite to the attainment of higher, more costly, environmental standards.

1. TYPES OF INSTRUMENTS

1.1 Prices

The function of prices as a MBI is to force actors to explicitly consider the environmental, ecological, or

 © 2004 Elsevier Inc. All rights reserved.

resource implications of their activities. By placing a price on an activity, the actor can then consider the trade-offs involved in avoiding that activity. For example, a price placed on each ton of emissions should induce actors to consider the cost of reducing emissions by 1 ton compared to the price they must pay if they do not reduce. This is illustrated in Fig. 1. Emissions reductions become progressively more expensive, as the Marginal Control Cost illustrates. These control costs are attributable to any options the actor wishes to employ to avoid emissions, including end-of-pipe controls, internal process changes, input selection, and reduced product output. The actor would have complete flexibility in selecting options and would presumably select those that are least costly. If a price is levied for emissions, an actor seeking to keep emissions-related costs low will find it cheaper to reduce emissions up to level ER* than to pay the price of not reducing emissions. The total costs of reducing emissions by an amount ER* in Fig. 1 are represented by area B and the net cost savings by avoiding the price levy are represented by area A. The actor will not reduce emissions beyond ER*, as it costs more to do so than would be saved by avoiding the levy.

Prices may be levied directly on the activity of concern to the regulator, such as emissions, or on related activities, such as the sulfur content of fuels. Where the levy is placed determines its effectiveness. Administrative concerns may determine where and how the price is levied. For example, it is administratively simpler to place a price levy on permitted activities, such as emissions volumes, than on other less readily observable activities. Legal and political concerns may determine whether the levy can be a tax or a fee, where the latter is reserved for levies that compensate the regulator for services rendered, such as a permit fee for financing the permitting process.

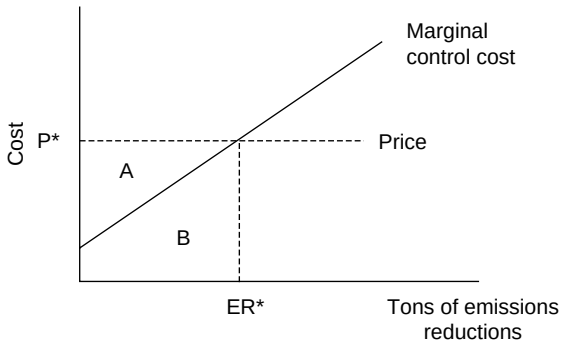

FIGURE 1 Emissions pricing and control.

The terms fines and penalties are reserved for charges based on violations of stipulated activities and are typically associated with CAC instruments.

Financial assurances, such as performance bonds, are a potentially useful MBI that place an explicit price on undesirable events. Typically the actor must post some financial assurance, such as a bond or letter of financial assurance, that can be drawn upon if some undesirable event, such as a spill or incomplete mining remediation, occurs. A price is placed on the event and the actor must pay it when the event occurs. The anticipation of this price obligation guides the actor's behavior. These assurances both manage undesirable activities through a price signal and ensure equity by holding the actor financially accountable, rather than leaving others with unwanted liabilities.

Pricing has many advantages from a social perspective. A single price sends the same signal to all actors, inducing each of them to control behavior to the same level of marginal control costs, which means that there are not some actors whose control costs far exceed the costs of others. It appears simple to administer, although it requires verification through monitoring, which may be more expensive than the cost savings from control efficiencies. Actors have incentives to consider new technologies that reduce their control costs, but only when the prices remain the same and are not lowered as all actors find cheaper methods of control. But actors may not be supportive of pricing, as they must pay for control plus the levies on remaining activities or emissions. Of course, levies may be placed on activities above a certain level to counteract potential opposition to this "double cost."

The benefits of pricing socially adverse environmental or ecological impacts of activities are reductions in welfare losses from overuse of the environment and overuse of resources in activities that harm the environment. In addition, some have claimed that using these environmental prices for public revenues allows the reduction in perverse or resource distorting taxes, such as income taxes, that diminish welfare. The benefit to welfare from environmental enhancement and reductions in otherwise distorting taxes is referred to as the "double dividend" or environmental tax reform. There is controversy over whether the second dividend is large or even positive. Environmental taxes may not raise significant revenues if the environmental activity can be easily reduced when taxes are imposed. The welfare costs of preexisting noncompetitive market structures may only be increased with such taxes. And revenue-neutral shifting of taxation to undesirable

environmental activities and away from desirable activities, such as work, would increase commodity prices to such an extent that real wages would fall, discouraging labor participation.

1.2 Marketable Rights

Endowing the actor with rights to some activity and allowing the actor to market those rights provide flexibility in achieving regulatory objectives. For example, a power plant can be allowed to emit a given volume of SO_2. But if it is allowed to buy or sell these permitted emissions allowances, they become marketable rights or tradable permits. The prudent plant will then buy or sell them based on the market prices of these allowances compared to the cost of emissions control. Plants that find it more costly to control emissions to levels permitted under their initial allowances than the market price of allowances will seek to buy allowances in the market and emit more than their initial allocation and vice versa. The result is that high-cost plants can avoid excessive control costs and low-cost plants can control to higher levels than their initial allowances. These marketable rights shift control responsibilities across sources so that a total emissions objective can be attained at lower costs than under the initial allocation of responsibility and they provide individual plants with complete flexibility in determining how much and how they will control emissions.

The rights can be for allowable activities, such as emissions allowances, or for reductions in activities, such as emissions reduction credits. The principle of trading is the same; responsibility is shifted from those who find it more costly to meet objectives to those who find it less expensive. For example, in Fig. 1, if an actor is required to reduce emissions more than ER* and the price of emissions reduction credits is P*, the actor will buy emissions reduction credits, thus allowing emissions to be reduced to a lesser degree. The actor would end up reducing emissions by ER*, as it would be less expensive to buy reduction credits than incur the greater costs of control. Similarly, an actor with an initially assigned responsibility of less than ER* will find it profitable to reduce emissions more, as more can be received for the sale of these excess reductions than it costs to create them.

The prices established through marketable rights trading guide the behavior of the actors, just as direct prices set by regulators. So there is a strong parallel between the two sets of instruments. They both have the potential to accomplish regulatory objectives at lower costs and with more flexibility than CAC instruments.

1.3 Subsidies

Subsidies are the opposite of the pricing instrument outlined in Section 2.1. Whereas a price is a payment extracted from actors enabling them to do something, a subsidy is a payment to an actor to do something. An example would be a payment to a power plant for each ton of SO_2 removed from the waste stream. In Fig. 1, if the subsidy is P* for each ton removed, the plant would remove ER*, as the reward for removal exceeds the cost of emissions reduction up to that point. So the subsidy and price instruments can achieve the same regulatory objectives and associated flexibility and cost-effectiveness. The major difference is in the wealth position of the actors under the two instruments. With a pricing system, the actor's wealth after regulation is the original wealth minus control costs (B); in a subsidy system, the actor's postregulatory wealth is the original wealth plus the net of subsidy payments over control costs (A). Clearly, the actor's postregulatory wealth is greater under the subsidy system.

The subsidy could be directly on the behavior the regulator wished to encourage or it could be indirectly related to it. For example, the subsidy could be directly on emissions reductions or a payment for installing a scrubber. The subsidy could be an explicit payment, or an indirect benefit, such as a special tax privilege.

A deposit–refund system is a hybrid price-subsidy system. For example, an electric battery purchase may require a deposit, which is a price. But if the battery is returned, the actor receives a refund, which is a subsidy for its return. The magnitude of the deposit and the differential between the deposit and the refund guide both the original purchase and the disposal of the battery.

1.4 Liability

Legal principles, such as common laws of trespass and negligence or statutorily designated liabilities, place implicit costs on actors for undesirable activities. Actors then face potential liabilities for undesirable and harmful activities. These are liabilities beyond regulatory obligations such as CAC fines and penalties. In a sense they are prices, but with a higher degree of uncertainty over magnitude and incidence than explicit regulatory pricing instruments. The potential obligation for an undesirable

activity is probabilistic, requiring a range of proofs from responsibility to magnitude of harm.

A variant of liability MBI is third-party insurance coverage. The purpose of insurance is to shift financial responsibility from an actor to the insurer. The insurer then has an incentive to establish premiums in accordance with risk and to monitor the behavior of the insured. Insurance coverage costs then reflect the insurer's assessment of risks, providing a signal of potential liabilities and the insurer becomes a quasi-regulator through monitoring. Insurance may not protect actors against liabilities due to negligence or illegal behavior.

1.5 Information

Information provided to the public about actors' behaviors may change environmental management activities. For example, public knowledge about a firm's emissions, or the "greenness" of its production processes, may galvanize public attitudes and induce firms to become good "corporate citizens." This moral suasion may extend to actual impacts on firms' profitabilities, as demands for their products are diminished or it becomes more difficult and costly to operate in the community.

2. PRINCIPLES AND APPLICATIONS TO ENERGY-RELATED ENVIRONMENTAL MANAGEMENT

The MBI are based on their ability to meet regulatory objectives in a manner that increases actor flexibility and reduces the costs of meeting objectives. The designs of these MBI are based on some principles of application. These principles suggest that some MBI are more appropriate for some circumstances and management objectives than others. These principles are discussed below, along with observations on strengths and weaknesses. Applications to energy-related issues are also presented for each MBI.

2.1 Prices

2.1.1 What to Price?

The regulator has control over actor behavior through the price. Prices may be placed on the behavior most immediately related to the regulatory objective. If the objective is to control emissions, the price can be placed directly on those emissions. The actor then has a host of activities that can be employed to avoid paying the price. However, the further the priced activity is from the regulatory objective, the less perfectly and the more costly it is for the regulator to manage for that objective. For example, SO_2 emissions from power plants may be regulated by placing a price on those discharges. Alternatively, levies based on the sulfur content of fuels would induce plants to shift to lower sulfur fuels but not induce them to change internal production processes, alter production levels, install scrubbers, etc. The pricing of fuel content does not induce the plant to engage in a whole host of activities downstream from the fuel purchase that could also reduce emissions, perhaps more cheaply.

Pricing the regulatory target may not be feasible, either economically or technologically. For example, nonpoint source run-off of nutrients from agriculture would be a candidate for targeted pricing if it were not so difficult to measure that run-off. Although it may not be impossible to measure, either directly or through nutrient transport modeling, it may be more feasible to price the nutrient inputs through charges on fertilizer. The total costs of meeting regulatory objectives must consider both the costs to agricultural production and the administrative costs. Pricing at points only indirectly related to the regulatory targets may be most cost-effective when considering both of these costs.

2.1.2 The Price Level

The level of the prices depends on the regulatory objective. A general economic principle is to set prices for activities at levels that reflect the cost to society of those activities. When traditional markets do not fully reflect these full costs, as would be the case for externalities such as pollution, a tax can be levied to correct for these price distortions. This tax is referred to as a "Pigovian Tax," named after the British economist who proposed taxing activities according to the damages they imposed on society but which were not accounted for in typical market decisions. This levy forces actors to "internalize" the adverse consequences of their actions. Such a levy would assure society that all benefits and costs of activities would become accounted for in market supply and demand conditions. For example, if it is known that a ton of emissions will change ambient concentrations by a known amount and that an estimable number of persons will become ill, one could set the emissions charge at a level reflecting the costs of those illnesses. For example, suppose that each ton of emissions harms society by an amount P*

in Fig. 1. A levy of P* would induce actors to consider those emissions and they would reduce emissions as long as the levy exceeded the costs of emissions reduction. In Fig. 1, they would control to point ER*.

But regulators are not likely to know these social costs with much exactness or to a level of certainty to avoid challenges of "arbitrary and capricious." The alternative is to establish charges related to the known costs of control. For example, in Fig. 1, if the regulator knows the marginal control costs over a wide range of emissions reductions, it can set the price to induce the actor to reduce emissions by ER*. In fact, setting the price and observing actor behavior will indicate what the marginal cost function is, if the actor engages in a rational comparison of control costs to prices.

When price levels are designed to reflect the social costs of activities, such as pollutant damages, non-uniformly mixed pollutants must bear different prices. Suppose the same emissions from two plants result in different health impacts, where 1 ton from plant A has half the impact as 1 ton from plant B. The levy on plant A should then be half that of plant B.

Pigovian taxation is designed to induce actors to behave in the best interests of society by guiding their activities and resources so that the full social costs are considered. When prices on activities do not reflect the potential social costs of those activities, the guidance advantages of MBI are lost. For example, some emissions pricing, such as permit fees that vary with permitted volumes, is designed to collect sufficient revenues to fund the regulatory program. Such prices may be greater or less than the damages they impose on society. They are not Pigovian taxes, but simply fees for services rendered.

2.1.3 Pricing with Uncertainty

In principle, when a price is placed on activities, the actor will engage in control of those activities to the point where the cost of control equals the price, as shown in Fig. 1. When control costs are not known, and a small change in price can result in large changes in control behavior, it may not be prudent to use price as a MBI when the adverse consequences of the activity can be severe. For example, polychlorinated biphenyls have such serious health impacts that it would be better to directly regulate them through quantitative restrictions or CAC regulations than to depend on pricing to ensure safe and acceptable levels. Clearly, there is a trade-off between the cost of being wrong in setting inappropriate prices and the cost of foregoing the incentive and flexibility benefits of price MBI. When the cost of being wrong can be too great, price MBI are not adequate.

2.1.4 Pricing Applications

Pricing has been used as a means of managing energy-related resource activities and environmental impacts in a variety of ways. Severance taxes and leasing payments, although they have the potential of a MBI, are typically levied as sources of revenue and payment for transfer of ownership from the public to private actors rather than a resource management instrument. Superfund taxes in the United States on inputs to chemical and refinery production, which were ended in 1995, would not qualify as MBI, as they are designed for revenue-raising and not to create incentives for behavioral changes. Fuel-use taxes are also primarily revenue-generating rather than behavior-inducing. Many U.S. states charge water effluent or air emissions permit fees, but the levels of these fees are based on the revenue needs of the regulatory programs. Such taxes and fees are not Pigovian taxes.

France introduced an industrial emissions levy on large power plants and incinerators in 1985. The charge was on sulfur oxide emissions, but the purpose was to raise revenues to finance air monitoring and subsidize installation of pollution control equipment. Japan has implemented an emissions charge for sulfur oxides also, although the charge and revenues are based on needs to compensate applicants for the health damages compensation fund. The Netherlands has implemented a manure charge system, whereby farmers pay for phosphate loadings on their land above what they are allowed to apply. Sweden has levied a charge on nitrogen oxide emissions from large furnaces. Several European countries find it more convenient to place levies on products rather than on environmental impacts, per se. For example, Norway and Sweden have imposed levies on pesticides and fertilizers. These countries and Finland have also levied carbon taxes on motor fuels, but the primary purpose is to raise revenues.

The state of Maine has a complex air-emissions permit fee system, where fees per ton of several pollutants are based on volumes, with increasing per-ton fees for larger volumes and more toxic emissions. In the South Coast Air Quality Management District of California, facilities exceeding allowable emissions must pay excess emissions fees. This district also levies fees on both criteria pollutants and air toxics, and toxics fees are considerably higher than criteria fees. Many U.S. states levy charges on the

generation and management of hazardous wastes. Taxes on landfill and incinerator disposal of hazardous waste have been high enough to reduce disposal by these methods, although it is unclear whether they have reduced the generation of such wastes or shifted disposal across state lines or to illegal disposal. The United States imposes gas guzzler taxes on automobiles, presumably to increase fuel efficiencies. The United States imposed taxes on ozone-depleting chemicals, based on their depletion factors, until such chemicals were completely phased out in the United States in 1996. Most U.S. states impose fertilizer fees, but they are based on revenues for fertilizer inspection. Texas introduced a clean fuel incentive surcharge on boiler fuel oil. Used oils and fuels derived from hazardous wastes are exempt. This surcharge is designed to shift fuel use rather than raise revenue.

2.2 Tradable Permits

The basis of tradable permits as a useful regulatory tool stems from the notion that all parties will benefit from free and voluntary trades. Markets are institutions for transfers of property rights. Ronald Coase, in his famous Coase Theorem, proposed that in the absence of transactions costs of trade, these property rights would be voluntarily redistributed so that the social value is maximized. It did not matter to whom the original property rights were assigned; the outcome would be the same and coincide with what society deemed best. By implication, if a fixed number of permits to do something were made available and trading was allowed, those permits would go to the entities most capable of profiting from them. For example, a fixed number of emissions permits, distributed across polluters, would be traded so that actors with low control costs would sell their permits to high-cost controllers; hence, low-cost controllers would do more control. The result was low social costs of attaining an emissions objective, a socially desirable goal.

2.2.1 What to Trade?

A wide variety of activities are amenable to the establishment of rights and trading. In fact, any activity that is identifiable and to which an enforceable property right can be feasibly established is ripe for tradable permitting. Emissions allowances establish a volume of permitted emissions, give an enterprise permits for that volume, and define the terms of trading. Enterprises may be given emissions reduction credits when they reduce emissions below allowable levels. They trade these reduction credits with others who will not reduce their emissions to allowable levels. Rules would be established that define the property rights implied by the permits, such as how long they are active, whether they can be banked and used later, whether some spatial trades are not allowed, and trading ratios across locations or types of activities. Tradable water rights, leaded gasoline, land development, and timber harvesting illustrate the broad range of tradable rights or permits. Some have even suggested biodiversity trading.

2.2.2 Problems with Trading

Permit and rights trading can have adverse consequences when the regulatory objective is to ensure an acceptable ambient concentration; for example, unrestricted trading of nonuniformly mixed pollutants may create "hot spots" where ambient conditions exceed objectives. This suggests trading rules in which restrictions or trading ratios are based on ambient concentration effects. A buyer of emission reduction credits may be restricted in how many they can purchase or trading among greenhouse gases may be based on CO_2 equivalents of different gases.

Since permits are required for activities, the level of permits one has will determine business viability. Actors may seek to hoard permits or employ the permitting process to enhance their market position. When tradable permitting results in market monopolization, the possible increased consumer costs must be weighed against any social gains from the tradable permit program.

A small number of trading partners limits the viability of the trading market in several ways. Transactions costs associated with finding and making trades may be higher than when the market has a large number of active participants. Also, manipulation of the market is more likely the smaller the number of traders. Any manipulation defeats the purpose of the trading and eliminates social gains. Monopolization of the trading market has the same disadvantages as monopolization of any market.

Limiting the time during which purchased permits or rights remain valid also reduces the viability of the trading market, as the property rights diminish over time. This is especially a problem when the regulator wants to reduce levels of the activity in the future. Allowing existing permits to depreciate just reduces the demand for them and reduces the potential gains from trading.

Although Coase's Theorem suggests that the initial assignment of rights or permits does not

matter to the final outcomes, this may not be true when the initial assignment affects the wealth of actors. A permit or right endows wealth. This wealth can be employed in a number of ways. Otherwise, failing enterprises may be able to obtain access to capital that allows them to endure or this wealth may be used to alter political processes in an actor's favor. These wealth effects suggest that the initial assignment does matter to the final outcome.

2.2.3 Applications

Tradable permits have been used in a variety of environmental regulatory applications. The first U.S. application was in air nonattainment areas in the early 1970s, where new sources had to obtain emissions reductions credits, or offsets, from existing sources. Those who generated reductions credits were allowed to bank them for future use. In the course of phasing out lead in gasoline, U.S. refineries were allowed to trade lead content. It is instructive that U.S. Environmental Protection Agency enforcement of trading relied on reports and random gasoline samples. There were fraudulent trades discovered, but only in less than 1% of the cases. The United States allowed chlorofluorocarbon producers to trade during the phase-out of ozone-depleting chemicals during the early 1990s.

U.S. power plants have participated since the mid-1990s in an active sulfur dioxide trading program under the Clean Air Act's Acid Rain Program. Emissions allowances are calculated based on allowable emissions per million British thermal units (Btu) times average Btu consumption. Plants with emissions less than allowables can trade with plants that exceed their allowances. The U.S. Environmental Protection Agency holds some allowances and offers them at annual auctions. This trading program has been estimated to save approximately $2.5 billion per year compared to costs without trading. Eight northeastern U.S. states also participate in a NO_x trading program.

The South Coast Air Quality Management District in southern California established a Regional Clean Air Incentives Market (RECLAIM) in the early 1990s. Emissions allowances for NO_x and SO_x were established and sources were allowed to trade emissions reduction credits, where trading ratios were set for trades between geographic areas. The district estimates that compliance costs were reduced by nearly 50% as a result of trading. Several other states, including Illinois, Michigan, New Jersey, and Texas, have trading programs similar to RECLAIM.

Trading within and between point and nonpoint sources has been applied in several cases in the United States. The state of Washington has a grass burning tradable permit system. Water effluent trading has had limited applications in the United States. Biological oxygen demand trading in the Fox River of Wisconsin had limited success because of limitations the state placed on trades and the fact that since the Clean Water Act does not explicitly allow trading, minimum technology-based standards placed on effluents limited source control flexibility. Phosphorous discharge trading in the Dillon Reservoir in Colorado has also had limited success. Trading between point (wastewater treatment plants) and nonpoint (development) was allowed. As treatment plants found cheaper means of source control, their demand for permits diminished. As a result, the market has not been active. The ability of point sources to reduce nutrient effluents inexpensively has limited the application of tradable nutrient permits in the Tar Pamlico Basin in North Carolina.

The Kyoto Protocol allows greenhouse gas trading through several provisions. The Joint Implementation provision allows Annex I countries, larger developed countries, to acquire emissions reduction units from other Annex I countries. These reduction units can be based on projects that either reduce emissions or increase sinks for greenhouse gases. The Clean Development Mechanism allows Annex I countries to invest in emissions reduction or sink projects in non-Annex I countries in order to obtain emissions reduction units. International Emissions Trading provisions then allow Annex I countries to trade with one another to meet greenhouse gas targets.

Trading programs designed to protect ecosystems and resources have also been established. Wetlands mitigation banking in the United States allows persons who engage in activities that destroy or impair wetlands to purchase credits from a wetlands bank, where persons who have created or improved wetlands place deposit credits. Rules of trading often restrict trades to geographic areas and employ trading ratios that presumably ensure no net loss of wetlands. Credits can be based on simple acreage or on quality-based measures. Transferable development rights in the United States have been used to shift residential and commercial developments to more appropriate urban areas in order to avoid urban sprawl. Landowners in protected areas are provided development rights to alternative areas in lieu of development on their property and can sell these rights to others. This market has had limited success in the United States, partially due to

municipalities' unwillingness or inability to restrict property rights to development and to the fact that effective sprawl-controlling trades may be between jurisdictions. Historic allocations of water rights in California to agriculture have created circumstances where water has not gone to its highest and best use, especially municipal and wetlands needs. The introduction of tradable permits has facilitated the movement of water rights from agriculture to these higher valued needs.

2.3 Subsidies

Subsidies are a means of rewarding actors for activities they may not have undertaken otherwise. Subsidies may be particularly useful when the actor is not legally obligated to undertake an activity or where restrictions on activities are not feasible for economic, political, or social reasons. For example, enforcement of nonpoint pollution restrictions in agriculture is costly and imperfect and farmers may be incapable, financially or politically, of controls. Pollution reduction may be achieved by subsidizing best management practices or the use of environmentally friendly fuels may be encouraged through subsidies to production or demand. Subsidies may be direct payments, such as price supports for crops used in ethanol production, or favored tax treatment, such as reductions in ethanol fuel taxes.

Although subsidies violate the "polluter pays" principle, by which social costs of activities are borne by the polluter, they may be the only means of achieving regulatory objectives. They face public resistance in cases where the undesirable activities are determined to be socially unacceptable and the public balks at paying someone for doing something they should have done anyway. Also, the perverse effect of subsidies may be to encourage the unacceptable activities in order to enhance the subsidy levels. For example, farmers may claim they would have drained more wetlands if they are subsidized for not farming wetlands.

The United States employs a variety of subsidy instruments for environmental and energy management. Favorable tax treatment in accelerated depreciation allowances for oil and gas drilling and production activities lowers energy costs. Reduced federal and state taxes on ethanol fuels, public procurement of recycled items, and favorable tax treatment of pollution control investments are further examples of subsidies impacting the demands for environmentally related goods and services. The RECLAIM program in southern California bought back old, high-polluting automobiles. An interesting, but short-lived, tax-based incentive program was the Louisiana Environmental Scorecard. Enterprises applying for industrial tax relief received exemptions based on their environmental performance, including violations, recent behavior, and Toxic Release Inventory (TRI) emissions per employee. A scoring system resulted in tax relief ranging from 0 to 100% of potential relief.

Of course, there are also many types of subsidies that harm the environment, such as energy development subsidies, below-cost timber sales, and grazing fees. Favorable tax treatment in timber, such as allowing enterprises to expense management and reforestation costs rather than capitalizing them, lowers timber costs and encourages timber development. Price support programs, such as those for sugar, have encouraged farming in sensitive ecosystems, such as the Florida Everglades. These agricultural price support programs also encourage the increased use of fertilizers.

2.4 Liabilities

The use of liabilities relies on the actor's willingness and ability to foresee the financial implications of its activities. Depending on the actor's foresight and time horizon, liabilities may be an effective means of attaining regulatory objectives. But there are many factors that may limit their effectiveness. The actor must foresee the implications of activities. There must be a high probability that adverse actions will eventually be penalized. But this depends on the effectiveness of the legal system and its enabling laws. Proofs must be made and penalties must ensue. Each element of the legal process is probabilistic. For example, can long-term health effects of a pollutant be proven? Can it be proven that a particular actor was responsible for the emissions? Will harmed parties pursue retribution? Will juries or judges convict? Will they impose punitive damages beyond proven damages? And to make liabilities an even less perfect enforcement tool, actors will use varying discount rates in assessing implications for current actions. They may accept bankruptcy as a better alternative to control.

Burdens of proof alter the liability landscape. It is one thing to have to prove that harm was done before halting an activity. It is another if actors must prove that no harm will be done before they can engage in an activity. Performance bonds may be one MBI that would hold society harmless while actors are allowed activities that may eventually prove

harmless. Actors would post them while engaging in the activity and bond values would be based on worst-case damages scenarios. Required bonding levels would be diminished as the actions are proven to be less harmful than the worst-case basis. The bonding makes the burden of proof of no harm fall on the actor. This would be appropriate when activities may have tragic consequences, such as loss of life or irreversible changes in ecosystem conditions. Bonding is a means of allowing potentially harmful activities when it is uncertain what their impacts will be. Actors have an incentive to discover their true implications.

Environmental performance bonds are used in the mining industry to ensure proper remediation of surface mines. Mining bonds in Pennsylvania have been set at values only one-tenth the average reclamation costs, leaving the state holding the financial responsibility for complete restoration. Bonding for oil and gas mining activities could similarly be applied to exploration, development, and production activities, especially in ecologically sensitive areas. Bonding of farmers for nutrient runoff, erosions control, and other adverse effects of agriculture could be used, although the ability of farmers to finance such bonds may be limited.

In the United States, the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) applies strict liability and joint and several liability to hazardous substance releases. Strict liability means that guilty actors are liable regardless of whether the act is purposeful or a result of negligence. Joint and several liability means that any party to a release can be held liable for the entire cost, regardless of its identifiable responsibility. Damages to natural resources from oil spills are included in CERCLA and require compensation to the public for lost resources.

Personal injuries from toxic agents can be litigated under U.S. tort law. However, a successful suit requires considerable demonstration of causality by plaintiffs. The willingness of courts to accept statistical analyses is limited, making proof of causation more difficult.

2.5 Information

Information provided to the public regarding actors' activities can have dramatic repercussions on the market conditions of the actors. Boycotts related to the environment can have impacts on product demand. Community opposition can increase costs of operations, such as legal battles over zoning and property assessments, and actors may just feel some social responsibility to be good citizens for the environment. Firms may be interested in the production conditions of suppliers and better environmental records may enhance labor supply conditions. Capital markets may look favorably at firms with better environmental records, as a reflection of potential liabilities.

Information may be casual and less than perfect, based on perceptions rather than facts. But it may also be well-established and certifiable, such as appliance and vehicle energy efficiencies or toxic releases. Good examples of effective information systems in the United States are the "right-to-know" federal and state statutes. The federal Emergency Planning and Community Right-To-Know Act introduced the publicly available TRI reporting system. Over 600 toxic chemicals have been reported by larger manufacturing facilities. Generation, treatment, and disposal information on the chemicals is available to the public. The TRI program has earned wide acclaim for its effectiveness. One study has shown that firms whose stock prices fell after releasing the TRI data were more likely to reduce TRI emissions in the future. California enacted Proposition 65, which requires firms to post warnings to the public of potential exposures to listed carcinogenic or toxic chemicals. Warnings include product labels and placards in business establishments.

Product labels, such as the Green Seal program in the United States, inform consumers about the environmental friendliness of products and their inputs and production processes. Manufacturers pay the Green Seal organization for an evaluation. The U.S. Federal Trade Commission has been developing "Green Guides" for recyclable, degradable, and environmentally friendly products. Scientific Certification Systems is a U.S. for-profit business that scores timber companies for their harvesting and management practices. The company also prepares internal environmental audits for firms. Several states and nonprofit foundations sponsor environmental awards.

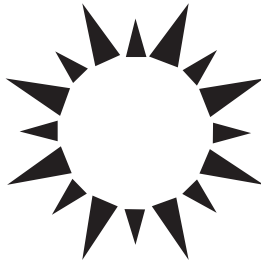
Market Failures in Energy Markets



STEPHEN J. DECANIO
University of California, Santa Barbara
Santa Barbara, California, United States

1. "Classical" Market Failures
2. Is Optimization the Correct Model of Behavior?
3. Additional Considerations

Glossary

consumers' surplus A measure of the benefit to consumers, net of the cost of the good, of their being able to purchase it at a particular price.
cost–benefit analysis The formal comparison of the economic costs and benefits of some particular action or policy.
general equilibrium model A model designed to represent the utility- or profit-maximizing behavior of all the agents in the economy, the solution of which is a set of prices and goods allocations that satisfy the maximization conditions of the agents.
Herfindahl index A measure of industry concentration equal to the sum of the squares of the market shares of the firms in the industry.
hurdle rate A rate of return that investment projects must achieve in order to be undertaken.
inelastic demand (or supply) A situation in which large changes in the price of a good lead to only small changes in the quantity demanded (or supplied).
marginal cost The additional per-unit cost of production as output increases.
price taker An economic agent that is not able to influence, by its own actions, the price at which any good is transacted.
producers' surplus A measure of the benefit to producers, net of the cost of production, of being able to sell their output at a particular price.
risk-adjusted cost of capital The price a firm must pay to borrow funds for an investment project of a particular risk.
traveling salesman problem Given a finite number of cities along with the cost of travel between each pair of them, find the cheapest way of visiting all the cities and returning to the starting point.

Market failure can be understood only as the opposite of some concept of market success. But what is market success? Defining it as a general improvement of the conditions of life is too vague; requiring achievement of the best of all possible worlds is too utopian. For economists, market success is ordinarily thought of as achieving Pareto optimality, a situation in which no one's material well-being can be improved without reducing the well-being of at least one other person. If the economic decisions of all the individuals in the society (that is, their activities as they participate in markets of all types) lead to a Pareto optimum, the criterion of market success has been met. Anything that falls short constitutes market failure. One of the achievements of modern economic theory has been to demonstrate that there is a set of ideal conditions under which decentralized decision-making leads to a Pareto-optimal social outcome. This remarkable result is embodied in the so-called First Welfare Theorem, which states that if every relevant good is traded in a market at publicly known prices (i.e., if there is a complete set of markets), and if households and firms act perfectly competitively (i.e., as price takers), then the market outcome without any government regulation or intervention will be Pareto-optimal. This result sets a scientifically meaningful standard—one with empirical content that is not a tautology—against which real-world situations can be compared. Policies cannot improve on the economic efficiency of a Pareto optimum, although it should be noted that many different Pareto optima having different income distributions are possible. Closely related to the notion of Pareto optimality is the concept of the Kaldor-Hicks test. According to the Kaldor-Hicks criterion (first introduced in the 1930s), situation B is socially preferable to situation A if those who would gain from moving from A to B

could compensate the losers and still have something left over. This type of move will be referred to subsequently as one that is cost-beneficial, drawing on the terminology of cost–benefit analysis. Market failure also occurs if the economy exhibits opportunities for cost-beneficial actions (investments, policy implementations, etc.) that are not undertaken. It should be noted that to be cost-beneficial, it is only necessary that a policy or private action generate enough additional output to make it *possible* for the gainers to compensate the losers. In the real world, such compensation is rarely paid even when cost-beneficial moves are undertaken. This is a feature of the political system, however, that is not entailed in the definition of market success or failure.

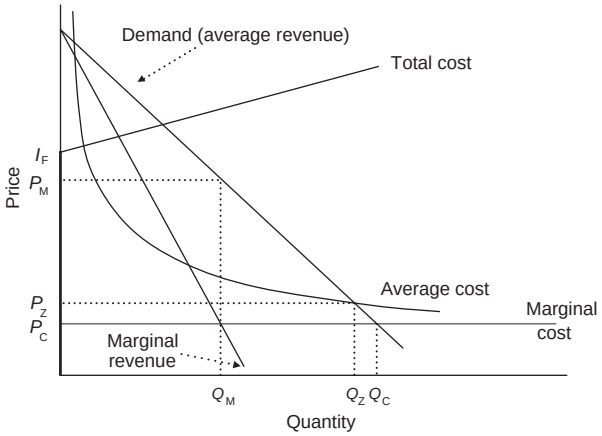

FIGURE 1 Prices and quantities under monopoly, zero profit, and perfect competition.

1. "CLASSICAL" MARKET FAILURES

In energy markets, the requirements of the First Welfare Theorem (FWT) are systematically violated, leading to a wide variety of market failures. Of course, the conditions for the FWT to hold are quite strong and are unlikely to be perfectly satisfied anywhere, but in the case of energy markets the failures are conspicuous.

1.1 Monopoly

Perhaps the most commonly recognized breakdown of the necessary conditions for market success is that energy markets are frequently subject to problems of monopoly. Some of the key agents do not act as price takers but would, in the absence of legal constraints, be able to control prices and quantities so as to improve their own position at the expense of general economic efficiency. The foremost source of such market power is the existence of economies of scale in production. Economies of scale imply that the unit cost of producing the output is declining as the scale of operations increases. If this decline in unit costs prevails over the entire range of market demand, the industry is said to constitute a natural monopoly. In energy markets, perhaps the clearest case of this is in electricity distribution, which historically has been characterized by very large fixed-cost investments in the grid.

Consider a simplified graphical representation of the electricity delivery market. Building the "backbone" grid requires a large initial investment, but once it is in place, the additional cost of connecting a new customer (that is, building a line from the grid to the customer) is small and roughly constant. In a stylized representation, this gives rise to Total Cost, Average Cost, and Marginal Cost curves, as depicted in Fig. 1. Total Cost consists of two parts: a fixed initial investment (I_F) that must be incurred before the first unit of output can be sold, plus an amount that increases linearly with the quantity of electricity delivered. This type of Total Cost curve implies an Average Cost curve that is falling over its entire range and a Marginal Cost curve that is horizontal. Demand is given by the Average Revenue curve, which slopes downward over the relevant range of potential output. The Marginal Revenue curve (defined as the additional unit of revenue per unit of additional output sold) is also a downward-sloping line with a slope steeper than the demand curve. Linearity of the demand and marginal cost curves is not essential to the argument, but simplifies Fig. 1 and the exposition.

The electricity distribution utility's economic profit (after accounting for payments to all factors of production including management and the return to capital) will be zero when average revenue equals average cost; in contrast, the perfectly competitive equilibrium will be the point at which price equals marginal cost, whereas an unregulated monopoly would maximize its profit by delivering an amount of product such that the marginal revenue equals marginal cost. The prices in these three cases would be P_M for the monopoly, P_Z for the point of zero economic profit, and P_C for the perfectly competitive equilibrium.

Market failure occurs because the unregulated monopolist charges too high a price for the electricity and delivers too little of it. If the fixed costs are high enough, no potential competitor could enter the market and make a profit. Even if the entrant's fixed

cost were low, no entrant would be able to make any positive profit so long as the entrant's average cost for whatever market share it could obtain were greater than the price prevailing in the market after the newcomer's entry. The monopolist collects "supernormal" profits, that is, profits over and above all the costs of production. Elimination of these monopoly profits requires that the price be no higher than average cost and the minimum output for which this is possible is (Q_Z, P_Z). This zero-profit point is often the target aimed for by utility regulators—the price the utility is allowed to charge is only enough to cover all costs including a "fair" return on capital.

Yet even at the zero-profit point (Q_Z, P_Z), the market failure is not entirely corrected. Although it is true that at this point there is no incentive for entry into the market and the existing firm is economically viable, the zero-profit point is not Pareto-optimal because it is possible to design taxes on consumers and subsidies to the utility that would induce the utility to expand its output (and lower its price) to (Q_C, P_C). At (Q_C, P_C) every member of society is potentially better off than at (Q_Z, P_Z). This can be seen by comparing the consumers' gain in moving from (Q_Z, P_Z) to (Q_C, P_C) to the subsidy that would be required to bring the utility back to the break-even point. Alternatively, it can be shown that the total surplus (producers' plus consumers') increases in moving from (Q_Z, P_Z) to (Q_C, P_C). Society gains on net in moving to (Q_C, P_C).

The example illustrated by Fig. 1 is a simple case in which economies of scale are the cause of the monopoly problem. In the real world, monopoly power is often more difficult to detect and may be very hard to control. Markets are rarely occupied by a monopolist producer, and although measures of concentration (such as the Herfindahl index) based on market shares are often used to provide a rough indication of potential market power, the absence of a general theory of oligopoly pricing makes unambiguous inferences of market power from data on market shares impossible. To complicate matters further, temporary market power can emerge in almost any dynamic setting. It often involves a time-sensitive component. Entering a market can take time—to build parallel infrastructure, establish a sales network, or obtain the required regulatory permissions, for example. Thus, it may be possible for a producer to enjoy a monopoly position in the short run that cannot be maintained over the long term. Much actual business practice involves seeking temporary monopoly advantages—being the first to offer a new product or service or developing a new process or technique that is protected by patent rights or as a trade secret. In such cases, the monopoly return may be viewed as a way to compensate firms for the expense of research and development and provides an incentive to innovate. The kind of temporary monopoly advantage that leads to technological progress can be an indicator of dynamism in the market economy. In the perfectly competitive equilibrium in which no one is earning any supernormal profits, there is no incentive for anyone's behavior to change. In the real world, the search for profit opportunities must have some positive probability of a payoff, or innovation would wither.

In many other circumstances, however, monopoly power not based on economies of scale has no social benefit. Taking advantage of temporary shortages, or collusion to create a shortage, is rightly condemned as a market failure. Energy markets are prone to problems of this type because of complex technical interdependencies or inelastic supply and demand curves (as in electricity markets). Controlling the opportunism that such conditions engender is one of the reasons firms exist and is also a legitimate role for government intervention. The debacle of "deregulated" electricity markets in California in 2000–2001 is an example of the kinds of things that can go wrong when such opportunities for the exercise of market power are not held in check. When electricity supply became tight in the summer of 2000, even producers with relatively small market shares could exercise market power because of the extreme inelasticity of short-term demand.

1.2 Externalities

A second source of market failure in energy markets stems from the existence of externalities. A negative externality arises when production or consumption decisions of some agents directly and adversely affect the happiness of other agents and the affected agents have no way of obtaining compensation for the harm done to them. (A similar inefficiency occurs if the externality is positive in that it provides benefits to some members of society that they do not have to pay for.) In the case of energy production and consumption, externalities are the rule rather than the exception. Examples include the local air pollution of coal-fired power plants (which produce harmful particulates and oxides of nitrogen and sulfur as a natural result of the combustion process), the congestion of streets and highways that results when individuals make uncoordinated personal

transportation decisions, and the climate-changing effect of the carbon dioxide that is emitted whenever fossil fuels are burned.

Essentially, the market failure from externalities comes about because some markets simply do not exist. There is no way that individuals can buy or trade "climate stability," for example. At the root of the externality is the absence of well-defined and enforceable property rights. Clear property rights of a suitable type would enable individuals to obtain compensation for the adverse effect on their well-being of the externality-producing activities of others. When such rights do not exist, people have no way of expressing their preferences through their willingness to exchange goods they own. In the case of monopoly, market failure occurs because not all participants in the market are price takers; with externalities, markets fail because they are not complete. The First Welfare Theorem does not hold because not every good is traded.

A number of strategies can eliminate the market failures caused by externalities, but all involve some kind of policy decision or collective action. Taxes (or subsidies in the case of positive externalities) can be imposed that make the private costs associated with the externality-producing activities (such as the burning of fossil fuels) correspond to what producers would have to pay those harmed by the externality if the appropriate property rights existed. Alternatively, the government can create new property rights and assign them to individuals so that the requisite market transactions can occur with low transactions costs. This enabling of new markets is exemplified by the creation of SO_2 allowances under the 1990 Clean Air Act (CAA) Amendments in the United States. Under the CAA Amendments, SO_2 emissions are curtailed in the aggregate (thereby creating a cost for SO_2 emissions and correcting the externality) and trading of allowances among producers makes it possible for the net aggregate reduction in SO_2 emissions to be achieved a minimum cost. Provided the participants in the newly created markets behave as price takers and not as monopolists or oligopolists, this kind of policy can eliminate the externality that arises from nonexistent markets.

It should be noted here that the distribution of wealth and income will be affected by how the property rights are assigned or tax revenues are collected and spent. Different assignments of rights will give rise to different Pareto-optimal equilibria and those different outcomes need to be judged according to a criterion of justice rather than economic efficiency (because all Pareto-optimal outcomes are efficient). According to the definition being used here, market failure pertains to the failure to achieve an efficient outcome, not to the intrinsic desirability or fairness of the resulting pattern of prices, incomes, and consumption.

1.3 Public Goods

A third source of market failure in energy markets is that energy production and consumption entail the production or diminishment of public goods such as macroeconomic stability or the scientific knowledge derived from basic research. A public good is a commodity or service such that if it is supplied to any of the members of society, it can be enjoyed by all at no extra cost. The consumers of the public good are not able to exclude others from its consumption. The classic examples are national defense and public order. A military establishment that is successfully able to deter potential aggressors and defend the nation's territory against attack necessarily provides this service for all citizens alike. This "nonexcludability" of public goods gives rise to the problem of free riders—if national defense protects citizens equally regardless of their contribution, individuals have no incentive to pay for the military. If left to the unregulated market, not enough public goods will be supplied because of this free rider problem. This is the fundamental reason why taxes that are used to purchase public goods must be compulsory.

It might be thought that fuels and energy services are commodities like any other. In their direct benefits this is true: the owner of an automobile can exclude others from driving it and a consumer's electricity bill reflects only his or her own consumption of electricity. However, because the use of energy is ubiquitous, and because the means of converting fuels into useful work requires complex and expensive capital equipment (power plants, motor vehicles, pipelines, etc.), the commodity-like nature of energy products gives rise to the problem of macroeconomic stability. Fuel prices can change much more rapidly than the capital stock can be adjusted and therefore the volatility of fuel prices creates situations in which capital that was profitable at previous fuel price levels becomes uneconomic at current fuel price levels. Uneconomic capital equipment is taken out of production and this in turn leads to job losses and unemployment. Thus, movements in energy prices can have a ripple effect throughout the economy, resulting in fluctuations in employment and output that affect the well-being of all. This is precisely what happened during the oil price shocks

of the 1970s. Unanticipated sudden increases in oil prices associated with market and political events had macroeconomic consequences around the world. Policy initiatives such as the Strategic Petroleum Reserve (SPR) are intended to stabilize the price of oil and thereby ameliorate macroeconomic disruptions caused by oil price volatility. The SPR provides a valuable buffer against the potential macroeconomic consequences of unexpected oil price movements just as discretionary monetary policy is an appropriate tool for responding to changes in aggregate demand.

Macroeconomic vulnerability to energy price shocks is sometimes characterized as a national security problem. Given that modern military vehicles require sophisticated power plants (whether fossil-fuel driven or nuclear), it is certainly true that the availability of suitable fuels is necessary for military operations. For some countries, such as the United States, domestic fuel sources are sufficient to satisfy military requirements in wartime so direct military needs are not part of the national security problem for those countries. Also, the relative proportions of foreign and domestic oil consumed are no indication of macroeconomic vulnerability. Because oil is a commodity traded in world markets, a supply disruption anywhere has an effect on the world oil price. So, for example, even if U.S. oil demand were supplied 100% domestically, a world oil price shock would have adverse macroeconomic effects in the United States as the domestic price followed the world price. Thus, the national security problem associated with energy has to do primarily with the flexibility of a nation's capital stock in the face of energy price fluctuations. In addition, foreign oil purchases may constitute a national security problem if the supply comes from a hostile state or states whose military capability is increased because of the wealth gained from their petroleum sales.

A second public goods aspect of energy markets is the role of research and development (R&D). Scientific knowledge is very much a public good, because once new knowledge is published it is available to all without the possibility of exclusion. The producer of the knowledge cannot hope to recover more than a fraction of the benefits resulting from the knowledge. Useful knowledge created through the research and development process has spillovers to firms or other organizations and individuals that did not carry out the research. As a result, there will be too little research and development in the aggregate unless the government intervenes. If the optimal level of research were being undertaken, the rate of return to R&D would be equal to the rate of return on other forms of investment. In fact, empirical studies consistently find social rates of return to R&D that substantially exceed the market return to capital. This discrepancy provides a rationale for government support of R&D, whether through universities, government research laboratories, tax incentives, or direct subsidies.

A related potential market failure comes about because of the tendency for unit costs to decline as producers and consumers gain experience with a product or technology—the phenomenon of "learning by doing." This dynamic pattern of cost decline has been observed across many technologies, including energy technologies such as wind power generators and solar voltaic panels. Unless private investors correctly anticipate the timing and extent of the cost reductions due to learning by doing, they may fail to invest sufficiently in promising emerging technologies. Consumers may be unwilling to pay the high price for new technologies in the early stages of their development, even though the technologies would be quite attractive if they could be utilized in sufficient volume to realize cost reductions from learning by doing and economies of scale. This is sometimes referred to as the "chicken and egg" problem. In some cases, market forces will lead to the emergence of the best technologies, but not always. A long history of the gradual improvement of an inferior technology (along with the growth of infrastructure associated with it) may lead to the lock-in of that technology and barriers to the adoption of superior alternatives.

2. IS OPTIMIZATION THE CORRECT MODEL OF BEHAVIOR?

The market failures described in Section 1 are commonplace staples of textbooks. There is another class of energy market failures about which there is less consensus. Prominent among these is the energy efficiency gap: the notion that even though sizable improvements in energy efficiency could be achieved by making investments that would be profitable at current prices, these investments are not carried out. Sometimes this phenomenon takes the form that the hurdle rates required for energy-efficiency investments are considerably higher than the cost of capital to the firm for projects of comparable risk. The existence of this type of market failure is controversial, because if profitable opportunities are available,

why do profit-maximizing firms fail to undertake them? (By definition, a profitable investment is cost-beneficial because the resources devoted to it create more wealth than if the investment were not made.) A very large body of empirical literature attests to the existence of these opportunities, yet the systematic failure to maximize profits conflicts with standard practice in economic modeling. It would seem that either the assumption of profit maximization does not hold or the studies documenting the possibility for energy efficiency improvements have missed essential elements of full cost accounting.

To see why the resolution of this issue has implications for market success or failure, consider the two situations depicted in Fig. 2. In both Fig. 2a and Fig. 2b, the axes represent desirable outputs from different activities that might be undertaken by the firm. The horizontal axis shows the reduction in pollution that would follow from enhancing energy efficiency (by suitable investments, changes in operating procedures, etc.) and the vertical axis shows the economic output from the other activities of the firm. The curves PP′ in the two diagrams represent the theoretical "production-possibilities frontier" of the firm. This frontier is the set of possible combinations of the two kinds of goods that the firm could produce from a given set of resources if it were fully optimized.

The empirical question is whether the firm is always operating on its production-possibilities frontier. Figures 2a and 2b represent alternate answers to this question. In both cases, the points A and A′ represent the initial situation of the firm and points B and B′ show the position of the firm after taking some action such as increasing its energy efficiency. If the firm is fully optimized, it is not possible to achieve reductions in pollution without sacrificing some other profitable activity. This case is shown in Fig. 2a. In contrast, Fig. 2b shows a situation in which it is possible for the firm to realize gains simultaneously from investments in energy efficiency and other activities. This case corresponds to the possibility that there are profitable energy-saving investments available to the firm. The increase in energy efficiency accounts for the pollution reduction along the horizontal axis and the additional profit earned from these investments allows the firm to expand its output in other directions. If the firm is not organized optimally to begin with, improvements are possible along multiple dimensions of its performance.

The situation displayed in Fig. 2b is commonly referred to as a market failure, even though it is perhaps more appropriate to describe it as an organizational failure or institutional failure. The point remains that in Fig. 2b it is possible to take actions that would be cost-beneficial. To assess how common or realistic is the situation shown in Fig. 2b compared to Fig. 2a, it is necessary to examine what kinds of factors might give rise to a firm's operating inside its production-possibilities frontier.

2.1 Nonunitary Organizations

Primary among the causes of organizational failure is the fact that firms are made up of distinct individuals having different interests. The firm has no mind or will of its own; it acts according to a set of decision-making procedures and there is no guarantee that the collective action of the individuals making up the firm will lead to fulfillment of the firm's formal objective (the maximization of profit). Even though

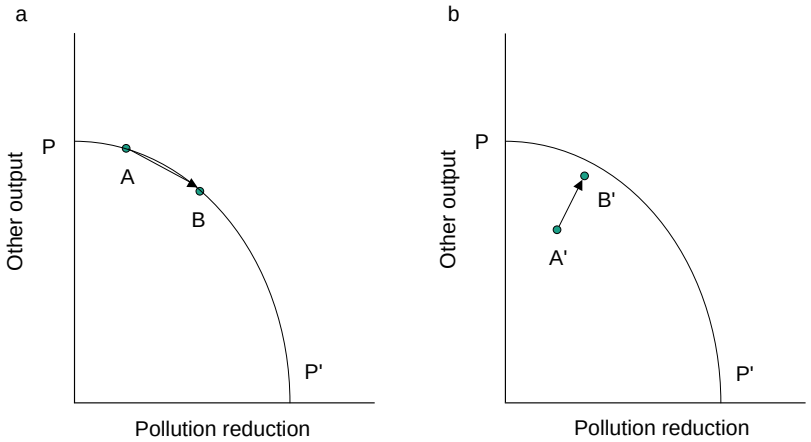

FIGURE 2 An energy efficiency gap? (a) Firm that is fully optimized. (b) Firm that is not fully optimized.

there are gains from cooperation (firms would not exist otherwise), the diverging objectives of the agents making up the firm are almost certain to result in a failure of complete optimization. The type of conflict arising from the nonunitary nature of firms and other productive organizations has historically been referred to as the principal–agent problem. The principal (in the case of firm, this would be the shareholders whose interest is that the firm maximize profits) cannot guarantee that the agents (the managers and employees of the firm) will act to further the principal's objective rather than improving the conditions of the workplace, creating perquisites of employment, or otherwise diverting profits into additional benefits for the agents. Because profit maximization by firms is required for Pareto optimality in a market economy, any deviation from that standard caused by managers' and employees' self-interested behavior is a cause of market failure.

The various manifestations of the principal–agent problem have been developed by scholars specializing in the theory of the firm. Adolph Berle and Gardiner Means in the 1930s identified how the separation of ownership and control in the modern corporation enables managers to advance their own interests at the expense of shareholders, but an awareness of the general problem can be traced back to Adam Smith and earlier. Managers typically have access to detailed inside information not available to the principals. To prevent managers from using this information to their benefit, principals sometimes have recourse to operating procedures that are second-best in terms of profit maximization, but that control the principal–agent conflict. This explanation has been proposed for the excessively high hurdle rates required for approval of investment projects in some firms. Principals cannot know the actual rates of return on all potential projects. If managers are interested in maximizing "organizational slack" (which includes managerial perquisites and inessential expenditures), the second-best solution for the principals involves setting a hurdle rate greater than the risk-adjusted cost of capital. The high hurdle rate serves as a substitute for expensive postproject auditing. The benefit to the principals comes at the cost of foregoing some profitable projects (for example, low-risk energy-saving investments in lighting retrofits or heating, ventilation, and air conditioning upgrades) having rates of return that are lower than the hurdle rate.

Managers also can exhibit myopia, risk aversion, and bias in project selection that make the managers' lives easier at the expense of the profit maximization objective of the owners of the firm. It is impossible for the owners to determine from the outside just what contribution each employee of the firm makes to its success; hence, the market rates of compensation for the agents cannot be known. Many of the incentive compensation plans that are observed in firms (stock options, performance bonuses, etc.) are compromises intended (on the part of the principals, at least) to bring the interests of owners and their agents into closer alignment. All of these sources of deviation from perfect profit maximization apply to the general operations of the firm, including the firm's energy use decisions.

2.2 Bounded Rationality and Agent-Based Models

The principal–agent problem undermines full optimization when all agents are entirely rational in the strong sense required by neoclassical economic theory. That is, the agents are assumed to have unlimited capacity to carry out whatever calculations are required to maximize their own utilities. This assumption of unlimited computational capacity is questionable, however. The alternative notion of "bounded rationality," first proposed by Herbert Simon, is based on the realization that the calculations necessary to achieve full optimization in economic activities are effectively beyond the reach of real people and firms.

Since the time of Simon's initial work, advances in mathematics and computer science have formalized the concept of computational complexity. It is widely believed (but not yet proven) that a wide class of practical problems such as the Traveling Salesman Problem require computation time that grows "faster than polynomially" with the size of the problem. John Rust and others have pointed out that many calculations in economics are subject to formal computational complexity constraints, and Michael Garey and David Johnson's long list of intractable problems (of the same class as the Traveling Salesman Problem) includes many standard management problems such as network design, storage and retrieval, database management, and sequencing and scheduling. Achievement of full maximization (including its energy efficiency component) involves calculations of this type in many cases. It is an empirical question how large the deviation from optimality might be in any particular instance, but the existence of

computational limits constitutes a formidable barrier to complete optimization by firms.

Aside from these mathematical foundations of bounded rationality, as a practical matter limitations on management time and attention mean that cost-saving energy efficiency investments not central to firms' strategic priorities are often given short shrift. Even this commonsense observation indicates a departure from Pareto optimality, because optimally efficient firms would take advantage of every profitable opportunity. Bounded rationality provides one justification for policies that simplify business decision-making by setting standards. In addition, the success of voluntary pollution prevention programs in the United States and other Organization for Economic Cooperation and Development countries testifies to the possibility of policy-driven cost-beneficial improvements if the government provides high-quality information and support services to boundedly rational firms. Michael E. Porter has even proposed the bold hypothesis that environmental regulation may, in some circumstances, stimulate firms to better performance than they would have achieved in the absence of regulation.

Some economists have begun to embody the concept of bounded rationality in models in which the entities (or agents) follow relatively simple rules of behavior, rather than being presumed to maximize an objective function. Because the rules are simple, it is possible to set up numerical simulations of systems containing large numbers of such agents and observe the development of such systems over time in a laboratory-like setting. Models of this type have the potential for reproducing features of the population of firms, such as the size distribution or the birth and death rates of companies, that do not emerge naturally in conventional maximization models. If the performance of the firms in agent-based models is compared to the ideal of full optimization, room for improvement will be seen. If the economic system is in fact made up of agents following relatively simple rules, then cost-beneficial gains are possible.

2.3 Behavioral Economics

Both principal–agent problems and bounded rationality take for granted that at least the agents in the economy are trying to maximize utility as it is conceived by neoclassical economic theory. Both within and outside of economics, however, there is recognition that people do not necessarily behave that way. Psychologists have noted that decisions about energy-saving investments frequently do not conform to the strict requirements of the economic paradigm. "Organizational Behavior" and "Management Science" are recognized as fields of inquiry distinct from economics. Indeed, it would be difficult to understand the considerable demand for management training and expertise (Master of Business Administration and executive education programs, for example) were it not for the fact that management activities, such as motivating employees, coordinating complex operations, and visualizing the uncertain future, require skills and talents of the highest order. The intricacies and subtleties of human and organizational behavior are far from being reducible to a simple economic calculus.

Some economists have begun to explore the consequences of behavior outside the conventional maximizing framework. A Special Section in the March 2000 edition of the *Journal of Economic Behavior and Organization* was devoted to "Psychological Aspects of Economic Behavior" and a session of the year 2000 annual meeting of the American Economic Association included papers titled "Emotions in Economic Theory and Economic Behavior" and "Thinking and Feeling." If irrational exuberance can account for stock market bubbles measured in trillions of dollars, it is perhaps naive to think that all decisions regarding energy technologies and investments are explicable as purely rational investment decisions. Market pressures surely push firms and individuals in the direction of rational choice, but social forces that individuals are barely conscious of, such as the imperatives of maintaining prestige and self-image and even considerations of style and fashion, are also powerful influences on behavior.

2.4 Evolutionary Economics

The inadequacy of the neoclassical model of the firm ("maximization of profits subject to the constraint of current technology and resources") has led some economists and other social scientists to explore a variety of alternative characterizations of production. Among the most promising is evolutionary economics—the idea that firms and the economy can be described and analyzed in terms analogous to biological populations and ecosystems. In this view, the market acts in the same way as natural selection in evolutionary biology to shape the characteristics of the population of firms. If a firm is not sufficiently fit (i.e., profitable), it dies (goes bankrupt or is acquired by a healthier firm), whereas the more profitable firms expand and propagate.

What are the implications of the evolutionary model for market failure as it has been defined here? First, it is important to realize that the biological analogy does not carry over perfectly. In biological evolution, species evolve over time through mutation and natural selection, whereas in the economy, firms are capable of consciously changing or adapting to new circumstances. Humans can learn, so the "inheritance of acquired characteristics" is to be expected in economic evolution, unlike in biology. Despite this difference, the crucial similarity between economic and biological evolution is that in both the evolutionary pressures of natural selection lead to improvements in performance over time. However, it is a common mistake to confuse market pressures that reward profitability with a mechanism that somehow leads to the *maximization* of profits (or full optimization by firms). According to such a view, market selection results in firms acting "as if" they maximize profits, regardless of what the managers think they are doing or limitations on their access to information or computational capabilities. It was pointed out by Armen Alchian in 1950 that though market competition favors firms that realize positive profits, this by no means implies that surviving firms maximize profits.

In neither economics nor biology can the evolutionary process be expected to achieve optimization of the fitness of all members of the population. Evolution takes existing populations as its raw material and works through incremental change. The consequence is that evolutionary processes are path dependent. Small differences in initial conditions can lead to different paths of technological progress or institutional development or, alternatively, to different ways of accomplishing the same function through different institutional arrangements or technologies. There is no reason to think that the particular path "selected" by the evolutionary process arrives at an optimal solution. Similarly, in the evolutionary context, optimality can be defined only in terms of the environment in which the population's members operate. If that environment is changing rapidly, the evolutionary process will lead to improvements that never entirely catch up to the changing conditions. In addition, some degree of diversity in the population (of organisms or firms) is likely to provide resilience against sudden shifts in the environment. This indicates that not all firms will be equally adept at dealing with any particular environment that exists at a moment in time. Finally, it is a fallacy to think that the population in existence today is optimally evolved, for if that were so, why was it not true also of the population that existed a year ago, a decade ago, or a century ago?

These departures from complete optimization apply to the behavior of firms and economic agents in general and are not specific to the energy sector or to energy markets. Nevertheless, the ubiquity of departures from optimality certainly indicates that market failure in energy markets (and in the energy decisions made by firms) will also be widespread. There is no reason to think that incomplete optimization is more severe with respect to energy decisions than it is with respect to other important decisions taken by firms, say with regard to employee benefit packages, advertising, or organizational structure. Nevertheless, the energy sector and the energy decisions of firms have been scrutinized extensively in an effort to discover empirical examples of failures to optimize. This is partly an historical accident because of the intense interest in energy issues that followed the oil price shocks of the 1970s. From a scientific standpoint, this focus on energy has been highly productive, for it led to the large literature documenting the energy efficiency gap and the noneconomic factors that influence energy decision-making. This empirical literature does not support the presumption of complete optimization.

3. ADDITIONAL CONSIDERATIONS

The discussion thus far has been couched almost entirely in economic terms. As such, it has given no consideration to the very real possibility that markets can fail even if Pareto optimality is achieved. A perfectly functioning market system may be a failure from a higher social or philosophical perspective. Ordinary economic theory ignores the question of where individuals' preferences come from and how they are shaped by the social context. In the same way, economic analysis typically takes the pattern of ownership of property rights as given, even though different assignments of those rights (and creation by the State of rights distinct from the set currently in existence) can have a major impact on the justice of social arrangements. Even if energy markets were not subject to market failure as outlined above, it might still be the case that the prices and consumption patterns emerging from them would not appropriately reflect the interests of future generations or that they might violate standards of fairness that transcend economics.

In addition, there is no guarantee even given a particular set of endowments of property rights that

the Pareto-optimal competitive equilibrium will be *unique*. Without any problems of monopoly, externality, etc., it is easy to set up simple models that exhibit multiple equilibria. Each of these equilibria is a Pareto optimum, but they can be quite different in their equilibrium prices, allocations, and distributions of income. There is no consensus on how society might go about choosing among such equilibria from a welfare perspective or about what dynamic processes might lead an economy to one or another of the equilibrium points (or from one to another if a particular equilibrium is disturbed). This lack of a theory of equilibrium choice is a gap in economic knowledge that would need to be filled before too much reliance is placed on Pareto optimality as a goal of policy.

It should also be noted that the Pareto criterion for market success makes operational sense only if individuals' utilities are not interdependent. If some individuals' utilities depend not only on their own consumption of goods but also on the consumption of others, then the First Welfare Theorem no longer holds. Striving after positional goods (that derive at least part of their value as a result of comparison to others rather than because of the goods' intrinsic characteristics) also leads to inefficiency. If organizations of one type (such as economics departments or universities) all seek to increase their academic rankings, a large part of their effort is bound to be wasted because not all of them can succeed in moving up. Market failures of this type are no less important than more conventional kinds of deviations from Pareto optimality nor should they be ignored in formulating policy.

At the same time, the ubiquity of market failures in the energy sector does not mean that markets should cavalierly be replaced by political decisions or central planning. Even where markets fail, there is no guarantee that their replacement by some other allocative process would perform better. The political process is also vulnerable to failure, and sometimes to more spectacular failure, than markets. Political systems may restrict competition, inhibit the generation and transmission of accurate information, and replace satisfaction of the wants and needs of the general population with implementation of the preferences of the decision-making elite. It is unrealistic to substitute the assumption that the government always acts in the best interests of society as a whole for the assumption that markets always conform to the requirements of the FWT. Neither assumption is justified. Nonetheless, an awareness of the possibilities of market failure should caution against embracing the market fundamentalism that rejects every attempt to make improvements in the functioning of the economic system and dismisses all forms of regulation as unwarranted government intrusion on the free functioning of the Invisible Hand. In energy markets, the balance between decentralization and regulation is a delicate one, but that only makes it more important to maintain.

Glossary

bioenergy Super ordinate to the terms "biofuel" and "wood fuel."
biofuels Fuels produced directly or indirectly from biomass.
biomass Material of biological origin, excluding material embedded in geological formations and transformed to fossil.
forest fuel Wood fuel that has not been used previously.
upgraded wood fuels Wood fuel briquette with a diameter equal to or less than 25 mm; wood fuel pellet with a diameter less than 25 mm; wood fuel powder with a main fraction less than 1 mm.
wood fuel All types of biofuels originating directly or indirectly from woody biomass.
woody biomass Biomass from trees, bushes, and shrubs.

The use of biofuels is widespread over various countries and regions all over the world. However, the reasons for use of biofuels are different. Historically, it has been a very important resource for what we today call the industrialized countries. There are several examples of successful industrial use in mining industries, ore industries, and the like. For example, charcoal still is used in ironworking industries in Brazil. Biofuels may be used for cooking, heating, industrial applications such as steam production, electricity production, and fuel for vehicles as well as in the ironworking industry. Modern use of biofuels, as described in this article, includes industrial production in district heating networks and production of electricity. This development has increased trade of biofuels and in some European regions has created markets for various qualities of biofuels.

1. INTRODUCTION

The use of bioenergy is a strategic resource used in the work to fulfill the Kyoto Protocol to replace fossil fuels on a large scale. Bioenergy and biomass generally could be used to mitigate greenhouse gas emissions and the global climate change. In some countries, the use of biofuels already holds a significant share of the energy supply to industrial processes, heat production, and (in some cases) electricity production. The Nordic countries are examples of this. Large-scale production and use of biofuels has to be done in an environmentally sound way. New technology and system solutions give biofuels possibilities to compete in new markets.

Traditionally, biofuels have been used in the same geographical regions in which they were produced. During more recent years, this pattern has been changed in Northern Europe by industrial and large-scale use of various forms of biomass for district heating such as a vast supply of recycled wood and forest residues. The trade situation has come about as a result of means of control on waste and energy. Sea shipments allow bulk transports of biofuels over long distances at low cost.

Climate change due to anthropogenic emissions of greenhouse gases is one of the greatest environmental challenges today, and greenhouse gas concentrations in the atmosphere will continue to rise unless there are major reductions in greenhouse gas emissions. Carbon dioxide (CO_2) is the most important greenhouse gas, and increasing the use of biomass for energy is an important option for reducing CO_2 emissions.

The European Union (EU) has no common energy policy, but there are different common goals mainly given in the European Commission's (EC) "White Paper for a Community Strategy," which sets out a strategy to double the share of renewable energy in gross domestic energy use in the EU by 2010 (from the recent 6–12%, with some 85% of the renewables being bioenergy). The strategy includes a timetable of actions to achieve this objective in the form of double the share of renewable energy in gross domestic energy use in the EU by 2010, including a timetable of actions to achieve this objective in the form of an action plan. The EC's green paper in November 2000, "Towards a European Strategy for the Security of Energy Supply," introduced the objective of substituting 20% of traditional fuels by alternative fuels in the road transport sector by 2020. A proposal for a directive "on the promotion of the use of biofuels for transport," adopted by the EC in November 2001, requires that an increasing proportion of all diesel and gasoline sold in the member states be biofuels, starting with 2% in 2005 and increasing progressively so as to reach a minimum of 5.75% of fuels sold in 2010.

The EU member countries are jointly decreasing the emissions of six different greenhouse gases with by 8% on average during the period starting in 1990 and ending in 2008–2012 (depending on type of action and type of gas). An example of this policy is the EU-funded research programs, where the focus is on nonfossil fuels and nonfossil techniques to target the goal of reducing emissions of greenhouse gases.

The Scandinavian countries and Austria have been the pioneering countries in the modern use of bioenergy. Other countries, such as Germany, the United Kingdom, The Netherlands, and Spain, are expected to increase their use of biofuels significantly. There are variable forest resources and variable uses of biofuels in Europe, and these are the key factors behind the trade that has grown rather quickly during the past years. Because of the incentives to increase the use of biofuels, so the prediction for the short and medium term is an increase in trade biofuels in Europe.

2. EXPERIENCES FROM SWEDEN

Sweden is one of the leading European countries in use of biomass based mainly on the large forest resources. Biofuels are used in the forest products industry, in the district heating sector, and for traditional heating mainly of houses in the countryside. Industrial use is 184 PJ per year of mainly wood fuel and black liquor, with the majority of this being internal use. The residential sector uses 38 PJ per year, also mainly internal use, on farms or self-supply among house owners.

Swedish experience of a commercial biofuel market is based on the development of the district heating sector over a period of at least 20 years, from a low level during the 1970s to a substantial market reaching 96 PJ in 2000. Wood fuel counts for 55% of the biofuel supplied to the district heating sector, reaching 54 PJ in 2000. The average growth rate of supplied wood fuel between 1990 and 2000 was approximately 10% per year. Wood fuels compete on the market with other untaxed biofuels. The highly taxed fossil fuels are not competitively priced for heat production.

Prices for biofuels, peat, and the like are reported by the Swedish National Energy Administration.

2.1 Imports

During the early 1990s, the import of biofuels was established in the Swedish market.

Many different assortments and qualities of biofuels were traded. Various projects were carried out to adapt fuels to existing technology. In some areas, cofiring between various biofuels and biofuel and coal is established.

Later results from the imports indicate much large activity and import figures reaching as much as one-third of the supply of biofuels to the district heating sector. No reliable figures for later than 1997 were available at the time of this writing, but the estimated level of imports today is a stabilization of the levels from the mid-1990s. One reason is the weaker Swedish currency, which made it more expensive to buy from other countries. An example of this is the strong U.S. dollar, which made it too expensive to continue with the import of wood pellets from North America.

Swedish currency is stronger and prices have increased due to a larger market. This gives good ground conditions for an increased import (Table I).

Importers are the energy companies themselves or specialized fuel companies. The imported fuels show a spectrum of various assortments and qualities. Sometimes, imports are double counting, and this gives a range of the imports (Table II).

2.2 Exports

During recent years, the acceptance of the Kyoto Protocol has started activities in many European

TABLE I

Imports of Untaxed Fuels (Biofuels) to Sweden in 1992, 1995, and 1997 (in Pentajoules)

	1992	1995	1997
Biofuels	2–4	11–15	29–36
Approximate share of wood fuels	0.2 (estimated)	0.33–0.45	0.5–0.62

TABLE II

Imports to Sweden of Untaxed Fuels in 1997: Combined Results from Telephone Survey to Fuel Users and Fuel Dealers

Assortment (quality)	Pentajoules	Share provided by importers (percentage)
Tall oil	8.73	59
Wood pellets	4.35	74
Recovered wood chips	3.65	80
Green wood chips	2.70	58
Peat	1.48	0
Rubber and tires	1.29	48
Railway sleepers	0.58	100
Round wood	0.21	100
Bark	0.19	100
Waste wood	0.17	100
Recycled paper	0.14	0
Sawdust	0.07	100
Total 1	23.56	(No double counting)
Total 2	14.70	(Only importers, i.e., maximum double counting)

Source. Vinterbäck and Hillring (2000).
Note. Figures in the survey did not represent the total population of possible users and importers. To get an estimation of the total, import figures were multiplied by 1.36.

countries, as mentioned earlier. Interest in exporting projects has started due to the fact that Sweden and the other Nordic countries, as well as the Russian Federation, have large forest resources. Importing countries in this future scenario are the densely populated European countries and some of the Mediterranean countries. No regular trade is carried out yet, but there have been projects in this field.

3. EXPERIENCES FROM FINLAND

In Finland, the annual use of solid wood fuels is approximately 127 PJ. During a recent 5-year period, more than 100 district heating plants and 500 MW_e of new additional capacity for electricity production from wood-based fuels were commissioned in Finland (total capacity 2000 MW_e). Each year, Finland exports approximately 1 PJ of wood pellets to Denmark, Sweden, and The Netherlands as well as peat and wood chips to Sweden. Each year, the Finnish forest industry imports approximately 13 million solid m^3 of wood for raw material, mostly from the Russian Karelia. Out of this, 11% is bark, which is used for energy production (11 PJ). This import of wood fuel as a separate fraction is equal to 1.3 PJ.

The Finnish national solid biofuel trade is carried out by various organizations. There are big diversified companies working on energy, wood processing, and biofuels business. These companies can exploit industrial wood residues from their own mills for production of wood chips and/or pellets. They can integrate harvesting of logging residues into timber or pulp wood harvesting and, in so doing, can keep fuel prices competitive. In small-scale heating of municipal buildings such as schools and small district heating plants, a special heating entrepreneurship model has been used in fuel procurement as well as in the operation and maintenance of the boiler plants. Usually, these entrepreneurs are cooperative, harvest small-sized wood of their own woodlots, or purchase industrial wood chips or cutter shavings from the local wood processing industry. The number of such entrepreneurs in Finland has increased to more than 130. In large-scale wood fuel procurement, various modern information technologies, such as mobile telephones and the Internet, are used in positioning fuel storage and logging sites, in ordering chippers, and so on.

In Finland and Austria, several electronic firewood marketplaces are established on the Internet (e-trade) for local, national, and even international consumers to select log and pellet suppliers.

4. EXPERIENCES FROM DENMARK

Denmark is a net importer of biofuels and imports trunks as well as wood chips and wood pellets. The import of wood chips covers approximately 25% of the annual Danish consumption of roughly 2 to 3 PJ. The Baltic states and Germany represent nearly 90%

of these imports, with the remainder coming from Poland. These imports consist mainly of wood qualities originating from clear-cuttings and trunks that are not chipped until after their arrival at a Danish harbor. Selling to the Danish market is competitive because it may be difficult to sell wood chips in Germany; furthermore, the prices in Denmark are a little higher than in Germany (Table I). In addition, an unknown amount of moist industrial by-products (e.g., bark, sawdust, chips) is imported.

The international market for wood fuels can be compared with the trading of straw for energy purposes. Straw is a local commodity, and in Denmark there is a geographic fluctuation in the prices due mainly to the bridge toll (Store Bælt) or ferry crossing, which make the straw transport very expensive. Long-distance transport of straw bales is expensive but is not an environmental problem given that a truck loaded with 12 tonnes of straw must drive 17,000 km with the straw before its emissions have compensated for the straw's CO_2-displacing effect in a heating plant.

5. EXPERIENCES FROM AUSTRIA

In Austria, biofuels have a 10.5% share of the annual consumption of approximately 105 PJ. Fossil fuels provide a significantly lower percentage of the primary energy in Austria compared with the European average. Austria has committed itself to an annual 13% reduction in greenhouse emissions. This is a highly ambitious goal that is all the more difficult and costly to achieve given that the per capita share of greenhouse gas emissions in Austria is already relatively low due to the fact that Austria meets a high percentage of its energy demand from hydropower, biomass, and natural gas.

The country is rich in both forest resources and agricultural land, giving Austria the opportunity to use bioenergy. Policy to promote the use of various biofuels in district heating is rather small scale compared with that in the Scandinavian countries.

Trade of wood fuels occurs with neighboring countries such as Germany, Slovenia, and Italy; however, such trade occurs at rather low levels.

6. EUROPEAN EXPERIENCES

Trade between countries has been established in various parts of Europe. In most countries, the customs statistics do not record trade in enough detail to identify international trade of different biomass types. Today, solid biofuels such as wood residues, pellets, and wood chips are already traded in Europe. In some countries, there is a growing interest in international trade because it can provide biofuels at lower prices, larger quantities, and better quality than can domestic alternatives.

6.1 European Trade

Solid biofuels such as wood residues, pellets, and wood chips are now traded in Europe and reached a level of nearly 50 PJ in 1999. Trade among European countries has resulted in a growing interest in biofuel trade because international trade can provide fuels at lower prices. In several cases, the national biomass market is not yet developed well enough for organized international trade. On the other hand, projects may benefit in countries with unexploited biomass resources when fuels are available on an international market. Although there may be cross-border trade of, for example, domestic firewood between neighboring countries, this trade is more or less occasional and beyond official statistics.

The largest volumes of biofuel are traded from the Baltic countries (Estonia, Latvia, and Lithuania) to the Nordic countries (especially Sweden and Denmark but also Finland). Some volumes are also traded from Finland to other Nordic countries as well as among neighboring countries in Central Europe, especially The Netherlands, Germany, Austria, Slovenia, and Italy. The traded biofuels most often include refined wood fuels (e.g., pellets, briquettes) and industrial by-products (e.g., sawdust, chips) as well as (in Central Europe) wood waste. The annual production of wood pellets in Europe is estimated to be 1.2 to 1.3 million tonnes.

Some biofuels are also traded intercontinentally. Sweden has imported biofuels from Canada, and Italy imports firewood from Northern Africa. In addition, Germany exports some firewood to the Middle East and Far East.

Scandinavian biofuel markets have increased, with national energy policies contributing strongly to this trend. Taxes on energy with a clear environmental profile were introduced in Scandinavian countries during the early 1990s. Fossil fuels are heavily taxed in heat production, whereas biofuels are untaxed. In electricity production, all fuels are untaxed, whereas consumers pay a tax. In Finland and Sweden, the investment supports called for growth in the

TABLE III

Minimum, Maximum, and Average Fuel Prices (Including Taxes) in 18 Selected European Countries: 1999 (in GJ)

Fuel	Minimum country	Maximum country	Average
Forest residues	1.02, Germany	8.33, Italy	3.42
By-products, forest products industry	0.58, Romania	9.07, Poland	2.38
Firewood	1.01, Slovakia	14.00, United Kingdom	5.26
Wood waste	−4.00, Ireland	3.31, Poland	0.97
Refined wood fuels	3.24, Latvia	18.22, Germany	8.37
Other biomass	0.83, Slovakia	12.00, Poland	4.68
Peat	2.10, Finland and Latvia	3.75, Ireland	2.83
Heavy fuel oil	1.40, Slovakia	12.00, Ireland	6.74
Light fuel oil	3.10, Slovakia	14.30, Denmark	6.74
Natural gas	1.10, Slovakia	16.21, Italy	5.80
Coal	1.19, Poland	12.78, Germany	4.53

capacities and also contributed to the demand for biofuels.

6.2 Fuel Prices

Prices of various fuels were collected in a 1999 survey. Since then, oil prices have risen significantly, and this also might have influenced the prices for other fuels (Table III).

6.3 European Price Level

The increase in trade among European countries has established international prices for wood fuels. Table IV gives examples of prices. Of course, there is a range in prices set by the market situation, production cost, and cost of competing fuels. By-products were traded at approximately 3 to 4 €/GJ, wood chips at 3.5 to 4.5 €/GJ, and wood pellets at 5 to 6 €/GJ.

7. CONCLUSION

There is a growing international trade in biofuels, and the largest volumes are traded from the Baltic countries (Estonia, Latvia, and Lithuania) to the Nordic countries (especially Sweden and Denmark but also Finland). Some volumes are also traded from Finland to other Nordic countries as well as among neighboring countries in Central Europe, especially The Netherlands, Germany, Austria, Slovenia, and Italy. The traded biofuels are most often refined wood fuels (e.g., pellets, briquettes) and industrial by-products (e.g., sawdust, chips) as well as (in Central Europe) wood waste.

There are international market prices established in Europe; however, volumes are still limited. Both the use and trade of wood fuels are expected to increase, at least in Europe, in the future.

Glossary

coal The solid fossil fuel ranging from hard anthracite to the softer subbituminous coals.
coking coal Coal converted into coke for pig iron manufacture and other uses.
energy Petroleum, natural gas, coal, nuclear power, waterpower, and alternatives such as geothermal and solar.
steam coal Coal used for heating in boilers.
synthetic fuels Liquid fuels and gases made from other sources such as coal.
unit trains A train dedicated entirely to hauling coal between a specific origin (almost always a coal mine) to a specific destination (either a consumer such as an electric power plant or a transfer terminal).

In many discussions of coal, its abundance is extolled with the implication that coal consumption can be and should be massively expanded. In practice, coal use became increasing specialized. Electricity generation is the major market. Although this is not true in every major consuming center, it is increasingly true for most. This article seeks to delineate and explain this pattern. Discussion begins by indicating patterns of coal use by country and end use. The situation in the early 21st century and differences from earlier years are examined.

1. PATTERNS OF COAL CONSUMPTION

Coal consumption is even more unevenly distributed around the world than total energy use. The amount of coal consumed is affected greatly by the level of economic activity in the country. The relationship, however, is not direct. Wide differences prevail among countries in "energy intensity" as measured by the amount of energy consumed per unit of gross domestic product (GDP) and in the relative role of coal in energy use. Were this not complicated enough, further issues arise about the proper ways to measure economic activity and energy use. Table I summarizes the critical data for the leading coal-consuming countries.

The most striking aspect of the tabulation is the existence of countries with high GDP and energy use and low coal use. France, Italy, Brazil, and Mexico are the main examples. In the French case, the critical influence was a decision to allow a slow death of the domestic coal industry and rely heavily on nuclear power. (Over 80% of French electricity has been nuclear generated since the middle 1980s.) The other three countries simply display a tendency to low coal use characteristic of countries lacking extensive domestic coal supplies.

Higher coal roles necessarily mean that a country will be more important in coal use than in total energy. Several important cases arise. Every country getting the majority of its energy from coal is among the leaders in coal tonnage consumed. China and India are the primary examples. Russia, the Ukraine, and Kazakhstan are notable for unusually high energy/GDP ratios.

Another consideration is that coal is a much less mobile fuel than oil. The basic problem is that solids are more expensive to move than liquids. Moreover, coal has 70% or less heat content per ton than oil.

The vast majority of coal is consumed in the country of production. Again, however, substantial international differences prevail (see Table II). In particular, the four leading coal-consuming countries are all substantial producers, and international trade in coal is less than 10% of each of these countries' output. In contrast, other major producers export

United Kingdom, Germany, Japan, and France are countries with substantially reduced coal production and shifts to imported coal. In every case, depletion has eliminated resources that can compete with alternative fuels or coal from elsewhere.

New more competitive sources of coal have emerged. Many of these—Australia, Indonesia, Colombia, and Venezuela—export well over half their coal; another case, South Africa, approximately 30%. Japan, France, and South Korea are particularly striking cases where domestic production is a small fraction of consumption. The role of domestic supplies is greater in the United Kingdom and Germany but contrasts sharply from the prior tendency to be a net exporter. Korea and Taiwan were never significant coal producers.

2. END USES

The history of coal use involves greatly increased specialization of use. In particular, consumption to generate electricity became the dominant use. The United States is the prototype for this development. Data are available on U.S. coal use since 1920 and show a massive shift in coal-use patterns (Table IV). In 1920, coal was used throughout the economy. Over one-half was employed as a general-purpose fuel for "industry" (which as reported apparently included residential and commercial use). Over one-quarter of use was to fuel the railroads. The mix of use persisted to 1945 (and the level of use was only 10% higher in 1945 than in 1920).

A precipitous decline of coal use prevailed from 1945 to 1961. The adoption of the diesel-electric engine eliminated the railroad consumption of coal. Sales for general industrial use and retail deliveries declined. Use in coking fluctuated without showing any persistent trend. However, growth in electric power use was maintained.

The post-1961 history involved continuation of both gains in sales to electric utilities and declines elsewhere. Indeed, coking joined other industry and retail deliveries as a declining sector. Since rail use

TABLE IV

U.S. Coal Use by End Use[a]

had almost disappeared, further losses in transportation were minute. Electric power use gains, however, began to outweigh the losses and coal use began rising. These trends have persisted. The other sectors shrink while electric power use rises. By 2001, electric power absorbed 91% of coal use. General industrial use was 6% and coking use was 2%.

The tendency to increased importance of electric power as a coal consumer prevails in most of the main coal-consuming countries. The details again differ but most countries and the world as a whole use more than half of their coal for electricity production. The main exceptions are China and Japan. In both cases, electricity is becoming an increasing portion of coal use. The Chinese electricity use already exceeds that for any other end use. Japanese electricity use is nearing parity with coking use.

Germany uses approximately 88% of its coal in electricity. Here the pattern of steady electricity growth and declines elsewhere produced steadily declining total coal use.

The below average degree of electricity use in South Africa reflects its unique venture into synthetic fuels from coal. South Africa under white rule undertook an extensive effort to produce liquid fuels, gas, and chemicals from coal. This generated at most approximately one-third of the inputs for producing petroleum products. Oil procurement problems were not as dire as feared. Even at the height of the United Nations boycott, major European oil companies such as Shell, British Petroleum (BP), and AGIP openly operated in South Africa. The majority of coal use in Poland is for electricity. The use has declined sharply since the fall of communism.

3. THE BASIS OF CHANGE: COAL IN "ENERGY"

The central proposition about coal is that it is a problem-plagued source of "energy." To see this, the basic propositions about energy need review. Energy as usually treated is defined to include only inanimate energy sources and usually not all of them. Five types of sources—coals, oils, gases, uranium, and waterpower—are invariably covered. Depending on their importance in a country and the interests of the observer, such substitutes as wood, animal wastes, other sources of biological origin, wind, and solar energy also are treated. (Coverage of these sources

has expanded in large part reflecting interest in increasing the use of "alternative fuels." The data show that present utilization is heavily concentrated in poor countries. China and India consume the largest amounts of such fuels and together account for approximately 38% of reported world totals. However, in both cases, the majority of reported fuel use comes from the five usually reported fuels. Smaller, even more impoverished countries such as all sub-Saharan Africa other than South Africa obtain the vast majority of their fuel from alternative sources. In short, these fuels are widely considered the last resorts for those not integrated into the world economy.) Thus, energy consists of things that are burned to secure work or close substitutes for such material.

Moreover, all three fossil-fuel sources actually are secured from heterogeneous occurrences. They differ within as well as among deposits in such key characteristics as amount and form of the fuel contained, the extent of contamination by other material, and the ease of extraction. In particular, solid fuels range from the very hard (anthracite) to the boggy (peat). Although classifications differ among countries, coals extend at most to the softer, more ash-laden forms called lignites or brown coals.

Outside the United States, lignite is treated as being distinct from the harder coals—anthracite, bituminous, and subbituminous—and even subdivided into better and worse qualities. Thus, the Germans distinguish between braunkohle and pechkohle. In contrast, the U.S. reporting practice was established long before lignite became a significant part of output. U.S. data still combine lignite with harder coals. (Conversely, the procedures arose when the United States had substantial anthracite production. Anthracite was reported separately long after it ceased to be important. Under the new methodology, anthracite is reported with bituminous and lignite with inclusion of separate anthracite subtotals.)

Those hard coals used to make coke for ironmaking are termed metallurgical or coking coals. All others are termed steam coals. The coals are not necessarily different; often the only difference is the use made. Considerable evidence exists that producers shift between the two sectors as market conditions warrant. (In particular, Queensland long has reported the disposition of coal from each of its mines, and shifts between steam and coking sales can be observed.) This may or may not alter what is mined and how it is processed. The flexibility, in any case, links the steam coal and coking coal sectors of the market.

The work done by these fuels, in turn, involves primarily providing heating, lighting, and cooling to residential, commercial, and industrial buildings, powering industrial processes, and fueling automobiles and other forms of transportation. With the rise of electric power in the late 19th century, a tendency has arisen increasingly to consume fuels to produce electricity.

The physical characteristics of each fuel are a major influence on their production, transportation, processing, and utilization economics and on the information that is known about them. Coals are solid fuels that are more readily found than oil, gas, or uranium. Being solid, however, is otherwise an economic drawback. Solids by definition lack the fluidity that makes oil and gas so attractive and, as noted, have less heat content per ton than oil. As a result, extraction, transportation, storage, handling, and use are more difficult than is true for oil and gas. With transportation, storage, and handling, more material must be handled by less supple methods. Coal must be pushed through every stage. For example, a coal-using facility requires larger, more complex, more expensive boilers than those needed to obtain the same amount of heat from oil or gas.

In particular, although oil can be fairly cheaply transformed physically and chemically, coals are expensive to transform. The expense has been such that only an economy such as South Africa with a strong desire for self-sufficiency heavily engages in coal transformation.

Among the drawbacks of coal are the environmental impacts. The original problem was of the high waste content that emerged as ash, much of which was discharged during combustion. This difficulty was alleviated at a cost by the development and adoption of techniques to collect the ashes before they would have been discharged. The next major concern was the sulfur contained. This was, in fact, also a problem for natural gas and oil but removal or shifts to naturally less-sulfur-containing sources were more economic than with coal. The coal options are naturally lower sulfur coals such as in the U.S. Rocky Mountain States or adoption of postcombustion clean-up technologies. Further concerns arise from other contaminants in coal.

The newest concern is that coal emits more of the carbon dioxide believed to be a critical greenhouse gas in the global warming threat. Thus, adoption of vigorous measures to limit greenhouse gas emission could produce major new pressures to reduce coal use.

During the 20th century, coal changed from a dominant fuel to one often beleaguered by competition from other fuels. With the prevailing scarcity pattern, the role of coal is to fill niches in which its drawbacks are less. Coal is attractive when location and size of operations justify use of coal. Energy use on a larger scale produces economies. Just where they are exhausted is unclear. It is at a level much smaller than the electric power market but apparently much larger than that maintained by most manufacturing plants and commercial facilities. These scale economies narrow, but do not eliminate, the cost disadvantages of using coal. If large cheap-enough coal supplies exist, savings on fuel costs will justify endurance of higher other costs and lead to coal use by electric utilities. Large boilers predominantly in electricity generation are a prime and indeed steadily growing market.

Coal as the input for the coke used in pig iron manufacture is a niche that has shrunk. The remainder of coal use is scattered, predominantly in manufacturing plants.

Steel is an old, beleaguered industry that has undergone remarkable changes. Coal use has been squeezed by adverse developments in this market. The alterations involve the location of raw material suppliers and steel producers, the technologies used in different stages of steelmaking, and the product mix. These have been good for consumers but bad for coal. Historically, coke-based iron-making provided most of the inputs for steelmaking. In what is termed the hot-metal approach, pig iron is refined into steel. Some scrap also can be used. Steelmaking technology has changed so that less coal is needed.

First, steel output has fluctuated without much net gain. New technology lessens processing losses and thus the gross input of steel per ton of finished steel output. The hot-metal route, moreover, is losing ground to the alternative of producing steel entirely from scrap (using electricity). This occurred despite introduction of the oxygen furnace that reduced costs of the ore-based route. A secondary consideration is the ability to supplement coke with other fuels such as oil and uncoked coal. Thus, coke has many direct and indirect rivals.

More innovations that would further reduce coal use are under consideration. Certain products such as the thin sheets used for automobile bodies could not be made satisfactorily from steel from scrap, but technology has emerged to overcome this limit. For decades, steel companies have experimented with technologies to make iron without coke. Application still is limited to countries in which coking coal is expensive to attain, but hope of change persists.

The growing dependence of the coal industry on electric-power customers has many important technical and economic implications. Coal suppliers are dealing with large entities participating in an industry with far more flexibility in fuel choice than any other fuel users. This means substantial substitution possibilities and widespread knowledge of these possibilities.

The components of an electric power network include generating units of different fuel-using capabilities in many different locations. A unit consists of a generator and whatever causes it to operate. A plant has the usual meaning of a total facility. Although one-unit plants exist, it is common to have several units. These sometimes consist of several identical units but often differ from one another in various degrees. Some simply have units that differ only in age and size, but many cases arise of major differences among units. One U.S. plant has a coal unit and a nuclear unit. Many have both boiler-powered plants and combustion turbine units (see below). Often only some of the boilers are designed to burn coal.

Nuclear units using technologies that rigidly determine fuel choice are one pole of the spectrum of flexibility. At the other extreme are plants on the U.S. East Coast physically able to burn coal, oil, and natural gas and located so that they can be economically supplied by all three fuels. Much lies in between. A boiler designed for coal can be (and often has been) converted to oil and gas use. In the 1960s era of cheap oil, utilities located at the center of interfuel competition on the U.S. East Coast built triple-firing capability and shifted among coal, oil, and gas as prices changed. Such plants were readily served by tankers carrying fuel oil and close to coalfields. Gas use was attractive at least during the warm months in which home heating use ceased. When natural gas appeared likely to remain a low-cost fuel, utilities in gas-producing states (most notably Texas and California) built plants designed to burn only gas.

When cheap oil seemed likely in the late 1960s, plants that burned only oil were built. This occurred mainly on the East Coast. Prevailing public policy then freed East Coast power plants from import controls that discouraged oil use elsewhere. A few inland (Illinois and Michigan) plants also arose in the expectation that Canadian oil sources would be an attractive alternative.

Finally, the demand for electricity fluctuates, with some of the variation being unpredictable; equipment,

moreover, is not continuously available. Thus, the need exists to maintain spare capacity to meet demand surges given equipment availability. In these circumstances, great short-run flexibility exists. Output mixes can and do shift in response to changing fuel prices. Plants already using cheaper fuel sources are used more; plants that can easily shift to cheaper fuels do so and also are utilized more.

In the longer run, the mix of available plants can be altered to allow still greater use of cheaper fuels. Thus, the enthusiasm for nuclear power in the early 1970s inspired a flurry of orders that was (partially) implemented through the rest of the decade and throughout the 1980s.

Similarly, as gas became more expensive, gas-using utilities started building coal-fired units. This process started in West North Central and Mountain states and later spread to the large oil-producing states such as Texas, with California choosing for various reasons to rely on coal-generated electricity transmitted from plants in Arizona, New Mexico, Nevada, and Utah.

4. THE MYTHOLOGY OF ENERGY SHORTAGES

In contrast to the limited prospects just sketched, restoration of coal to a role of eminence often was advocated. Tendencies exist to exaggerate both the advantages and disadvantages of coal use. Coal is regularly proclaimed a highly abundant fuel. The implication often is that a great potential has not been realized and coal should be restored to its historical role as the leading source of energy for general use. These assertions, however, ignore or at least mute debate of the formidable barriers to such a massive return. The correct view is that the industry has done extremely well in a hostile environment.

At least immediately after the rapid oil price increases of 1973–1974, discussions of energy routinely argued that a massive return to coal is essential. (Those with longer memories know this idea often has risen and fallen since oil competition emerged in the middle of the 19th century and that the coal industry perennially reiterates the contention.)

The advocacy of a return to coal is based on the presumption that the economics will change radically within a few decades. Some add that since so much oil comes from a small group of politically unstable countries engaged in efforts to cartelize supplies, the supply problems will emerge sooner. Coal then will become competitive again.

This then inspires an unending debate in which both sides remain impervious. Both views have some truth on their side, albeit not to an equal extent. Nothing lasts forever, but oil and gas supplies are greater than those expecting an immediate demise realize. The disparity between expectation and outcome arose from misunderstanding of the basic economic principles affecting coal. Unfortunately, many people believe in the desirability of more expensive energy. Therefore, clearly premature predictions of vanishing oil and gas supplies frequently appear and error fails to discredit the advocates.

The available data suggest that the physical supply of coal is much greater than that of oil and gas. Since oil and gas, as noted, are harder to find than coal, the appearance may be incorrect. The data are biased because coal outcrops more than oil seeps. Thus, more can be and is readily learned about physical endowments of coal than about oil and gas. Indeed, coal resource data are based almost entirely on physical availability. In contrast, oil and gas reserves cover only the well-delineated resources in fields developed for production. Thus, whereas coal estimates change little, oil and gas resources are steadily augmented.

Ignorance remains about the true state of future energy supplies because acquiring the knowledge involves costs from which investors see inadequate benefit. Those who might use the knowledge to assist investment in developing energy supplies are aware that they can safely delay their decisions until possible use is nearer at hand.

Even if the assertions about physical abundance are true, relative physical availability does not dictate a massive swing to coal. Physical endowment is not economic supply and not even a good proxy for economic supply. Supply relates to the cost of extraction and use. The best is used first. The available physical stocks of oil and gas contain a larger portion of the cheapest resources to produce, process, and use than do the available coal resources. This is why oil and gas attained a larger energy role than coal.

The impacts of physical availability will occur so far in the future that research and development may have succeeded in making competitive energy sources that have even greater physical availability. It can readily be seen that at least another half-century's worth of extensive oil and gas supplies remains. Oil and gas prices may remain at 2002 levels for many more decades. The balance among coal, oil, and gas, therefore, will not change radically at least until the middle of the 21st century.

No guarantee exists that the coal industry is ensured an ultimate victory. The interim could permit the development of many alternative sources of energy. Instead of being the only option, coal may be one of several. Over such a time span, more will be learned about the availability of oil, gas, and coal and if profitable, even more ample energy supplies (e.g., uranium—given supply-augmenting techniques called breeding, nuclear fusion, and solar energy) will be developed as will new ways to use them.

For example, nuclear fission involves the release of energy by splitting atoms. Such fission occurs only with unstable materials such as uranium 235 and plutonium. However, as demonstration projects proved, it is possible to build reactors in which the splitting produces both energy and the conversion of uranium 238 into a fissionable material. Since more fissionable atoms are added than used, the process is termed breeding. Plans to build a larger demonstration project were terminated by the Carter administration. Although it stressed environmental concerns, another problem was that the effort was another example of reaction to premature warnings of resource exhaustion.

Indeed, in the years since 1973, coal has become increasingly déclassé. Resource pessimists are stressing a future in which conservation and alternative energy rather than coal (or even worse for them nuclear power) replace oil and natural gas.

Thus, many outcomes are possible. It would be a serious mistake to commit the world to any option for this distant future. The need to act has not arisen and it is still not known what the best approach will be when the time comes.

The enthusiasts of government assistance to promote rapid changes in energy utilization believe that oil and gas soon will become very expensive and that energy producers and consumers are not acting rapidly enough to prepare.

Two (questionable) reasons exist for arguing that public policy has a major role in ensuring a more efficient transition. The first relates to the externalities in research on energy possibilities. The core issue here is whether government assistance will be more efficient than forming consortiums of private companies. A second issue is the perennial debate about whether markets or governments take better care of the future. Governments possess greater resources and thus potentially are better able to hedge against risks. However, the need to win elections puts stress on preserving the status quo and concentrating on quick payoffs. Thus, controversy persists over how much of a role should be played by governments.

Contentions about the abundance of coal often lead to proposals for increasing coal use. The coal industry thought (probably incorrectly) that President Nixon was committed to doubling coal output; President Carter made a clear commitment to such a doubling. Neither president did much to promote the outcome.

In the Nixon case, optimism was killed by analysis. A massive effort was undertaken to appraise the feasibility of Nixon's call for attaining energy independence. Those studying coal-production prospects tentatively suggested that, with effort, coal output could be doubled. The work actually grossly understated the ability to expand coal output. It posited barriers that failed to matter.

However, this proved irrelevant. Those producing the computer analyses that synthesized all the studies into estimates of possible market clearing production–consumption patterns could not devise a plausible combination of market conditions that would lead to utilizing all the physical possibilities for expanding coal output and thus reflected economic realities that limit the ability to use coal.

Extensive evidence of the ability of energy markets to adapt to changing circumstances is available. Energy consumption growth slowed radically with the rises in oil prices of the 1970s. The pattern of energy use also changed. A substantial part of the alteration involved shifts by U.S. electric utilities to coal and nuclear power. U.S. refineries long produced a higher proportion of gasoline and less of fuels used in industry than other industrialized countries. The U.S. pattern reflected the availability of low-cost alternatives, such as natural gas and coal, that were formidable competition for oil products in industrial markets. Changing oil prices combined with rising natural gas, nuclear energy, and foreign coal supplies produced a European move to a similar pattern.

Coal possesses a niche that has expanded. Efforts to alter this must carefully appraise the consequences of reducing coal use.

As attention turned to the environmental side effects of energy production, processing, distribution, and use, it appeared that more serious effects were associated with coal than with oil and natural gas. This further reduced the competitiveness of coal.

Policy makers deal with these contradictions by professing to want more coal consumption while imposing barriers to its production and use. Whatever the realities, the practical implication has been that generally greater stress is placed on taming

the environmental impacts of coal than on promoting its use.

Contrary to statements often made by alarmists about energy, the existence of "special" uses is another irrelevance. All the proposed nonmarket criteria prove defective. Both economic theory and energy practice indicate deficiencies with fascination about critical uses. Basic supply–demand analysis shows that what is served depends on market conditions. The greater the supply, the more demands that can be met. The case for consumption control involves misunderstanding of these basic economic principles.

The proposed alternatives to market allocation have serious drawbacks. Each suggestion for administratively allocating energy has clear defects and conflicts prevail among different proposals. The proposed rules for overriding market decisions prove neither clear nor appropriate.

One of several widely used concepts of urgency is satisfying some end use such as transportation and chemical production. Some concentrate on favoring types of users—favoring households over commercial establishments, commercial establishments over factories, and factories over electric power plants.

The differences in urgency, however, can be greater within any broad category than between categories. The chemical uses of fuels extend from life-saving drugs to fancy wrappings. The marginal chemical uses of fuels, such as packaging, are less urgent than some of the applications simply to provide heat. An apparently superior use may not persist as with coke for iron-making. A new basis, moreover, may conflict with the old. The widespread political preference for direct household use over use in producing goods for households is inconsistent with a stress on chemicals.

More basically, favoring direct consumption is clearly harmful to such final consumers. Indirect uses are undertaken to provide goods for final consumers. Such uses can outbid households for energy because the industrial use has more value to consumers than direct consumption of energy.

However, the price system is preferable to political earmarking in determining preferable uses of energy resources. Markets decide on the basis of willingness to pay; this approach responds to the differences within broad categories ignored by policies giving blanket favoritism. No convincing evidence exists of market failures to anticipate future demands. In addition, the preferred ways of meeting a need are not even the only ones already known and new modes could emerge. Thus, even if best uses could be identified, saving fuels for them may not prove the best way to serve them.

The contentions perpetrate one of the oldest errors in economics (dating back at least to John Law, a notorious speculator of the early 18th century) over when it is efficient to extend use beyond the most vital ones. The debate is epitomized by the diamond–water paradox—why does a decorative good sell for so much more than something vital for life? When supply is sufficiently ample, it proves good economics to serve less valuable uses—water for car washes and gas for a barbeque.

The environmental impacts associated with extracting and using coal justify regulation. However, the controls should deal directly with the environmental problems. An indirect indicator, such as energy use, can be a poor proxy for pollution impacts.

Nonintervention avoids both tying up resources and unnecessarily acting before relevant information develops. Too rapidly anticipating demand can lead to choice of technologies that prove obsolete. Preserving reserves may be as onerous for this century as preserving a supply of horses sufficient to cover the return of animal power would have been to the last century.

Thus, whatever the truth about the availability of coal, it does not by itself determine the optimal pattern of coal-consumption evolution. Even if a shift back to coal were ultimately to occur, this does not necessarily require that oil and gas be hoarded and more critically indicate that special government policies are needed to promote that hoarding.

5. INNOVATIONS IN MINING, TRANSPORTATION, AND USE

Coal and its producers have a reputation for stodginess that is belied by the record. Over the years since 1960, a major building program has taken place. Substantial expansion occurred in the western United States. Other important developments included those in Australia, South Africa, western Canada, Colombia, Indonesia, and Venezuela.

This has involved many innovations in extraction and distribution technology. Mechanization of underground mining has increased considerably. Better machines have been developed to cut the coal and transfer it to the intramine transportation system. Methods to mechanize the installation of mine supports have been adopted. An earlier simpler step was to develop a technology for placing bolts to hold

up roofs. Traditionally, the ability to avoid expensive systems of supporting the roofs with elaborate props was an advantage of U.S. mining. Extensive European efforts to mechanize prop installation proved so attractive that they became widely adopted in U.S. mining. A technology that failed to reverse the unprofitability of deep, thin-seamed European mines even more greatly benefited shallower mines in thicker seams. Similarly, heavy equipment builders developed large machines called draglines to remove the masses of material that cover coal extracted by surface mining.

Other innovations have occurred in transportation. Railroads around the world run dedicated (unit) trains between mines and their customers (or a transfer point to water-borne shipment). Various methods have been devised to speed loading and unloading. One approach is to turn each car upside down and to empty it into a receiving pit; another is to empty the coal from the bottom of the cars as they slowly move over the receiving pit. Conveyers can move the coal to storage areas and then into ships or power plants. Bulk shipping terminals are used to transfer coal from trains to ships.

The most important changes in utilization were improvements in the efficiency of electric power plants. Such improvements clearly proceeded for much of the 20th century. Concerns are widespread, however, that the innovation process had hit serious barriers by at least the 1970s.

However, the intrinsic difficulties have thwarted the desire to widen use. Considerable attention has been devoted for many decades to a combination of transformation and utilization technologies that would facilitate coal use. Coal can be converted by long-known technologies into both gases and liquids of various qualities. Thus, the gas might be as good as naturally occurring gas (methane) or have a much lower energy content. The liquid might be gasoline or a thicker fuel suitable only for large boilers. Various alternative utilization technologies have been proposed. However, widespread commercial adoption of these technologies has been difficult to attain. The costs remain difficult to reduce to competitive levels.

A key element of coal promotion rhetoric is claiming that such new technologies will soon emerge. For example, in 1948, the Bituminous Coal Institute (an industry trade association that was subsumed into the National Mining Association) proclaimed in a pamphlet extolling the virtues of coal that "...coal and lignite comprise over 98% of the U.S. mineral fuel energy reserves...." (p. 12). The discussion suggested that coal use would expand through synthesis of liquids and gases from coal, greater use of electricity, and better methods of direct coal burning, including utilization in gas turbines (an adaptation of the jet engine for stationary use, called a combustion turbine). Only the electricity prediction came true. The gas turbine was developed but still cannot directly use coal. Attention shifted to coupling the turbine to a coal gasification plant.

Two main realms of research arise: improved combustion technologies and synthetic fuel approaches. In both realms, a range of options exists. At least three alternative combustion technologies have been explored. The range of synthetics extends from better solids to efforts to produce gasoline and methane (the principal component of natural gas).

Hybrids have been suggested. For example, the combined-cycle approach involves attaching a conventional boiler to a combustion turbine. The boiler utilizes the waste heat from the turbine. Efforts have been made to develop a technology to produce synthetic gas from coal with a heat content above that from 19th century gasification technologies but less than that of methane. Building such a gasifier next to a combined cycle could allow plant coal use. However, none of the technologies proposed has proved to be economically feasible.

These concepts have regularly been presented by various U.S. government agencies as new salvations for coal. U.S. government agencies have gone from the Office of Coal Research in the 1960s to the Energy Research and Development Administration of the 1970s to President Carter's synthetic fuels program to the Department of Energy's clean coal technologies in the 1990s. Throughout, it has been difficult to produce competitive new technologies. This necessarily engenders skepticism about current claims.

Glossary

distribution of gas Operations necessary to deliver natural gas to the end users, including low-pressure pipeline transportation, supply of natural gas, metering, and marketing activities vis-à-vis the several types of customers.

liberalization Reduction of public authorities' intervention to coordinate the behavior of actors in (gas) markets.

market for gas System of institutional, economic, and physical elements and determinants through which gas is produced, transported, and sold by suppliers to the consumers.

natural gas Mixture of methane and other gases, as it is found in gas fields in geological layers of the earth crust, that may be either associated or not with crude oil. Natural gas is not a fraction of distilled crude oil.

production Exploration, drilling, production, and the collection of gas from the fields' wellheads.

regulation of gas market Intervention by public authorities to coordinate gas businesses' and consumers' behavior through sets of rules, standards, and prescriptions.

transmission Long-distance, high-pressure pipeline transport of gas from the producers to the distribution systems in the consumer markets.

A continuous, steady growth of gas consumption in domestic households, industry, and power plants in North America, Europe, Asia, and Latin America has gradually turned natural gas into a major source of energy during the past century. Main drivers in this development are the technical and economic advantages of natural gas as a clean, versatile, and easily controllable fuel. A major challenge, however, has been the establishment and management of the markets for gas. This article examines how gas markets have been constituted in the past as a function of economic, technical, and institutional components and how they have been altered in recent times. In particular, it illustrates how the setup and later restructuring of these markets have been influenced by the characteristics of the complex production, transmission, and distribution systems through which the gas is transported from increasingly remote on- and offshore fields to a wide range of users.

1. INTRODUCTION

Natural gas supplies approximately one-fourth of the world's total commercially traded primary energy requirements. A continuous, steady growth in gas consumption in domestic households, industry, and power plants has gradually turned natural gas into a major source of energy. Main drivers in this development are the technical and economic advantages of natural gas. It is a clean, versatile, and easily controllable fuel for which no on-site storage is needed. Further growth in gas consumption is expected as a consequence of its relatively low carbon content compared to that of coal and oil products. On this basis, gas is often considered the form of energy that will be the "bridging fuel" to a sustainable energy system, sometime after 2050.

Unlike other main sources of energy, such as oil and coal, gas is not traded on an actual world market. This is because gas is made available to its consumers by means of complex production and transport systems, through which it is moved often from remote fields to its users. The geographical reach of these pipeline transport and distribution systems is essential for supply and demand to develop.

Traditionally, the development and exploitation of these systems posed a great challenge because of the great risks and uncertainties involved. Huge investments must be committed to facilities that, once constructed, have only one purpose and destination and no alternatives. In addition, producers, transporters, and consumers are tied into a relationship of mutual dependency. In response to these characteristics and the specific local setting of systems, a variety of contractual relationships and organizational structures were established to reduce the risk involved and to establish the terms of trade for a longer time period so that the producers' as well as the consumers' investments would not be jeopardized.

This has resulted in the development of truly regional gas markets in different areas of the United States and later in continental Europe, the United Kingdom, Japan, the Soviet Union, and Latin America. Each market has its own market structure, characteristic institutional framework and role for governments and local authorities, and specific outcome in terms of the economics of supply and demand.

During the 1980s, a gradual shift in economic thought began to take shape in which the stabilizing role of the state and the need to control markets in general were questioned. It was argued that the state would never be able to coordinate the economy more efficiently than the market. The state could never acquire and process the necessary information to do so, whereas government failures would undermine the economy's efficiency. Moreover, in the process of planning, the government ran a serious risk of being affected by interest groups or by political deadlock. The arguments for restructuring were reinforced by a plea to integrate national and regional markets for goods because international trade theory argued that economic welfare would be enhanced by allowing production to take place in the most efficient location or country. Because countries differed widely in their energy resource endowments, national (energy) markets needed to integrate to the extent that the process of producing and trading energy would no longer be confined to national territories. To achieve this, national trade regimes had to remove existing barriers to trade, whereas the physical infrastructure to efficiently transport energy between and within countries, such as pipelines, ports, and railways, had to be developed.

Gradually, in the several gas-consuming regions processes of structural and regulatory change were undertaken. Again, the evolution of these processes was influenced by local, economic, and (geo)political circumstances. This is reflected in the timing of these processes, the speed with which they evolved, and the structural models chosen to reform the gas supply "systems" into actual gas "markets." This article provides some illustrations of the manner in which some of the main gas markets have been organized in the past and how they are currently being restructured. Due to space limitations, it does not provide a wide overview of such developments. Neither does it present a quantitative overview of the actual development of gas consumption and supply in the countries and areas discussed.

2. HISTORICAL DEVELOPMENT OF MARKETS FOR NATURAL GAS

The use of natural gas on a large scale is a relatively recent phenomenon, occurring in the 20th century. Much earlier, however, gas was used in local systems as so-called "town gas" produced in coke works, sometimes associated with steel mills, or in specific gas manufacturing plants. In part, however, it involved natural gas, from small-scale underground gas reservoirs, supplying nearby villages and cities. Thus, in the United States the first recorded major use of natural gas was in 1821 in Fredonia, New York. In Russia, the first use of natural gas was associated with the production of oil in the Baku in 1871.

It was not until the 1920s that developments in welding technology facilitated the construction of steel pipes capable of handling higher pressures. This allowed the development of much larger systems over extended areas, through which actual systems of wells could be connected with consumers attached to local distribution systems, and in which depleted fields could be replaced by newly found deposits farther away. In the United States, the evolution of long-distance gas began in 1925. Elsewhere, it would take until the end of the 1950s until these systems developed. In Europe, major gas discoveries in The Netherlands in 1959 marked the start of the development of a natural gas system during the 1960s, stretching to Germany, Belgium, France, Switzerland, and Italy. The United Kingdom followed in 1967 after the discovery of significant fields in the North Sea. In the Soviet Union, large-scale use of gas began in the 1950s.

The systems that have developed since then normally involve the following: the production of gas, pipeline transportation, distribution, trading, and supply. The production segment involves exploration, drilling, production, and the collection of

gas from the fields' wellheads to move it to the transmission pipelines. Gas transmission involves the long-distance, high-pressure pipeline transport of gas from the producers to the consumer markets. Trading refers to the resale of natural gas in the wholesale market and retail market. Natural gas distribution consists of the operations necessary to deliver natural gas to the end users, including low-pressure pipeline transportation, supply of natural gas, metering, and marketing activities vis-à-vis the several types of customers.

Traditionally, a major challenge has been the establishment and management of these complex production, transport, and distribution systems. There is great risk involved. Huge, specific investments have to be made into facilities that, once constructed, have only one purpose, namely to produce gas and transport that gas from a specific field to the consumers attached to the system. If either the consumers decide to turn to alternative fuels or the gas supplier stops producing, the system becomes useless and the capital invested worthless. Thus, the system ties producers and the consumers in a heavily dependent relationship. Each side has to face the risk that the other side will drop out for whatever reason or that prices will increase or decrease to unacceptable levels. For producers, the former implies a volume risk in the sense that sunk investments in exploration and production become worthless because they will not be able to sell the gas they produce; for consumers, it may mean that their gas-fired appliances and equipment will fail to perform. The price risk implies that because of the tight relationship between them, either producers or consumers are able to put pressure on the other side to sell the gas at either too high or too low prices.

In a growing market, a key challenge over time is to maximize capacity utilization of the system, as well as revenue, to cover high fixed costs, including an acceptable level of profit. The main instrument to achieve this goal is a supply portfolio that dynamically balances the sales to these several markets as a function of the relative prices that these markets will bear and the capacity available in the system. In the energy market, gas has to compete with other fuels. Depending on the sector, fuels such as coal, city gas, fuel oil, and heating oil are substitutes for natural gas.

Main sectors with specific characteristics are the domestic household sector, the commercial market (also involving public use in schools, hospitals, etc.), the large industry sector, and the electricity production sector. In each of these sectors, the use of gas for purposes of space or process heating, hot water supply, or as a feedstock involves particular patterns of demand with respect to the load factor and daily and seasonal swing factors. Gas for domestic and other space heating purposes is subject to an enormous seasonal load variance. The electricity sector is a dynamic market, which relatively easily switches from one source of energy to another. A cyclical pattern develops over time. The highly profitable market for domestic household hot water supply and cooking is normally associated with sales in the space heating segment, driven by the cold season. Sometimes short-term sales to industry may be used to fill the free capacity during the summer.

This cyclical pattern is very significant for gas marketing in systems in which normally a constant, close-to-supply capacity production of gas is required for geological and technological/economic reasons. It is also significant for the planning of transmission capacity, distribution, and storage systems used to transport the gas from the wellhead to areas of consumption and to individual consumers. The pattern imposes very stringent requirements for coordination of marketing and planning and investment in production, transport, and storage capacity. Depending on specific regional circumstances, these aspects may be more or less relevant, but in general they induce a great degree of risk and, thus, affect suppliers' and consumers' willingness to invest.

A crucial spatial element in the evolution of the supply systems during the second half of the 20th century was the phenomenon that, by and large, the distance over which gas was transported from the production location to the centers of consumption increased. As a principle, gas exploration, the development of reserves, and eventual production must take place as close to the location of gas consumption as possible. Transport is expensive and it reduces the flexibility of gas supply to meet the daily and seasonal variation in demand. Therefore, the development of gas resources should evolve in a pattern of concentric circles around the center(s) of gravity as regards consumption.

This pattern, of course, is not completely consistent with what is actually observed. Old fields maintain production because they are huge, because technological development facilitates a "second life," or because they are conserved for reasons of national resources policy. Nevertheless, most of the "greenfield" gas production will take place increasingly farther away, requiring longer pipelines and more compressors to move the gas through the pipelines. It

will also involve the pipelines passing through more countries. Moreover, in many places large volumes of gas are produced in joint production, dissolved in crude oil. The characteristics of the joint production of gas and oil traditionally resulted in major difficulties in coordinating the output and marketing of both types of output. Often, the commercialization of these volumes of gas was not economical because oil production took place far away from potential customers. The cost of transporting the gas by pipeline was prohibitive, so it was flared. However, expected shortages in gas in some markets such as the United States, the declining cost of liquefied natural gas (LNG) transport and handling, and environmental considerations may change this practice. Of course, if oceans are to be crossed, the whole concept of supply through pipelines must be abandoned and LNG is the only option. Thus, geographical patterns of gas supply may experience radical changes in the near future.

In response to these characteristics, a variety of contractual relationships were established between gas producers, transporters, and consumers. In these contracts, the volume and the price risk were reduced by fixing prices and establishing specific terms of trade for a longer time period so that the producers' as well as the consumers' investments would not be jeopardized. Often, it involved a role for public entities, taking ownership and management over parts of these systems. These factors have resulted in the development of truly regional gas markets, each with its own market structure, characteristic institutional framework and role for governments and local authorities, and specific outcome in terms of the economics of supply and demand.

Traditionally, in the U.S. system, strict state and federal regulation stabilized a market with predominantly private firms. In Europe, a variety of national arrangements were unified within an international system of trade and supply. This Europe-wide system was highly coordinated under the aegis of a few governments of gas-producing countries and a limited number of gas-producing oil companies. In the United Kingdom, a single state-owned distribution company, British Gas, purchased all gas from private and public offshore producers and supplied it to the consumers. In Japan, LNG was imported under long-term contracts between buyers consortiums of Japanese gas and power companies and foreign suppliers, often state oil and gas companies from producer countries or the international majors. In the Soviet Union, the planning bureaucracy stabilized the market. In Latin America, stabilizing regulatory arrangements were established in the countries in which gas developed as a significant source of energy, namely Argentine, Chile, and Venezuela. The following sections illustrate the specific patterns of market coordination in the United States, Europe, and the Asian Pacific area (Figs. 1 and 2).

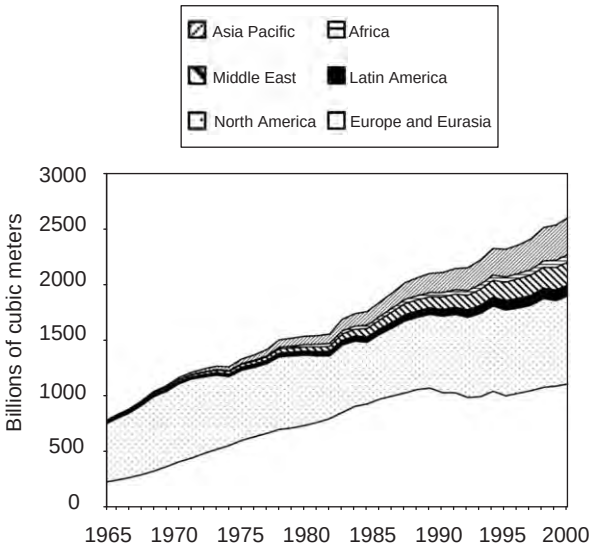

FIGURE 1 Natural gas consumption by region.

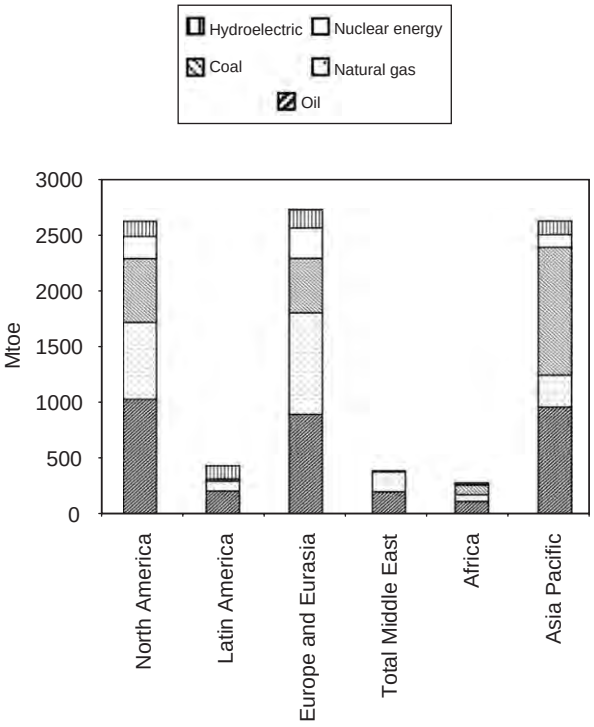

FIGURE 2 Primary energy consumption by source and region.

2.1 The United States

The U.S. natural gas industry is the largest gas industry in the world and it comprises a huge number of fields of various sizes. Initially, the development of gas use was haphazard and locally confined. After a period of limited oversight, with mainly municipality involvement, the Natural Gas Act of 1938 established a basis for the regulation of gas prices and the activities of companies. The following period saw a rapid expansion of the industry and the industry's regulation. Interstate transactions came under regulation by the Federal Energy Regulatory Commission (FERC). Intrastate transactions came to be regulated by the state public utility commissions. The industry was vertically separated into production, pipeline transportation, and distribution. However, all transactions were regulated and took place under long-term contracts. Thus, the industry was vertically integrated. Most of the gas produced was sold by the producers to pipeline companies under long-term, take-or-pay contracts. These pipeline companies supplied the distribution companies also under long-term contracts.

Attempts to regulate wellhead prices at a low level, however, discouraged gas exploration and production. Also, the transportation and distribution systems became private monopolies, imposing high costs on consumers. This delayed the growth of the industry considerably in a period in which enhanced indigenous energy supply was seen as crucial. The costly gas shortages in the 1970s prompted Congress to embark on a reform of the gas industry. In 1978, Congress adopted the Natural Gas Policy Act, through which the FERC was enabled to liberalize interstate natural gas markets.

2.2 Europe

Crucial to the development of the European system—and different from conditions elsewhere—was the ability to produce flexible load curves from the Groningen field in The Netherlands. Because of its geological structure and because of large investments in wellhead production capacity, the field had a capacity of approximately 100 billion m^3 annually. Daily capacity was sufficient to supply the required peak demand for the whole northwest European gas system in the early 1970s. On this basis, the European supply system was developed. Initially, The Netherlands supplied the lion's share of all requirements, to be sold to Germany, Belgium, and France.

However, during the 1970s, new foreign suppliers appeared, attracted by the high revenues from gas sales in Europe. The producers in these countries undertook the exploration and production activities and sold the gas produced to the state-owned wholesale buyer and exporters, such as Gasunie in The Netherlands, British Gas, GFU in Norway, Gazprom in Russia, and Sonatrach in Algeria. These firms coordinated the production and sales both nationally and abroad with other suppliers. They sold the gas at the borders to transmission companies and/or traders that transported the gas throughout Europe and supplied it to the national and local gas distribution companies and large industrial customers. With the exception of Germany, every country in Europe had one transmission company, operating the whole national high-pressure transport system. The local, municipal, or regional distribution companies operated and owned the local, low-pressure network, through which the gas was transported to small domestic users and businesses.

Trade between the several parties in the gas chain was arranged through medium- or long-term contracts. The producers delivered the gas via long-term contracts, (15–20 years) to transmission companies. These companies had medium-term contracts (1–5 years) with the local distribution companies and large-scale users. The small users had exclusive supply agreements with their local distribution companies. Throughout Europe, the transmission companies and local distribution companies had been given a local monopoly for pipeline operation and distribution.

By means of concessions, public ownership, indicative planning, and regulated prices, the producers and distributors were able to coordinate purchase and sales volumes of gas and prices. Through these contractual provisions, the risk involved in the funding of the expensive production and transport facilities over the longer term was reduced. This, of course, stimulated enormous investment in the system, as long as gas could be produced and transported at such a cost that the end-use price allowed for a reasonable profit. An important element of the contracts was the so-called take-or-pay clause, obliging the distributor or consumer to pay even when the whole volume of gas agreed upon had not been taken from the system, for example, because of lagging demand.

The only competition to gas emerged from the threat that consumers would switch to other energy sources, of which oil was the most relevant. However, the end-use gas prices were always slightly less than local prices for substitutable oil products. Importantly, the contracts contained destination clauses through which the volumes of gas were

committed to a specific area and could not be sold elsewhere at a higher profit or undercut official sales. The revenues to the producers were thus dependent on the retail prices for oil products to the several types of end users (the netback principle). The transporters and distributors were remunerated with a fixed fee, which was dependent on the cost of the pipeline and the negotiation position of its operator (normally having a monopoly position).

2.3 Asia and the Pacific

Unlike the United States and the European natural markets, the Asian Pacific gas markets are essentially markets for LNG. Japan and other main LNG users, such as Korea and Taiwan, import most of their LNG under long-term contracts. Most of the gas is used in power generation, and relatively smaller shares, compared to the United States and the European Union (EU), are used in industry directly. The shares of domestic household use are comparable.

Traditionally, pipelines have been a difficult issue in Asian markets as a consequence of geopolitical tensions between supplier, transit, and consumer countries, sometimes in combination with problems of scale with regard to the size of the markets and relatively low prices for other fuels. As a consequence, the whole region consists of a number of national submarkets with their own dynamics, economics, and institutional frameworks.

The national markets in Japan, India, China, Taiwan, and Korea are heavily regulated. In some countries, natural gas is supported and subsidized, whereas in others gas is priced at its full cost. Both situations may hamper further development: The former because it may impose an additional burden on the subsidizing states, and the latter because it may scare away the (potential) consumers that have to make a choice for natural gas. Regarding the Asian natural market, there is a huge potential for growth in gas consumption in most countries, as well as in gas supply from a few of them. There are, however, major problems specific to each country in bringing about the expansion of the gas systems, not to mention a market.

3. THE LIBERALIZATION OF GAS MARKETS

As it is generally stated, liberalization of the gas industry envisages to reduce the costs of supply, enhance quality, and enhance the overall efficiency of the gas supply system. By providing the consumers, or traders, with a choice with respect to their suppliers and the type of contract, the customer is in a position to select the supplier offering the most attractive conditions. It is assumed that suppliers will try to gain, or protect, their market share by improving supply and price conditions. The traditional wholesale traders and distribution companies will have to develop new strategies and adjust their organizations because they will lose both their secured market, while the integration and coordination between their several activities in the supply chain disappears. These firms will also adjust their structure and operations—through mergers and acquisitions—so that their size and activities fit the requirements of the newly emerging competitive market.

Competition in the gas market can be achieved by altering the structure of the market, as suggested by economic theory. Whereas the traditional perspective denied the feasibility of competition in the gas industry, structural change started from the hypothesis that the introduction of competition would be possible in some segments and that this would improve the performance of the whole system. Actually, only the pipeline transportation and distribution segments of the industry were accepted as being a natural monopoly because of economies of scale and scope, high fixed costs of pipeline construction, and relatively low variable costs. The other segments, production and wholesale and retail trade, were considered to be potentially competitive markets. Therefore, by changing the ownership structure of the sector and by dividing the competitive segments into a number of different firms, competition could be introduced into the sector. A number of models can be distinguished to break up the industry.

One model separates production from the rest of the industry and introduces competition among producers. Producers sell natural gas to a gas utility, which then resells it to the end users. The transactions between the producers and the utility lead to the development of a wholesale natural gas market, in which natural gas is traded for further resale. Regulation is needed to restrict the market power of the gas utility relative to both the consumers and the producers. End-user prices are regulated. The price of gas sold by producers to the utility is determined through competitive bidding for a supply contract with the gas utility.

A more ambitious model introduces open access in pipeline transportation to third parties that either sell

or buy gas from each other. The gas utility thus supplies gas to the captive, small consumers and it provides transportation services to large consumers that purchase gas independently in the wholesale market. A gas utility may also be further separated into a pipeline company and several distribution utilities, all providing access to their networks. Open access promotes competition in the wholesale and end-use market. Producers benefit because of the increase in the number of potential buyers, whereas distribution utilities or large end users benefit from a greater choice in gas suppliers and conditions. The high transaction costs involved in buying gas create room for natural gas traders, which aggregate demand and supply for a number of smaller market participants by purchasing natural gas and transportation services on their behalf. In this model, the end users have to be protected from the monopoly power of gas utilities. The price of transport and other services is another crucial factor in achieving competition in the wholesale market.

A third model separates natural gas supply from pipeline transportation and distribution and introduces full competition into these markets. Unbundling creates a level playing field for all participants in the natural gas market and creates a large number of supply companies that purchase natural gas in the wholesale market and resell it downstream using the transportation systems of pipeline and distribution companies. As competition among suppliers reduces excess margins and forces the savings on to the end users, the need for stringent price regulation at the wholesale and retail level will be reduced. In this model, new flexible short-term trading and contractual arrangements will be provided to balance supply and demand and give market participants the flexibility they need. Liquid spot markets are expected to emerge, yielding prices that continuously reflect the market value of natural gas at a specific location.

The advantages of a more efficient market may be offset by the transaction costs, high risks, and high volatility in volume and price. It increases the uncertainty of demand for gas and transportation services, exceeding or falling below available capacity. In part, this may be resolved by contracts that offer secure or interruptible transportation services, storage and conversion contracts, and other techniques to moderate changes in supply and demand. However, it is too early to effectively evaluate the outcome of processes of structural change. Only in a very few countries, such as the United Kingdom, has the third model been implemented to its full extent. Other European countries are contemplating this step in several forms, and the United States is also moving in this direction.

It has become clear that a structural change of the gas market to introduce competition requires complex organizations and administrative systems to carry out and control all these transactions. Strict and independent regulatory oversight is required to keep owners of distribution networks or other parties from abusing their dominant economic positions. Indeed, such transport systems remain natural monopolies, of which the owners and operators are in the position to jeopardize others' interests.

3.1 The United States

In 1978, Congress adopted the Natural Gas Policy Act authorizing FERC to liberalize interstate natural gas markets. Since the major producing and consuming regions in are in different states, this had a major impact on the operation and efficiency of the natural gas industry. During the 1980s and 1990s, FERC gradually established a framework for the actions of market forces in the natural gas industry.

By Order No. 436, FERC instituted an open-access regime for interstate pipeline transportation. This regime enabled local distribution utilities and large end users to bypass pipeline companies' gas sales and purchase natural gas directly from producers. Although the open-access regime was voluntary for pipeline companies, it was widely accepted because it enabled them to increase the utilization of pipelines. However, large-scale implementation occurred only after FERC resolved the issue of how the costs of the transition to open access were to be distributed. Because customers were allowed to exit long-term supply contracts, the pipeline companies were left with large take-or-pay obligations to producers. FERC Order No. 500 allowed them to pass a share of the transition costs to procurers, distribution utilities, and end users. Subsequently, the Wellhead Decontrol Act of 1989 deregulated the wholesale price of natural gas in all interstate transactions, promoting competition in the wholesale natural gas market.

Order No. 636 required pipeline companies to unbundle natural gas sale operations from pipeline transportation activities and set up separate transportation and trading affiliates. This attracted many new companies into marketing and promoted fierce competition among marketing firms. Order No. 636 also reformed the regulation of interstate pipeline transportation. It allowed resale of transportation

contracts by shippers, creating a secondary transportation market in which shippers can purchase pipeline capacity from other shippers that have temporary or permanent spare capacity. This enhances an efficient allocation of transportation contracts among shippers and high utilization of natural gas pipelines.

A subsequent series of measures was designed to promote transparency and flexibility trading practices. It facilitated short-term capacity resale, shippers' choice of delivery locations on interstate pipeline systems, and the standardization of contracts and pipeline system operation. Additional rules guided the development of a short-term transportation market in which capacity and interruptible contracts can be traded among pipeline companies and shippers.

However, by the end of the 20th century questions began to arise about the future of the U.S. gas and energy markets. Fear began to arise that the supply of new, additional volumes of gas, in response to the continuous increase in demand, would not materialize. Low prices in the context of specific market circumstances, fiscal regulations, disputes about pipeline construction, and difficulties in the establishment of storage facilities all contributed to an awkward situation with regard to gas supply. The difficulties in the operation of the market mechanism seem to be a consequence of the fact that excess production, transport, and storage capacities for gas and substitute fuels have been eroded, as illustrated by a number of local and regional energy crises. The workings of the market seem to have reduced the incentives for private industry to maintain sufficient spare capacity. It remains questionable whether this phenomenon is part of a learning experience, or whether the energy is structurally unable to establish long-term balanced behavior.

3.2 Europe

The situation in Europe has not reached that of the United States. There are no signs of immediate capacity shortages in the gas industry, although the situation in the United States is raising questions. The main issue, however, seems to be the progress of the liberalization of the EU gas market and the lagging implementation in several member countries. During the 1980s, the perception that the economies of the EU countries would be better off if linked, through integration and/or internationalization, was gaining widespread recognition as European countries were increasingly confronted with large internationally operating firms from the United States and Japan selling goods and services in their relatively small and often somewhat protected home markets. In 1985, Jacques Delors, supported by powerful European industrial leaders, launched the Single European Market initiative. The aim was to achieve a free market for the whole community by dismantling impediments to the free movement of goods, services, labor, and capital.

The EU gas directive (98/30/EC) mandated that member states of the EU had to adjust the organization and regulation of their national gas sectors in such a way that consumers would receive the right to contract with national or foreign gas suppliers of their choice. It had fundamental consequences for the structure of the existing gas market and the way in which the gas was produced and moved to the final consumer. First, the member states had to open up a first tranche of 20% of the national market and after 10 years 35% of the market had to be open for supplies by third parties.

To facilitate supplier and trader access to consumers, two main changes were necessary. First, the EU member states had to adjust their rules so that producers would no longer be forced to sell their production to one national wholesale gas buyer. The EU hydrocarbons directive stated that producers were to be given the right to sell their gas to anybody interested and acceptable to them, including large consumers, intermediate traders, and retail sellers. To achieve this, a second important requirement was that the existing transport and distribution network had to be made accessible to third parties. Producers, traders, and consumers should be given the right to contract transport capacity in these systems to transport the gas to the customer at the end-use location. Instead of selling the gas to the network owners and traders, the producers and independent traders had to acquire transport and distribution services for a fee.

By 2003, the gas directive has been implemented by the EU member countries only partially and to a varying extent. In part, this is a consequence of the fact that the EU countries are free to choose how to implement the provisions of the directive. It provides a framework, leaving the actual instruments of regulation, including the way in which regulatory oversight is created, to the discretion of the member states. This has created a situation in which some of the countries, such as the United Kingdom, The Netherlands, Spain, Austria, and Denmark, are fairly advanced in opening up their markets. Also, the trading instruments referred to in the discussion of

the U.S. situation are being developed in these countries.

However, other countries are delaying the implementation of the gas directive or the national adoption of an effective regulatory framework. Thus, access provisions to the several national EU markets are quite different and the market positions of the several companies involved are unequal. In addition, there are important differences between countries' perspectives on issues such as security of supply, in light of their dependence on a limited number of suppliers, and the recognition of the interests of gas-producing countries, such as The Netherlands and Norway, vis-à-vis the consumers.

Unless Europe radically changes its position on nuclear energy, increased dependence on gas imports will be unavoidable for the foreseeable future, with a possible share of gas in the EU primary energy portfolio of approximately 30%. In principle, there is enough gas in the area to meet Europe's additional demand for energy for the foreseeable future. However, doubts have been cast over this supply perspective because it is maintained that policy-makers in the consumer countries fail to accept the conditions necessary to bring this gas to the EU markets. The size of the investments required, their timing, and the quantities of gas involved in the new developments are such that producers and suppliers from outside the EU cannot undertake these ventures without a high degree of certainty that the gas will be taken by the market at the time it is produced. This implies that such supplies need to be carefully arranged with the contractual (and other) support of those buyers in the market that have the ability to evaluate and aggregate the many small parcels of demand in local markets.

During the past 40 years, the European gas industry obtained security of demand by means of long-term supply contracts with provisions on a take-or-pay basis, providing limited flexibility, and price indexation ensuring the competitiveness of gas in the specific markets. As noted previously, this industry structure is being dismantled and a new system is being introduced that focuses on short-term rather than long-term deals. This is causing significant uncertainty regarding the market and the business environment. Gas-producing countries, particularly Russia, Algeria, and Norway, and some of the large oil companies and financing groups involved are showing signs of confusion and discontent with these developments. For example, at conferences in Algiers in May and September 2002, with the exception of Norway and The Netherlands, it was made clear that the concepts that have emerged from the process of liberalization are not helpful in creating an environment for an expansion of the gas market.

4. THE FUTURE OF NATURAL GAS: NEW PATTERNS OF SUPPLY AND DEMAND?

This examination of the structuring of markets for natural gas has illustrated the importance of the way in which governments, alone or together, are involved in the organization of these markets. Although natural gas has a number of inherent advantages as a clean, versatile, and easily controllable fuel, its development also involves fundamental problems. In the past, the establishment and management of the newly developing markets for gas in the United States and Europe occurred essentially under a system of tight coordination of the economic, technical, and institutional components of these systems. The rationale for this was clear: Private investors simply could not afford to take the technical, financial, and market risks.

During the past 25 years, it has been argued that times have changed and that the state should withdraw from such ventures. However, as argued in this article, a number of experiences have posed new questions with respect to the feasibility of markets as a coordinating device for large-scale, technologically and (geo)politically complex systems such as international gas markets. It remains to be seen to what extent the development of increasingly advanced risk sharing and trading mechanisms, and regulatory instruments to mimic market behavior in parts of such systems, may be sufficient to overcome the need for public regulation. Although the pseudomarket may be a forceful means to slim down a sector, it may not necessarily be helpful in establishing and expanding the complex gas production, transmission, and distribution systems that will be required to support growth of gas use in North America, Europe, Asia, and Latin America.

1. Oil Markets
2. Natural Gas

Glossary

forward market A market in which physical crudes are traded for future delivery, usually only a few months into the future.
integration (vertical) The degree to which companies participate in upstream and downstream aspects of the industry (crude production, shipping, refining, and marketing).
liquefied natural gas (LNG) Methane that is cryogenically cooled to form a liquid for easier storage and transport.
marker crudes Large-volume crudes that are widely traded and referenced in other contracts.
middle distillates Light petroleum products that are heavier than gasoline, primarily used as diesel fuel and heating oil.
methyl tertiary butyl ether An octane enhancer used in gasoline, manufactured from methanol.
New York Mercantile Exchange (NYMEX) The largest futures market for petroleum.
resid Residual fuel oil; also called distillate fuel oil 6 or C (in Japan).
sour/sweet Degree of sulfur content, where high sulfur means more sour.
take-or-pay A contract requirement that the buyer accept a specified amount of the contracted volume or pay for it.
upgrade To improve the value of the crude or product by cleaning or lightening it through a variety of processes.
Very Large Crude Carriers Supertankers.
West Texas Intermediate (WTI) The U.S. marker crude.

Two major changes characterize energy markets of the early 21st century: globalization and growing competitiveness. Where markets used to be fragmented and opaque, in part due to heavy regulation, they have become increasingly connected to one another at the same time that transparency and competition have increased. This reflects a combination of falling transportation costs and policy changes as many governments pursue economic reform. In addition, as economic growth spreads around the world, there are many more companies large enough to operate on a global or at least regional basis.

1. OIL MARKETS

The world petroleum market remains the most important of the energy markets, in terms of both volume and global penetration. The ability of oil to provide energy in a wide variety of uses, combined with the high energy density that most petroleum products contain, makes it the most flexible and useful of fuels. Although prices are relatively high in 2003, oil has long been one of the cheaper fuels, especially after the discovery of the supergiant oil fields in the Middle East.

Until 1970, oil consisted of the U.S. domestic market, which had many small producers, refiners, and marketers, and the international market, which was dominated by a small number of multinational corporations, known as the Seven Sisters. Before World War II, and for nearly two decades afterward, those companies controlled almost all oil that was traded on the international market, producing it, shipping and refining it, and marketing it in the major consuming countries. Although some oil was sold on long-term contracts to independent companies or partly owned affiliates, most oil remained within the systems of these large companies.

The situation has completely changed in the past two decades, especially since the oil crises of the

 © 2004 Elsevier Inc. All rights reserved.

1970s. A large portion of the world's oil is now produced by national oil companies, especially in the Organization of Petroleum Exporting Countries (OPEC) nations. Some of that oil is sold on the world market, some is sold on longer-term contracts to individual companies, and some is sold to their former concessionaires. In addition, a host of smaller companies, some privately held and others controlled by governments—mostly in the Third World—produce and sell oil on a national, regional, and occasionally global basis.

1.1 Spot Markets

One of the major changes in the world oil market in the past two decades, compared to most of the 20th century, is the rise of the spot market. Although the United States has long had a very active internal trade in petroleum, given the abundance of small producers, on a global level the amount of crude traded on the spot market has been relatively small. Oil products usually are traded only regionally, because of the higher cost of delivery. Gasoline and middle distillates especially require clean tankers so that they do not become contaminated and this has relegated their trade to local and regional markets. Rotterdam, the Mediterranean, and to a lesser extent Singapore have long seen a relatively active spot trade in oil products.

However, because the number of small producers has increased so much, more oil has entered the world's spot market. Additionally, many of the larger oil companies no longer keep their production within their own systems. A major company might sell African production into the spot market and buy spot crude in Asia rather than ship their own production between those markets, depending on the respective prices of crude and shipping. Also, advances in refinery technology have made it much easier for refiners to handle different types of crude, so that they are much more able to utilize many types of crude.

As a result, where spot crude trade was 3 to 5% of world oil markets until the 1970s, it is now estimated to be 30 to 35% on a regular basis. This could change over time with the rise of the new players in the market, such as China National Petroleum Co. and Petrobras, in Brazil, which have different goals and behavior patterns from the U.S. and European privately held oil companies. Increasing integration on the part of OPEC countries might also eventually reduce their sales on the open market.

1.2 Futures Market

One new development (actually a revival of a 19th century market) is the use of financial futures to hedge and/or speculate on the price of oil. This resumed in 1978, with the trading of heating oil in the United States on the New York Mercantile Exchange (NYMEX). Most futures trading takes place on the NYMEX and consists primarily of contracts for sweet crude [West Texas Intermediate (WTI)], gasoline, and middle distillates. Although this is a very active market, it is much less developed than those for many other commodities. The amount of open contracts on a given day is only a few times daily physical trade, whereas for many agricultural commodities, the trade is several times higher. Additionally, trading beyond 3 to 6 months is very thin.

In part, this reflects the fact that this market is still, relatively speaking, a new one and many of those active in the physical market are very large and thus are reluctant to use futures to hedge their trading, for fear their volumes would overwhelm other traders and thus drive the market. Actors such as OPEC producers also have particular foresight into future oil prices, since their decisions directly affect prices, so that any trading they undertook would influence the market. If the Saudis were to go short, for example, traders would take that as evidence that they were planning to raise production and would sell along with them. This is different from that of many other commodities, where much of the uncertainty reflects factors that are beyond the control of the players in the market, such as weather and economic uncertainty, rather than policy choices by a cartel.

However, the futures market does provide substantial transparency, especially combined with the Internet. Virtually everyone in the world can have access to oil prices on an instantaneous basis. Compared to the 1970s, when world oil prices were rarely published, this is a huge difference. It has been argued that the existence of a futures market can, by itself, influence oil prices, as speculators will tend to behave in a herd and often move in illogical ways, that is, reacting to psychological events such as headlines rather than fundamental indicators such as oil inventories. There is some truth to this, but the impact tends to be exaggerated; foresight is still rewarded and mistakes penalized, on average. Deviations from the "true" price of oil tend to be relatively small and brief and it is usually the case instead that observers are attempting to rationalize oil price movements that they cannot explain otherwise.

1.3 Price Setting and Volatility

For most of the history of the world oil market, the price of oil has been set or at least strongly influenced by one or another body. This began in the late 19th century with Rockefeller's Standard Oil Trust, which effectively monopolized the market by setting the price at which it would buy crude. After the Trust was broken up by the U.S. government, prices became more volatile, until two particular steps were taken to stabilize them. In Texas in the 1930s, the state government gave control over production to the Texas Railroad Commission, which set quotas for individual producers based on its estimate of the market situation. Other producing states in the United States followed their lead and imposed similar quotas. Since the United States represented the bulk of the world oil market through the middle of the century, this had the effect of stabilizing the world crude oil price, as the export price equaled the domestic price.

This was especially true since the world oil trade was dominated by the Seven Sisters, or major oil companies. They established a price known as "Gulf plus," which meant they would pay the price of crude oil in the Gulf of Mexico plus the cost of transportation to the point of sale. Prior to World War II, this was economically logical as Gulf crude represented the marginal barrel. In order to protect this price, the majors agreed to limit their production to avoid undermining crude prices. Since most production growth after the 1930s came from the Middle East, where consortia consisted of interlocking major oil companies, it was very easy for them to cooperate in this manner. (Earlier, they had been inclined to poach on one another.) In fact, the consortia had the power to penalize any partner who wanted additional oil that would allow them to take market shares from a competitor. It was only in the 1960s, as independent oil companies began to break into new areas such as Libya, that the system began to erode.

In the 1950s, the world oil price was often referred to as the posted price; however, this was increasingly a tax reference price. Companies paid taxes to the governments based on the posted price, but the actual price was determined by their tax payment plus the cost of production. As the cost of production was declining, actual prices increasingly diverged from the posted price. But since most crude stayed within single-company systems and was not traded openly, there was very little transparency in the market.

By the middle of the 1970s, however, most OPEC nations had completely nationalized the producing operations in their own territories and thus the posted price no longer represented the tax on production, but rather the actual sales price set by the governments. At that time, the official sales price came into wide use. OPEC nations would hold meetings to agree on a standard price, which they would then offer to all buyers. Production then fluctuated according to changes in sales, but prices remained relatively steady. Thus, Fig. 1 shows that

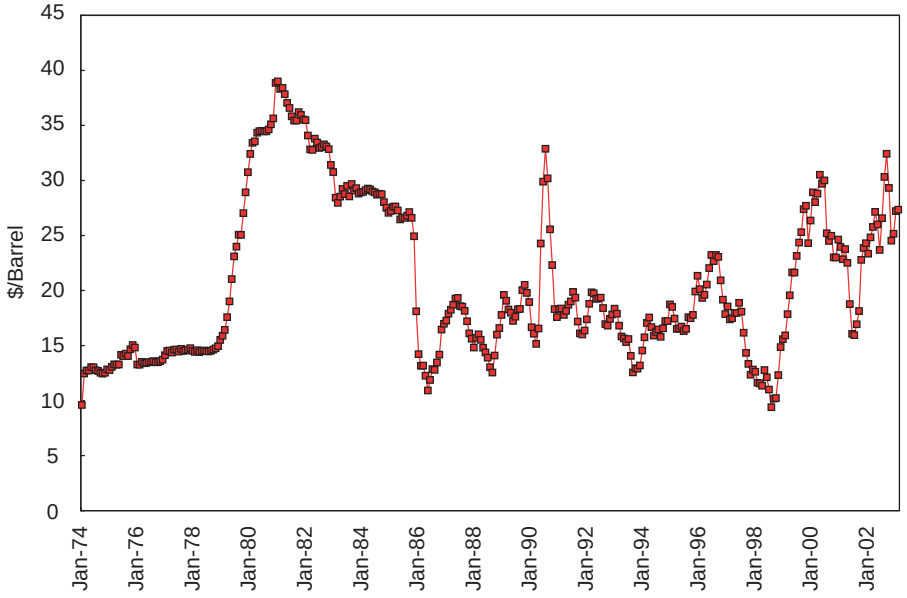

FIGURE 1 U.S. refiners' acquisition cost for imported crude (nominal dollars). From Monthly Energy Review, U.S. Department of Energy.

the world price moved very little from month to month during this period, except for the Iranian oil crisis in 1979.

The system broke down as a result of OPEC setting the price too high for too long a period after 1979, causing a substantial drop in the demand for OPEC oil, the impact of which was heaviest on Saudi Arabia, whose cash sales had practically vanished by 1985. During this period, the Saudis had been acting as the cartel's swing producer, meaning that they would absorb seasonal and short-term fluctuations in demand for OPEC oil. But they found themselves actually absorbing the long-term decline in demand for OPEC oil instead and had to initiate a price war to force the other members to both lower the price of crude oil in the long term and accept a greater share of the burden.

Since that time, prices have fluctuated much more on the world market, as Fig. 1 shows. The cartel is now allowing price to balance the market rather than their production. Since there is substantial uncertainty about global oil supply demand and inventories in the short term, the cartel is always setting a target and achieving it imperfectly.

In the past few years, prices have become even more volatile, reflecting changes in the overall market. The oil crises of the 1970s resulted in a huge amount of surplus capacity in OPEC, as well as in the global refining and shipping industries. Over time, this declined (Fig. 2), and there has been less surplus capacity to deal with short-term market tightness. Instead, prices have had to balance the market on several occasions, including 1996 and 2000. In both of those cases, most OPEC nations were producing at full capacity and the market did not balance. (Of course, the Saudis could have raised production further in both cases, but chose not to do so.)

1.4 Marker Crudes

Although crude petroleum is thought of as a fungible commodity, that is, one within which units are highly interchangeable, there are substantial quality differences in different crude types, which translates into differences in value. There are three primary aspects of quality: weight, indicating the amount of carbon relative to the amount of hydrogen; sulfur content, which is often referred to as sweetness (low sulfur) or sourness (high sulfur); and contaminants, particularly heavy metals, such as nickel and vanadium. Typically, a given field will contain one particular type of crude whose qualities are well known to buyers and even a region can produce sweet or sour crude, heavy or light crude, and so forth. Also, it is

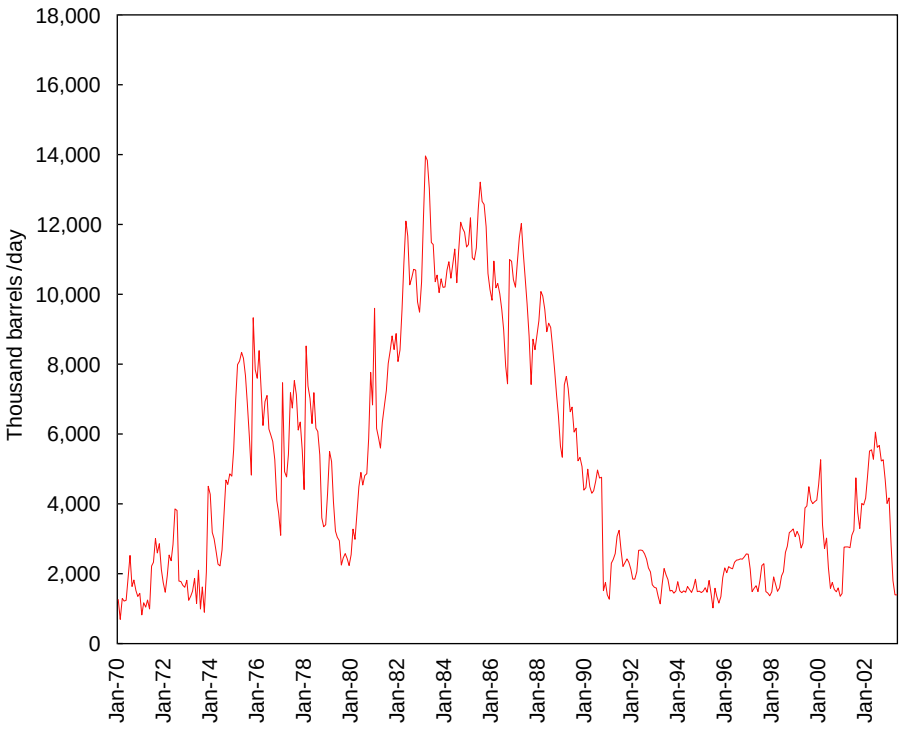

FIGURE 2 OPEC surplus capacity (thousand barrels/day). From U.S. Central Intelligence Agency and Energy Intelligence Group.

common for crudes produced in an area to be blended so that buyers do not have to differentiate between minor differences in small volumes.

Since it is difficult to track all of the many prices for crudes according to quality differences, many contracts rely on what is called a marker crude. In Europe, Brent crude is used, whereas in the United States, WTI is the primary marker crude and Asian buyers and sellers tend to rely on Dubai crude. All are traded in the open market and have well-publicized prices. Most contracts will fix prices relative to those crudes, adjusted according to differences in the quality of the crude being traded.

However, these crudes are increasingly suffering from problems of declining volumes, which leaves them vulnerable to squeezes that can cause their prices to diverge from the overall market. This has been a problem particularly for Brent crude produced in the British North Sea, which is actively traded in the forward market, and where the number of cargoes is approximately 24 per month. It is thus possible for a company to corner the market in a given month, leaving players in the forward market unable to find physical crude cargoes.

Some have suggested that the Saudis once again accept the role as a marker crude for its Arab Light, which is one of the largest volume crudes produced, but the Saudis have refused and do not allow their crudes to be traded in the spot market as a rule. They fear that Arab Light would become the target of manipulation, possibly causing their prices to rise relative to the market, thereby hurting sales, as well as making in their role in the price-setting more obvious and thus subject to political criticism.

1.5 Trade Flows

Over time, the trade in petroleum has changed significantly. In the 1970s, for example, the United States began importing increasing amounts of crude from the Arabian Gulf. However, rising production in the North Sea and the Atlantic Basin caused a sharp drop-off in that trade. Europe relies heavily on Russian and African production for its import needs and Asian imports are primarily from the Middle East. The United States still imports significant amounts of Middle Eastern crude, but most of its import needs are met by short-haul Atlantic basin producers: Canada, Mexico, Venezuela, and West Africa.

This primarily reflects the difference in transportation costs, where differences as little as pennies per barrel will shift trade between regions. Although countries such as Mexico and Venezuela may prefer to avoid being overly dependent on sales to the U.S. market, they receive much more for their production by not having to pay the higher transportation costs into more distant markets. At the same time, some oil-exporting nations continue to have an almost political concern about their market shares in certain areas, especially the U.S. market, where the Saudis sell approximately 1 million barrels of crude a day at a loss (compared to prices in Asia) to retain a foothold. It is hard to know how much this reflects a marketing strategy, such as diversification, versus a diplomatic tactic, maintaining the so-called "special relationship" with the United States.

At the same time, differences in demand and a variety of market fluctuations mean that the price in different markets can vary over time by as much as $2 per barrel for similar crudes. This then encourages balancing shifts in the trade flows to offset the differential. However, the value of crude in a given market is a reflection of a combination of factors, such as type of product demanded in the region, refinery sophistication, and openness of markets. However, isolated markets such as California are more likely to face higher prices on a regular basis.

Figure 3 shows the oil trade flows in the year 2002.

1.6 OPEC Integration

The tendency of OPEC national oil companies to move downstream is also an important recent change. Especially since the early 1950s, most crude oil was shipped to consuming nations and refined there. This was partly in response to the problems that resulted from the Iranian nationalization of British Petroleum holdings, including the Abadan refinery, in 1951, which led to a policy of "refining on the consumer's doorstep" in many industrialized nations. Also, the development of Very Large Crude Carriers made it cheap to ship very large quantities of crude.

However, as the OPEC nations gained control over their own operations, and especially as their income rose, they decided to refine their own oil where possible, partly as a corporate strategy and partly as an economic development strategy. Seeking to capture the larger share of the value added to their raw materials, OPEC countries first sought to build export refineries on their own territory and then to buy refineries overseas in consuming nations. As Fig. 4 shows, their own refinery capacity rose sharply in the late 1970s and early 1980s and then leveled off as their oil revenues weakened. Subsequently, they

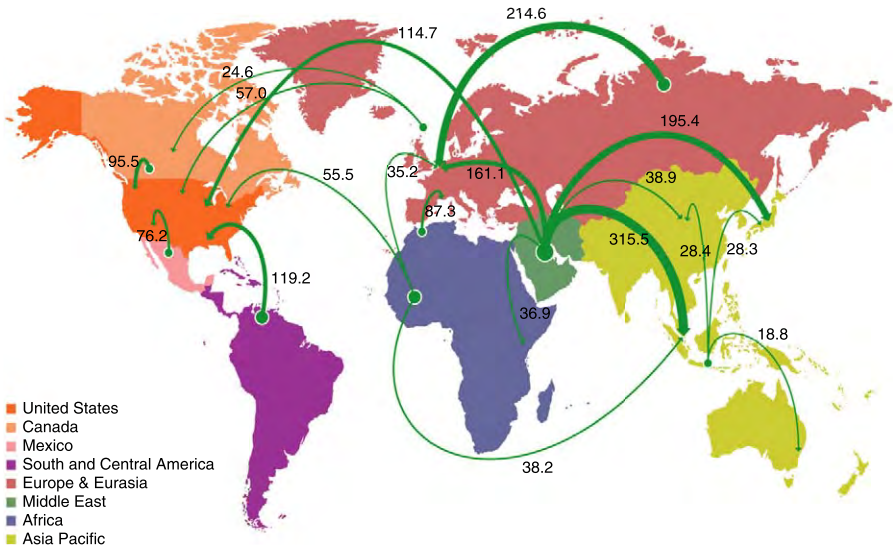

FIGURE 3 World oil trade flows (in millions of tons). From BP Statistical Review of World Energy Industry.

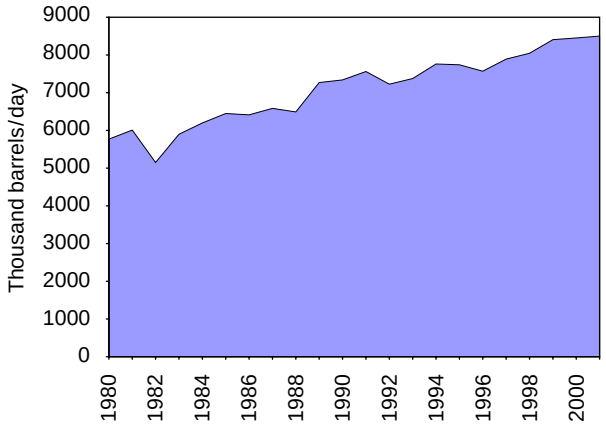

FIGURE 4 OPEC refinery capacity (thousand barrels/day). From OPEC.

realized that it was cheaper to buy into existing, underutilized assets in consuming nations, and Venezuela, Kuwait, and Saudi Arabia in particular have led in this regard, owning part or all of numerous refineries, especially in Europe and the United States.

1.7 Regional Differences

The wide variety of differences in energy usage around the world reflect a combination of economic circumstances and geography. Most important has been the abundance of commercial hydrocarbons in the United States, which meant that most stationary energy needs, such as for power generation and industrial boilers, were met by coal and later natural gas, so that petroleum was used more in the transportation sector than in many other countries. This trend continued when nuclear power became an important source of electricity beginning in the 1970s. Many other parts of the world switched from coal to oil for large users after World War II and have only just begun moving toward a more balanced mix of energy (Fig. 5).

The ready availability of cheap energy has also meant that U.S. industry and consumers have come to anticipate the ready availability of cheap energy. As Fig. 6 shows, this still remains the case. In most parts of the world, most types of energy are more expensive than they are in the United States, with a few exceptions.

Certainly, it is true that taxes play a role in raising energy prices in many parts of the world. Many countries tax gasoline at much higher levels than the United States, with gasoline taxes often higher than the final price of gasoline in the United States. But also, subsidies for coal long made it expensive in some parts of the world, such as Germany, although they are diminishing, and the high cost of natural gas transportation as well as past contracting practices have made that fuel expensive in Europe and much of Asia.

The higher rate of taxes on gasoline stems from a combination of reasons: energy security, fiscal policy, and simple protectionism. At the same time, diesel fuel is often taxed at much lower rates, which is why diesel automobiles are much more common in Europe than the United States. One side effect of this is that Europe has a surplus of gasoline produced, which it ships to the United States, whereas

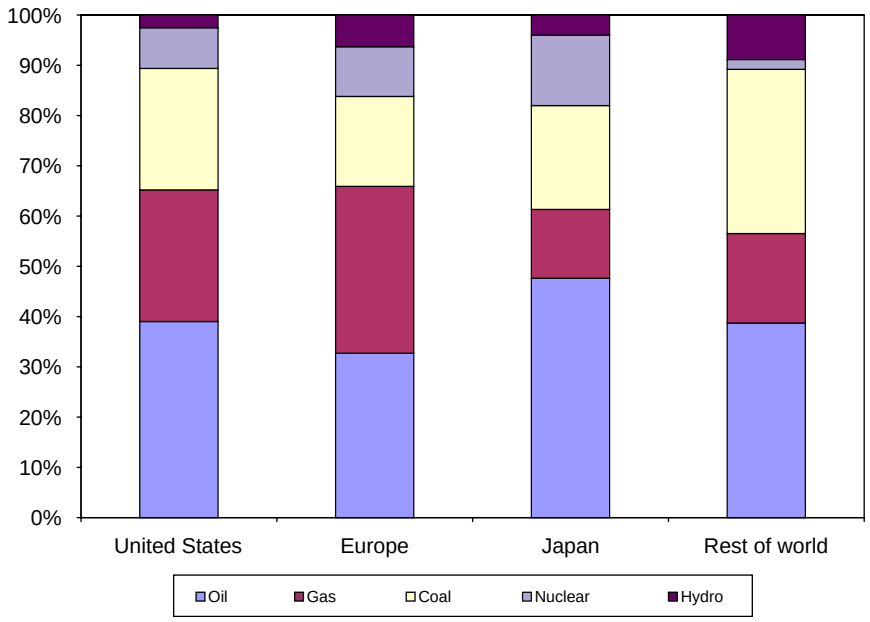

FIGURE 5 Primary energy share by region, in the year 2002. From BP Statistical Review of World Energy Industry.

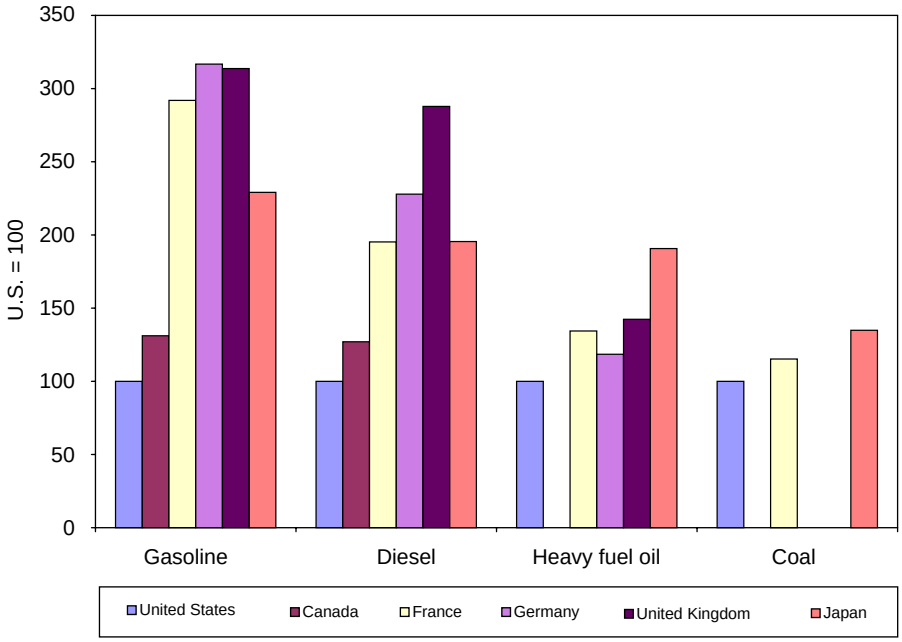

FIGURE 6 End-user prices in various countries (indexed to the United States). From International Energy Agency and Monthly Energy Review, U.S. Department of Energy.

the United States produces a surplus of middle distillates, which it exports to Europe.

1.8 Product Markets

There are a large number of products derived from crude petroleum, including many minor specialty chemicals that are not traded in quantity. But the three primary products, gasoline, middle distillates—including diesel fuel and heating oil—and residual fuel oil, make up the bulk of world oil traded, $\approx$75%. Each of these serves somewhat different markets, given their chemical nature and the competition they face.

Gasoline is used almost exclusively in transportation. Its volatility makes it explosive and unusable in many applications and its high price makes it less competitive with other fuels, such as coal and natural gas. Thus, it is rarely used in stationary applications, such as boiler fuel or to operate backup power generators, as diesel is. Because of its use in internal combustion engines, it is necessary for gasoline to remain very clean and uncontaminated and as a result it can be moved only in specialized vehicles, which means that bulk transport is somewhat expensive. Some gasoline moves internationally, but at volumes that are much smaller than those for crude oil.

Middle distillates play a dual role because of their nature. They are less volatile than gasoline and thus they can be used in diesel engines, which rely on high compression to ignite the fuel rather than a spark plug. But also, they can be used in small boilers, especially as a heating fuel for households. Typically, higher sulfur middle distillates are used as heating fuel, a practice that will increase as more advanced engines require lower and lower sulfur fuels.

Residual fuel oils, which are the heaviest of the major products, are named after their original origin, that is, the part of the crude that is left in the barrel after the higher value products have been refined. These fuels tend to be thicker, are harder to handle, and thus are not used by individual consumers but instead are used in factories, power plants, and large vessels, in which case they are referred to as bunker fuels. It is also the case that many of the contaminants in the original crude oil are left behind in the residual fuel oil, so that they are the least wanted of the fuels, although additional processing can improve their value by upgrading a portion to light fuels, or removing pollutants.

Prices for the different fuels are determined in large part by their competition, where gasoline faces virtually no competition in the transportation sector, automobiles being unable to switch fuels. And although diesel engines cannot readily switch fuels, some users are capable of switching, such as utilities running diesel-fired turbines. Some turbines can be switched to natural gas, should it be cheaper, but most utilities also have the option of running different power plants depending on relative cost, in which case a diesel turbine might even be competing with coal plants. Residual fuel oil, or resid, competes directly with natural gas, as many boilers are capable of using either fuel, as well as coal, typically the cheapest fuel available for power plants.

However, the use of both residual fuel oil and middle distillates is somewhat limited in the United States, as many power plants face pollution regulations that make it difficult for them to reduce usage of natural gas in favor of those fuels, which tend to give off higher levels of sulfur and other contaminants. Even so, in recent years the United States has seen as much as a half million barrels a day increase in the usage of middle distillates and residual fuel oil when natural gas prices were high.

Other major petroleum products include jet fuel, which is obviously used primarily in the airline industry and as such is very sensitive to the economic situation rather than prices of competing fuels. Liquefied petroleum gas (LPG) is another fuel used in many parts of the world for heating and cooking, especially when there is no distribution network for natural gas. Rural areas rely on this quite a bit in developed nations and less developed nations often use it even in urban areas as a convenient source of fuel for households.

Petroleum products are not completely interchangeable by any means but there is a degree of flexibility at the refinery level. By use of catalysts, cracking, blending, and other processes, refiners have the ability to alter their product streams, thereby accommodating changes in the market somewhat. For example, U.S. gasoline production increases during the summer and the production of heating oil rises in the fall and winter.

Similarly, some products can be altered when markets dictate. A variety of products can be used in petrochemical plants, including natural gas, LPG, and naphtha (which is an ingredient of gasoline), and refiners can moderate the amount of jet fuel or middle distillate they produce when conditions warrant.

1.8.1 Product Quality

The past decade has seen a major change in the impact of the environmental regulations on product formulas, especially for gasoline and diesel fuel. Historically, there have been tight regulations on the sulfur content of residual fuel oil in some parts of the industrialized world since the early 1970s, and lead in gasoline was phased out in the United States beginning at that time. These measures were in response to local pollution and had a relatively small impact on oil product trade inasmuch as low-sulfur crudes produced residual fuel oil with a low sulfur content, so that it was regularly available. As demand for low-sulfur crude began to outstrip availability, desulfurization units had to be installed at refineries. On the other hand, lead was an additive in gasoline

rather than an inherent part of the product and could be replaced with other octane enhancers.

However, regulations have become both stricter and more widespread in the past decade, covering many parts of Europe and increasingly the less developed countries, requiring both lower sulfur content and also specific formulas for gasoline and diesel fuel. In the United States, there are numerous formulas for gasoline depending on the location and season, that is to say, the particular environmental problem being addressed. Factors such as benzene content, Reid vapor pressure, and sulfur content face more rigorous regulations.

This has required refiners to make two types of changes. First, they must reduce the amount of sulfur in the products been produced, but in many cases, additives are required to enable them to meet both octane needs and specific formula requirements. Also, one of the most popular additives, methyl tertiary butyl ether, is being banned in many places as a water pollutant, requiring refiners to search for other additives, such as ethanol, to replace it, although it is more expensive and difficult to handle.

Aside from requiring substantial investments in upgrading capacity, the effect has been to segregate markets in many places, as some products are not clean enough to sell legally in some markets. Most Third World refineries are not capable of producing the kinds of products needed in some parts of the industrialized world and, depending on the specific product requirements, product trade cannot take place even within a country at certain times of the year.

As a result, there have been a number of localized problems with product supply, as any difficulties at the refinery level in an area cannot be offset by nearby supplies because they do not meet the specific environmental regulations in that location. California is in the worst situation because of the severe air pollution problems and the lack of connections to other markets—products must be shipped in via the Panama Canal or across the Pacific Ocean, if they can meet the environment rules. The problem overall has been exacerbated by the rise in capacity utilization in the downstream industry (Fig. 7), which has reduced the amount of capacity available to meet unexpected supply problems.

2. *NATURAL GAS*

Natural gas is unusual, a premium fuel with high value to customers but low prices at the wellhead. Because of its very low density, transportation costs are extremely high. The result is that natural gas markets developed much later than those for other fuels and regional markets remain relatively isolated from one another, although that is slowly changing.

Before the development of welding technologies that allowed high-pressure steel pipelines to be constructed, global natural gas markets consisted primarily of synthetic natural gas manufactured from coal, called town gas, and the exploitation of local deposits particularly for industrial purposes. Synthetic gas had a relatively low energy content and

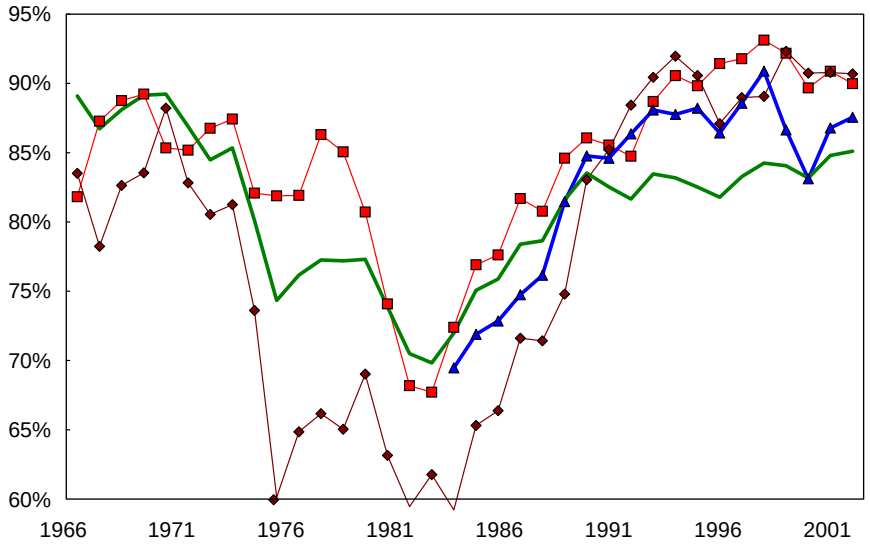

FIGURE 7 Refinery capacity utilization by region. Boxes, United States; diamonds, Europe; triangles, Asia/Australia/New Zealand; boldface line, world. From BP Statistical Review of World Energy Industry.

produced a large amount of waste products. It was used mainly in lighting in urban areas during the 19th century and began to be replaced by electricity in the early 20th century.

The early downstream petroleum industry—refining and petrochemicals—often relied on natural gas deposits as a source of cheap energy. Since long-distance transportation was impossible until the postwar era, most gas could be sold only locally and the lack of demand kept prices very low. Given this fact, it was usually not sought after intentionally, but found by those seeking oil, and often gas discoveries were abandoned unless there was a nearby facility that could use it. Some industrial centers developed specifically to take advantage of existing natural gas deposits that had no market, including the chemical industry in West Virginia and later Texas.

The U.S. natural gas market began to develop after World War II with the construction of numerous long-distance pipelines to bring the gas to consumers. European markets developed later, especially after the 1962 discovery of the supergiant Groningen field in the Netherlands, a low Btu gas that was extremely cheap to produce. Asian markets did not begin to develop until the 1970s, as high oil prices made liquefied natural gas (LNG) trade economically feasible, with the prices for gas and/or services set on a cost-plus basis. Fig. 8 shows the trade flows in 2002.

2.1 U.S. Gas Markets

The United States was the first to develop a large, well-articulated natural gas market because of the ready abundance of large amounts of gas resources and the early development of long-distance pipelines. The construction of oil pipelines from the Gulf of Mexico to the East Coast during World War II was a boon to the industry, as the two major pipelines were converted to natural gas after the war. But the ownership of large amounts of gas reserves by major oil companies and the nature of gas distribution as a natural monopoly raised concerns about possible abuse by reserve owners. In response, the U.S. government insisted that long-distance gas pipelines be owned by independent companies and that they be treated as regulated monopolies.

As a result, the U.S. gas market consisted of producers particularly in the Southwest who sold their production to pipeline companies that delivered and resold the gas to local distribution companies in the consuming areas. Since wellhead natural gas prices for the interstate market were regulated after 1954, this meant that the production, transportation, and distribution of natural gas were regulated by a combination of the federal and state governments.

However, since wellhead prices were allowed to rise only in response to inflation, the oil price boom of the 1970s made natural gas very competitive with oil in many areas and resulted in rising demand. At the same time, low prices discouraged drilling and supplies began to become scarce. The Natural Gas Policy Act of 1978 deregulated prices of some supplies and some pipeline companies signed grievously high-priced contracts for them, planning to roll the expensive gas in with their cheap, price-controlled gas. This proved disastrous, as weak demand meant that pipelines cut back on cheap gas in favor of high-

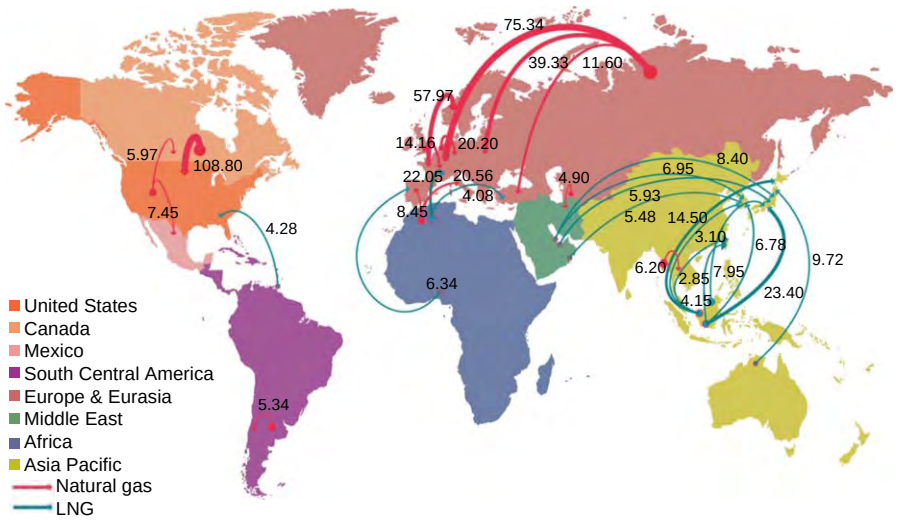

FIGURE 8 International trade flows of natural gas. From BP Statistical Review of World Energy Industry.

priced gas, for which they had guaranteed the volumes they would lift ("take-or-pay" clauses). The government deregulated all wellhead prices as a result, and the average price fell (Fig. 9).

By the 1980s, the long-distance pipeline business had also grown to the point where there were few areas that did not have multiple sources of supply, making it much more difficult to monopolize supply in an area. This led to the deregulation of the pipeline business and caused it to turn into a common carrier, rather than buyers and sellers of natural gas. It also led to the rise of natural gas traders, who located buyers and sellers of gas and then procured the necessary pipeline capacity to provide delivery.

At this point, the U.S. gas market split into the competitive, large end-user sector made up of power plants and other industrial facilities and the captive residential market, which remained regulated. The former could bid for natural gas on the open market and, having the option of switching to cheap residual fuel oil, could see its prices capped by that competing fuel. But residential users remained captive to the local distribution companies, having to pay their capital cost plus the cost of fuel.

The past few years have seen a sudden departure from the previous two decades of relatively low and stable prices, as rising demand for gas in the power sector and poor upstream performance combined with cold weather to yield extraordinarily high prices. Most analysts think that U.S. gas prices will remain well above those observed in the 1990s, but the ultimate outcome is unclear.

2.2 Canada and Mexico

The Canadian market resembles the U.S. gas market in some respects, including the presence of many gas-producing companies and the need to transport gas long distances to the major consuming areas. These include the major cities of eastern Canada, served by TransCanada Pipeline (TCPL), as well as the exports to the U.S. Midwest and Northeast, where Canada is a major source of supply.

Historically, TCPL was a regulated monopoly with partial government ownership that used its systemwide revenues to expand its pipeline further eastward, including projects that might not have been economical on their own. The province of Alberta contains the bulk of Canadian gas resources and production is gathered into a number of large pipelines and then sent south and east. There is also a major chemical industry in Alberta, which acts as a primary consumer, and the booming tar sands fields, which require heat to produce their heavy oil.

In Mexico, natural gas is produced and shipped by Pemex, the government's national oil company. Most of the gas is associated gas that is found with oil fields and only recently has Pemex been seeking to find and develop gas fields. The gas is primarily used to displace residual fuel oil in industrial and utility

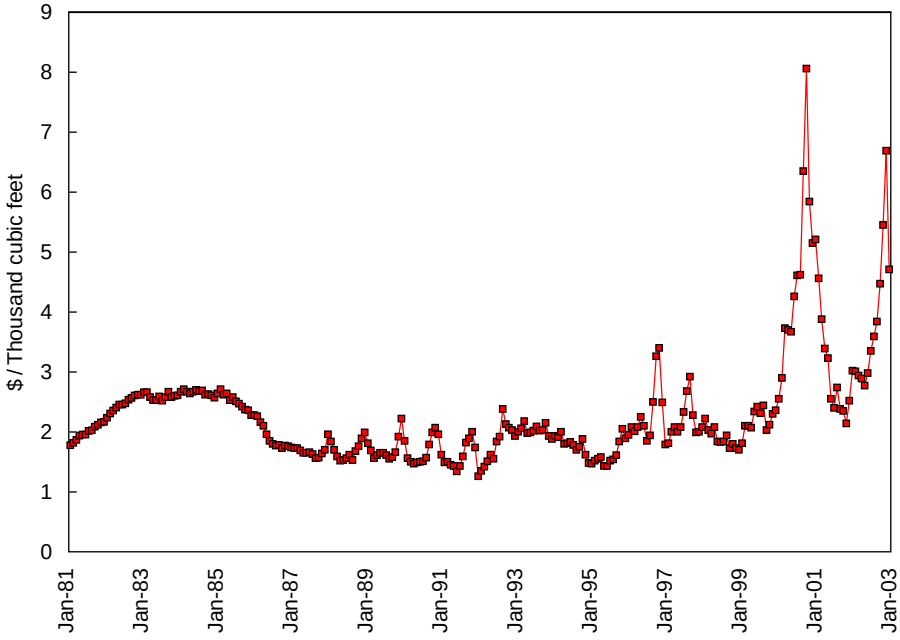

FIGURE 9 U.S. average wellhead natural price. From Monthly Energy Review, U.S. Department of Energy.

uses, which rely heavily on it. (The government monopoly on oil and gas has had the perverse effect of raising oil consumption by causing underinvestment in natural gas.)

2.3 European Gas Markets

In 1959, the discovery of the supergiant Groningen field in the Netherlands led to the beginning of the modern gas era in Western Europe. Before that time, countries such as Germany, France, and Italy had minor amounts of domestic gas production and many cities had town gas facilities. The Dutch began the large-scale international trade of natural gas in Europe and encouraged the building of national pipeline systems, by initially offering their gas at prices designed to be competitive with coal, which was the main competing fuel at the time. Their strategy was to build markets and encourage customers to make the necessary expenditures to put in the infrastructure needed for their gas to be exploited.

With the 1970s, Norwegian gas discoveries began to be marketed into Western Europe and the development of liquefied natural gas shipping also brought supplies from Algeria and Libya to the Continent. The Russians, who have the largest natural gas reserves in the world, developed long-distance pipelines from Siberia into Western Europe in order to gain hard currency. With the oil price shocks of the 1970s, these suppliers became more aggressive in seeking higher gas prices, with the Algerians going so far as to demand prices above those for crude oil, arguing that natural gas was a superior fuel. Many of these price demands did not stick, although exporters succeeded in raising prices to approximately those of crude oil equivalence, as Fig. 10 indicates.

The European gas market remains dominated by a few suppliers on one side and a few consumers on the other. In France, the buyer is Gaz de France, which delivers and resells to other customers. In Germany, Ruhrgas continues to control most of the national pipeline system, and in Italy, Snam is the main pipeline company. The heavy investment needed for the development of the gas infrastructure encouraged governments to maintain state-owned monopolies to run their gas pipeline systems and these companies have been particularly willing to accept long-term contracts with the suppliers paying prices indexed to oil prices. The European Union has been trying for some years to open up the closed markets.

The British market is somewhat unique, in that it was separated from the Continental gas market until recently, and it produced most of its own supplies in the North Sea for the past several decades. Initially, British Gas served as a monopsony buyer, purchasing gas produced by oil companies in the North Sea at fixed prices and transferring it through its pipeline system to companies and residential users. For a time, extremely low prices were paid to domestic gas

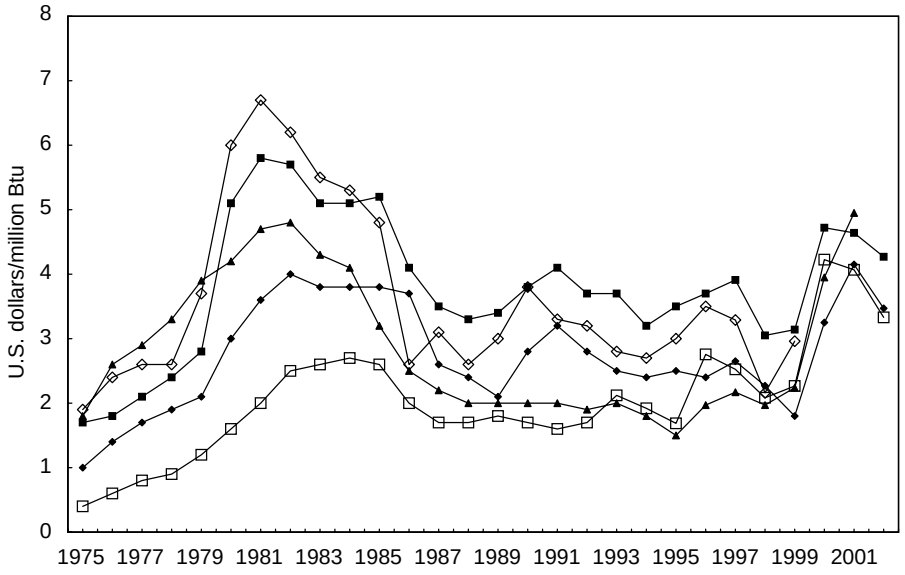

FIGURE 10 World gas and oil prices, $/million Btu (nominal). Closed squares, Japan LNG; diamonds, Western Europe gas imports; triangles, U.S. gas imports; open squares, U.S. wellhead gas; open diamonds, crude oil CIF. From BP Statistical Review of World Energy Industry and Monthly Energy Review, U.S. Department of Energy.

producers, which discouraged drilling and led to British Gas importing gas from Norway at much higher prices. The Thatcher government discontinued that practice, privatizing British Gas and allowing producers to sell their gas freely.

Norway has become a primary exporter to the European Continent, with a very mixed heritage. Although most of its natural gas has been discovered and produced by private companies, the nation relies on a national oil company, Statoil, as a primary participant and operator in many fields and used the Gas Fuel Committee to act as a monopoly marketer of its gas until recently. This reflected partly a desire to gain oligopoly rents for its gas by not having different producers bid the export price down to competitive levels and partly the fact that much of its gas exports went to areas that were dominated by monopsony buyers, particularly in France and Germany.

Norwegian sales did not begin until the 1970s, when the oil crises created a buyers' market for non-OPEC energy supplies. Thus, the Norwegians were able to achieve premium prices for their gas, selling the gas reserves in given fields and gearing their development plans according to the contracts they signed. However, after selling the gas from the supergiant Statfjord field at a significant premium in 1981, they found substantial buyer resistance in the weakening market, worsening as the price of oil collapsed in 1986. This led to a reversal of policy and an effort to price at competitive levels in order to lock in buyers.

The natural gas market is growing strongly, particularly in southern Europe, and new LNG trade is being arranged from West Africa and potentially the Middle East. At the same time, new pipelines from North Africa and Russia are being built and the Caspian producers are attempting to place their reserves into the lucrative European market.

2.4 Russian Gas

Russia contains the largest natural gas reserves in the world and is the world's largest producer and exporter. Natural gas provides the country with approximately one-fifth of its foreign currency earnings and accounts for a similar proportion of the federal government's budget. The domestic and export markets are dominated by the company Gazprom, a privatized firm that is little changed from the Soviet days (including continued partial government ownership). Gazprom produces approximately 80% of the gas in Russia and the relatively new marketing firm Itera accounts for most of the rest, with a small amount produced from oil deposits by the various oil companies. Itera also buys gas from Caspian producers and resells it to other customers, principally the Ukraine.

Gazprom continues to be the primary exporter to the West, accounting for nearly all sales outside the country, including to most of the former Soviet Bloc nations as well as the daughter republics of the Soviet Union. Sales are essentially carried out on a monopoly basis, primarily to large buyers such as Gaz de France and Ruhrgas, typically on a long-term basis with prices fixed relative to petroleum prices, usually on a moving average basis.

Domestic gas sales are a different matter, where many areas have their own local distribution companies and buy gas from either Gazprom or Itera. However, difficulties in obtaining payments from many customers have meant that many local companies have gone bankrupt and some of them have been bought out by Gazprom. The domestic price remains fixed at a fraction of the international price, although the government hopes to raise that over time. As of 2003, it is approximately 20% of the European Border price, although residential customers pay a flat monthly fee, with no metering of consumption.

Russia also holds huge reserves in the Far East, particularly in the Yakut area and near Lake Baikal, where British Petroleum holds a major interest in the supergiant Kovytka field. Hopes are that exports will be begin soon to China and other Far Eastern countries, which would require the construction of large-scale, long-distance pipelines. The primary delay relates to questions of pricing and ownership of the pipelines, although most of the major players appear to be very interested in beginning such trade, as it would have the effect of reducing coal consumption in China—a major source of pollution both locally and regionally—and reducing reliance on Middle Eastern oil imports in Korea and Japan.

2.5 Asian Gas Markets

The Asian gas market has been one of the last to develop, primarily because most gas supplies are at a great distance from the major consuming areas. Aside from minor amounts of consumption in countries such as India and Pakistan, which have exploited small domestic deposits for some time, the primary consumption of natural gas has been in the form of LNG, transported across oceans. Unlike North America and Europe, much of the gas has

been consumed by the electric utility sector rather than by households.

The LNG trade began in the 1970s when Japanese utilities, looking to reduce their emissions resulting from direct consumption of crude oil, began to arrange for small quantities of LNG to be shipped from Alaska, Brunei, and other areas. Initial prices were relatively low to be competitive with crude oil prices. As crude oil prices soared in the 1970s, and many LNG exporters became more aggressive in seeking higher prices, the Japanese buyers agreed to pay prices equivalent to delivered crude oil prices in Japan. This practice has remained for some time and still dominates the trade in Asia.

Because of the greater expense of transporting natural gas in the liquefied form, the market has been much slower to develop than pipeline markets in North America and Europe. Natural gas's market share has grown slowly in Asia but remains far behind that of other regions and still does not penetrate the residential market significantly. In part, this reflects warmer climates in some areas, but it also reflects the expense of building residential distribution systems. Large consumers, such as power companies, require minimal investment in pipelines, which makes them ideal customers for a new regasification terminal, as it maximizes consumption relative to initial outlays.

However, the fact that price is not set by the market (i.e., long-run marginal costs) but rather by the price of crude oil has left prices for LNG usually well above costs and made the business fairly attractive. As a result, there are a number of projects unable to find customers. In many markets, this would mean downward pressure on prices, but such has been slow to develop in Asia for two reasons. First, many of the sellers already have large volumes committed at the higher prices and they do not wish to sacrifice the revenues from existing sales, since these customers would almost certainly demand lower prices for their contracts. Additionally, the high price of transportation means that supplies from more distant regions are not particularly competitive.

The Asian gas market is slowly changing due to a combination of falling liquefaction costs and a slowly developing gas pipeline system in the region. The construction of pipelines from Russia to Japan, China, and Korea would change the marketing of natural gas. Also, the slow growth of domestic gas usage in India, Pakistan, and Indonesia as well as development of pipeline connections in Southeast Asia mean that LNG is no longer as dominant as it once was.

2.6 Other Markets

Gas consumption is sparse in other parts of the world, but some usage occurs in areas with large resources, such as the Middle East, as the cheap gas attracts energy-intensive industry, and in areas where there is some gas and at least a local market, as in parts of Africa and Latin America. Nigeria has large amounts of associated gas and in addition to exporting LNG, it is trying to develop a local pipeline network, as are other countries with nonassociated gas, such as Bolivia and Tanzania. Power plants dominate the customer list, but this should change as the systems mature.

2.7 LNG Contracting

The LNG business is somewhat unusual, in that it involves a basic commodity that is traded almost exclusively on long-term contracts. The particularly high capital costs necessary for building liquefaction plants, combined with the small number of importers with the necessary facilities for unloading LNG, have made producers very sensitive to demand-side risk. In most cases, they have not begun construction until they have located enough gas reserves to supply their plant for its lifetime and sold nearly all of its planned production on fixed contracts.

Typically, plants would line up contracts to sell 80 to 100% of their output before beginning construction and most of those contracts would have very strict take-or-pay clauses, requiring that buyers accept most or all of their contract amounts on a regular basis. Buyers were usually not allowed to resell any of their gas either, which tended to make them hesitant to be aggressive in signing up new volumes.

Because most LNG, especially in Asia, was sold into markets without directly competing fuels, there was no real market price for the natural gas. As a result, nearly all contracts called for prices to be set equivalent to the crude oil price level, converted on a Btu basis. This has reduced the price risk, at least to some degree since crude oil prices are also volatile and uncertain, but it has generally meant that prices are adequate to provide sufficient if not quite hefty profits to the producers and the exporting governments.

However, this has also meant that market penetration has been constrained by the combination of strict contracts and high prices. The high storage costs for LNG meant that buyers did not wish to hold large inventories and thus have been reluctant to sign up for volumes that might not be used in a short period of time, reducing sales on a spot basis or

for seasonal purposes. Also, where the gas competes in the industrial sector with fuel oil, usually sold at a discount to crude oil, it finds itself unable to gain a large market share.

Glossary

Otto Neurath (1882–1945) A famous logical empiricist philosopher of the Vienna Circle, he was also an economist or economic historian, and a Marxist. Neurath introduced the idea of incommensurable values in the economy, a concept now embraced by some ecological economists.

Sergei Andreyevich Podolinsky (1850–1891) A Ukrainian physician, economist, public and political figure, and a contemporary of Karl Marx and Fredrick Engels, who performed early detailed studies of energy flows in agriculture.

social metabolism An idea adopted by Karl Marx and others in the 19th century that nature and society were linked by material floes. Marx largely ignored energy flows, while others embraced them as a key concept.

Marx (1818–1883) and Engels (1820–1895) were contemporaries of the physicists and physiologists who established the first and second laws of thermodynamics in the 1840s and early 1850s (J. R. Mayer, 1814–1878, J. P. Joule, 1818–1889, R. Clausius, 1822–1888, W. Thomson, later Lord Kelvin, 1824–1907). Marx and Engels followed with a few years' delay many of the remarkable scientific and technical novelties of their time including the developments in thermodynamics or energetics. Engels wrote in 1888 that the nineteenth century would be remembered as the century of Darwin, Mayer, Joule, and Clausius. It had been not only the century of the theory of evolution but also of the theory of the transformation of energy. However, Marx and Engels never expressed or translated their analytical concepts (productive forces, surplus value, exploitation) into the language of energy as they could have done in their mature work after the 1850s. They never said that the productivity of labor in agriculture and in industry would depend on the energy subsidy to the economic process. After all, they were historians and economists, not yet environmental historians, ecological economists, or industrial ecologists. Increases in productivity depended on the development of the productive forces (*Produktivkr…fte*), where "Kraft" (force) was not used with the physical meaning of energy. The productive forces could be furthered or could be fettered by the social relations of production. Capitalism had meant an enormous development of the productive forces but it provoked economic crises by its very nature—that is, the exploitation of wage labor. Malthusian crises of subsistances were not relevant. These were essentials points of their theory.

1. SOCIAL METABOLISM

The first volume of *Capital* was published in 1867. There were certainly precursors of a biophysical approach to the economy from the 1880s onward, and at least one of them was close to Marxism (such as S. A. Podolinsky, 1850–1891). These proto-ecological economists did not form a school. In the 1970s, the study of the human society and economy from a physical point of view (flows of materials and energy) started to be practiced by coherent research groups with little relation to Marxism. Histories of the use of energy in the economy are not connected to Marxism (even if their authors might sometimes have Marxist pasts). The notion of energy return on

energy input (EROI) was applied in the 1970s to the economy by Charles Hall and other ecologists with no relations to Marxism. Explanations of economic growth model the use of energy in the economy (or rather physical work output as distinguished from energy [exergy]). They criticize neoclassical production functions and growth theories but draw no inspiration from Marxism.

Marx and Engels had a profound interest in the interactions between the human economy and the natural environment, particularly as regards capitalist agriculture. This was expressed in Marx's use in his own drafts after 1857–1858 and in *Capital,* of the notion of metabolism between humans and nature. Marxist use of "metabolism" (by Marx himself, also by Bukharin) is well known. Alfred Schmidt was the first author to insist in the role of the concept of *Stoffwechsel* in Marx's work on the development of capitalism, noting Moleschott's and Liebig's influence, noting also its substantive use for the cycling of plant nutrients. Marx became so keen on the concept of metabolism that in a letter to his wife, he nicely wrote that what made him feel like a man was his love for her, and not his love for Moleschott's metabolism or for the proletariat. There is a rediscovery of Marx's social metabolism. Authors working on industrial metabolism or in social metabolism look at the economy in terms of flows of energy and materials. They insist that the economy should be seen as a subsystem embedded in a larger physical system. Is this perspective to be found in Marx already?

Marx and Engels were one generation younger than the agricultural chemists who published from 1840 onward their researches on the cycles of plant nutrients (phosphorous, nitrogen, potassium), influenced by the debates on the threat of decreasing agricultural yields and the wholesale imports of guano, mainly from Peru, which became an essential bulk commodity for agricultural production. About 11 million tons of guano were exported from Peru in four decades. The analyses of the composition of imported guano, and also of other manures and fertilizers (bones, for instance) already well known to farmers, laid the foundations for agricultural chemistry. Liebig's name was associated, by his own wish, to a new future leading sector of the economy, the fertilizer industry. It may also be associated to an ecological vision. He is recognized as one of the founders of ecology, before the name itself was invented. Politically he developed an argument against latifundist agriculture and agricultural exports because the plant nutrients would not return to the soil. He was in favor of small-scale agriculture and dispersed settlements. Marx quoted this opinion very favorably on several occasions.

Before proceeding further, it must be emphasized that Marx and Engels were also contemporaries of the physiologist Jacob Moleschott (1822–1893). To the present day, Marxists call him a "vulgar materialist" (meaning a reductionist materialist, in opposition to historical materialists who favor dialectics and coevolution). However "vulgar," Moleshott was a main figure in the introduction of the concept of metabolism in physiology and in what now is called ecology. Moleshott had been dismissed after 1848 from Heidelberg, he taught in Zurich and in Rome, he became a well-known professor and editor of a scientific journal, and he had been an activist. Materialism was used against the doctrine of vitalism and against religion. His book on the theory of human nutrition of 1850 had the subtitle *Ffr das Volk*. This was certainly different in intent from the studies by other authors on how to feed cheaply and efficiently soldiers, industrial workers or slaves (in America). In 1851 he published *Physiology of Metabolism in Plants and Animals*, one year later, *Der Kreislauf des Lebens* (The Cycle, Circuit or Circle of Life). Engels, in a letter to Piotr Lavrov of 1875 discussing Darwinism, summarized the idea of the "cycle of life" in "the fact that the vegetable kingdom supplied oxygen and nutriment to the animal kingdom and conversely the animal kingdom supplied plants with carbonic acid and manure." This had been interpreted as cooperation in nature by that trinity of "vulgar materialists" (Vogt, B*f*chner, and Moleschott, who, incidentally, now were talking loudly about "struggle for existence") and had been stressed by Liebig.

Indeed, Marx's use of *Stoffwechsel* (metabolism) in *Capital* (vol. I) and, before that, in some drafts of the late 1850s was influenced by Liebig, probably by other authors, and certainly by Moleshott. Marx used "metabolism" in two senses. First, as a biological analogy or metaphor to describe the circulation of commodities. Second, more relevantly for the present article, he used the expression "metabolism between man and earth, or between society and nature" to refer specifically to the cycles of plant nutrients, quoting, and praising Liebig. Such metabolism was broken by an agriculture of spoliation.

Marx found Liebig supremely relevant because he talked on the natural conditions of agricultural fertility and on the possibility of development of the productive forces by the fertilizer industry. This was useful for the polemics against Malthus and for

the theory of land rent. Foster has analyzed in depth Marx's debt to Liebig, and he has wrongly dismissed Moleshott's influence on Marx's use of "metabolism." Foster does not quote Moleshott's books of 1851 and 1852 on the "circle of life" and on the physiology of metabolism in plants and animals.

In conclusion, Marx was a historian and an economist, he was also a student of agriculture and he read on agricultural chemistry and adopted the notion of "metabolism" between man and nature. The material flows between humans and nature were mobilized by human labor, except perhaps in very primitive societies that lived from gathering. The development of tools by humans was essential for the metabolism. Marx did not include the metabolic flow of energy in agriculture and in industry in his analysis, so he could not trace a fundamental distinction (as Lotka was to do 40 years later) between the use of energy in nutrition (endosomatic) and the use of energy by tools (exosomatic). This difference between biometabolism and technometabolism is crucial for the understanding of human ecology. We as a species have genetic instructions regarding our use of endosomatic energy but not our use of exosomatic energy, which must be explained by history, politics, economics, culture, and technology. This is not to be found in Marx. Not only he left energy flow aside, he did not count material flows in detail or even roughly, he was not a protoindustrial ecologist. But on the positive side, he did not see the economy as a closed system, or nature as an immutable purveyor of free gifts, as the neoclassical economists were to do.

Humans were part of nature, humans used nature's materials, we could increase its produce by the development of the so-called productive forces but we could also undermine the natural conditions of production. This was the case with capitalist agriculture. Marx wrote:

> *Capitalist production disturbs the metabolic interaction between man and the earth, i.e. it prevents the return to the soil of its constituent elements consumed by man in the form of food and clothing, hence it hinders the operation of the eternal natural conditions for the lasting fertility of the soil… Moreover, all progress in capitalist agriculture is a progress in the art, not only of robbing the workers, but of robbing the soil. (Capital, I)*

He added that the separation of town and country, caused by latifundist agriculture and by the concentration of sources of energy in cities, provokes an "irreparable rift" in the process of social metabolism. The result of this was a squandering of the soil, aggravated by trade, undermining the conditions of agricultural production. Engels wrote, "As the individual capitalists are engaged in production and exchange for the sake of the immediate profit, only the nearest, most immediate results must first be taken into account." In modern-day parlance, Engels was saying that individual capitalists discounted the future and did not include externalities in their accounts. He continued:

> *As long as the individual manufacturer or merchant sells a manufactured or purchased commodity with the usual coveted profit, he is satisfied and does not concern himself with what afterward becomes of the commodity and its purchasers. The same thing applies to the natural effects of the same actions. What cared the Spanish planters in Cuba, who burned down forests on the slopes of the mountains and obtained from the ashes sufficient fertilizer for one generation of very profitable coffee tress—what cared they that the heavy tropical rainfall afterward washed away the unprotected upper stratum of the soil, leaving only the bare rock! (Dialectics of Nature)*

Such quotations, which could be multiplied, should not be seen as anecdotal, they arose, as Foster has shown, from a theory of "metabolic rift." So Marx was "greener" than usually thought. However, what Greens can learn in Marx is not new to them, the knowledge of the cycles of plant nutrients and the damage to soil and forests.

"Metabolic rift" is not equivalent to "decreasing returns." Marx wrote to Engels on February 13, 1866, saying that Liebig's agricultural chemistry was more important for the discussion on decreasing returns than all the economists put together. Marx dismissed the notion of decreasing returns in agriculture, pointing out in the context of his praise for Liebig's agricultural chemistry and its promise of artificial fertilizers, that it did not make sense to assume in Britain that the produce of the land would increase in a diminishing ratio to the increase of the laborers employed, because in practice there was at the time both an increase in production and an absolute decrease (already) in the number of laborers. Marx was not worried about crisis of subsistances. Marxists attacked Malthus, which could be expected because Malthus had made the point that improving the situation of the poor was counterproductive because they would have more children. There were many debates on how many people could the earth feed around 1900. Some Marxists not only attacked Malthus, they also attacked the Neomalthusians of the late 19th century and early 20th century who were often political radicals and feminists (Paul Robin, Emma Goldman).

2. PODOLINSKY'S AGRICULTURAL ENERGETICS

The link between material metabolism (*Stoffwechsel*, literally exchanges of materials) and the flow of energy at the level of cells and organisms was made in the 1840s. It was then also understood that agriculture might be represented in terms of changes in the flow of energy and not only as an intervention in the cycling of plants nutrients (in 1845, Mayer used *Stoffwechsel* for energy flow). Metabolism was therefore used no only for materials, also for energy. Of course, materials could be cycled, energy could not. The theory of the direction of the flow of energy was developed after 1850 and the establishment of the second law.

Marx and Engels were interested in energy. For instance, Engels wrote to Marx on July 14, 1858, commenting on Joule's work on the conservation of energy (of 1840) as something of well known to them. Marx was of course interested in new sources of energy. One example will suffice: it was already discussed at the time whether hydrogen could be a net source of energy, depending on the energy requirement for electrolysis. Marx wrote to Engels on April 2, 1866, that a certain M. Rebour had found the means of separating the oxygen from hydrogen in water for very little expense. However, Marx did not refer to the flow of energy as a part of metabolism throughout his lifetime.

At a more general level, one interesting point arises from Engels's unwillingness to understand how the first and second laws could apply at the same time: the "dialectics of Nature" failed him there. As Engels became aware of Clausius's concept of entropy, he wrote to Marx on March 21, 1869:

> *In Germany the conversion of the natural forces, for instance, heat into mechanical energy, etc. has given rise to a very absurd theory—that the world is becoming steadily colder... and that, in the end, a moment will come when all life will be impossible... I am simply waiting for the moment when the clerics seize upon this theory.*

Indeed, not only the clerics but also W. Thomson (Lord Kelvin) brandished the second law in his religious tirades about the "heat death," although he had and could have no inkling of the source of energy in the sun in nuclear fusion. One understand Engels's dislike for the uses to which the second law was put. Josef Popper-Lynkeus (1838–1921), who with Ernst Mach became one of the sources of inspiration for the analytical, antimetaphysical philosophy of the Vienna Circle, complained since 1876 about W. Thomson's theological handling of Carnot's law. However, Engels's dislike of the second law was not only motivated only by its religious use, or abuse. He believed that ways would be found to reuse the heat irradiated into space.

Another interesting point is the reaction by Engels in 1882 (in letters to Marx) regarding Podolinsky's work on energy flows in agriculture. Podolinsky had studied, we might say, the entropy law and the economic process, and he tried unsuccessfully to convince Marx that this could be brought into the Marxist analysis. Podolinsky's work has been seen as a first effort to develop ecological economics. Politically he was not a Marxist, he was a Ukrainian federalist narodnik. He had criticized Marx's overpowering behavior at the congress of the International of 1872, praising the anarchist James Guillaume. However, Podolinsky himself saw his work on the energetics of agriculture as a contribution to Marxist theory, and he would not have objected to appear under "Marxism and Energy" in an encyclopedia. Writing to Marx on April 8,1880, he said, "With particular impatience I wait for your opinion on my attempt to bring surplus labor and the current physical theories into harmony."

In his article (published in long versions in Russian in 1880 and in German in 1883, and in short French and Italian versions in 1880 and 1881), Podolinsky started by explaining the laws of energetics, quoting from Clausius that although the energy of the universe was a constant, there was a tendency toward the dissipation of energy or, in Clausius's terminology, there was a tendency for entropy to reach a maximum. Podolinsky did not discuss explicitly the difference in thermodynamics between open, closed and isolated systems, although he stated explicitly, as the starting point of his analysis, that at the present time the earth was receiving enormous quantities of energy from the sun, and would do so for a very long time. All physical and biological phenomena were expressions of the transformations of energy. He did not enter into the controversies regarding the creation of the universe and its "heat-death," nor did he discuss the relations between thermodynamics and the theory of evolution. In March 1880 he published an article against social Darwinism. He certainly realized that the availability of energy was a crucial consideration for the increase (or decrease) of population. However, he thought that the distribution of production was explained by the relations between social classes: "in the countries where capitalism triumphs, a great part of work goes towards the production of luxury goods, that is to say, towards a

gratuitous dissipation of energy instead of towards increasing the availability of energy."

He explained that plants assimilated energy, and animals fed on plants and degraded energy. This formed the *Kreislauf des Lebens*:

> *We have in front of us two parallel processes which together form the so-called circle of life. Plants have the property of accumulating solar energy, but the animals, when they feed on vegetable substances, transform a part of this saved energy and dissipate this energy into space. If the quantity of energy accumulated by plants is greater than that dispersed by animals, then stocks of energy appear, for instance in the period when mineral coal was formed, during which vegetable life was preponderant over animal life. If, on the contrary, animal life were preponderant, the provision of energy would be quickly dispersed and animal life would have to go back to the limits determined by vegetable wealth. So a certain equilibrium would have to be built between the accumulation and the dissipation of energy.*

Not only plants, also human labor had the virtue of retarding the dissipation of energy. Human labor achieved this by agriculture, although the work of a tailor, a shoemaker, or a builder would also qualify, in Podolinsky's view, as productive work, since they afford "protection against the dissipation of energy into space." The energy available for humankind came mainly from the sun. Podolinsky gave figures for the solar constant. He explained how coal and oil, wind energy, and water power were transformations of solar energy. He mentioned tides as another possible source of energy. He then started his analysis of the energetics of agriculture, remarking that only a very small proportion of sun energy was assimilated by plants. Human work, and the work of animals directed by humans, were able to increase the availability of energy by agricultural activity. This he showed by comparing the productivity of different types of land use taking statistics from France (he was living at the time in Montpellier). Table I summarizes his data.

TABLE I

Annual Production and Energy Input (Only Work by Humans and Domestic Animals) per Hectare, Averages for France in 1870, According to Podolinsky

System	Production (kg)	Production (kcal) Energy input (kcal)
Forest	900 (dried wood)	2,295,000 Nil
Natural pastures	2,500 (hay)	6,375,000 Nil
Sown pastures	3,100 (hay, excluding seed)	7,905,000 37,450 (50 horse-hours and 80 human-hours)
Wheat	800 (wheat) and 2,000 (straw) (excluding seed)	8,100,000 77,500 (100 horse hours and 200 human-hours)

Podolinsky then compared wheat agriculture and sown pastures and forest, concluding that production was higher when there was an input of human and animal work. Thus, comparing wheat agriculture to natural pastures, each kcal put in contributed to an increase of 22 kcal of production. If forest were taken as the terms of comparison, the energy productivity of human and domestic animals work was even higher. Notice that Podolinsky was counting human and animal work—that is, not the food intake but the work done. He did not include solar radiation in the input of energy, because he was writing as an ecological economist. Solar radiation is indeed a free gift of nature (moreover, without an owner, so that there is no payment of rent).

Energy values of wood, ha,y and straw, 2550 kcal/kg, of wheat 3750 kcal/kg. Hours of work converted into kcal: 645 kcal/hour of horse-work, 65 kcal/hour of human-work.

The conclusion was that work could increase the "accumulation of energy on earth." Although Podolinsky mentioned guano, and although he must been keenly aware of the war then raging for Peruvian or Chilean saltpeter, he did not subtract from the output, or include in the input, the energy contents and cost of fertilizer. Nor did he consider the energy spent for steam engines for threshing. His methodology is nevertheless basically the same as that used later for establishing the energy balance of particular crops, or for small scale societies, or for the entire agricultural sector of particular countries.

Podolinsky then went on to explain the capacity of the human organism to do work. Otherwise "it would be difficult to explain the accumulation of energy on the surface of the earth under the influence of labour." Quoting from Hirn and Helmholtz, he concluded correctly that "man has the capacity to transform one-fifth of the energy gained from food into muscular work," giving to this ratio the name of "economic coefficient," remarking that man was a more efficient transformer of energy than a steam engine. He then used a steam engine metaphor to put across a general theoretical principle on the minimum natural conditions of human existence, from an energy point of view. He wrote that humanity was a "perfect machine" in Sadi Carnot's sense: "Humanity is a machine that not only turns heat and other physical

forces into work, but succeeds also in carrying out the inverse cycle, that is, it turns work into heat and other physical forces which are necessary to satisfy our needs, and, so to speak, with its own work turned into heat is able to heat its own boiler."

Now, for humanity to ensure its elementary conditions of existence, each calorie of human work must then have a productivity of 5 calories. Taking into account that not everybody is able to work (children, old people), and that there other energy needs apart from food energy, the necessary minimum productivity would be more like ten or more. If that minimum is not achieved, then, of course, "scarcity appears and, many times, a reduction of population." Podolinsky then established the basis for a view of the economy in terms of energy social metabolism, looking at the energy return to energy input in a framework of reproduction of the social system. He thought than he had reconciled the Physiocrats with the labor theory of value, although the Physiocrats (in the 18th century) could not have seen the economy in terms of energy flow.

Podolinsky also emphasized the difference between using the flow of solar energy and the stock of energy in coal. The task of labor was to increase the accumulation of solar energy on earth, rather than the simple transformation into work of energy already accumulated on earth, more so since work done with coal was inevitably accompanied by a great dissipation of heat-energy into space. The energy productivity of a coal miner was much larger than that a primitive farmer could obtain, but this energy surplus from coal was transitory, and moreover (Podolinsky added in a footnote) there was a theory that linked climatic changes to concentrations of carbon dioxide in the atmosphere, as Sterry Hunt explained at a meeting of the British Society for the Advancement of Science in the autumn of 1878. Notice here that the emphasis here was not on capital accumulation but on increasing the availability of energy and certainly also its dissipation. Podolinsky was not, however, at all pessimistic about the prospects for the economy, and he was hopeful for the direct use of solar energy for industrial purposes, referring to the "solar engine of M. Mouchot." One could envisage that one day solar energy would be used directly to make chemical syntheses of nutritive substances, by-passing agriculture. Thus, a proper discussion of the demographic question had to take into account "the relations between the general quantity of energy on earth and the quantity of energy who live on it," and this was a more relevant consideration, in his explicit view, than the Malthusian prognosis. He was also hoping (as he had written to Marx on March 30, 1880, sending his work to him) to develop applications of his energy accounts to different forms or modes of production. Marx died in 1883 and apparently never commented on Podolinsky's work, beyond a letter of acknowledgement at the beginning of April 1880. He asked Engels to write a comment, which Engels did not do until December 1882. Podolinsky himself became ill in 1881 or 1882 and never recovered until his death ten years later, back in Kiev.

3. ENGELS'S REACTION TO PODOLINSKY

Engels had some knowledge of the energetics of human physiology, and in a note of 1875 (later included in the *Dialectics of Nature*) he referred to Fick's and Wislicenus's experiment in climbing the Faulhorn in 1865, which became popularized under the name "a day of hunger for science." Fick (1829–1901) had written in 1857 and 1958 on the amount of kilocalories (2700) that a man would need and spend per day, when not working, and how different types of work implied different energy expenditures over that rate. An idea being circulated at the time (for instance, in an article in *Das Ausland* in 1877) was that the economic values of different types of work could be established in physical terms. Engels already explicitly rejected this notion in 1875.

On December 19 and 22, 1882, Engels wrote two letters to Marx (about 1000 words) explaining that Podolinsky had "discovered" the following facts, already well known. If the food intake of one person per day were equal, say, to 10,000 kcal, then the physical work done would be fraction of this energy. This physical work could become economic work if employed in fixing solar energy, for instance through agricultural activity. With a daily food intake of, say, 10,000 kcal, a man will work in agriculture. Podolinsky's discovery was that human labor had the power of detaining solar energy on the earth's surface and permitting its activity longer than would be the case without it. All the economic conclusions he drew from this were wrong. The economic labor, which a person working in agriculture performed by the employment of these 10,000 kcal, consisted in the fixation for a greater or less time of new energy radiated to that person from the sun. Whether, however, the *new* quantity of energy fixated by the application of the original 10,000 kcal of daily nourishment "reaches 5,000, 10,000, 20,000, or 1,000,000 kcal depends solely on the degree of

development attained by the means of production." In agriculture, "the energy value of the auxiliary materials, manures, etc. also enters into the calculation"—a perceptive comment that directly makes one think of the agricultural energy balances of the 1970s, which showed that the energy return to energy input of modern agriculture was on the decline although the economic productivity was increasing. "In industry," wrote Engels, all calculation comes to an end; in most cases the work added to the product (he wrote on December 19, 1892) "can no longer be expressed in kcal." Engels was right that in industrial production, there would be an economic added value although not a net gain of energy—on the contrary, there would be more available energy in the raw materials than in the final product. Actually, also in agriculture the energy in the product does not come from human work but it comes really from photosynthesis, human labor helping and guiding the process. In fact, Engels wrote on December 22, 1982:

> *Storage of energy through work really takes place only in agriculture; in cattle raising the energy accumulated in the plants is simply transferred as a whole to the animals, and one can only speak of a storage of energy in the sense that without cattle-raising, nutritious plants wither uselessly, whereas with it they are utilised. In all branches of industry, on the other hand, energy is only expended…. So that if one chooses one can translate into a physical language [ins Physikalische fbersetzen] the old economic fact that all industrial producers have to live from the products of agriculture, cattle raising, hunting, and fishing—but there is hardly much to be gained from doing so.*

Engels also wrongly wrote that "the energy value of a hammer, a screw or a needle calculated according to the costs of production is an impossible quantity," concluding, "In my opinion it is absolutely impossible to try and express economic relations in physical magnitudes." We are here as far away as possible from the "social metabolic" perspective.

Engels was most unfair when he wrote, "What Podolinsky has entirely forgotten is that man as a worker is not merely a fixer of *present* solar heat but a still greater squanderer of *past* solar heat. The stores of energy, coal, ores, forests, etc. we succeed in squandering you know better than I." Podolinsky had not forgotten this at all. Finally, Engels also wrote, "Podolinsky has strayed away from his very valuable discovery into mistaken paths because he was trying to find in natural science a new proof of the truth of socialism, and has therefore confused physics and economics."

Engels's negative reaction to Podolinsky's work, and Marx's 3-years silence from 1880 to 1883 (when he was still intellectually active, much involved in discussions on Russian peasant communes), may be seen as a missed change for an ecological Marxism. Actually Podolinsky's work is relevant not only in the Marxist context. His work and life has an entity of its own, apart from his encounters with Marx and Engels. He had a short life (he was severely ill the last 10 years of it), but he left a strong trace in Ukrainian federalist politics (as a friend of Drahomanov) and also in the Narodnik movements against the Russian autocracy (as a young colleague of Piotr Lavrov but also connected to the Narodnaya Volya group). He was trained as a medical doctor and physiologist. His work on energy and the economy received Vernadsky's approval. In a section of *La Geochimie* (1924) Vernadsky wrote about several authors (Felix Auerbach with his notion of *Ektropismus*, John Joly) who had explained that life was a process which reversed or slowed down the dissipation of energy. He then wrote a memorable phrase: Podolinsky had studied the energetics of life and tried to apply his findings to the study of the economy.

The link between the use of energy and human culture, in the form of "social energetics" (without historical statistical work), became well established and debated in European culture around 1900. Some Marxist authors adopted this outlook, and their work has been seen as an anticipation of Bertalanffy's systems theory, which grew out of the links between thermodynamics and biology. But, to repeat, there is no line of ecological Marxist history based on quantitative studies of material and energy social metabolism. Moreover, Lenin wrote a diatribe against Ostwald's social energetics in the context of his polemics against Bogdanov and his tirades against Mach's empiriocriticism. This was before the October Revolution of 1917. Afterward, Lenin's ill-considered remarks became sacred to the faithful. Thus, on the occasion of the publication of Engels's *Dialectics of Nature* in 1925 (out of drafts and notes he had left behind) and the 30th anniversary of his death, Otto Jenssen printed once again Engels's letters to Marx on Podolinsky (which were first published in 1919) and explained that Engels had anticipated a critique of Ostwald's social energetics even before Ostwald himself appeared on the scene.

4. OTTO NEURATH'S NATURALRECHNUNG

Marx wrote that wealth was undoubtedly created both by human labor and by nature, quoting William

Petty: "Labour is the Father, Nature is the Mother." Beyond facile jokes on whether fathers or mothers are more important, the interesting point is the distinction between value and wealth. Marx's objective was to explain in a capitalist wage economy the appropriation of surplus labor. Such exploitation was not so obvious as in a slave economy or a feudal (serf) economy, since wages were apparently freely established in a market. Surplus labor became surplus value.

An important contribution to the links between Marxism and a biophysical approach to the economy was made later, in the first half of the 20th century, by Otto Neurath (1882–1945). A famous logical empiricist philosopher of the Vienna Circle, he was also an economist or economic historian, and a Marxist in at least two senses. First, he defended a democratically planned economy based on physical accounting in energy and material terms (*Naturalrechnung*) influenced by Popper-Lynkeus's and Ballod-Atlanticus's quantitative, realistic "utopias," in the so-called Socialist Calculation debate of 1919 and following years. Neurath introduced the idea of incommensurable values in the economy, hence the interest in his work by ecological economists. Second, some years later, in the context of the Vienna Circle' project of the Encyclopedia of Unified Science of the 1930s and 1940s, he defended a dialectical view of history (although he did not like the word "dialectics") as the putting together the findings of the different sciences regarding concrete processes or events. The findings of one science, collected in the encyclopedia, with regard to one particular process or event, should not be contradicted by the findings of another science also present in the encyclopedia, and leave things at that. At attempt at reconciliation or removal of the contradiction should be attempted. "Consilience" (to use Edward Wilson's word) should be the rule of the encyclopedia.

Hayek's strong criticism against "social engineering" (1952) was directed, as John O'Neill has put it, "at the whole tradition which attempts to understand the ways in which economic institutions and relations are embedded within the physical world and have real physical preconditions, and which is consequently critical of economic choices founded upon purely monetary valuation." Translated into Foster's language: Hayek critized the view of the economy in terms of social metabolism. While Patrick Geddes, Wilhelm Ostwald, Frederick Soddy, and Lewis Mumford were all rudely dismissed by Hayek, it is the work of Otto Neurath that was the primary target of Hayek's criticism.

One is also reminded not only of the comments of Max Weber against Otto Neurath in *Economy and Society* but even more of his polemics against Wilhelm Ostwald in 1909. Ostwald (who was a well known chemist) was trying to interpret human history in terms of the use of energy. He proposed two simple laws, which are not untrue, and which might act or not in opposite directions. First, the growth of the economy implied the use of more energy and the substitution of human energy by other forms of energy. Second, this came together with a trend toward higher efficiency in the transformation of energy. Max Weber (1909) wrote a famous, ironic review of Ostwald's views, where he insisted on the separation between the sciences. Chemists should not write on the economy. The review was much praised by Hayek in the 1940s. Max Weber's basic point was that economic decisions by entrepreneurs on new industrial processes or new products were based on prices. It could so happen that a production process was less efficient in energy terms and nevertheless it would be adopted because it was cheaper. Energy accounting was irrelevant for the economy. Max Weber did not question energy prices as we would today when externalities such as the enhanced greenhouse effect or when the intergenerational allocation of exhaustible resources are taken into account.

Ostwald influenced many authors, among them Henry Adams (1838–1918) who proposed a "law of acceleration" of the use of energy: "the coal output of the world, speaking roughly, doubled every ten years between 1840 and 1900, in the form of utilized power, for the ton of coal yielded three or four times as much power in 1900 as in 1840." Since Marxism is in this article under critical review, it is worthwhile pointing out that from the opposite camp, Karl Popper, in *The Poverty of Historicism,* which is a polemic against Marxist laws of history, thought it worthwhile to attack also Henry Adams in a footnote, without even mentioning the word "energy" because he dared propose a historical law. Henry Adams was certainly not a Marxist; on the contrary he was a Boston aristocrat who thought the world would probably come to a bad end socially and technologically.

When the anthropologist Leslie White (1943) wrote on energy and the evolution of culture inspired by Morgan and Taylor as evolutionary anthropologists, he realized that Ostwald and Soddy were precursors of his views. He looked for stages of evolution in terms of harnessing energy in increasing magnitudes and in various forms, in a dialectical

framework between the technological level (defined by the availability and the efficiency in the transformation of energy), the social system (in terms of Marxist "relations of production"), and the cultural-symbolic system.

Marx's doubts on the benefits of economic growth, clearly expressed in his ecological critique of capitalist agriculture, was not forgotten within Marxism (think of Walter Benjamin) although the technological optimists, who believed in the development of the productive forces, predominated. One of most influential Marxist technological optimists of the 20th century was the historian of science J. D. Bernal. He was in the 1950s totally in favor of the "civil" use of nuclear energy, which Lewis Mumford was strongly criticizing already at the time. Mumford, described by Ramachandra Guha as the "forgotten American environmentalist" (forgotten in comparison to G. P. Marsh, John Muir, Gifford Pinchot, Aldo Leopold, and Rachel Carson), was a heir to Patrick Geddes, William Morris, and John Ruskin; he does not belong in the Marxist tradition.

Mumford's mentor, Patrick Geddes (1854–1932), a biologist and urban planner, early on attacked neoclassical economists such as Walras because they did not count flows of energy, materials, and waste, but he did not discuss Marx. Geddes proposed the construction of a sort of input-output table inspired by the *Tableau Economique* of the Physiocrat F. Quesnay. The first column would contain the sources of energy as well as the sources of materials that are used, not for their potential energy, but for their other properties. Energy and materials were transformed into products through three stages: extraction, manufacture, transport and exchange. Estimates were needed of the losses (dissipation and disintegration) at each stage. The quantity of the final product (or "net" product, in physiocratic terms) might seem surprisingly small in proportion to the gross quantity of potential product. Now, however, the losses at each stage were not accounted for in economic terms. The final product was not added value at all. It was the value remaining from the energy and materials available at the beginning once they had been through all three stages.

Geddes's scheme is relevant to the attempt by several authors to develop a theory of ecologically unequal exchange between the metropolitan centers and the world peripheries. In neoclassical economics, provided that markets are competitive and ruled by supply and demand, there cannot be unequal exchange. This could only arise from monopoly or monopsony conditions, or because of noninternalized externalities (or excessive discounting of the future). In an ecological-economics theory of unequal exchange, one could say that the more of the original exergy (available energy or "productive potential" in the exported raw materials) has been dissipated in producing the final products or services (in the metropolis), the higher the prices of these products or services. This was indeed implied by Geddes with different words. Thus, Hornborg concluded, "market prices are the means by which world system centers extract exergy from the peripheries," sometimes helped, one must say, by military power.

A social metabolic perspective shows that capital accumulation does not take place by itself, and it is not only based on the exploitation of labor. Capitalism must advance into commodity frontiers because it uses more materials and energy, therefore it produces more waste, and it undermines not only its own conditions of production but the conditions of livelihood and existence of peripheral peoples, who complain accordingly. Such ecological distribution conflicts are more and more visible. They cannot be subsumed under the conflict between capital and labor.

1. **The Conceptual Approach**
2. **Energy Saving Potentials by Reduced and Changed Demand for Materials**
3. **Joint Impact of Material Efficiency, Substitution, and Intensified Product Use and Plants**

Glossary

dematerialization The declining trend of material use per capita in highly industrialized countries. This is due to the facts that a large capital stock and infrastructure are already in place and that reinvestments tend to need less material for the same service (material efficiency) or the capital stock is used more efficiently (intensified use of durables and plants).

energy intensity The relation between primary energy use and the gross domestic product (GDP) of a country in a given year.

intensified use of durables and plants The same quantity of material services is able to be carried out with fewer durables (goods, vehicles, machinery, and plants) because of more intensive use. For this purpose, additional services (e.g., car sharing, solvent service, and harvesting service) and/or additional organization (e.g., contracting and just-in-time delivery) are needed.

material efficiency The same function of a product, a material, or a technical system is performed with less material due to more intelligent design or improved properties of the materials used. Material efficiency has the largest relevance for energy use with regard to vehicles and moving parts.

material intensity The relation between primary material demand and the GDP of a country in a given year. Sometimes, the expression is defined as the relation between primary material demand and the population of a country.

material substitution The substitution of a material by another material or a different system that delivers the same or similar functions to the application considered (e.g., e-mail instead of mailing letters or books). In this context, the energy use for producing the two optional materials and for their operation during their lifetimes is compared; a net energy gain is expected in the case of material substitution.

The more efficient use of materials by improved construction design and material properties has a long success story with regard to reducing the energy demand of energy-intensive materials, vehicles, and moving parts of machines and plants. However, this more efficient use of materials, which can reduce the specific material and energy demand by approximately 1% per year, is scarcely known or perceived as a challenging development. Until recently, it was not even considered to be a promising option for energy and climate change policy in many countries. In addition to the technological option of material efficiency, the substitution of energy-intensive materials by less energy-intensive materials and the intensification of product and plant use are other options that may play a more important role in reducing the quantity of materials produced and hence energy demand. Entrepreneurial innovations will support these technical options to achieve intensified uses of machinery and vehicles by pooling (leasing, renting, and car sharing). The impact on reduced primary energy demand may range from approximately 0.3% per year (autonomous technical progress in material efficiency without specific policies) to more than 0.6% per year if supported by various policies oriented toward sustainable development.

1. THE CONCEPTUAL APPROACH

Considerations of future improvements in energy efficiency and energy demand often focus on energy-converting technologies and the distribution of grid-based energies where the energy losses amount to approximately 60% of primary energy in most economies. However, there are two additional areas for reducing future energy demand to which little attention is currently being paid (Fig. 1):

1. Energy losses at the level of useful energy (currently approximately 40% of the primary energy demand of industrialized countries) could be substantially reduced or even avoided through technologies such as low-energy buildings, membrane techniques or biotechnological processes instead of thermal processes, and lighter vehicles or reuse of waste heat.
2. The demand for energy-intensive materials could be reduced by recycling or substituting these materials with less energy-intensive ones; reusing products or product components; improving their design or material properties; and the intensified use of products, plants, and vehicles through pooling (e.g., car sharing and leasing or sharing of machines and energy-intensive plants).

This article focuses on some of the latter aspects (excluding material recycling and product reuse). Many energy demand analyzes and projections implicitly assume that the demand for energy services is a "given market demand" that has to be fueled by the various forms of useful and final energies. However, the demand for energy-intensive products and materials is not a fixed, noninfluenceable energy service; on the contrary, the demand reflects a certain status of consumer preferences, choices, and behavior; market traditions and policy boundary conditions; the division of labor in production; and technology, which can be positively influenced by many technical options and entrepreneurial innovations without reducing the services delivered by the (technically changed) products, machinery, or vehicles. Examples and their impact on energy demand are given in the following sections.

The concept of dematerialization, reducing energy demand by using less primary material, was developed more than 20 years ago. This concept integrates the different options of reducing energy services and is often measured by the indicator of material intensity, the ratio of material use in physical terms to gross domestic product (GDP) in deflated constant terms. Malenbaum was one of the first researchers to use this indicator at a global level and in 1978 made preliminary projections for the following two decades. Dematerialization is foremost a long-term concept, tied to long-term changes in the nature of technology, infrastructure, and the economy of a country. Care is required to distinguish it from short-term changes in material intensity resulting from business cycle effects. Empirical dematerialization analyses published by Bernadini and Galli in 1993 concluded two basic postulates:

1. The intensity of use of a given material follows the same bell-shaped pattern for all economies. At first, in its industrializing phase, it increases with per capita GDP, reaches a maximum, and eventually declines afterwards; the growth in material use declines to lower rates than GDP. The decline is

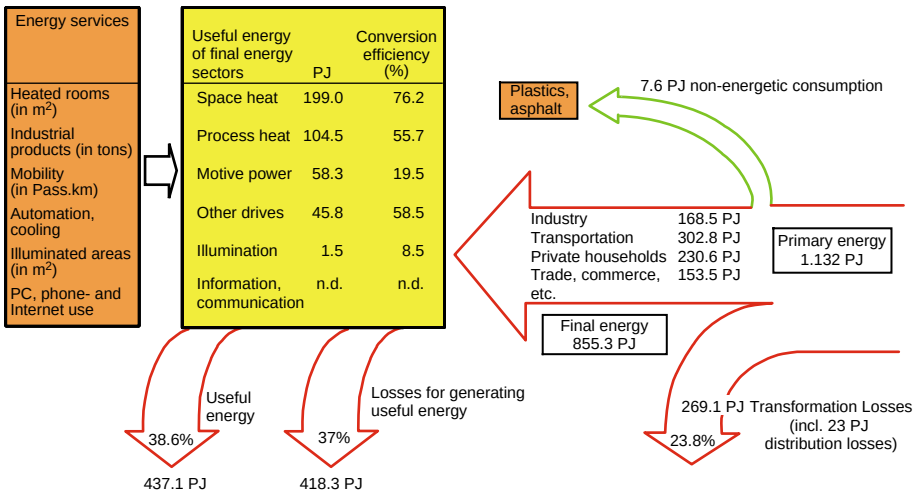

FIGURE 1 More efficient use of materials to reduce energy services demonstrated by the Swiss energy system from energy services to primary energy demand. Source: ISI, Karlsruhe Germany.

frequently accelerated by the growth of competing new materials with process, product quality, and cost advantages (e.g., aluminum or plastics instead of steel or glass).

2. The maximum intensity of material use declines the later it is attained by a given country, reflecting the technological learning and globalization of technical know-how over time.

These two postulates have been found to be valid for individual materials, and they also apply to primary energy intensity, which shows a very similar bell-shaped development. Integrating the substitution and life cycle concept of materials into a total material intensity, a further contribution to the decline of the total material intensity stems from saturation and the development of new markets based on more sophisticated intermediates and commodity products with a relatively higher value added per weight of material input.

For the total material use per capita (t/cap.) and year (including material demand for imported raw materials) of mature economies, it seems that its maximum level of approximately 80–90 t/cap. at an annual per capita GDP level of $25,000 has been reached. It is at this stage that per capita total material use may level off and even begin to decline, as Biondi and Galli found in 1992. This was confirmed by Cleveland and Ruth in 1999; see also declining U.S. figures from 100 t/cap. in the 1970s to 85 t/cap. in the 1990s published by Bringezu. This author and others, such as Rogers, stress that this trend of material use can be influenced by relevant product, recycling, and material-related policies of governments and companies in industry, trade, and other service sectors.

These changes in material intensity and their impact on energy demand were collectively treated in energy demand modeling and forecasts as intra- and interindustrial structural changes. Only recently have they been explicitly analyzed at technical levels of reduced energy and avoided greenhouse gas emissions in the national communications of the reporting process within the Framework Convention of Climate Change.

2. *ENERGY SAVING POTENTIALS BY REDUCED AND CHANGED DEMAND FOR MATERIALS*

The close relationship between the efficient use of energy-intensive materials and energy demand did not receive much attention from energy analysts and policy makers in the past, even though approximately one-third of total industrial energy demand is required for material production and it is obvious that moving parts and vehicles would need less energy during their lifetime if they weighed less. In most energy demand projections to date, more efficient use of materials, products, vehicles, and production plants or the substitution of materials were not seen as flexible and policy relevant but, rather, as a fixed level of activity. The following are the options to reduce energy demand by reduced material intensity discussed in this article.

1. More efficient use of materials by better design and construction; improved properties of materials, oils, or solvents, or even foamed plastics or metals; or reduced use of energy-intensive products such as nitrogen fertilizers. This strategy is particularly important in the case of moving parts or vehicles because lighter construction may contribute to significantly lower energy demand over the lifetime of the particular application (e.g., cars).

2. Substitution of highly energy-intensive materials by less energy-intensive materials or even by other technologies (e.g., substitution of steel and cement/concrete by wood; synthetic fibers by biobased fibers; and newspapers, journals, or books by electronic news and information).

3. Intensified use of products, machinery, and vehicles through short-term leasing, sharing, or renting, reducing the demand for materials by diminishing the nonused capital stock that may even include more efficiently used floor areas of residential and office buildings. This option of the strategy "renting instead of owning" seems to be a purely entrepreneurial and organizational issue at first, but it may also involve new supporting technologies (e.g., clear documentation by electronic devices on the use of the product or vehicle to identify responsibilities during its operation and to develop adequate rental tariffs).

All three elements contribute to structural changes within industrial production, mostly in the direction of lower energy intensity of total industrial production, and they offer numerous opportunities in the service sector to sell product services instead of products.

2.1 More Efficient Use of Materials

Energy-intensive materials as semifinished or final mass products make up a substantial part of

industrial energy demand; of particular interest are paper, glass, steel, aluminum, plastics, rubber products, solvents, and fertilizers. When used in mobile applications, they also contribute to high energy demand, particularly in transportation. Material efficiency means that less material per product function is needed in the future. The direct energy use for primary production of energy-intensive materials is more than 5% of the primary energy demand of an industrialized country, and the indirect energy use for transportation and moving parts (e.g., lifts, moving staircases, and machine components) amounts to more than 25–30% of primary energy demand. In total, approximately 35–40% of the global primary energy use is related to the production of materials, according to estimates of Hekkert and colleagues made in 2000. Examples of past and future increased material efficiency were published by the Enquête Commission of the German Parliament in 2002 and include the following:

- Lower weight of mass papers per square meter: This has been reduced by 15% during the past 30 years.
- Lower glass weight per bottle: This has been reduced by 30% during the past 30 years (ultralight glass bottles with PET films for safety reasons are entering the market).
- Lower weight steel products [e.g., cans (reduced by 50% during the past 30 years), vehicle steel sheets, machines, and appliances]: Competition between steel, aluminum, and plastics has resulted in revolutionary changes in steel shaping and finishing technologies. Powder metallurgy, thin casting, ion beam implantation, directional solidification, cold forging, cold automatic heating, and extruding have allowed savings up to 50% of steel input during the past 30 years;
- Lower specific weight of aluminum per application [e.g., packaging (reduced by 40% during the past 20 years), facades, window frames, vehicle sheets, and construction (airplanes, packing, and cans)].
- Lower specific weight of plastics through better quality plastics produced by improved catalysts and copolymers (e.g., the development of radial tires in the 1970s led to a 25% reduction in tire weight and doubled its lifetime; linear low-density polyethylene allows the use of thinner films in plastic products and savings up to 50%; in the future, the use of foamed plastics will reduce the weight of parts in vehicles, window frames, floor materials, and home and office textiles): Supercellular alloys of magnesium and aluminum and foamed nonferrous metals may contribute to less material input required for many applications.

Worrell and colleagues made the interesting observation in 1995 that the amount of nitrogen fertilizer used can be reduced by several measures applicable to many crops; the reduction potential is between 30 and 50% (e.g., for The Netherlands, from 230 to 130 kg/ha) within one decade.

2.1.1 Potentials and Drivers of Material Efficiency

Besides cost reduction potentials, material efficiency will also be enhanced by increasing the useful life, for example, by improving surface layers protecting buildings and infrastructure against ultraviolet radiation, acid rain, algae growth, and pollution. Surface protection is of particular interest in coastal regions with salty air. Other technological developments rely on the progress in microelectronics, information, and communication technology—miniaturization, design and quality control, and improved logistics. Computer-aided design and manufacturing has allowed the optimization of the number of components that can be produced by a given quantity of material, leading to a significant reduction of waste or to fewer unfinished or rejected goods.

As indicated by these examples, the strategy of reducing a product's material use while maintaining identical functionality is not a new development. In particular, much attention has been paid to post-consumer wastes by national policies or by the European Union regarding the reduction of packaging wastes. The first analytical work by Gielen in 1999 suggests that material efficiency has improved in the past decades by approximately 1% per year on average, which indicates a comparable rate of energy efficiency improvement. The question is whether these trends can be maintained or even accelerated. Competition among the materials and legal frameworks that strive for the internalization of the external costs of material production, waste disposal, and energy conversion will be a major driver for maintaining progress in material efficiency.

The future energy saving potential stemming from improved material efficiency has not been systematically analyzed. However, the methodological approach used to analyze the impact of material efficiency on energy demand (and energy-related emissions) has been developed and described by several authors, such as Worrell and colleagues in 1995 and Hekkert and colleagues in 2000. These

authors have also performed a number of case studies for several basic materials, products, and packaging materials. Tentative analyses suggest two major conclusions:

1. The energy savings during the lifetime of vehicles and moving components is approximately three times higher than the savings for reduced material demand.
2. The direct and indirect primary energy savings from the more efficient use of materials range between 0.1% per year (autonomous technical progress) and, according to the findings of the Enquête Commission, approximately 0.25% per year if technical progress is supported by relevant policies.

2.1.2 Obstacles and Issues of Research and Development

Many of the new materials and their specific properties and production processes are known today, but, as for energy efficiency potentials, various obstacles hinder the rapid diffusion of many new materials and the related benefit of reduced energy demand. Because many of the new material technologies are based on expensive, high-quality materials, price is often the most common barrier to their widespread implementation. For this reason, apart from research and development (R&D), Ayres stresses the fact that the promotion must also integrate favorable economic and policy conditions, including innovation and market introduction policies.

In some cases, there are conflicts of interest that have to be taken into account for future market introduction and acceptance. There may also be problems in the transition phase from today's products to light material products (e.g., safety aspects of heavy traditional cars and new light cars and road vehicles in cities).

In order to realize the high-end energy saving potential of material efficiency in the coming decades, some of the research involved is very basic applied research (e.g., foamed plastics or even metals and alloys of magnesium or aluminum). The R&D for the different applications seems to be very dispersed but is often very advanced applied research. In many cases, the higher quality of the improved materials and their applications require high-performance production machines and high production expertise; for example,

- R&D on new polymer catalysts, particularly for polyethylene, polypropylene, polystyrene, polyester, and interesting copolymers, to improve their properties and to substitute specialized, more energy-intensive plastics (polycondensates and polyadducts).
- R&D on improved surface protection to avoid corrosion and/or to increase the life span of the products, facades, or vehicles, including economic optimization over the product's and component's lifetime.
- R&D on foamed plastics and nonferrous metals for lightweight construction, particularly for moving parts and vehicles.

2.2 Substitution of Energy-Intensive Materials

The specific energy demand for producing materials can vary significantly. Replacing mass-produced, energy-intensive materials with less energy-intensive materials can generate a large energy saving potential. This depends on the specific substitution involved, where different product life spans may also have an influence. Substantial energy savings can be achieved by substitution of

- Heavy materials with lightweight materials in the transport sector. Conventional steel constructions, for example, may be replaced with lighter aluminum or magnesium constructions. Although the production of aluminum or magnesium components is more energy-intensive, this additional energy consumption can be compensated for during the components' lifetime. The average weight of U.S. cars declined approximately 20% between 1976 and 1990; most of this decline was accounted for by the use of aluminum, plastics, and composites as substitutes. Schön and colleagues concluded that this past achievement is likely to be repeated in the next 20 years by further substitution using nonferrous metals and plastics.
- Energy-intensive metals, paper, and glass with plastics; their advantages are often lighter weight, greater resistance to tear, relative inertness to moisture and organic environments, and less storage space requirements. Not only do plastics continue to substitute for metals, glass, and paper in traditional applications but also new polymers with improved properties (e.g., high strength-to-weight ratio, transparency, greater durability, and specific surface properties) are increasingly replacing older generation plastics widely in use today. These new polymers often have a lower manufacturing energy demand than the materials they displace when the comparison is made in terms of end-use qualities rather than on a unit weight basis.

• Petrochemically based plastics with biobased polymers or plastics or natural materials. Well-established substitution routes are oleochemical surfactants and lubricants from vegetable oils, as Patel and colleagues reported in 2000. Future examples are the increased use of wood as a construction material, the renaissance of flax and hemp as natural fibers instead of the use of chemical fibers, manufacturing and cooling oils, and bioplastics produced from starch. In the long term, Hüsing and colleagues expect major innovations such as polyhydroxyalkanoates from gene-manipulated plants, which have similar properties as those of the petrochemically based polypropylene.

There are many other small substitutions of materials, such as the substitution of copper in the telecommunication market with optical fibers with 30–40 times the transmission capacity of conventional wiring and by mobile telecommunications, substitution of metals with ceramics (e.g., spark plugs, insulation layers, titan oxide-based solar cells, superconductors, and high-temperature protection layers), and substitution of printed media with electronic information and communication.

A fundamental connotation of substituting old materials with new ones is the trend from commodities to specialty materials adapted for specific products, such as car frames or other car components and biodegradable packaging materials, specific functions of surfaces (e.g., zero corrosion and improved heat transfer), or specific mechanical properties per weight of material. These advanced materials (e.g., produced from nano powder) are becoming more important as they substitute for basic traditional metallic materials or plastics.

2.2.1 Potentials and Opportunities

The future energy saving potentials stemming from material substitution have not been systematically analyzed; the evidence for the energy saving effect of material substitution is restricted to a limited number of metals and plastics applied to a limited number of products. The impact of bioengineered basic natural materials, for example, is an unresolved issue but theoretically implies high energy saving potentials. In addition, the competition between different materials within the substitution process and the simultaneous process of material efficiency makes the analysis of energy saving potentials extremely complex. Initial tentative and partial analyses suggest results similar to those of the impact studies on material efficiency:

1. The energy savings due to substituted materials during the lifetime of vehicles and moving components are approximately three times higher than the energy savings due to material substitution in other fields of application.
2. The direct and indirect primary energy savings from material substitution are estimated to be less than 0.1% per year (autonomous substitution) and 0.2% per year or more if the technical progress by material substitution is supported by relevant policies. This potential may increase during the next decades due to new opportunities resulting from technologies such as nano- and biotechnology and genetic engineering.

2.2.2 Obstacles and Policy Issues

Traditional consumer wishes, the traditional material choice of producers, a certain "image" of a given material in its societal context, and sometimes the higher cost of the substituting and less energy-intensive material can adversely affect the realization of the energy saving potentials in various applications. Early R&D on biobased polymers and products, including applied genetic engineering to improve properties and yields (e.g., natural fibers, starch, and wood), may be important given the perspective of changing boundary conditions in the 2000 "World Energy Assessment," edited by Goldemberg and Johannson: increasing prices of oil and natural gas within the next two decades when global crude oil production is likely to pass its middepletion point. Reducing the production costs of the less energy-intensive materials by learning and economy-of-scale effects may also be an issue of public policy through limited financial incentives, procurement schemes, information and training, as well as by setting technical standards to be met by the new materials.

2.3 Intensified Use of Products, Machinery, and Vehicles

Durables and investment goods are generally purchased but could often be leased, rented, or hired, particularly in cases of small annual usage times (e.g., cars, 200–500 h per year; harvesting machines, <50 h; construction machines, <500 h; and many high-temperature industrial processes in small and medium-sized companies operating on one-shift schedules or <2500 h per year). Regarding material use (and the imbedded energy to produce durables and investment goods), Friend stated in the mid-1990s that the low annual usage time implies a huge idle capital and

material stock of an economy due to the concept of selling and owning products instead of selling and buying product-based services. In the case of high-temperature industrial processes, the energy losses for daily startup and shutdown may be substantial.

The strategy of product-based services of manufacturers or service companies is based on the concept of selling the total service (e.g., harvesting, partial outsourcing of energy-intensive production steps, using centralized voice mail instead of answering machines, and renting solvents from chemical suppliers) or pooling durables and investment goods. Mont describes many cases in great detail in which the intensified use of the durables and investment goods reduces their capital cost and compensates for the additional service cost for either the total service or contracting, operating, reservation, billing, controlling, and additional insurance. In many cases, ecological or environmental arguments and considerations contribute to the acceptance of these new services, which are labeled ecoefficient services by Popov and DeSimone. However, very seldom are these product-based services examined from the perspective of material efficiency and indirectly reduced energy use.

At first glance, using products, machinery, and vehicles more intensively through short-term leasing, sharing, or renting and its technical dimension of material efficiency (and, indirectly, of energy efficiency) seems to be a research area more related to the social sciences. In order to realize the strategy "renting instead of owning" at the commercial level, however, experience strongly suggests the need for supporting technologies in many cases. These technologies would offer the user clear documentation on the use of the product or vehicle, identify responsibilities during its operation, and develop adequate rental tariffs. These predominantly information and communication technologies require research focused on small, inexpensive, and reliable electronic systems.

2.3.1 Potentials and Opportunities

The realizable direct energy efficiency potential of these numerous options of intensified use of products, vehicles, and production plants has scarcely been analyzed and depends very much on the future acceptance and market diffusion of services such as car sharing (studied by Meijkamp in The Netherlands), pooling public (municipal) or company vehicle fleets or machinery (studied by Fleig), and moving elderly people into adequate but appropriately sized apartments (first analyzed by Zanger and colleagues in 1999). Assuming moderate market shares of two of these new services in 2050 (e.g., 10% of car-using households opt for car sharing, and 2% of elderly people move to smaller apartments with an average gain of $20\,m^2$ per move and apartment), the energy savings in industrialized countries may be on the order of 3% of current levels of primary energy demand. Increased renting of products and vehicles may indirectly affect energy use through, for example, the higher energy efficiency of "younger" capital stock or vehicle fleets, walking or cycling displacing the car for short trips, and a more sensible use of machines or vehicles due to the accompanying documentation system. The indirect effects are estimated to be approximately 10% of the direct effects.

The impact of these numerous possibilities of intensifying the use of products and production machinery and plants on energy demand is almost unknown because very few existing services have been assessed under energy aspects and many conceivable services to intensify the use of products, vehicles, or production facilities have not been offered on suitable markets. The estimates of known and offered services thus assume yearly primary energy savings of less than 0.02% per year (autonomous substitution), but in the longer term the Enquête Commission estimated that they may contribute to the annual energy savings of 0.1–0.2% of total primary energy demand if relevant incentives and policies are in place.

2.3.2 Obstacles and Policy Issues

To realize the full impact of intensifying the use of products, vehicles, and apartments, new entrepreneurial forms are also required that reduce the capital stock for those applications in which intensified use is being targeted.

Obviously, much research must be undertaken to develop a clearer understanding of the possible potentials of energy savings:

- Research on customer acceptance: In many cases, the various services will be innovative—for example, incentives for machinery and car sharing or improved awareness about the fixed and capital costs of owning machinery and vehicles with low annual operating hours.
- Research on the willingness of innovative companies to invest in pooling services: R&D on inexpensive accompanying information and technology-based monitoring and control techniques for easy and fair pricing, easy scheduling and access, and protection against theft.

New services may first require pilot projects with socioeconomic evaluations in order to design the

necessary policy and financial boundary conditions, clarify legal questions, and design professional training and educational programs.

3. JOINT IMPACT OF MATERIAL EFFICIENCY, SUBSTITUTION, AND INTENSIFIED PRODUCT USE AND PLANTS

Although the relation between these three elements of sustainable material use on energy demand has only been partially analyzed, the results of analytical technology-specific studies suggest substantial energy saving potentials. These potentials may materialize less quickly if policy action is not taken by governments, the scientific community, and the industrial players (Table I). It seems that the energy saving potential of the strategy of material efficiency may be most important during the next few decades but will have decreasing importance thereafter, whereas the potentials of material substitution and intensification of the use of products, vehicles, and production plants may require much additional research (e.g., on biomass-based plastics) and changes in social values and decision making (renting instead of owning) before they can substantially contribute to a reduced use of energy. However, the energy saving potentials of these two options may be quite high in the long term (i.e., over many decades during this century).

TABLE I

Estimates of Annual Primary Energy Saving Potential from Material Efficiency, Substitution, and Intensified Use of Products, Vehicles, and Production Facilities

Energy-related material aspect	Annual primary energy saving potential (%)		Comment
	Autonomous development	Policy-induced development	
More efficient use of materials	0.1	Up to 0.25	Relatively well analyzed, but still unknown potentials
Substitution of materials	<0.1	Up to 0.20	Open to major technical break throughs (biomass, nanotechnology)
Intensified use of durables, vehicles, etc.	<0.02	Up to 0.20	Unknown potential due to changes in societal values
Total effect	<0.2	Up to 0.5 or 0.6	

Preliminary estimates of the energy saving potentials for the next three decades have been made for an industrialized country such as Germany. The results showed approximately 450 PJ saved in the reference scenario, which is expected to occur without additional policy activities and is reflected in the assumptions on structural change in the economy (Table II). This energy saving potential corresponds to an annual decrease in the total primary energy demand of Germany of 0.12% per year. In the policy scenario, called the sustainability scenario, the energy saving potential was assumed to double. Approximately half the savings are estimated to come from improvements in road vehicles [material efficiency (light vehicles) and car sharing/truck leasing]. Other major savings are expected to result from the lighter construction of machinery and plants and the substitution of primary aluminum, which is a light but energy-intensive material.

There are indications that recycling seems to play a smaller role compared to material efficiency and material substitution mainly due to the savings in vehicles and moving parts of machinery and to the substitution of primary aluminum. The contribution of the intensified use of products, vehicles, and production plants is certainly underestimated, but analytical and empirical work still has to be done in many product areas to obtain reliable estimates of energy savings in this area of activity and entrepreneurial innovations. The results do not reflect changes in exports and imports of energy-intensive products, which may affect the saving potentials at the national level of an economy. Finally, the integration of the four options cited in Table II is highly dependent on socioeconomic conditions; hence, the joint effect on energy savings will depend on the constellation of the four options.

There is no doubt that the energy saving potentials will very much depend on future progress in the R&D of improved properties of existing materials, such as steel, nonferrous metals, cement, glass, plastics, and fibers, as well as the invention, market introduction, and diffusion of new materials (e.g., plastics or fibers based on biomass that may be genetically designed or modified). In addition, the intensified use of products, vehicles, and production plants will be dependent on changes in social values and entrepreneurial innovations that must

occur to realize the potentials expected in the coming decades.

The following conclusions can be made with regard to the preliminary findings of the relationship between the various options of sustainable material use and energy demand:

- The impact of material efficiency, material substitution, and the intensified use of durables has not been explicitly treated as an energy policy option in the past, nor has it been explicitly analyzed in energy demand projections. It has only been treated as an unexplained aggregate of structural change.
- If consciously adopted as a policy of sustainable development by interested companies in industry and the new service sectors, the impact of the three options for energy demand may be significant—an approximately 0.5% reduction in annual primary energy demand in the coming decades.
- The obstacles to these potentials are manifold, but the material and energy savings provide opportunities to recover the R&D expenses and additional investments; the value added in the new materials and systems may also be an incentive for companies as well as for governments.

The close relationship between material use and energy demand opens up an entirely new area of energy systems analysis and, more important, offers major entrepreneurial opportunities for a lighter, more efficient, and less polluting industrial society. It opens up new jobs in many service areas by substituting the use of natural resources by know-how-intensive products and services. These effects have been studied and calculated by Walz and colleagues for Germany, with the conclusion that more efficient use of material and capital stock is likely to contribute to a sustainable development in the long term.

Glossary

cermet A mixture of ceramic and metal.
chromogenic Pertaining to the ability to change optical properties persistently and reversibly by the action of an external stimulus.
electrochromic Pertaining to the ability to change optical properties reversibly and persistently by the action of a voltage.
float glass Solidified glass floated on a bed of molten metal so that the glass surface is nearly atomically smooth.
infrared Referring to wavelengths of light longer than 0.7 μm.
iridescence A rainbowlike exhibition of color.
photocatalysis Chemical reactions on an "active" surface, stimulated by light.
photochromic Pertaining to the ability to change optical properties reversibly and persistently by the action of light irradiation.
Planck's law A relationship describing the spectral distribution of thermally emitted radiation.
smart window A window incorporating a chromogenic material.
spectrally selective Having distinctly different optical properties in different wavelength ranges.
thermochromic Pertaining to the ability to change optical properties reversibly and persistently by the action of temperature.
ultraviolet Referring to wavelengths of light shorter than 0.4 μm.

This article summarizes work on materials with properties tailored to meet the specific parameters of the spectral distribution, angle of incidence, and intensity of the electromagnetic radiation prevailing in our surroundings. Spectral and angular selectivity are introduced to specify many of the desired properties. Materials with optimized transmittance, reflectance, absorptance, and emittance are discussed. A general introduction of the properties of glasses, polymers, and metals is followed by an account of thin film technology, which is of importance for solar energy materials of many different kinds. The article treats materials for transparent thermal insulation, solar thermal converters, radiative cooling devices, solar cells, architectural windows with static as well as dynamic properties, and solar photo-catalysis. The aim is to introduce basic concepts and commonly used materials, and also to bring the exposition up to the work in today's scientific laboratories.

1. SOLAR ENERGY MATERIALS

Solar energy materials have properties tailored to meet the specific parameters of the spectral distribution, angle of incidence, and intensity of the electromagnetic radiation prevailing in our natural surroundings. Materials for thermal and electrical conversion in man-made collectors, as well as for energy-efficient passive design in architecture, are typical examples.

Figure 1 introduces the ambient electromagnetic radiation of Earth's environment in a unified manner. The most fundamental property of this radiation, which ensues from the fact that all matter emits electromagnetic radiation, is conveniently introduced

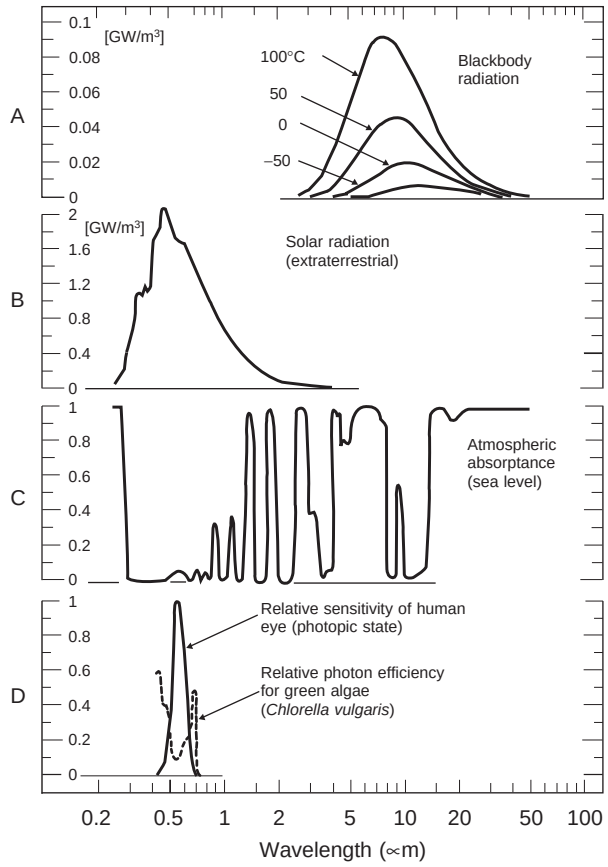

FIGURE 1 Spectra for (A) black-body radiation pertaining to four temperatures, (B) solar radiation outside Earth's atmosphere, (C) typical absorptance across the full atmospheric envelope, and (D) relative sensitivity of the human eye and relative photosynthetic efficiency for green algae.

by starting with the ideal blackbody. The emitted spectrum–known as the Planck spectrum–of blackbody radiation is uniquely defined if the temperature is known. Planck's law is a consequence of the quantum nature of the radiation. Such spectra are depicted in Fig. 1A for four temperatures. The vertical scale denotes power per unit area and wavelength increment (hence the unit GW/m^3). The spectra are bell-shaped and confined to the $2 < \lambda < 100$-μm wavelength range. The peak in the spectrum is displaced toward shorter wavelengths as the temperature increases. At room temperature, the peak lies at about 10 μm. Thermal radiation from a material is obtained by multiplying the Planck spectrum by a numerical factor (the emittance), which is less than unity. In general, the emittance is wavelength dependent.

A solar spectrum is depicted in Fig. 1B for radiation just outside Earth's atmosphere. The curve has a bell shape, defining the sun's surface temperature ($\sim 6000^\circ C$). It is important to observe that the solar spectrum is limited to $0.25 < \lambda < 3\,\mu m$, so that there is almost no overlap with the spectra for thermal radiation. Hence, it is possible to have surfaces with properties that are entirely different with regard to thermal and solar radiation. The integrated area under the curve gives the solar constant ($1353 \pm 21\ W/m^2$); this is the largest possible power density on a surface oriented perpendicular to the sun in the absence of atmospheric extinction.

Most solar energy conversion systems are located at ground level, and it is of obvious interest to consider to what extent atmospheric absorption influences solar irradiation and net thermal emission. Figure 1C illustrates a typical absorption spectrum vertically across the full atmospheric envelope under clear weather conditions. The spectrum is complicated with bands of high absorption–caused mainly by water vapor, carbon dioxide, and ozone–and bands of high transparency. It is evident that most of the solar energy can be transmitted down to ground level and only parts of the ultraviolet ($\lambda < 0.4\,\mu m$) and infrared ($\lambda > 0.7\,\mu m$) radiation are strongly damped. The maximum power density perpendicular to the sun is about $1000\ W/m^2$. Thermal radiation from a surface exposed to the clear sky is strongly absorbed except in the $8 < \lambda < 13$-μm range, where the transmittance can be large, provided that the humidity is moderately low.

Two biological conditions of relevance for solar-energy-related applications are illustrated in Fig. 1D. The solid curve shows the relative sensitivity of the human eye in its light-adapted state. A bell-shaped curve extends across the $0.4 < \lambda < 0.7$-μm interval, with its peak at 0.555 μm. Clearly, a large part of the solar energy comes as invisible infrared radiation. The dashed curve indicates that photosynthesis in plants operates at wavelengths in approximately the same range as those for the human eye, which is relevant for greenhouse applications.

Figure 1 depicts an important fact about ambient radiation: that it is spectrally selective, i.e., confined to specific and usually well-defined wavelength ranges. This property is of great importance for most types of solar energy materials. Another type of selectivity–known as angular selectivity–results from the fact that different angles may apply for different types of radiation; for example, solar radiation comes from a point far from the horizon during most of the day, whereas the visual contact between a person and his or her surroundings is often at near-horizontal lines-of-sight.

2. FUNDAMENTAL OPTICAL PROPERTIES OF MATERIALS

When electromagnetic radiation impinges on a material, one fraction is transmitted, a second fraction is reflected, and a third fraction is absorbed. Energy conservation yields, at each wavelength, that

$$T(\lambda) + R(\lambda) + A(\lambda) = 1, \quad (1)$$

where T, R, and A denote transmittance, reflectance, and absorptance, respectively.

Another fundamental relationship, also following from energy conservation and referred to as Kirchhoff's law, is

$$A(\lambda) = E(\lambda) \quad (2)$$

with E being the emittance, i.e., the fraction of blackbody radiation (cf. Fig. 1A) that is emitted at wavelength λ. It is evident that Eq. (2) is of relevance mainly for $\lambda > 3\,\mu m$.

It is frequently convenient to average the spectral data over the sensitivity of the eye, a solar spectrum (with or without accounting for atmospheric effects), or a blackbody emittance spectrum (for a certain temperature). Luminous, solar, or thermal values pertinent to the respective optical properties are then obtained; these are denoted X_{lum}, X_{sol}, and X_{therm}, with X being T, R, A, or E.

3. TRANSMITTING AND REFLECTING MATERIALS

3.1 Glasses

Glass can be used for protection against an unwanted environmental impact, for convection suppression, and as a substrate for surface coatings (normally referred to as thin films). Float glass, a highly standardized product used in a great majority of windows in buildings, is characterized by uniformity and flatness almost on the atomic scale. The latter feature is an outcome of the production process in which the molten glass is solidified on a surface of molten tin. The middle curve in Fig. 2 shows the spectral transmittance of 6-mm-thick standard float glass within the wavelength range relevant to solar radiation. A characteristic absorption feature at $\lambda \approx 1\,\mu m$, due to the presence of Fe oxide, limits T_{sol} to some extent. Special float glass is available with varying amounts of Fe oxide. Fig. 2 shows that low-Fe content leads to glass with very high T_{lum} and T_{sol} values, and also with substantial transmittance in the ultraviolet region.

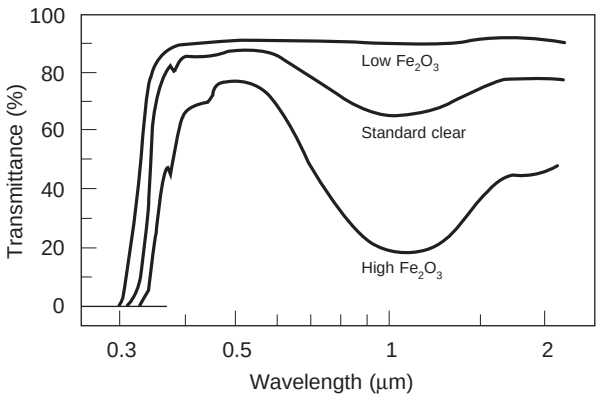

FIGURE 2 Spectral transmittance for float glass with three different amounts of Fe_2O_3.

Glass with a large Fe content limits T_{sol} whereas T_{lum} remains rather large; such glass has a distinctive greenish tint. The reflectance of each interface between glass and air is about 4% in the $0.4 < \lambda < 2$-μm range, implying that the maximum transmittance for a glass pane is 92%. Glass is strongly absorbing for $\lambda > 3\,\mu m$, and E_{therm} is as large as about 85%.

Laminated glass may be used for safety and other reasons. This glass comprises a layer of polyvinyl butyral sandwiched between two glass panes and bonded under heat and pressure. The laminate is an efficient absorber of ultraviolet light, and the transmittance at $\lambda < 0.38\,\mu m$ is almost zero for a layer thickness of the order of 1 mm. Photochromic glass is able to darken under irradiation of ultraviolet light from the sun and clears in the absence of such irradiation. Fatigue-free photosensitivity is normally accomplished by adding metal halides–particularly silver halide–to the vitreous matrix of the glass. A number of other additives are important as well. Figure 3 shows T_{lum} as a function of time for darkening and clearing of two photochromic glass plates. Darkening progresses rapidly and reaches about 80% after 1 minute. Clearing is much slower, though, and is still incomplete after 1 hour. The photosensitivity occurs almost entirely in the $0.4 < \lambda < 1.0$-μm interval, and hence the modulation of T_{lum} is much more pronounced compared to the modulation of T_{sol}. Photosensitivity exerts no effect on the reflectance or on E_{therm}.

3.2 Polymers

Many polymers can be transparent and can, in principle, replace glass. However, polymers degrade more easily than glass and hence have fewer

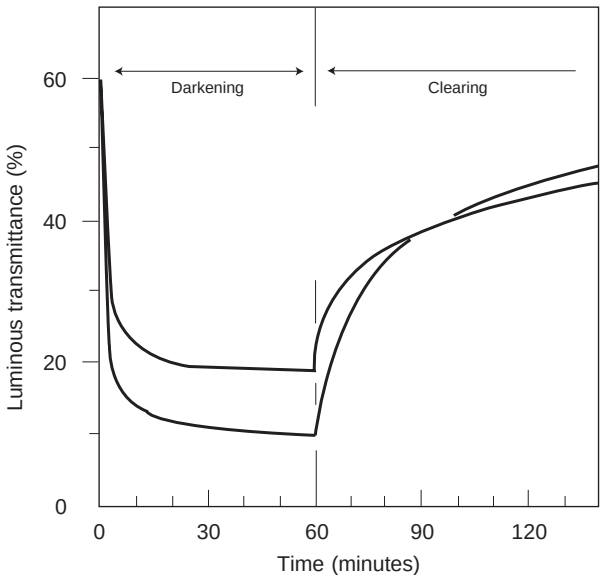

FIGURE 3 Luminous transmittance vs time for two photochromic glasses.

applications. Polyester foil deserves special mention because it can serve as a flexible and inexpensive substrate for thin films of many different kinds, transparent as well as reflecting. Another alternative is ethylene tetrafluoroethylene. Photochromism is known in a number of polymers, and detailed information is available for spirooxazine in a host of cellulose acetate butyrate. The coloration dynamics are similar to those for photochromic glass, but the bleaching is faster for the polymer and takes place in about 20 minutes. The photoeffects are limited to T_{lum}; they vanish at elevated temperatures.

3.3 Metals

Metal surfaces can be used to accomplish high R_{lum} and R_{sol} (for example, in mirrors of various types), or for providing low E_{therm}. Figure 4 shows spectral reflectance for five different metals. The highest values of R_{lum} and R_{sol} are found in silver (Ag) and aluminum (Al), and these metals are used in bulk form or as thin films supported by substrates in several solar-energy-related applications. Surface protection of such surfaces is normally needed to obtain long-term durability. More corrosion-resistant metals, such as platinum or rhodium, are less reflective. All of the metals can yield a low magnitude of E_{therm}.

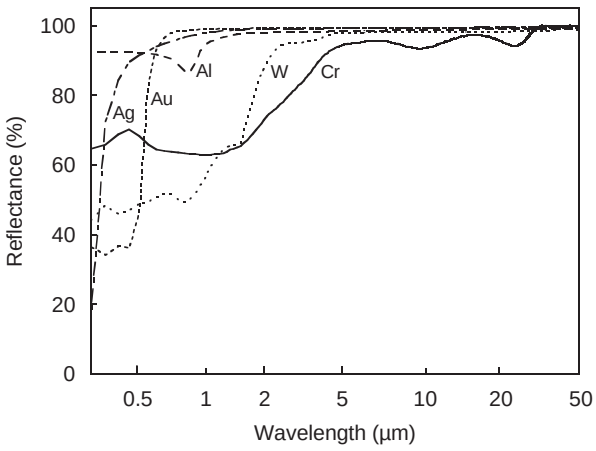

FIGURE 4 Spectral reflectance for some metal surfaces.

4. THIN FILMS

4.1 Thin Film Deposition

Surface treatments can be used to modify the optical properties of an underlying material and thus enhance its ability to adapt to the conditions of the ambient radiation (cf. Fig. 1). Many specific types of solar energy materials are used in this way. Thin film deposition, a particularly important application, represents a vast technological field, and only the most common methods are mentioned here.

Sputter deposition is widely used to make uniform coatings on glass, polyester, metal, etc. Typical film thicknesses are 0.1 to 1 μm. Essentially, a plasma of inert and/or reactive gases is set up under low pressure, and energetic ions in the plasma dislodge atoms from a solid plate of the raw material of the film (known as the "target"); these atoms are deposited as a uniform film on an adjacent surface (the substrate).

Evaporation can be an alternative to sputter deposition. Here, the raw material of the film is heated in vacuum so that a condensing vapor can transfer material to the substrate at a sufficient rate. Other technologies can be applied without recourse to vacuum: For example, sol-gel deposition involves dipping the substrate in a chemical solution, withdrawing it at a controlled rate, and subsequent annealing. Alternatively, the chemical solution can be applied by spray coating.

Chemical vapor deposition uses heat to decompose a vapor of a "precursor" chemical to produce a thin film of a desired composition. Electrochemical

techniques include cathodic electrodeposition from a chemical solution and anodic conversion of a metallic surface to form a porous oxide. Numerous alternative techniques exist.

4.2 Antireflection Treatment

Antireflection treatment (for example, to obtain high T_{lum} through glass) can be accomplished by the application of a layer with a refractive index that is close to the square root of the refractive index of the underlying glass (i.e., 1.23) and with a thickness corresponding to one-quarter of the wavelength of visible light (i.e., $\sim$100 nm). The condition imposed on the refractive index allows for good durability for only a few materials. Figure 5 shows an example of a glass slab of which two surfaces have been coated with a layer of porous silica obtained via sol-gel technology. It is seen that T_{lum} exceeds 99% in the middle of the luminous spectrum. Other antireflection treatments of practical interest include thin films of aluminum oxyfluoride or magnesium fluoride, and porous or microstructured surface layers produced by etching the glass surface in fluorosilicic acid or by application of a submicrometer-structured layer.

Simple antireflection treatments are able to lower the reflectance within a rather narrow wavelength range, but if a low magnitude of R_{sol} is required, a multilayer film with carefully adjusted refractive indices and thicknesses could be used. It should be noted that antireflection is efficient only for a specific range of incidence angles, especially in the case of multilayer films.

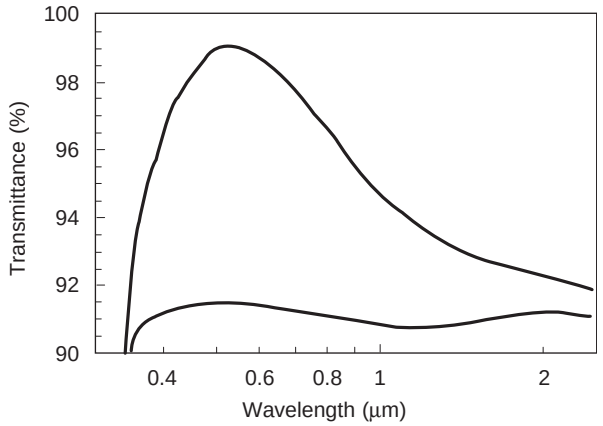

FIGURE 5 Spectral transmittance of a glass plate coated on both sides by antireflecting thin films of porous silica.

5. TRANSPARENT THERMAL INSULATORS

5.1 Principles

Heat transfer occurs via the additive effects of radiation, convection, and conduction. Cutting back this transfer is of concern for many different applications of solar energy. Radiation transfer can be diminished by having surfaces with low values of E_{therm}. Convection, which is of interest for gases, can be lowered by breaking up the gas into cells with dimensions of the order of 1 cm or less (or, possibly, by decreasing the gas pressure), and conduction heat transfer can be minimized by suitable constructions using low-conductance materials.

5.2 Solid Materials

Figure 6 shows four types of solid transparent insulation materials, including flexible polymer foils; polymer honeycomb materials; bubbles, foam, and fibers; and inorganic microporous materials such as silica aerogels. If the honeycomb cross-section is small compared to the cell length, a capillary structure exists. Foils and aerogels can be almost invisible to the eye, whereas honeycombs, bubbles, foam, and fibers cause reflection and scattering and hence a limited direct transmittance; thus, only the former group of materials is of interest when unperturbed vision is required–such as in many windows–and the other materials find applications in translucent wall claddings and solar collectors. The materials can be used in vertical, horizontal, or inclined positions, depending on the type of application.

Flexible polyester foils can be suspended to break up a thick gas slab into $\sim$1-cm-thick layers with

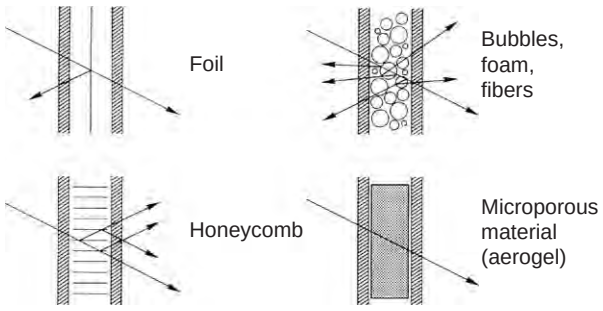

FIGURE 6 Principles underlying performance of four different types of solid transparent insulation materials placed between glass panes. Arrows signify light rays. Reflections at the glass surfaces are not shown.

diminished convection, and thin films can be applied to adjust the magnitudes of T_{lum} and T_{sol}, and to minimize E_{therm}. Similarly, the macroporous materials–typically made of polystyrol, polyamide, polyvinylchloride, or polycarbonate–produce gas-filled cells of a sufficiently small size to practically eliminate convection. A characteristic value of the heat transfer of the honeycombs, capillaries, bubbles, foam, and fibers is $1\,W/m^2\,K^{-1}$ for a material thickness of 10 cm.

Silica aerogel can be made by supercritical drying of colloidal silica gel under high temperature and high pressure. The ensuing material consists of $\sim$1-nm-diameter silica particles interconnected so that a loosely packed structure with pore sizes of 1 to 100 nm is formed. The relative density can be as low as a few percent of the bulk density. The material can be produced as translucent granules or as transparent tiles with a certain degree of haze. Figure 7 shows spectral transmittance through a 4-mm-thick tile. The low transmittance at short wavelengths is due to optical scattering. Heat transfer lower than $1\,W/m^2\,K^{-1}$ can be achieved in 1-cm-thick slabs of aerogel under favorable conditions (positioning between surfaces with low E_{therm} and at low gas pressure).

5.3 Gases

The heat transfer between two surfaces can be lowered by use of a gas other than air, as is common in modern fenestration technology involving hermetically sealed glazing units. The heat transfer across a typical 1.2-cm-wide gas slab is diminished on the $\sim$10% level if air is replaced by argon or CO_2, whereas larger effects are found with krypton or xenon. The relative role of the gas filling is enlarged (in practice, to the $\sim$20% level) if the radiation component to the heat transfer is decreased by the use of surfaces with a low E_{therm}. Infrared-absorbing gases can diminish the heat transfer across a given distance, but the limited availability of suitable gases makes this possibility less interesting. Among other options related to gases, some improvement of the thermal properties can be combined with sound insulation by the use of SF_6 gas. Finally, minimized heat transfer can be achieved by eliminating the gas, so that both the conduction and the convection components vanish. Obviously, the mechanical strength of the device must be sufficient to allow a vacuum. This necessitates inconspicuous spacers for "vacuum windows."

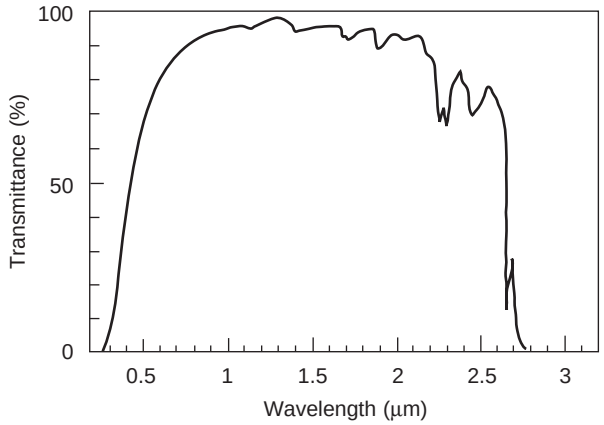

FIGURE 7 Spectral transmittance of a silica aerogel tile.

6. SOLAR THERMAL CONVERTERS

6.1 Principles

Photothermal conversion of solar energy, to produce hot fluid or hot air, takes place in solar collectors. Efficient conversion requires that a solar-absorbing surface is in thermal contact with the fluid or gas, and that thermal losses to the environment are minimized. The absorber should be positioned under a transparent cover, and a transparent thermal insulation material may be used as well. The back and sides of the solar collector should be well insulated using conventional techniques. The most critical part for the photothermal conversion is the actual solar absorber surface, which obviously should have maximum A_{sol}. Its radiation heat losses should be minimized, and this requires low E_{therm}. The absorber is nontransparent, and the conditions can be written in terms of an ideal spectral reflectance as

$$R(\lambda) = 0 \quad \text{for} \quad 0.3 < \lambda < \lambda_c\ \mu m \tag{3}$$

$$R(\lambda) = 1 \text{ for } \lambda_c < \lambda < 50\ \mu m, \tag{4}$$

where λ_c denotes a "critical" wavelength lying between 2 and 3 μm, depending on the temperature (cf. Fig. 1). Clearly, this is one example of how spectral selectivity is used to obtain optimized properties of a solar energy material.

A number of different design principles and physical mechanisms can be used in order to create a spectrally selective solar-absorbing surface. Six of these are shown schematically in Fig. 8. The most straightforward approach would be to use a material with suitable intrinsic optical properties. There are

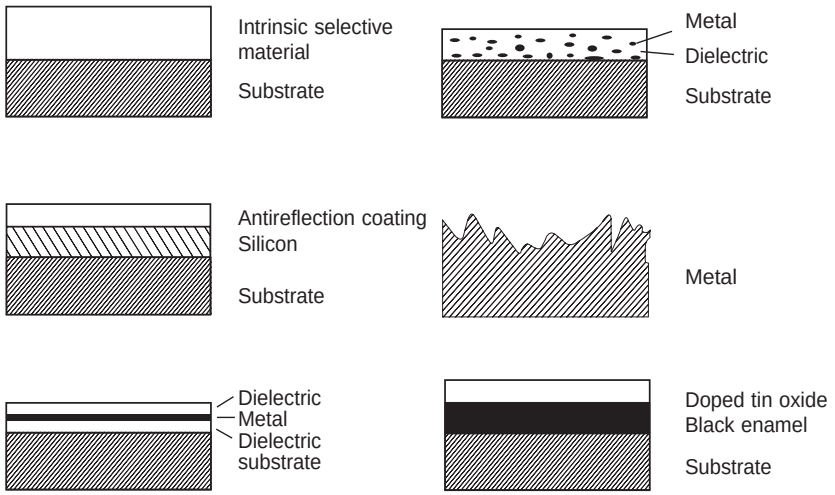

FIGURE 8 Cross-sectional schematic designs of six types of thin films and surface treatments for selective absorption of solar energy.

few such materials, though, and this approach has not been particularly fruitful. Semiconductor-metal tandems can give the desired spectral selectivity by absorbing short-wavelength radiation in a semiconductor with a bandgap corresponding to a wavelength of $\sim 2\,\mu m$ and having low E_{therm} as a result of the underlying metal. The pertinent semiconductors all have large refractive indices, which tend to give strong reflection losses and lower A_{sol}, implying that complex antireflection treatments must be invoked. Multilayer-metal tandems can be tailored so that the thin film stack becomes an effective selective absorber of solar energy. Metal/dielectric composite-metal tandems contain metal nanoparticles in a dielectric (often oxide) host. The composite is often referred to as a cermet. This design principle offers a large degree of flexibility, and the optimization of the spectral selectivity can be made with regard to the choice of constituent materials, film thickness, particle concentration, and grading, as well as the shape and orientation of the particles. The particles are much smaller than any relevant wavelengths of solar (or thermal) energy, and the composite behaves as an "effective medium" with properties intermediate between those of the metal and the dielectric. Textured metal surfaces can produce a high A_{sol} by multiple reflections against metal dendrites that are $\sim 2\,\mu m$ apart, but the low E_{therm} is rather unaffected by this treatment because the relevant wavelengths are much larger that the dendrite separation. Finally, selectively solar-transmitting films on blackbody-like absorbers can be used to impart spectral selectivity. The relevant thin films are discussed in the following section.

6.2 Spectrally Selective Thin Films

A number of thin films, coated onto metallic substrates by one of the thin film technologies discussed in the preceding section, have been developed in the past, and some of these have reached commercialization. These films normally exploit several of the design principles and physical mechanisms mentioned previously. Electrochemical techniques have been used for several decades to make spectrally selective surfaces (suitable for flat-plate solar collectors) based on electrodeposited films containing chrome or nickel (referred to as black chrome and black nickel, respectively) of complex compositions. Another technique employs anodic conversion of aluminum to make a porous surface layer, followed by electrolysis to precipitate out nickel particles inside the pores. The solid curve in Fig. 9 illustrates a spectral reflectance curve. $A_{sol} \approx 96\%$ and $E_{therm} \approx 15\%$ at 100°C are typical performance data. The durability of these films has been modeled in detail.

The electrochemical techniques involve the handling of large quantities of environmentally hazardous chemicals, and this has led to a current trend toward thin film techniques based on deposition in vacuum. The dotted curve in Fig. 9 shows a spectrum for an optimized sputter-deposited film based on nickel (Ni); the design includes an antireflection layer that boosts A_{sol}. The data correspond to $A_{sol} \approx 95\%$ and $E_{therm} \approx 10\%$ at 100°C. Other sputter-deposited and evaporated films of practical use include a number of cermets with stainless-steel and metal nitride, and compositionally graded films containing chrome oxide and chrome nitride. These films can be used

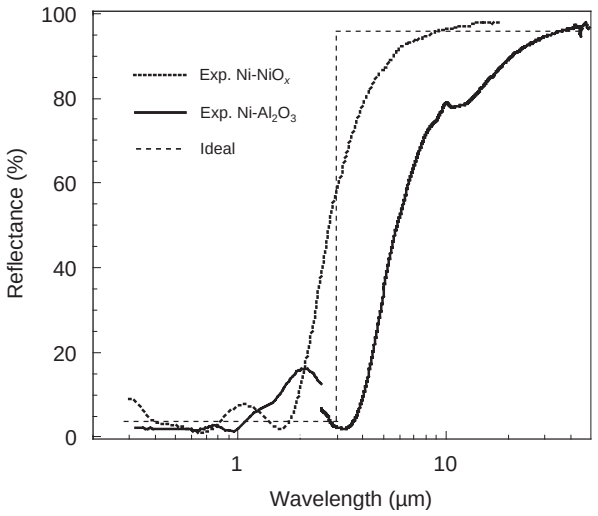

FIGURE 9 Experimental spectral reflectance results for two types of selectively solar-absorbing surfaces, compared to the ideal performance.

for different types of solar collectors, including concentrating ones. Advanced selectively solar-absorbing surfaces have been developed for solar thermal power stations with parabolic trough reflectors and tubular solar collectors. The absorber surfaces used in this case employ sputter deposition to manufacture a complex multilayer film stack incorporating graded molybdenum (Mo)/oxide films, antireflection treatment, and an emittance-suppressing Mo film on the stainless-steel tube serving as a substrate. These absorbers have $A_{sol} \approx 97\%$ and $E_{therm} \approx 17\%$ at 350°C.

6.3 Spectrally Selective Paints

Paints have an obvious advantage in that they can be applied by commonly available techniques. Typically, a strongly absorbing pigment (for example, an oxide of FeMnCu) is mixed in an infrared-transparent polymeric binder such as a silicone or a siloxane. The paint is applied in a layer 2 to 3 μm thick onto a metallic substrate with low E_{therm}. Characteristic data are $A_{sol} \approx 90\%$ and $E_{therm} \approx 30\%$; these data are not as good as those for the thin films. Possibilities to prepare thickness-insensitive spectrally selective paints by including metallic flakes in the binder may lead to interesting products in the future. Visibly colored solar-absorbing surfaces, which may be desirable for aesthetic reasons, can be obtained by relaxing the requirement on A_{sol} somewhat.

7. RADIATION COOLING

As was shown in Fig. 1, the atmosphere can be transparent to thermal radiation in the $8 < \lambda < 13$-μm "window" range. This effect can lead to radiation cooling of surfaces oriented toward the sky. The resource for this cooling has been evaluated through detailed calculations showing that the cooling power for a blackbody surface is 80 to 120 W/m^2, depending on the atmospheric conditions, when the surface is at ambient temperature. If nothing but radiation exchange is considered, the surface can drop to 14–26°C below the air temperature. In the presence of a nonradiative heat transfer equal to 1 W/m^2 K^{-1}, the maximum temperature drop is expected to be 10–20°C. Practical tests, using a multistage radiation cooler placed under an exceptionally dry atmosphere, have demonstrated that a temperature decrease as large as ~33°C can be achieved in practice by purely passive means.

The temperature drop can be enhanced if radiation exchange takes place only within the atmospheric "window." This calls for surfaces with infrared selective emittance, with an ideal reflectance of

$$R(\lambda) = 1 \quad \text{for} \quad 3 < \lambda < 8\ \mu\text{m} \quad \text{and} \quad 13 < \lambda < 50\ \mu\text{m} \tag{5}$$

$$R(\lambda) = 0 \quad \text{for} \quad 8 < \lambda < 13\ \mu\text{m}. \tag{6}$$

If cooling should take place also in the day, it is desired to have $R(\lambda) = 1$ for $0.3 < \lambda < 3$ μm. Calculations have shown that infrared-selective surfaces can have a cooling power between 60 and 95 W/m^2, depending on the atmosphere. Maximum temperature drops of 26–60°C with nothing but radiation exchange, and of 18–34°C when the nonradiative heat influx is 1 W/m^2 K^{-1}, have been predicted. The significance of spectral selectivity for reaching low temperatures is hence evident. Spectral selectivity approximately according to Eqs. (5) and (6) has been achieved with ~1-μm-thick silicon oxynitride films backed by aluminum and by some aluminized polymer foils, including Tedlar. Another possibility is to use confined gas slabs of NH_3, C_2H_4, C_2H_4O, or mixtures of these, with thicknesses of a few centimeters. In both cases, the low reflectance in the atmospheric "window" range is associated with molecular vibrations, and the high reflectance outside this range is caused by the aluminum.

Practical tests of the cooling ability of these materials have been carried out with devices in which the cooling surface, or the gas, is located under an infrared-transparent convection shield. High-density polyethylene foil has suitable optical

properties but requires stiffening in order not to cause convection heating due to mechanical movements caused by wind. Using a radiation-cooled gas, the coolant can be circulated and heat exchanged so that it provides a continuous source for cooling under the clear sky. Radiation cooling can be used for condensation of water from the atmosphere. Preliminary measurements have demonstrated that significant amounts can be collected even under unfavorable conditions (during drought months in a semidesert part of Tanzania). The material used in this case was a 0.4-mm-thick polymer foil pigmented by white TiO_2 and $BaSO_4$.

8. SOLAR CELLS

Solar cells for generating electricity depend on certain materials. In principle, all that is needed to generate electricity is a carrier in an excited state or states; a carrier can be excited from a ground state to an excited state by photon absorption, and to generate electricity requires some means of extracting or supplying carriers to or from these states. There are many options but, despite much research and development over decades, the attention has been focused almost entirely on a few materials.

Silicon (Si) is an excellent material for solar cells and is by far the most widely used one. It is nontoxic, very abundant, and has a well-established technological base due to its ubiquitous uses in microelectronics. Essentially, a slab or film of Si is n-doped and p-doped in the two film surface regions, and this structure is positioned between a transparent front electrode arrangement and an opaque metallic back electrode. (Elements that serve as dopants are either p-type acceptors or n-type donors; adjoining n and p regions form a junction that passes current from p to n.) The Si can be of three types: crystalline (cut from a single crystal ingot), polycrystalline (made from a multicrystalline ingot or prepared by "ribbon growth"), or amorphous and hydrogenated (typically a $\sim$0.3-μm-thick film made by glow discharge deposition of a silane gas). High photoelectric conversion efficiency demands low reflection losses, which can be achieved by an antireflecting film or–in the case of a single crystalline material–by using anisotropic etching to make a pyramid-type texturing.

Compound semiconductors of the III–V type (gallium, arsenic, aluminum, indium), based on GaAs, (Al,Ga)As, InP, or (In,Ga)P, can show high efficiency as well as good resistance to ionizing radiation; they are costly, though, and mainly used for space applications. Among the II–IV compounds (cadmium, tellurium), CdTe and Cd(S,Te) are known for their robust manufacturability and are of interest for ground-based solar cells, although environmental concerns regarding large-scale use of a technology including cadmium should not be overlooked. Among the I–III–IV_2 compounds (copper, indium, selenium), $CuInSe_2$, $Cu(In,Ga)Se_2$, and $Cu(In,Ga)\ (S,Se)_2$ are notable for their possibility to reach high photothermal conversion efficiencies in potentially low-cost thin film solar cells. Numerous other materials–including polymers–and approaches to solar cells are possible, and many other compound semiconductors may well turn out to have favorable properties. Some of those may find applications in thermophotoelectricity, i.e., cells operating with thermal irradiation. Others may be used in tandem cells, encompassing superimposed cells with optical bandgaps that are large on the exposed surface and gradually shrink toward the underlying substrate.

Alternatively, photoelectrochemical techniques can be employed to generate electricity, and studies of nanocrystalline dye cells are presently of interest. These cells absorb light in the dye molecules–normally containing a ruthenium-based compound–coated onto nanocrystals of TiO_2 made by colloidal technology or other means. Electrons are excited in the dye and can flow into the conduction band of the adjacent n-type TiO_2. The electron is transferred to a transparent front surface electrode, through the load, and to a counterelectrode having a thin layer of platinum. Here it reduces triiodine to iodide, which then diffuses to the dye molecules and reduces them back to their original state. Sealing and durability are issues that need to be resolved before widespread applicability is possible. Also, the fact that the fundamental principles of functionality remain obscure may hamper rapid progress.

Generally speaking, solar cells lose efficiency when they become warm. It is therefore of interest to devise cells and cell systems that minimize heating. One possibility is to use external surfaces that reflect the subbandgap wavelengths useful for photothermal conversion onto the solar cell while absorption prevails at longer wavelengths. Mirrors of SnO_2-coated aluminum have been developed for this purpose. One aspect of today's solar cell technology that requires particular attention, because it proliferates, is the global availability of the raw materials. Gallium, selenium, and ruthenium are all rare components of Earth's crust. Indium is also widely

believed to be rare, but recent assessments indicate that availability is not a serious issue.

9. COATINGS FOR GLAZINGS: STATIC PROPERTIES

9.1 Principles

Architectural windows and glass facades are problematic from an energy perspective. On the one hand, their primary function, to provide visual contact between indoors and outdoors, as well as day lighting, should not be compromised. On the other hand, there are often unwanted energy flows, with too much thermal energy leaving or entering the building via the window and a concomitant demand for space heating and cooling; furthermore excessive solar energy may be admitted, which puts additional demand on air conditioning. Present architectural trends tend to increase the window areas, so that the energy issue becomes even more pressing.

The radiation part of the heat transfer can be controlled by thin films with a low E_{therm}, which, in a multiply glazed window, should face one of the confined air (or gas) spaces. In this way, the heat transfer across a vertically mounted window can drop from ~ 3 to $\sim 1.5\,\text{W/m}^2\,\text{K}^{-1}$ for double glazing and from ~ 1.8 to $\sim 1.0\,\text{W/m}^2\,\text{K}^{-1}$ for triple glazing. Obviously, T_{lum} must be large for these films. The infrared part of the solar radiation, which transmits energy through the glazing but is not needed for vision, can be stopped by a thin film having low transmittance at $0.7 < \lambda < 3\,\mu\text{m}$. These demands have led to the development of two types of thin films, i.e., "low-emittance coatings" (low-E coatings), characterized by

$$T(\lambda) = 1 \quad \text{for} \quad 0.4 < \lambda < 0.7 \quad \mu\text{m} \tag{7}$$

$$R(\lambda) = 1 \quad \text{for} \quad 3 < \lambda < 50 \quad \mu\text{m} \tag{8}$$

and "solar control coatings," characterized by

$$T(\lambda) = 1 \quad \text{for} \quad 0.4 < \lambda < 0.7 \quad \mu\text{m} \tag{9}$$

$$R(\lambda) = 1 \quad \text{for} \quad 0.7 < \lambda < 50 \quad \mu\text{m}. \tag{10}$$

The spectral selectivity inherent in these relationships is of course idealized.

Another way to achieve energy efficiency is to use angular selective thin films on the glass. In this way, it is possible to take advantage of the fact that the indoor–outdoor contact across a window normally occurs along near-horizontal lines-of-sight, whereas solar irradiation comes from a small element of solid angle high up in the sky during most of the day. It is also possible to combine spectral and angular selectivity.

9.2 Spectrally Selective Thin Films

Very thin metal films can have properties resembling those defined in Eqs. (7)–(10). Calculations for extremely thin bulklike films of silver, gold, and copper predict that large values of T_{lum} and T_{sol} can be combined with low values of E_{therm}. However, such films cannot be made on glass or polyester. Rather, the thin film goes through a number of distinct growth phases, and large-scale coalescence into a metallic state with low E_{therm} requires thicknesses exceeding 10 nm, and then T_{lum} and T_{sol} are limited to about 50%. Most of the transmittance loss is due to reflectance at the film interfaces, implying that the transmittance can be boosted by embedding the metal film between dielectric layers, serving, essentially, for antireflection purposes.

Silver (Ag) has the best optical properties and is used in most applications. Gold (Au) and copper (Cu) tend to produce colored films that are undesirable for many architectural applications. Titanium nitride (TiN) can serve as a replacement for Au. The dielectric layer can be of several different kinds, such as Bi_2O_3, SnO_2, TiO_2, ZnO, and ZnS. The multilayer structure may also include corrosion-impeding layers, such as Al_2O_3. Figure 10 illustrates $T(\lambda)$ for three types of thin films based on TiO_2/Ag/TiO_2 and

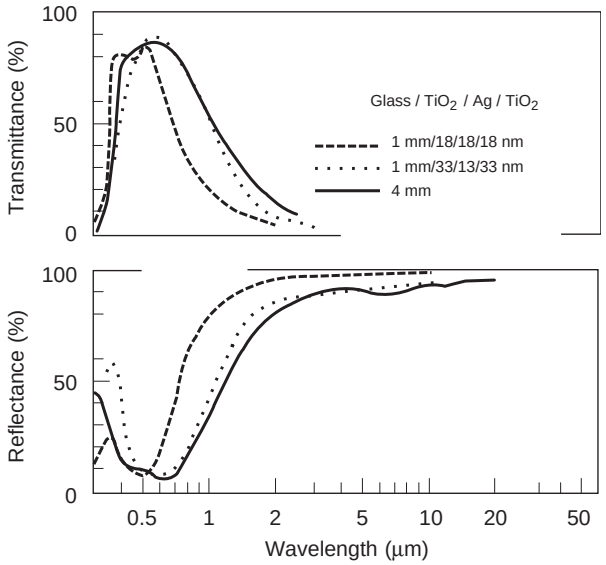

FIGURE 10 Spectral transmittance and reflectance results for glass having thin films based on TiO_2/Ag/TiO_2. Thicknesses are given for two of the film stacks.

deposited onto glass. Depending on the film thicknesses, it is possible to optimize T_{lum} or T_{sol}, whereas E_{therm} is invariably low. Thus, low-E coatings as well as solar control coatings can be made from metal-based thin films. Much of the glass that is used in modern windows and glass facades employs sputter-deposited films based on Ag. The films can be used only under protected conditions, such as inside sealed, double-glazed windows. The film thicknesses are small enough that iridescence, i.e., a rainbow-like exhibition of colors, is not a problem.

Doped oxide semiconductor coatings offer an alternative to the spectrally selective metal-based films just discussed. The practically useful materials include In_2O_3:Sn, SnO_2:F, SnO_2:Sb, and ZnO:Al. Many alternatives can be found among the ternary and quaternary oxides as well as among mixtures of the mentioned oxides. Nevertheless, the binary oxides have remained popular. The indium-based oxide has the lowest E_{therm}, the selenium-based oxides are most durable, and the zinc-based oxide is most popular for some applications (such as in many solar cells). The films are electrically conducting with a minimum resistivity of $\sim 10^{-4}\,\Omega\,\text{cm}$ for optimally prepared In_2O_3:Sn. Achieving such properties is notoriously difficult, though, and typically requires thermal treatment at $\sim 300^{\circ}\text{C}$ or above.

Figure 11 shows $T(\lambda)$ and $R(\lambda)$ in the full $0.3 < \lambda < 50$-μm range for a 0.2-μm-thick film of In_2O_3:Sn. The parameter denoted n_e is the density of free electrons, which is directly associated with the amount of tin (Sn) doping; in practice, this amount is of the order of a few percent. The data in Fig. 11 were computed from a fully quantitative theoretical model of heavily doped semiconductors and give a clear representation of the salient features developing on increased doping: an onset of high reflectance in the near-infrared (i.e., a lowering of E_{therm}), bandgap widening tending to enhance T_{sol}, and disappearance of absorption features in the thermal infrared (approximately at $20 < \lambda < 30\,\mu\text{m}$). The doped semiconductor oxides can be very hard and resistant to corrosion, and they can be applied on glass surfaces exposed to ambient conditions. The practically useful thicknesses are larger than $\sim 0.2\,\mu\text{m}$, implying that thickness variation, which may be difficult to eliminate in practical manufacturing, may lead to aesthetically unpleasing iridescence.

The refractive index of the doped oxide semiconductors is about 2 for luminous radiation, which tends to limit T_{lum} to $\sim 80\%$. Higher transmittance values can be obtained by antireflection treatment,

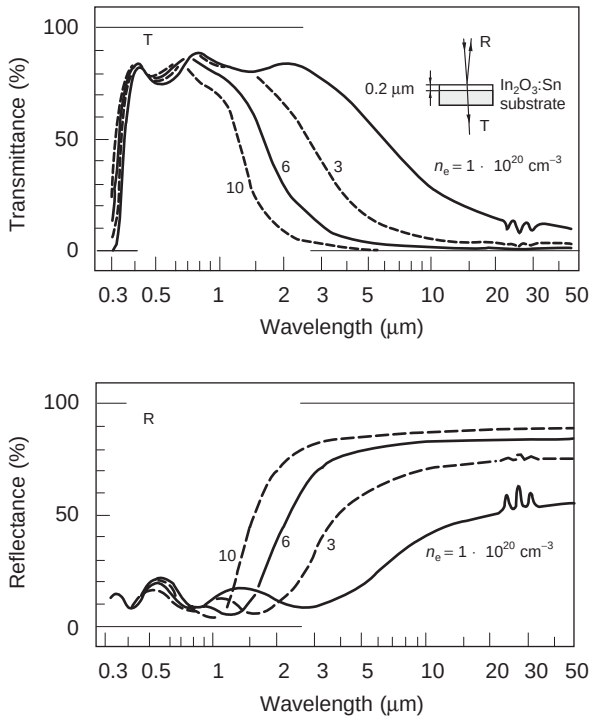

FIGURE 11 Spectral transmittance (T) and reflectance (R) computed from a fully quantitative model for the optical properties of In_2O_3:Sn, using the indicated values of film thickness and free-electron density (n_e).

and T_{lum} can then even exceed the value for uncoated glass. The antireflection layer lowers E_{therm}, but on an insignificant level of a few percent only.

9.3 Angular Selective Thin Films

Pronounced angular properties can be used to invoke energy efficiency for glazings, as mentioned previously. Figure 12 illustrates this feature as computed for a five-layer stack of thin films, specifically with two 12-nm-thick silver films embedded between three SiO_2 films with thicknesses of 120 or 170 nm. Strong angular effects prevail at the larger of these thicknesses, and T_{sol} is 23% for normally incident light and as large as 58% at an incidence angle of 60°. The data in Fig. 12 are symmetrical around the surface normal of the film. However, angular properties that are distinctly different at equal angles on the two sides of the normal can be obtained by the use of films with inclined columnar microstructures. Figure 13 shows a polar plot of T_{lum} recorded for a chromium-based film prepared by evaporation under conditions so that the incident flux arrives at the substrate at an almost glancing angle. The columns needed for the angular selectivity then

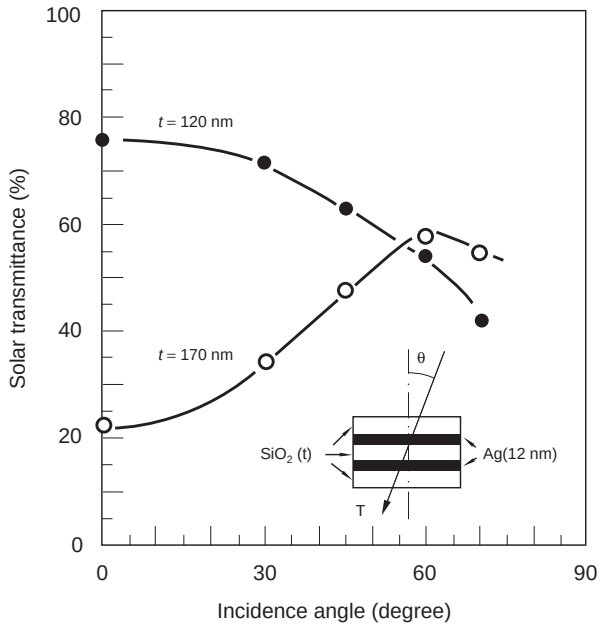

FIGURE 12 Solar transmittance for thin films of SiO_2/Ag/SiO_2/Ag/SiO_2 as a function of SiO_2 thickness (t) and incidence angle (θ).

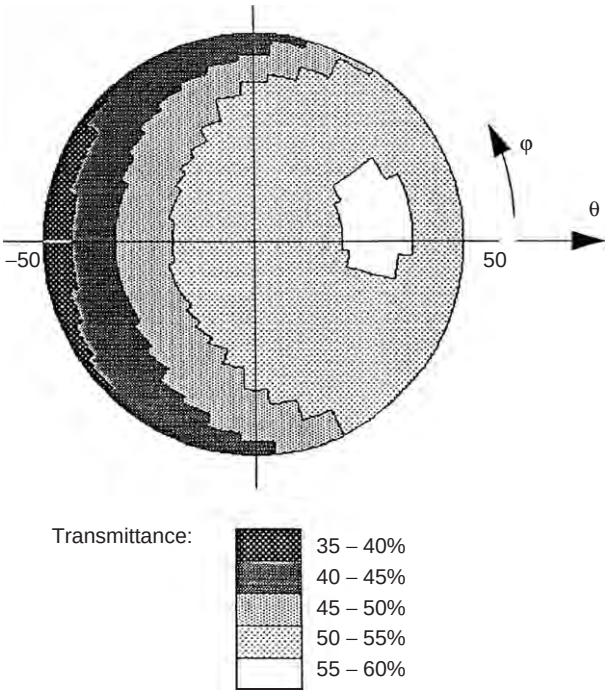

FIGURE 13 Polar plot of luminous transmittance through an obliquely evaporated Cr-based thin film. Data are given as a function of incidence angle (θ) and azimuthal angle (φ).

tend to form an array inclined in the direction toward the evaporated flux. Sputter deposition can also be used for making angular selective films.

10. COATINGS FOR GLAZINGS: DYNAMIC PROPERTIES

Windows and glass facades with variable properties have been the dream of architects for years. Such products are now becoming possible by exploiting "chromogenic" materials. Electrochromic devices are now being used in windows, albeit as yet on a small scale. A range of other options for dynamic fenestration also exists.

10.1 Electrochromic Devices

Electrochromic devices are able to vary their throughput of visible light and solar radiation on electrical charging and discharging, using a low voltage. Thus, they can regulate the amount of energy entering through a "smart window" so that the need for air conditioning in a cooled building becomes lessened. The energy efficiency inherent in this technology can be large, provided that the control strategy is adequate. Additionally, the transmittance regulation can impart glare control as well as, more generally, user control of the indoor environment. The absorptance, rather than the reflectance, is modulated so that the electrochromic devices tend to heat up in their low-transparent state, which has to be considered in a practical window construction. Modulation of E_{therm} is possible in principle, and development of variable-emittance surfaces for temperature control of space vehicles, as well as for other applications, is in progress.

Figure 14 shows an electrochromic five-layer prototype device that introduces basic design concepts and types of materials. A kinship, in principle, to an electrical battery is noteworthy. The central part of the construction is a purely ionic conductor (i.e., an electrolyte), either a thin film or a polymer laminate material; it must be a good conductor for small ions such as H^+ or Li^+. The electrolyte is in contact with an electrochromic layer and a counter-electrode. For a transparent device, the latter must remain nonabsorbing, irrespective of its ionic content, or it should exhibit electrochromism in a sense opposite to that of the base electrochromic film. This three-layer configuration is positioned between transparent electrical conductors, normally being doped oxide semiconductors of the kinds previously discussed; they are backed by glass or polyester foil. By applying a voltage of a few volts–conveniently obtained from solar cells–between the outer layers, ions can be shuttled into or out of the electrochromic

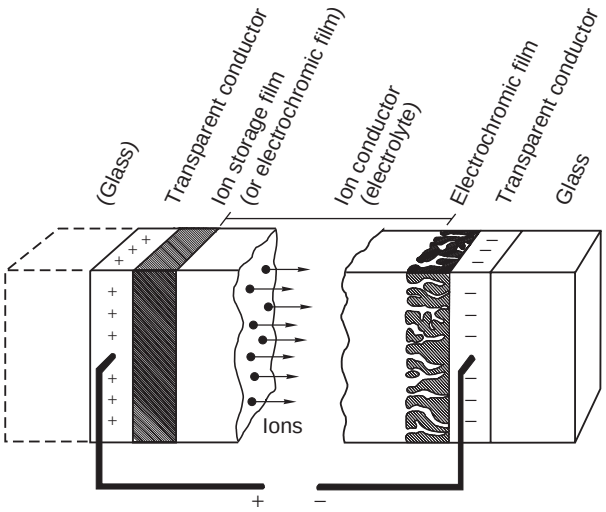

FIGURE 14 Basic design of an electrochromic device, indicating transport of positive ions under the action of an electric field.

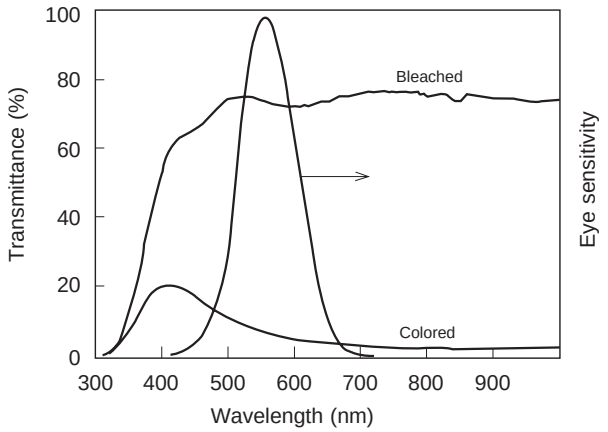

FIGURE 15 Spectral transmittance through an electrochromic foil including thin films of tungsten-based and nickel-based oxides. Data are shown for fully bleached and colored states.

film(s), the optical properties of which are thereby changed so that the overall optical performance is changed. The voltage needs to be applied only when the transmittance is altered, i.e., the electrochromic devices exhibit open-circuit memory. The time for going between bleached and colored states is largely governed by the electrical resistance of the transparent conducting films. Smart windows of the scale of a square meter require about ten minutes to change from a bleached state to a moderately colored state. Smaller devices can display much faster dynamics.

There are many materials and design issues for practical electrochromic smart windows. Electrochromism is found in numerous organic and inorganic materials, the latter mainly being transition metal oxides. Films of WO_3 are used as the base electrochromic layer in almost all devices studied until now. However, many options exist for the counterelectrode, with good results having been documented for oxides based on Ce, Co, Ir, Ni, and V, whereas other designs have used $KFe^{3+}Fe^{2+}(CN)_6$ (known as "prussian blue"). Additions of Al and Mg to oxides of Ir or Ni can enhance the bleached-state transmittance of the devices, which is important for architectural applications. In the case of Ir oxide, the additions lead to significant cost reduction. Many alternatives exist for the central electrolyte, which can be an adhesive polymer with high ionic conductivity or–in an all-solid-state approach with superimposed thin films–a hydrous layer of Ta_2O_5, ZrO_2, or SiO_2 serving as a conductor for H^+.

Figure 15 illustrates the optical performance of a laminated polyester-based electrochromic foil device comprising films based on WO_3 and NiO in the bleached state and after maximum coloration. It is seen that T_{lum} can be modulated between 74 and 7%. There is a trade-off between durability and maximum coloration, though, and a minimum T_{lum} of $\sim$30% may be more adequate for practical applications.

10.2 Some Alternative Chromogenic Technologies

"Gasochromic" thin films represent an alternative to the electrochromic devices, with specific pros and cons. Glass is coated with a WO_3-based thin film having an extremely thin surface layer of catalytically active Pt. The coated side of the glass is in contact with the gas confined in a carefully sealed double-glazed window. By changing the amount of H_2 in contact with the thin film, it is possible to insert a variable amount of H^+ and the transmittance is then modulated in analogy with the case of the electrochromic device. Among the many other possibilities to control T_{lum} and T_{sol} electrically, of particular note are suspended-particle devices and phase-dispersed liquid crystal devices. These have much swifter dynamics compared to electrochromic devices, but require higher voltages. Rapid technological progress, as well as the proprietary nature of much basic information, make a detailed comparison of the various techniques difficult.

Thermochromism represents another possibility to control T_{sol} in order to create energy efficiency in buildings. The most interesting material, a thin film based on VO_2, undergoes a structural transition at a certain "critical" temperature τ_c, below which the material is semiconducting and relatively nonabsorbing in the infrared. Above τ_c, it is metallic and

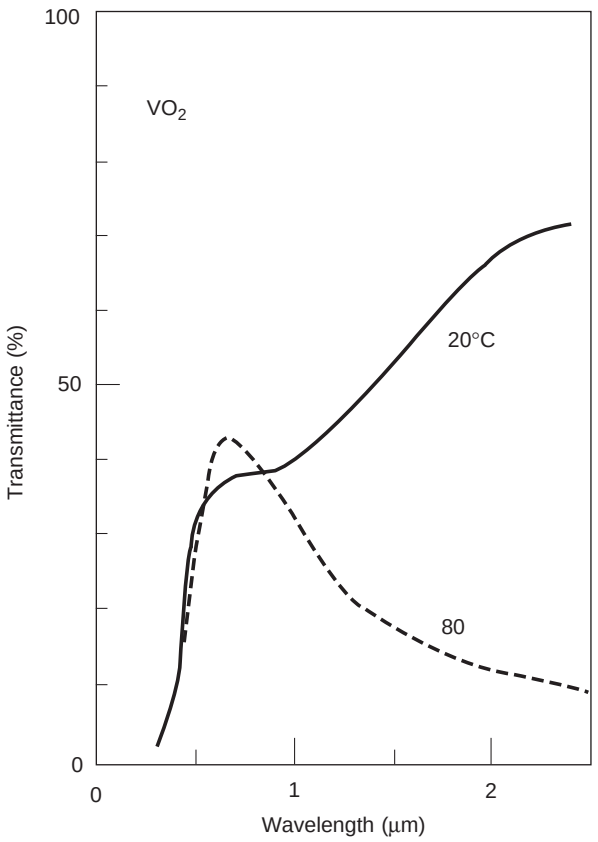

FIGURE 16 Spectral transmittance through a thermochromic VO_2 film at two temperatures.

infrared reflecting. Figure 16 shows typical data on $T(\lambda)$ above and below τ_c. Bulklike VO_2 has $\tau_c \approx 68^\circ C$, which obviously is too high for architectural applications in buildings, but τ_c can be decreased to room temperature by additions of Mo, Nb, or W, for example.

Still another possibility to vary T_{lum} as a result of temperature changes is found among the "cloud gels," which can be interposed between the panes in a double-glazed window. These are polymers for which "clouding"–i.e., transition to a diffusely scattering state–can set in above a certain τ_c due to a reversible thermochemical dissolution and a thermally induced modification in the lengths of the polymer molecules.

11. SOLAR PHOTOCATALYSIS

Under the action of solar irradiation, photocatalytically active surfaces can cause the breakdown of organic molecules as well as microorganisms adsorbed on these surfaces. Thus hazardous or otherwise unpleasant pollutants in air or water can be decomposed into tasteless, odorless, or at least less toxic compounds. Well-known photocatalysts are oxides of Cd, Ce, Fe, Sb, Sn, Ti, W, Zn, and Zr, with most developmental work having been devoted to TiO_2. All of these oxides are able to use ultraviolet light only. This is an advantage for some applications, and, for example, a double-glazed window may be transformed into a photocatalytic reactor with an outer ultraviolet-transparent pane (cf. Fig. 2) and an inner pane with a TiO_2 film. In other cases, it is also an advantage to employ visible light for inducing photocatalysis; transition metal additions to the oxides previously mentioned , as well as nitrogen incorporation, are able to widen the spectral range for photocatalysis.

Photocatalytic decomposition of water into hydrogen and oxygen has been investigated for many years, but it has turned out to be difficult to accomplish effectively using solar irradiation. Present research includes studies of noble-metal-loaded oxide catalysts of many kinds, sometimes covered with NaOH or Na_2CO_3. Ultrasonic irradiation of the catalyst can improve the efficiency of water splitting.

Glossary

automobile An average light-duty vehicle representing passenger cars, sport-utility vehicles, minivans, and light trucks.
composites A material composed of a reinforcing material (e.g., glass or carbon fibers) in a matrix material (e.g., polymers).
lightweighting Using lighter materials or efficient system design to reduce vehicle weight.
monocoque A type of motor vehicle design in which the body and frame are integrated into eggshell shape, resulting in a small number of relatively large parts.
recovery rate The percentage of usable recycled materials recovered from discarded vehicles.
recycling rate The percentage of vehicles from which materials are collected, separated, or processed and returned to the economic mainstream to be reused in the form of raw materials or finished goods.
thermoplastic A polymer in which the molecules are held together by weak secondary bonding forces that can be softened and melted by heat, then shaped or formed before being allowed to freeze again.
thermoset A polymer that solidifies irreversibly when heated due to a chemical reaction involving cross-linking between chains.
unibody A conventional body on frame motor vehicle body structure design composed of a relatively large number of hollow sheet metal components onto which body panels are welded by welding robots or in multispot welding units.

Material composition continues to play an important role in automobile engineering, particularly with the renewed importance of fuel economy standards and advanced vehicle designs such as hybrid and fuel cell vehicles. Of the numerous types of materials currently in use in automobiles, lightweight materials, particularly aluminum, polymer composites, and magnesium, have received increasing attention because of their potential to reduce the weight of vehicles. Most of these lightweight materials are more energy intensive to produce than conventional steel, the predominant material in current vehicles. A life cycle energy comparison that addresses the vehicle-use phase, which contributes the major share of a vehicle's life cycle energy use, is appropriate to examine the materials' energy implications. The effect of vehicle weight on its safety is an overriding sensitive issue to consumers, and it remains a hotly debated issue in vehicle lightweighting.

1. MATERIAL USAGE TRENDS IN AUTOMOBILES

Automobiles play an important role in the world economy with a share of about 50% of total transportation energy demand. The transportation sector accounted for about 27% of total U.S. energy consumption in 2000. Growth in U.S. energy consumption of the past decade averaged about 2% annually, with automobiles accounting for about 57% of total transportation energy in 2000. Between 1978 and 2001, the average U.S. automobile weight has decreased only by 7.3% (3570 lbs versus 3309 lbs), whereas sales-weighted fuel economy improvements in automobiles have been more than 40% (19.9 miles per gallon versus 28.6 miles per gallon). As the share of heavier SUVs, minivans, and light trucks continued to grow during the past decade, the percentage increase in average vehicle weight in the fleet is significantly higher. A combination of technology improvements and weight reduction brought

 © 2004 Elsevier Inc. All rights reserved.

about this fuel-economy gain. The technology improvements range from reduced internal engine friction to reduced aerodynamic drag. Major improvements were provided by the transition from rear- to front-wheel drive, which allowed interior volume to be maintained while weight and exterior size were reduced, and by conversion from carburetors to electronically controlled fuel injection. There were many other improvements as well: more efficient automatic transmissions, improved lubricants, lower rolling resistance tires, reduced accessory loads, material substitution, and so forth.

The technology choices in U.S. automobiles have been a concern since the environmental movement of the 1960s, the oil crisis of the 1970s, the Clean Air Act of 1970 mandating standards for emissions, and the Energy Policy and Conservation Act of 1975 mandating national standards for automotive fuel economy (popularly known as corporate average fuel economy). These events and policies prompted automakers to address fuel economy, formerly a minor factor in automotive design, as a vital engineering requirement. The 1994 Partnership for a New Generation of Vehicles (PNGV) program (lately superseded by Freedom Cooperative Automotive Research (FreedomCAR), which is unlike independent of any specific vehicle platform with a focus on fuel cell vehicles without any specific fuel economy goal), has a formidable goal of developing production-ready mid-sized vehicles that are 40% lighter than baseline vehicles and achieve 80 miles per gallon fuel economy. This program considered many new research areas, including advanced powertrain concepts with as much as 40 to 45% powertrain thermal efficiency, body and chassis weight reduction technologies, alternate design concepts, and more efficient accessories development. To achieve this goal, the focus was on hybrids and fuel cells for propulsion systems; aluminum, magnesium, and glass-fiber composites for body and chassis; and a range of improvements in accessories.

With improved vehicle performance and emission requirements, vehicle weight is becoming increasingly important to achieving better fuel economy. It is estimated that each 1% reduction in vehicle weight provides a 0.66% improvement in fuel economy, after a vehicle has been fully redesigned to account for the reduced power demands of a lower mass. The primary weight savings leads to secondary savings with lighter engine and powertrain configuration. Although more than 85% of fuel economy gain observed during the past three decades can be credited to technology improvements, the use of lightweight materials has played a key role in maintaining the vehicle weight, countering the weight added by the technology gains and passenger safety and comfort features. Furthermore, since 75% of a vehicle's energy consumption is directly related to factors associated with vehicle weight, the need to produce lightweight vehicles that also are safe and cost-effective is critical.

An average U.S. automobile weighs about 3240 lbs, of which body, chassis, and powertrain vehicle subsystems contribute 35%, 34%, and 27%, respectively, of its total weight. Compared to a U.S. automobile, European and Japanese automobiles are lighter in total vehicle weight due to a significant growth in the use of nonferrous metals and plastics/composites in the past. A European automobile has the least share of ferrous materials content (i.e., about 60%), and its current share of plastics/composites is estimated to be more than 10% of its vehicle weight. Despite the competition from other materials, ferrous metals continue to be the dominant material in an automobile, as shown for the United States in Fig. 1. Ferrous materials are flexible in use and relatively cheap, and their properties including its crash behavior and recyclability, are well understood and established. Although there has been a steady decline in conventional steel usage, the increased use of lighter, high-strength steel, with its improved formability in combination with efficient system design with lower weight, has helped to maintain steel's $>50\%$ share of total materials. Tailored blanks, hydroforming, and various metallurgical improvements have also kept the steel content of vehicles relatively constant. The decrease in iron content is due mainly to the switch to aluminum engine blocks and heads. The use of stainless steel is very limited to exhaust systems and engine gaskets applications today. The use of lightweight materials is largely responsible for the decline of 7.3% in total vehicle weight during the 1978–2001 period, as shown in Fig. 1.

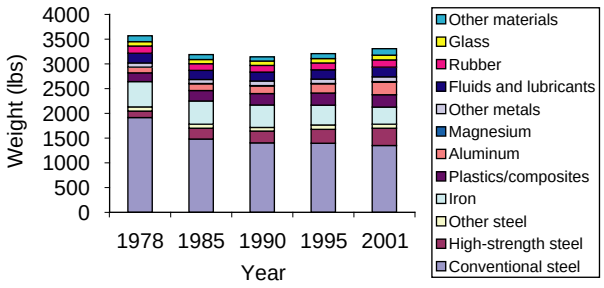

FIGURE 1 Material composition trend of a U.S. automobile.

Of the lightweight materials, aluminum, plastics/composites, and (to a far lesser extent) magnesium continue to have significant roles in automotive materials usage. The new Lincoln LS represents a current example of lightweight materials on a high-volume production vehicle. Aluminum, plastics, and magnesium total more than 20% of the vehicle's weight. Between 20 and 25% of the ferrous materials are high-strength steels selected to achieve weight reduction. Aluminum, composites, and magnesium have weight reduction potentials ranging from 25 to 75%, depending on the material replaced and automobile part application, as shown in Table I. Due to some inferior mechanical properties and manufacturing technology limitations, the mass reduction achieved using some of these lightweight materials in commercial applications is generally lower than the theoretical densities shown in this table. Consumer preferences—such as performance, style, comfort, economy, and the brand image—are relatively less important than many other hard-headed criteria—such as cost—which dictate the material choice selection by the vehicle manufacturer. Life cycle (e.g., recyclability, manufacturability, environmental issues, etc.) and engineering needs are also gaining momentum in material selection criteria.

Of the nonferrous lightweight metals, aluminum, having a density one-third that of steel, has seen the most use, with applications ranging from body closure panels to wheels and engines. Although aluminum parts are generally 1.5 times as thick as steel to achieve comparable stiffness, they still offer a significant weight savings. Aluminum use in automobiles has grown steadily from an average of 180 lbs in 1978 to 257 lbs in 2001, with roughly 80% of that in cast components, mostly engines and transmissions. This substitution of steel has been on a part-by-part basis, not the result of any radical design change. Aluminum is rapidly becoming the material of choice for vehicle's cylinder blocks.

Use of wrought aluminum sheet, however, is limited to air conditioning units and a few closure panels for the car body. Both panels and structures are still largely an unfilled dream for aluminum. The most popular body panel application is the hood (e.g., F-series pickup truck) due to weight balancing advantages. Liftgates are a rapidly growing application. Currently, only 5 to 10% of body panels are made of aluminum. A significant displacement of steel by aluminum would occur if and when steel as the primary material is being replaced in the chassis or the body of the car, since the latter contributes more than 30% of the average total vehicle weight. Aluminum panels on an extruded aluminum spaceframe were first used in the 1994 Audi A8—a low-volume production car. Price is a major problem presently, but the price (and its variability) is likely to be reduced as more aluminum scrap becomes available.

Composites have been the important peripheral contender in the material war between steel and aluminum with magnesium. Automotive composites consist of a reinforcing fiber in a polymer matrix, with polyester, vinyl ester, and epoxy resins the most often used matrixes. These polymer-based composites—having densities one-sixth to one-third that of steel, depending on the fiber type, fiber loading, and resin type—are the most common type of composites used in automotive applications. The fibers have densities ranging from 1.8–2.5 gm/cm^3, as shown in Table I; the commonly used polymer matrix materials have densities ranging from 1.1 to 1.4 gm/cm^3. About two-thirds of all composites currently use glass fiber and polyester or vinyl ester resins and provide a wide range of potential automotive applications, including body panels, suspension, steering, brakes, and other accessories. Demand varies widely by application. The composite materials have not changed significantly over the past 30 years, with glass fibers being the mainstay among reinforcement materials, while in some select applications carbon and aramid fiber materials are used. Today's average automobile is about 8% plastics and composites, combined, and their use has grown slowly, increasing by only 73 lbs during the 1978–2001 period, as shown in Fig. 1.

Polymer composites have been used for applications with low production volumes because they

TABLE I

Weight Savings and Relative Cost of Lightweight Materials

Lightweight material	Density (gm/cm^3)	Material replaced	Mass reduction (%)	Relative cost (per part)
High strength steel	7.8	Mild steel	10–24	1
Aluminum	2.7	Steel or cast iron	40–60	1.3–2
Magnesium	1.8	Steel or cast iron	60–75	1.5–2.5
Magnesium	1.8	Aluminum	25–35	1–1.5
Glass FRP	2.5 (fiber)	Aluminum	25–35	1–1.5
Carbon FRP	1.8 (fiber)	Mild steel	50–65	2–10+
Titanium	4.5	Alloy steel	40–55	1.5–10+
Stainless steel	7.9	Mild steel	25–40	1.2–1.7

require less lead times and lower investment costs relative to conventional steel fabrication. Important drivers of the growth of polymer composites have been the reduced weight and parts consolidation opportunities the material offers, as well as design flexibility, corrosion resistance, material anisotropy, and mechanical properties. Composites use is still predominantly in nonstructural elements of the vehicle because they are highly competitive for bolt-on exterior panels such as hoods, decklids, and fenders, especially in low- and mid-volume light-duty vehicles such as Corvette, Dodge Viper, and AP minivans. In addition, composite cross vehicle beams, radiator housings, fascia supports, bumper systems, and floor trays have contributed to weight savings. Corvette's body has been made largely of composites since the 1950s, and General Motor's Saturn and other vehicles use composite side panels. The latest growth in automotive composites has been mostly in exterior parts such as fenders, tailgates, and pickup beds.

Automotive manufacturers are becoming increasingly interested in carbon-fiber-based polymer composites because they offer high stiffness and low density for structural applications. They can also be made lighter than their glass-reinforced counterparts, providing a significantly higher weight-savings potential. Its most significant use to date has been in concept cars (e.g., about two decades ago in the Ford Granada and in General Motors' 1991 Ultralite). Carbon fiber composites became part of the government's research plans with the PNGV goal of achieving by 2011 a production-ready, 100-mpg, mid-sized vehicle, which is expected to contain at least 10 lbs of carbon fiber. In addition, there has been interest in fiber-reinforced thermoplastic composites that have the typical advantages of polymer matrix composites—such as weight savings, high strength, high stiffness, corrosion resistance, parts integration, and energy absorption—and have an indefinite shelf life, are recyclable, and are feasible for automated, high volume processing with a potential for rapid and low-cost fabrication. The most-used thermoplastics today are glass-filled thermoplastics developed for a variety of applications from intake manifolds to engine covers and, to a lesser extent, for body panels.

Magnesium is becoming a significant automotive material in varied applications such as engine blocks, seat frames, steering column components, transmission housings, wheels, and valve covers. Despite density that is 25% and 67% lower than aluminum and steel, respectively, magnesium use in automobiles has been limited to die castings because of its high cost and limited supply. The lower cost of producing die cast parts helps to offset its high cost. The market for automotive magnesium parts has grown rapidly, nearly 15% annually during the 1990s, achieving a level of about 8.5 lbs per vehicle in 2001. Some high-end models, such as the 2003 Dodge Viper, are slated to contain over 44 lbs of magnesium, mostly in the one-piece instrument panel that has been incorporated into the design. Magnesium use in wrought automotive products, such as seat frames, wheels, and body panels, has been very limited because of the lower process throughput and the metal's cost. Magnesium's creep resistance is inferior to aluminum's and limits its application in automotive powertrains today.

The "other metals" category in Fig. 1 mainly includes copper, brass, powder metal parts, and zinc die castings, where the latter represents only about 3% of this category. Zinc is also used for the coating of steel and being considered to protect automotive underbody parts. Nonferrous metals are important in powder metallurgy and metal matrix composites, both of which are being used increasingly in components such as camshafts, connecting rods, pistons, gears, and pulleys. The use of ferrous powder metallurgy parts in applications such as connecting rods has been trending upward primarily because it is less expensive than other methods. Metal matrix composites are gaining wide acceptance in niche applications such as brake discs, drums and calipers, pistons, prop shafts, and tire studs. Copper use in automobile radiators has been declining as manufacturers shift to aluminum, which is lighter and perceived to have a stable market price.

Another promising lightweight material that has only recently seen even limited use is titanium. It has potential application in suspension springs, exhaust systems, and a number of engine and chassis parts. Passenger car components that could benefit from titanium include engine valves, connecting rods, valve-spring retainers, and valve springs. Titanium has the benefits of being half the weight and twice the strength of steel (as shown in Table I), with great potential for a reduction in engine noise and vibration and improved durability due to reduced component loads, vehicle weight reduction, and improved powertrain efficiency. However, the cost (both raw material as well as component fabrication) is prohibitive, four times higher than even stainless steel. Titanium's high strength, low density, excellent corrosion resistance, and the relative worldwide abundance of its ore make it a

long-term viable lightweight alternative to steel in engine and body/chassis applications. Because of its high corrosion resistance at elevated temperatures, titanium is the only lightweight substitute for stainless steel in exhaust systems. The first use of titanium in a production automobile was for connecting rods in the Acura NSX V-6, and the use of titanium springs in the 2001 model year Volkswagen Lupo FSI has contributed to about 180 lbs reduction in weight.

2. FACTORS IMPEDING LIGHTWEIGHT MATERIALS GROWTH

Although lightweight materials have significantly penetrated the aerospace and defense industry, their cost has been the major barrier to their large-scale penetration in the automotive industry. A part-cost comparison (which includes both materials and manufacturing) of these materials indicates that relative part costs are anywhere from 1.3 to 10+ times higher than the materials they replace (see Table I). At the higher end of these cost differences are carbon fiber reinforced polymer composites, titanium, and magnesium, which are very little used in automobiles today. In most cases, the cost of the primary material is significantly higher than conventional steel's cost, and the manufacturing-process cost is only a small share of the overall part cost. Thus, any automotive system application with a greater potential for parts integration improves the economic viability of parts made of lightweight materials. These expensive lightweight materials have comparatively penetrated in Europe and Japan more than the United States due to lower fuel cost in the United States. In addition, there is a lack of economies of scale due to these materials' relatively smaller industry base. The current consumption of these materials is relatively small compared to steel, and in some cases (e.g., magnesium and rubber) the automotive industry accounts for a major share of the materials' total consumption, as shown in Table II. Most of the lightweight material industries are small, causing instability in material price that promotes substitution among the competing materials. Plastic in Table II does not include polymer composites, whose total consumption by the automotive industry is estimated to be 156 K tonnes in 2001.

Factors in addition to cost that have dampened the growth in lightweight materials use include relatively less pressure for improved fuel economy and from environmental pollution concerns, along with the availability of inexpensive gasoline and to some extent recent subsidies available to traditional materials such as steel. The existing well established manufacturing base is always a big positive factor for steel—there is always reluctance in the industry to avoid the enormous potential capitalization costs of large-scale conversion from steel to lightweight materials. All of the industries lack experience and play a small role in the automotive industry, situations that will only change with the materials' improved economic viability.

A widespread use of aluminum in automobiles would require a dramatic shift in wrought applications. Aluminum stamped parts are more expensive than extruded and cast parts because production-line rates are slower, there are difficulties in welding and assembly, aluminum sheet cost is higher as are die costs because they require special coatings to compensate for springback. The tendency of aluminum sheets to tear requires low stamping rates and extra hits for the stampings. Most aluminum used in outer-body panels is heat-treatable, 6000-series aluminum alloys, which are still relatively expensive to produce. The potential exists to produce 5000-series aluminum alloy for inner body panels at $1/lb using continuous casting and exploiting large economies of scale. Under existing fabrication conditions, only a drastically consolidated design such as a spaceframe is even slightly competitive with the conventional unibody design. A cost comparison indicates that aluminum body structures made of continuous-cast, coated aluminum at $1/lb (unlike ingot and stamped sheet rolling cost at $1.30/lb) cost 1.6 times more than body structures made of conventional steel. It is not only raw material cost difference, but also the rivet bonded assembly for aluminum structures that causes this large cost difference.

TABLE II

2001 Material Usage by the Automotive Industry

Material	U.S. total consumption (tonnes)	Automotive share (%)
Steel	90 M	14
Iron	9 M	31
Aluminum	11 K	32
Plastic	46 K	4
Magnesium	96 K	47
Zinc	1 M	23
Rubber	3 M	68

As with other lightweight materials, the price of resins and glass fiber reinforcements poses a major barrier to the growth of automotive composites. The long cure-cycle times required for automotive part applications make it impossible to maintain high automotive production rates. For composites to be cost competitive on a part-by-part substitution, improvements are necessary in cycle times and material utilization, which in some cases have been estimated to currently contribute 21% and 60%, respectively, of the total cost of carbon-fiber-reinforced thermoplastics. On a $/lb basis, the cost of polymer composites is about two to three times higher than steel, but a recent study comparing the monocoque designs indicates that the cost of glass-fiber reinforced thermosets and carbon-fiber-reinforced thermoplastics are about 62% and 76% higher than the conventional steel unibody. The material cost plays a key role in the economic viability of polymer composites, particularly at higher production volumes for glass-fiber-reinforced thermosets and for carbon fiber-reinforced thermoplastics composites. A 50% reduction in the carbon fiber cost (to prices in the $3 to $5/lb range) and smaller cost reductions in other thermoplastic materials are needed for the composites to be economically viable. Also impeding large-scale use of composites is a curious mixture of concerns about material issues such as crash energy absorption, recycling challenges, competitive cost pressures, the industry's general lack of experience and comfort with the material, and industry concerns about its own capabilities.

Technical and institutional drawbacks, in addition to cost, have limited magnesium use in vehicles, especially for wrought magnesium products. Because magnesium is very reactive, corrosive, hard to form at room temperature, and has a relatively high percentage of scraps and refuses, its part production cost is significantly higher than that of competing materials. In addition, magnesium has a small supply base, with annual production about 1400 times and 45 times less than steel and aluminum, respectively. Because it is a small industry and not traded on the London Metal Exchange, its price is more prone to swings as demand grows and absorbs available production. In addition, past supply expansions in magnesium production capacity have not been systematic enough to harness potential demand for low-cost material in the auto industry. Automakers' demand surpassed industry capacity, causing wild price swings, which caused parts manufacturers to switch from magnesium to other competing materials. Recent cheap imports, particularly from Russia and China, have caused a severe blow to the industry, forcing several magnesium production plants worldwide to close down, including one of the two remaining plants in the United States.

Several current governmental R&D programs (e.g., the Automotive Lightweighting Materials Program by the United States Department of Energy in collaboration with the automotive industry) focus on the viability of primary material production and manufacturing technologies for significantly reducing automotive vehicle body and chassis weight without compromising other attributes such as safety, performance, recyclability, and cost. Aluminum and glass-reinforced polymer composites have been considered as the near-term automotive materials, whereas, magnesium, titanium, and carbon-reinforced polymer composites are considered for the long term. Similarly, the Canadian Lightweight Materials Research Initiative (CLiMRI) coordinates research and development of materials and processes for weight reduction in transportation applications, besides the multidisciplinary auto-related research and development initiative "Auto21" to influence the vehicle in the 21st century. The Industrial and Materials Technologies program of the European Union indicates similar activities in this area of research. The resulting ongoing research is expected to address some of the aforementioned impediments to lightweight material use.

3. ROLE OF LIGHTWEIGHT MATERIALS IN ENERGY CONSUMPTION

Due to the increasing use of automotive lightweight materials, concerns have surfaced regarding the fuel savings, lower emissions, and weight savings, particularly with respect to aluminum and magnesium. Life cycle analysis has shown that high energy consumption during production of virgin aluminum and magnesium is offset by the reduced energy consumption in the use phase, bringing the breakeven point to within the lifetime of the car. The point at which a breakeven is reached depends on the amount of lightweight materials included, the amount of recycled material used for production of the part, and the system and conditions assumed in the study. Life cycle assessments with the consideration of "cradle to grave" aspects of a material used in automobiles have been instrumental in providing a

more holistic view of energy consumption, considering energy consumption beyond the materials production stage and demonstrating a significant potential for energy savings.

The major stages of "life" included in the life cycle analysis of automotive lightweight materials are material extraction, part production, use phase, and end-of-vehicle stage. The second and last life cycle stages consume considerably less energy than the first and third stages and have only sparse data about them available in the literature today. The use phase energy consumption has the biggest impact on the life cycle analysis, contributing 60 to 80% of the total energy consumption. The next two largest shares, in order, are material production and part manufacturing. The transportation necessary within each of the phases has often been included in the past studies. The life cycle energy benefit in switching to a lighter weight material is not just a function of weight saved; it is also dependent on material production energies and substitution factors and vehicle operational efficiency.

Table III shows the primary- and secondary-production energy of various materials used in automobiles today. There is considerable variation—as much as 40%—in reported values of material production energies, depending on the estimation methodology used and assumptions about production technology and its efficiency. The primary production energy is the sum of all energies required to extract raw materials from the earth (e.g., mine ore or pump oil) and to process (wash, concentrate, or refine) it into a usable form (ingot or rolled sheet). Much of this production energy is avoided by recycling, although getting a recycled material of a comparable purity to virgin stock is often not readily achieved due to the difficulty in removal of impurities. The recycled content is an important factor in the overall life cycle analysis, as less than 15% of the energy used for production of virgin material is needed for remelting in case of aluminum and magnesium, compared to 30% in the case of steel as shown in Table III. Recycling is gaining momentum with the End-of-Life directive in the European Union affecting the design phase and material decision making processes of automobile manufacturers as well as influencing other industrial activities such as automotive dismantlers and shredders. The directive's recycling targets are 80% and 85% by 2006 and 2015, respectively, with a considerable higher recovery rate of 85% and 95%, respectively, for the corresponding years. This is in contrast with 75% recycling rate today, mostly limited to ferrous materials.

TABLE III

Primary and Secondary Production Energy for Automotive Materials

	Energy (MJ/kg)	
Material	Primary	Secondary
Steel	30	9
Cast iron	34	24
Wrought aluminum	201	29
Cast aluminum	189	26
Cast magnesium	284	27
Reinforced plastic	56	37
Unreinforced plastic	79	14
Copper	140	35
Zinc	53	16

The life cycle energy consumption of a generic family U.S. sedan based on 120,000 lifetime mileage is estimated to be about 974 GJ, which corresponds to the consumption of 46,000 pounds of hydrocarbons (coal, oil, and natural gas). Weight reduction through the use of lightweight materials is shown to significantly reduce the life cycle energy of a vehicle. Several life cycle analyses on a single product basis indicate that although aluminum production is about ten times more energy intensive than steel production, aluminum in automotive applications is less energy intensive during its life cycle than conventional steel. Since vehicle operation dominates overall life-cycle energy use, "lightweighting" with aluminum increases fuel efficiency enough to reduce overall energy use.

For example, a radical use of carbon fiber composites and aluminum (i.e., replacement of all steel and iron with carbon fiber composites and aluminum, respectively, resulting in overall 40% vehicle weight savings) is predicted to yield a life cycle energy savings of 16% for a conventional mid-sized vehicle. The use of recycled materials improves life cycle energy consumption considerably—for example, a 7.5% life cycle energy reduction for a particular aluminum substitution example becomes 12% when the part is 50% recycled aluminum. If aluminum-intensive light-duty vehicles were commercialized on a mass scale by 2005, the reported national petroleum energy savings would be quite significant, about 4% and 5% by 2020 and 2030, respectively. The impacts of lightweight materials on non-conventional vehicles such as electric and hybrid are comparatively less due to the use of highly energy

efficient power-plants that reduce energy consumption in the vehicle use stage.

Life cycle energy comparisons on a single product basis are quite sensitive to the underlying assumptions made for major input parameters. For example, a comparative assessment of material substitution examining automatic transmission cases made from die-cast magnesium and aluminum finds aluminum use more favorable, despite magnesium's significantly higher weight reduction potential. This result is assumed to be due to the different recycling rates for the two materials. On the other hand, magnesium substitution ranging from 10 to 30% in automotive parts like gearbox housing and dashboards, indicated a breakeven point around 40,000 miles.

Recent studies argue that since new product designs are introduced progressively in a fleet, only a fleet level analysis can account for the temporal effects of use and the distribution of energy over a vehicle lifetime. Since the product manufacture and use are distributed over long periods of time that are not simple linear combinations of single product life cycles, it is all the products in use over a period of time, rather than a single product that are more appropriate for the life cycle analysis. This approach allows the prediction of time when benefits are realized. A recent study looking at the rolled products for body-in-white applications (in which aluminum provides the greatest weight saving potential compared to steel and ultra light steel autobody) found that it would take about 4 and 10 years, respectively, for aluminum vehicles to achieve a life cycle energy equivalence with steel and ultra light steel autobody on a single vehicle basis. It would take twice as long to realize the benefits of aluminum in the fleet.

4. AUTOMOTIVE LIGHTWEIGHT MATERIALS OUTLOOK

During the next two decades, a combination of customer expectations, environmental stewardship, and tightened regulations will lead to significant changes in the automobile technologies, where materials will be at the forefront. As technological improvements continue to address the cost and manufacturability issues of automotive lightweight materials, a shift from current high-end and niche applications to widespread applications on a part-by-part basis will be seen. The pressure to boost the light-truck corporate fuel economy with an anticipation of higher future sales in this vehicle category will provide impetus to the growth in the automotive lightweight materials during this decade. As long as the pressure of the 'hypercar" strategy based on a conceptual vehicle combining very low weight with a highly aerodynamic design and a electric drive system capable of achieving a fuel economy 80 to 100 mpg continues, a much greater role for composites, aluminum, magnesium, and possibly titanium in automotive use will be seen. These materials would enable less powerful engines to be used for equivalent performance, compounding the weight reduction throughout the vehicle. This higher usage of lightweight materials trend can be seen in the concept cars developed by the three automobile manufacturers (i.e., Precept by General Motors, ESX3 by DaimlerChrysler and Prodigy by Ford) during the end of the past decade to meet the three-times-greater fuel efficiency goal of the PNGV program, as shown in Table IV. There is a significant increase in aluminum use for all of these concept vehicles, whereas composites use increases significantly in the case of ESX3 only. Carbon fiber and titanium, now rarely used in vehicles, had a significant share in the material composition of these concept vehicles. Development of more efficient design and manufacturing initiatives, as well as parts consolidation, will be necessary for the widespread use of lightweight material

TABLE IV

Material Composition of PNGV Concept Vehicles by Three Automobile Manufacturers

Material	Baseline	Prodigy	ESX3	Precept
Wrought aluminum	47	462	330	304
Cast aluminum	159	271	120	820
Magnesium	6	86	122	7
Titanium	0	11	40	33
Platinum	0.0033	0.01	0.01	0.01
Ferrous	2168	490	528	487
Plastics	193	209	52	187
Resins (for composites)	28	40	428	86
Carbon fiber	0	8	24	22
Glass fiber	19	19	60	35
Lexan	0	30	20	0
Glass	97	36	70	57
Rubber	139	123	148	77
NiMH or LiIon batteries	0	138	88	138
Other	391	83	212	338
Total	**3248**	**2010**	**2250**	**2591**

applications. Lightweighting will become more important as the trend for comfort and safety related system gadgets continue to add weight to the vehicle. With the European directive establishing considerably higher recycling goals, recyclability will pose major barriers to these lightweight materials unless viable recycling technologies and infrastructure are solved and in place.

The development of high-strength steels and relevant design opportunities mean major weight savings can be made without resorting to other materials. Hence, steel is likely to be a substantial automotive material for at least the first third of the century. The $22 million ultra light steel auto body (ULSAB) project recently completed by American Iron and Steel Institute (AISI) demonstrated a 36% mass reduction using high-strength steels based on drastic design changes on benchmark vehicles using tailor-welded blanks, lighter material, and advanced forming processes. A similar ultra light steel auto closures (ULSAC) project demonstrated a number of weight-saving vehicle closure elements such as doors, hoods, decklids, and hatchbacks. Faster growth is predicted for high-strength steel than for aluminum in body panel applications. High-strength steels in optimized designs enable substantial weight reductions when made by innovative manufacturing and assembly technologies. In addition, an extensive use (i.e., about 80%) of advanced high-strength steels (AHSS)—a new category of steels that combine very high-strength with excellent formability—defines the latest ULSAB-Advanced Vehicle Concept (AVC) project by AISI.

Growth in the use of aluminum castings is anticipated to continue, particularly for engines and wheels. Another aluminum-casting growth area is anticipated to be suspension (e.g., suspension knuckles and control arms, as well as structural components, drivelines, and interiors). The possibility exists for other lightweight materials to capture some of these substitution opportunities (e.g., for intake manifolds to be made with reinforced nylon and other polymers and for transmission transfer cases made by magnesium casting). Panel and structures applications are still largely an unfilled dream for aluminum. Aluminum still has to overcome significant technological and economic hurdles before it can replace steel in the car body, and competing with recent advancements in high-strength steel will be difficult. The shift of aluminum producers from being merely material suppliers to being partners with the automakers will facilitate larger-scale use of aluminum. Developments in aluminum stamping, legislative pressures to improve of fuel economy, and recycling targets might make aluminum the primary material in the auto body.

Glass-fiber-based polymer composites using thermosets as the matrix material will likely hold their own, but usage will grow at a much lower rate than expected for reinforced thermoplastics, which are likely to capture nearly all the growth anticipated later this decade. These materials will play a significant role where part consolidation is great, at a system level rather than on part-by-part substitution. Low tooling cost and lightweighting potential will continue to be the driving force for increased penetration into the light truck area. Due to the cost and toughness advantages of thermoplastic composites, automotive underbody shield application areas look promising. Carbon-fiber-based polymer composites use will be limited to high-end and niche applications demanding substantially higher weight reduction; further growth will be impeded by the significant cost of carbon fiber.

There appears to exist a general commitment towards the use of magnesium by the automotive manufacturers as evidenced by the partnerships formed between them and major magnesium suppliers. These partnerships include Volkswagen and the Dead Sea Works, Ford and Australian Magnesium Company, and General Motors and Norsk-Hydro. Although magnesium remains a major competitor of aluminum, its growth will be limited mainly to niche automotive applications from the die casting industry until major breakthroughs are achieved in wrought automotive applications. The historical, worldwide growth rate for magnesium die casting has been 13 to 14%, a rate that appears to be sustainable with continued pressure to increase fuel economy and as more vehicles use magnesium dashboards, seats, transfer cases, knee bolsters, and so on. Since the largest current use of magnesium is for aluminum alloying, growth in use of these materials are complementary in the context of lightweighting the automotive fleet. If magnesium's wild price swings observed during the past decade—resulting from the mismatch between supply and demand and the more recent market oversupply with cheap imports from non-Western countries—continue, they will be detrimental to the industry's viability. It is anticipated that a slow expansion in the supply base and prices maintained at above $1.40/lb can lead to a more stable demand and supply growth—in the range of 20 lbs to 80 lbs of magnesium per vehicle by 2015 compared to less than 10 lbs today.

5. SAFETY CONSIDERATIONS IN AUTOMOBILE LIGHTWEIGHTING

It has been strongly argued that improving fuel economy by reducing vehicle weight reduces vehicle safety. Technological improvements that have played a key role in fuel economy improvements appear to be neutral or beneficial to safety. The relationship between vehicle weight and safety is important by itself. Vehicle safety concerns have been gaining momentum lately with the growth of light-duty trucks and sport utility vehicles (SUVs) and the pending legislation to boost the CAFÉ for light duty trucks by 1.5 mpg in model year 2007 vehicles. In 1988, light trucks constituted roughly 30% of the vehicle fleet; by 1994 they were more than 40%; and by 2000 they reached an estimated 45% of the fleet. As the number of car-light truck collisions increased, it raised the question whether the growth in the number and weight of light trucks is having an adverse impact on the safety of passenger car occupants and other road users, possibly exceeding any safety benefits of the vehicle-weight increases for the occupants of the trucks.

Safety issues surrounding a general downsizing are concerned with the details of how vehicle designs may change, differences in the performance of lighter weight materials, the precise distribution of changes in mass and size across the fleet, and interactions with other highway users. Of the driver, environment, and vehicle, the vehicle is the least important factor in highway fatalities. To isolate the effects of a less important factor from the effects of more important yet related factors is often not possible. Measure of vehicle exposure with which to control for confounding influences of drivers, environment, and other vehicle characteristics are almost always inadequate—resulting in biased inferences in the literature today.

In a collision between two vehicles of unequal weights, the occupants of the lighter vehicle are at a greater risk whereas occupants of the heavier vehicles benefit, and so there may not be a win-win situation from a societal perspective. In addition, because of the powerful heavier light-truck designs, lighter vehicles are at a serious safety disadvantage. A clear pattern has been observed: reducing a vehicle's weight increases net risk in collisions with substantially larger and heavier entities, reduces net risk in collisions with much smaller and more vulnerable entities (e.g., motorcyclists, bicyclists, and pedestrians) and has little effect on net risk in collisions with vehicles of about same size. Overall, it has been found that the variation of weight among cars results in a net increase of fatalities in collisions, as the reduction in the fatality risk for the driver of the heavier car is less than the increase of the fatality risk for the driver of the lighter car. This increase of fatalities in collisions is offset some by benefits to smaller, lighter highway users (pedestrians and cyclists) in collisions with lightweighted vehicles. The relative weight of the vehicles rather than their absolute values, as well as the distribution of vehicle weights, is what leads to the adverse consequences for the occupants of the lighter vehicle. In fact, some evidence exists, such as the 1997 National Highway Traffic safety Administration study, that proportionately reducing the mass of all vehicles would have a beneficial safety effect in vehicle collision. However, if cars are downweighted and downsized more than light trucks, the increased disparity in weights would increase fatalities.

There is also evidence that smaller, lighter cars have historically had a greater propensity to roll over, and single-vehicle rollover crashes are a major component of all traffic fatalities. The stability of vehicles depends on their dimensions, especially track width, and the height of their center of gravity. The correlation between vehicle weight and the stability has not been strong particularly for light trucks, given the historical tendency that reduced mass means narrower, shorter, less stable cars. It has been argued with some evidence that increase in fatalities due to downweighting and downsizing in single vehicle accidents is a matter of vehicle design rather than mass and that smaller and lighter vehicles have better crash avoidance capabilities. The effect of weight reductions on fatalities in passenger car rollovers might be smaller if weight could be reduced without changing track width.

A recent ACEEE study provides additional evidence to contradict conventional wisdom. This study was based on a measure of risk comparing driver fatalities to the number of vehicles on the road, associated with recent vehicle models sold between 1995 and 1999 with up-to-date safety designs and restraint technologies. The study found that many small cars have lower fatality rates among their drivers than do SUVs or pickups. SUVs have been the major concern, as they are the fastest growing segment of new vehicles, today comprising 21% of the new vehicle market, up from 6% just 13 years ago. This study further illustrated the importance of design in determining a vehicle's safety. Among all major vehicle groups, minivans have the lowest

fatality rates among their drivers, while pickups have the highest. Minivans generally are built on car rather than pickup truck platforms, which may reduce the risk to their drivers.

Overall, there does not appear to be any direct correlation between improved fuel economy and vehicle safety, perhaps largely because fuel economy improvement to date have been the result of technology advances rather than decreased weight. The relationships between vehicle weight and safety are complex and not measurable with any reasonable degree of certainty at present. The distribution of vehicle weights is an important safety issue. It is important to know how vehicle weight and size changes will affect the size/weight distribution of the fleet and, finally, how this distribution will affect different fatality rates (i.e., single-vehicle versus vehicle-to-vehicle rates). Vehicles of uniform weight would correct for the negative social externality that encourages individuals to transfer safety risks to others by buying ever larger and heavier vehicles. It appears that in certain kinds of accidents, reducing weight will increase safety risk, while in others it may reduce it. Reducing the weights of light-duty vehicles will neither benefit nor harm all highway users; there will be winners and losers. Lastly, there appears to be no definitive answer to the fuel-economy and safety question, but to the extent that fuel economy can be improved with advanced technology rather than size and weight reductions, adverse safety impacts, if any, can be minimized.

Glossary

conservative force When the net work done by a force is zero for every path that ends up at the starting point.
energy The capacity or ability of an object to do work, with the joule (*J*) as the measuring unit.
Hooke's Law When an elastic object exerts a force proportional to the displacement of the object and in the opposite direction.
joule (J) The unit of work and energy; a force of 1 newton (N) acting over a distance of 1 m does 1 J of work.
kinetic energy The ability of an object to do work as a result of having mass and speed; in terms of mass (m) and speed (v), kinetic energy is $\frac{1}{2}mv^2$.
mechanical energy The sum of the kinetic energy and potential energy of an object.
nonconservative force When the net work done by a force is not zero in a path that ends up at the starting point.
potential energy The ability of an object to do work as a result of an advantageous position.
power The rate of doing work or converting energy; the watt (W) is the metric measuring unit, where 1 W is equal to a rate of 1 J per second.
restoring force A force on an object that tends to restore the object to its condition prior to application of the force.
watt (W) A rate of doing work or converting energy; the watt is the metric measuring unit, where a rate of doing work of 1 J per second is a watt (P = work/t).
work The result of a force acting on an object as the object moves from one position to another; in one-dimensional motion, work is the product of the force (F) and displacement (d).

The physical concepts of work, kinetic energy as energy due to motion, and potential energy as energy due to some favorable position are discussed in this article. Added together, kinetic energy and potential energy are called mechanical energy. In the absence of nonconservative forces (e.g., friction), the mechanical energy of an object does not change with time and is said to be conserved. The motion of a child on a swing is discussed in light of the conservation of energy. A wide variety of important types of kinetic energy are derived from the conversion of other forms of energy. Such is the case in a hydroelectric system that is discussed in some detail in the article.

1. MECHANICAL ENERGY

Energy has some meaning to everyone. A person often does not have energy following a bout with a cold. Concerns about depletion of our energy resources, solar energy, wind energy, and nuclear energy are common topics in newspapers and on television. Although energy has several meanings, in a physical sense it is considered "a capacity for doing work." An object can have a capacity for doing work due to its motion and by virtue of an advantageous position. The combination of these two types of energy is called mechanical energy. The implications of mechanical energy are tied to the meaning of work.

2. WORK

A person does physical work when cleaning a room. A student does mental work when preparing for an exam. Whether physical or mental, work involves an effort directed toward producing some outcome. In the physical sense, effort is associated with force (push or pull), and work is done when a force acts on an object as it moves through some distance. The

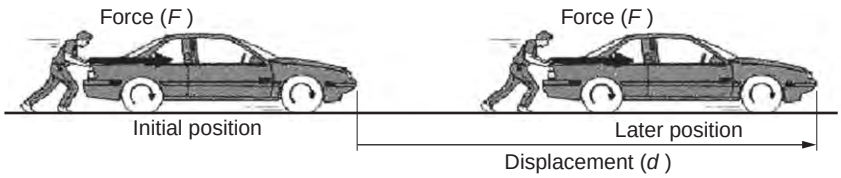

FIGURE 1 Illustration showing a car moving to the right that has been displaced by an amount d. During the displacement, the person exerts a force F to the right. The work (W) done by the person is the product of force and displacement ($W = Fd$).

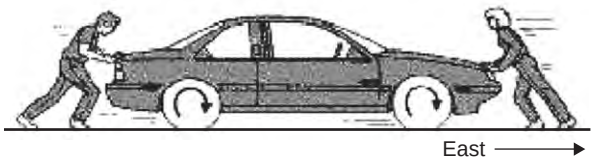

FIGURE 2 Illustration showing a car traveling east that is aided by a person pushing east and hindered by a person pushing west. The work done by the person pushing east is positive. The work done by the person pushing west is negative.

person cleaning a room does work on the broom by displacing it through some distance. In the simplest situation, the direction of the force is either the same as the direction of the displacement or opposite to the direction of the displacement. This being the case, the numerical value of the work (W) is the product of the force (F) and the displacement (d) (Fig. 1):

$$W = Fd \tag{1}$$

Measuring force in newtons (N) and displacement in meters (m) gives work the units of newton-meters. One newton-meter is called a joule (J).

The physical definition of work retains much of the popular notion with one important difference. No matter how much force (effort) is exerted, no work is done in the physics sense if the object does not move. A person may fret and sweat while pushing on a heavy box, but no work is done if the box does not move.

A force in the same direction as the direction of the movement produces an effect that is very different from that if the directions were opposite. A person pushing eastward on a car moving eastward tends to help the car along (Fig. 2). However, a person pushing westward on the same car tends to slow the car. We distinguish these two situations by labeling the work as "positive" when force and movement have the same direction and as "negative" when force and movement have opposite directions. The car is moving eastward under the action of one person pushing eastward and another person pushing westward. The person pushing eastward does positive work. The person pushing westward does negative work.

The net work on an object is the algebraic sum of the works done by each force acting on the object. Suppose that a sled moves 2 m eastward as a result of a girl pulling due east with a force of 100 N and a boy pulling due west with a force of 50 N. The girl does

$$+100\ \text{N} \times 2\ \text{m} = 200\ \text{J of work},$$

the boy does

$$-50\ \text{N} \times 2\ \text{m} = -100\ \text{J of work},$$

and the net amount of work is

$$+200\ \text{J} - 100\text{J} = +100\ \text{J}.$$

3. KINETIC ENERGY

A day does not pass without a person being involved in physical work. The forces that move one in walking and running perform work. Lifting food to one's mouth and chewing food involves forces doing work. On some days, a person works more easily and more efficiently than on other days. One's activities may be cast in terms of his or her ability to do work. Because physical work involves forces and movement, one might ask, "Under what conditions does something have a capacity for moving an object through some distance?" A car in motion has this capacity because if it slams into the rear of a car stopped at a red light, the struck car will surely move some distance. The energy associated with masses in motion is called kinetic energy. A big car colliding with a stopped car will "do more work" on the stopped car than will a smaller vehicle colliding with a stopped car. Similarly, a fast-moving car colliding with a stopped car will "do more work" on the stopped car than will a slow-moving car of the same type colliding with a stopped car. A numerical evaluation of kinetic energy should reflect these observations. Formally, the kinetic energy (K) of an object having mass m moving with speed v is defined as one-half the product of mass and square of speed:

$$K = \tfrac{1}{2}mv^2. \tag{2}$$

Both energy and work are measured in joules. Importantly, Eq. (2) shows that kinetic energy increases if the mass and/or the speed increase. Doubling the mass of an object while keeping its speed the same will double the kinetic energy. Doubling the speed of an object while keeping its mass the same will increase the kinetic energy by four times. The dependence on speed is especially significant.

4. WORK–ENERGY PRINCIPLE

At some time, an object such as a car may have speed v and kinetic energy $K = \frac{1}{2}mv^2$. Later, its speed may change to V so that its kinetic energy is $\frac{1}{2}mV^2$. The change in kinetic energy is the later value minus the earlier value, that is, $\frac{1}{2}mV^2 - \frac{1}{2}mv^2$. The work–energy principle states that the net amount of work on the object between the initial and later times is equal to the change in kinetic energy:

$$W_{net} = \tfrac{1}{2}mV^2 - \tfrac{1}{2}mv^2. \qquad (3)$$

When a hockey player hits a stationary 0.16-kg puck with a hockey stick and imparts to it a speed of 45 m/s (100 miles per hour [mph]), its kinetic energy changes from zero to $\frac{1}{2}(0.16\text{ kg})(45\text{ m/s})^2 = +162\text{ J}$. The change in kinetic energy is $+162\text{ J} - 0\text{ J} = +162\text{ J}$, and the net work is $+162\text{ J}$. The glove of a baseball catcher receiving a 0.15-kg baseball traveling 40 m/s (90 mph) reduces the speed of the baseball to zero. The change in kinetic energy of the ball is $0\text{ J} - \frac{1}{2}(0.15\text{ kg})(40\text{ m/s})^2 = -120\text{ J}$, and the net work is -120 J.

You see this principle in operation in many processes. The kinetic energy of water flowing over a dam increases as its speed increases. The increase in kinetic energy is the result of positive work done on the water by the gravitational force. When a car starting from rest is set into motion, its kinetic energy increases. This is due to work done by a force in the direction of motion of the car. Likewise, when the car slows down, its kinetic energy decreases. This is due to (negative) work by a force on the car acting in a direction opposite to the direction of motion.

5. CONSERVATIVE AND NONCONSERVATIVE FORCES

A box being lifted from the floor is acted on by an upward force provided by the lifter and a downward force due to gravity. Positive work is done by the lifter because the force and movement are in the same direction. The gravitational force does negative work because the force and movement are in opposite directions. If the person lowers the box back to the floor, the gravitational force does positive work because the force and movement now have the same direction. The negative work done by gravity in the upward movement is equal in magnitude, but of opposite algebraic sign, to the work done by the gravitational force in the downward movement. Accordingly, the net amount of work done by the gravitational force in the round trip of going up and back down is zero. When the net amount of work done by a force in any trip that ends up at the starting point is zero, the force is said to be conservative. If the net amount of work done by a force in a trip that ends up at the starting point is not zero, the force is said to be nonconservative. A friction force is a nonconservative force. A friction force acting on an object always opposes its movement so that the work due to friction is always negative. Consequently, the net work due to friction in a trip that ends up at the starting point is never zero.

6. POTENTIAL ENERGY

When an object such as a box is in an elevated position, it has "a capacity for doing work" because if it is dropped and hits something, it can exert a force on that something and push it through some distance. The box at an elevated height is an example of potential energy. Potential energy is associated with conservative forces. By definition, the change in potential energy when moving from one position to another is the negative of the work done by the conservative force acting during the change in position. Labeling U the potential energy and ΔU the change in potential energy, the definition may be expressed as

$$\Delta U = -W_{\text{conservative}}. \qquad (4)$$

6.1 Gravitational Potential Energy

The gravitational force on a box of mass m is mg, where g is the acceleration due to the gravitational force. If the box is raised a height h, the work done by gravity is $W = -mgh$. The change in potential energy of the box is then $\Delta U = -W_{\text{conservative}} = +mgh$. The positive sign means that the potential energy has increased. When the box falls from the height h, the work done by gravity is positive and the change in

potential energy becomes $\Delta U = -mgh$; the potential energy has decreased. The potential energy acquired by the box by placing it in an advantageous position can be recovered by letting it drop to its initial position on the floor. Water atop a dam in a hydroelectric plant has potential energy. When it falls toward the bottom of the dam, it loses potential energy but gains kinetic energy. At some point, the water does work by pushing on the blades of a water turbine, and the kinetic energy of the water is converted to rotational energy of the turbine.

6.2 Elastic Potential Energy

A material is said to be elastic if it returns to its original condition after being stretched or compressed. A spring, a rubber band, the bow of a bow and arrow, and a shock absorber on a car are examples of elastic objects. Somewhat like the earth pulling downward on a box that is being lifted upward, an elastic object pulls in an opposite direction to the force that is stretching or compressing it. The object has potential energy in the stretched or compressed condition due to its capacity to do work if it is released. For many elastic objects, the force exerted by the object, called the restoring force, is proportional to the extension or compression and in a direction opposite to the extension or compression. This being the case, the object is said to obey Hooke's Law. A force obeying Hooke's Law may be expressed as

$$F = -kx, \tag{5}$$

where F is the force exerted by the elastic object, x is the extension or compression, and k represents the strength of the force. For a linear spring, k is called the spring constant having units of newtons per meter. The stronger the spring, the larger the spring constant. The potential energy of a spring obeying Hooke's Law is given by

$$U = \tfrac{1}{2}kx^2. \tag{6}$$

Elastic potential energy is used in many ways. The kinetic energy acquired by an arrow has its origin in the elastic potential energy in the flexed bow. Pole vaulters acquire much of their vault from a bent pole. Toy guns expel projectiles by releasing the elastic potential energy of a compressed spring. Atoms in a molecule are held together by spring-like forces that lead to a form of potential energy. Release of that potential energy often leads to the emission of light.

7. CONSERVATION OF MECHANICAL ENERGY

Friction is always present in a mechanical system, but if it can be ignored, the mechanical energy (i.e., the sum of the kinetic energy and potential energy) does not change with time. To illustrate, a girl waiting to move down a playground slide has potential energy but no kinetic energy because she is at rest. Moving down the slide, she loses potential energy but gains kinetic energy. If friction between the girl and the slide can be ignored, the mechanical energy at any moment is unchanged. At the bottom of the slide, all of her initial potential energy would have been converted to kinetic energy. The constancy of mechanical energy is called the conservation of mechanical energy.

To the extent that friction can be ignored, the mechanical energy of a child on a swing is constant at any moment (Fig. 3). Held in an elevated position waiting for the swing to begin, the child has only potential energy. When released, the child gradually loses potential energy but gains kinetic energy. The sum of the two energies is unchanged at any moment. At the lowest portion of the swing, the potential energy is zero, making the kinetic energy a maximum. As the swing moves upward from the lowest position, the child gradually gains potential energy but loses kinetic energy. The child is momentarily at rest at the uppermost position of the swing, making the kinetic energy zero and the potential energy a maximum. If friction were absent, the back-and-forth motion would continue unabated and mechanical energy would be conserved at any moment. But as anyone who has taken a child to a playground knows, friction is always present and the motion gradually dies out unless the person pushes the swing to replace the energy lost to friction.

8. ENERGY CONVERSION

An object in an elevated position clearly has potential energy because if it is dropped and contacts something during its downward flight, it may do work on that something. Similarly, a compressed spring has potential energy because if it is released, it may strike something and do work on it. The general idea of potential energy as a capacity for doing work and the rearrangement of things when the potential energy is converted goes beyond these two mechanical cases. For example, gasoline has potential energy because if

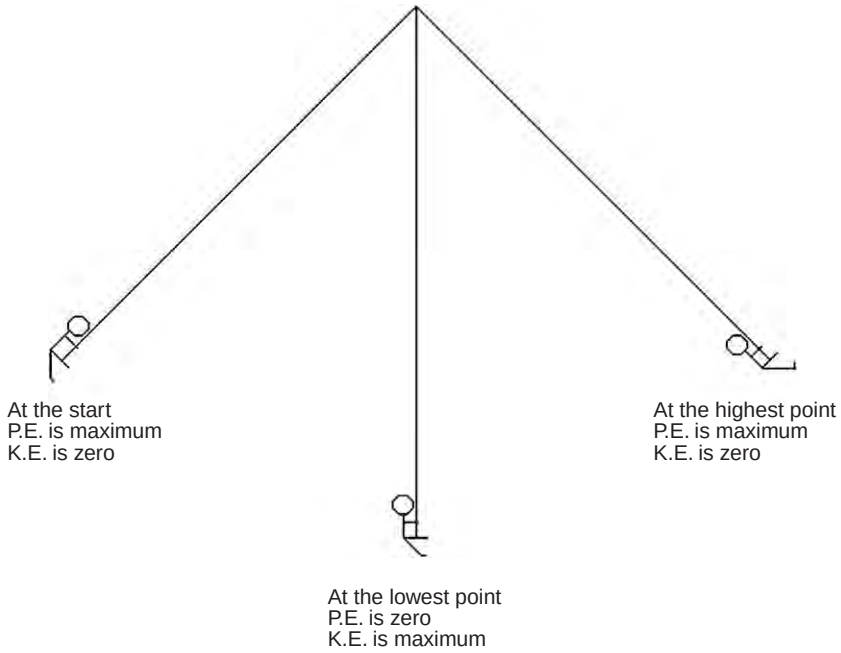

FIGURE 3 Illustration showing that, to the extent that friction can be ignored, the mechanical energy of a child in a swing is unchanged at any moment. P.E., potential energy; K.E., kinetic energy.

a gasoline vapor/air mixture is ignited in the cylinder of an internal combustion engine, the expanding gas pushes against a piston and does work on it. The root of the potential energy is found in the molecules from which the gasoline is formed. Energy is extracted from these molecules when their atoms are rearranged into different molecules during the combustion process. Similarly, the uranium fuel in a nuclear reactor has potential energy that is extracted from rearrangement of neutrons and protons through nuclear fission reactions. The energy produced from the nuclear reactions is then used to produce steam, which pushes against the blades of a turbine, producing rotational kinetic energy.

An industrial society finds myriad uses for kinetic energy. Pistons moving up and down in an internal combustion engine have kinetic energy. Wheels rotating on an automobile or a truck have kinetic energy. Water falling from atop a dam has kinetic energy. Around a home or in a factory, there are numerous motors providing rotational kinetic energy for a multitude of purposes. In all of these examples, the kinetic energy evolves from a conversion from some other form of energy. The force behind the movement of a piston comes from an expanding gas produced by the ignition of a gasoline/air mixture. The kinetic energy acquired by water rushing to the bottom of a dam comes from a conversion of gravitational potential energy. Motors convert electric energy to rotational kinetic energy. Whether large or small, and whether simple or complex, converters producing kinetic energy all subscribe to the principle of conservation of energy. Each one converts energy into some form of kinetic energy regarded as useful, and each one diverts energy that is not immediately useful and might never be useful. Because energy is diverted, the efficiency defined as

$$\text{efficiency} = \frac{\text{useful energy}}{\text{total energy converted}}$$

can never be 100%.

9. APPLICATIONS OF MECHANICAL ENERGY

9.1 Pile Driver

A pile is a large metal or wooden post driven into the ground. A pile driver (Fig. 4) lifts a rather massive object (hammer) above the pile and drops it. Each drop of the hammer drives the pile farther into the ground until the required depth is reached. Lifting the hammer requires mechanical work. In so doing, the hammer acquires potential energy. When released, the hammer gradually loses potential energy

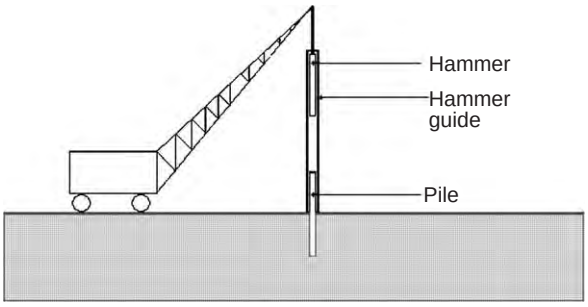

FIGURE 4 Basic components of a pile driver.

and gains kinetic energy. Work is done on the pile during contact, causing the kinetic energy to decline, eventually to zero.

9.2 Hydroelectric System

Whenever an object has gravitational potential energy, some agent had to do work on the object. In the case of a pile driver, there is a hoist of some sort. Water atop a dam has potential energy. Nature provides the means to fill the water reservoir through evaporation followed by condensation and rain. To see the energy transformations involved when the water falls from the top of the dam onto the blades of a turbine, it helps to visualize the motion of an object having boundaries. Accordingly, imagine the motion of a cube of water moving with the stream (Fig. 5). At the top of the dam, the cube of water of mass (m) and speed (V) has kinetic energy $\left(\frac{1}{2}mV^2\right)$, and potential energy ($mgh$) due to its position at the top of the dam. As the gravitational force pulls the cube from the top of the dam to the bottom, it loses potential energy but gains kinetic energy. At the bottom of the dam, all of the potential energy (mgh) has been converted to kinetic energy $\left(\frac{1}{2}mv^2\right)$. The total kinetic energy now includes its kinetic energy before falling plus the kinetic energy gained by falling:

$$\tfrac{1}{2}mv^2 = \tfrac{1}{2}mV^2 + mgh. \qquad (7)$$

The cube of water arrives at the paddle wheel with energy $\left(\frac{1}{2}mv^2\right)$. The force of the cube on the paddle wheel causes work to be done on the wheel. Accordingly, the paddle wheel rotates, acquiring energy (E) while the cube of water loses kinetic energy. The kinetic energy of the cube after it passes by the paddle wheel (K) equals the kinetic energy it had before striking the paddle wheel minus the energy acquired by the paddle wheel:

$$K = \tfrac{1}{2}mv^2 - E \qquad (8)$$

In a hydroelectric power plant, the turbine would drive an electric generator and the energy (E) would be used for generating electricity.

9.3 Pumped Storage Hydroelectric System

The demand for electric energy by a community varies with the time of day and with the time of year. An electric power utility must be prepared to meet these demands. This poses an engineering problem because there is no practical method of storing electric energy on a scale that will meet the demands of a large community. To meet short-term increases in demand, electric utilities employ generators that can be turned on and off on short notice. For example, they may use a gas turbine similar to a jet plane engine to drive a generator. Another scheme is to use a pumped storage hydroelectric system. Such a system does not rely on nature to replenish the water in a reservoir but rather uses electrically run pumps. Importantly, the system can generate electricity on short notice. A schematic diagram of the system is shown in Fig. 6. Water is forced to an elevated reservoir by a motor-driven turbine. The water in the reservoir has gravitational potential energy by virtue of the work done on it. When electricity is needed, the water is allowed to flow downward into the turbine that drives the motor, which now functions as an electric generator. The energy required to elevate the water is never completely recovered in the process. Nevertheless, the system is economical because the reservoir can be filled when electric energy demands and costs are low. It is also possible to have a system in which water flows from ground level to underground turboelectric generators. In this case, work has to be done to restore the water to ground level.

9.4 Warning

Steel is a very hard metal that behaves like a very stiff spring when compressed or stretched. Bolting two steel plates together compresses each plate to some extent. Although the compression may be small, the elastic potential energy $\left(\frac{1}{2}k\,x^2\right)$ in the plates can be large because the spring constant (k) is large. If the nut on the bolt holding the plates together is released gradually, the elastic potential energy declines gradually. But if for some reason the nut cannot be turned and the bolt is freed by chiseling the bolt in two, the elastic potential may be released suddenly, causing the nut to spring away. So violent is the separation that a person may be seriously injured if

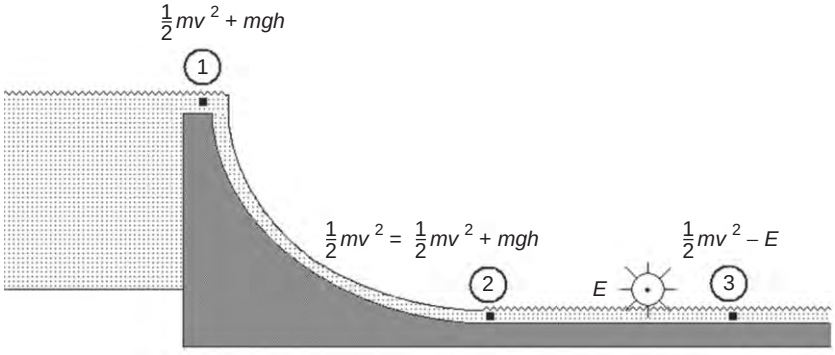

FIGURE 5 Energy transformations involved in water flowing over a dam. (Position 1) At the top of the dam, the cube of water has kinetic energy $(\frac{1}{2}mv^2)$ due to its motion and potential energy (mgh) due to its position above the bottom of the dam. (Position 2) At the bottom of the dam, all of the potential energy (mgh) has been converted to kinetic energy. The energy of the cube of water is kinetic $(\frac{1}{2}mv^2)$ and includes the kinetic energy it had at the top of the dam plus the kinetic energy acquired by falling over the dam. (Position 3) Passing by the paddle wheel, the cube of water transfers energy (E) to the wheel. Its energy after passing the wheel is still kinetic and is equal to its energy before impinging on the wheel $(\frac{1}{2}mv^2)$ minus the energy (E) imparted to the wheel.

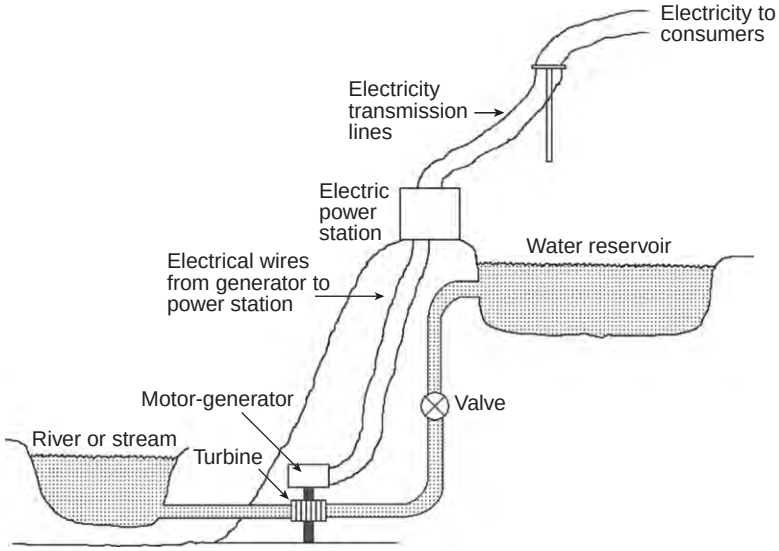

FIGURE 6 Principle of a pumped storage hydroelectric system. Water in an elevated reservoir has potential energy as a result of being pumped from a river or stream. Electricity is generated when the water flows through a turbine–generator combination on its way back to the river or stream.

he or she has the misfortune of encountering the nut. Such incidences have actually happened and have prompted warnings to workmen who may have to free a frozen nut.

4. Media Effects on Public Opinion and Policy

Glossary

environmentalism A social movement of the 20th century focusing on the threats to human health posed by a variety of pollutants. Includes a broad swath of concerns, such as air and water pollution, climate change, wilderness protection, endangered species protection, and sustainability.

mass media The system of communication by which large, commercial organizations produce entertainment and news content for large, heterogeneous audiences. The term usually includes television, radio, newspapers/magazines, popular music, publishing, and films.

muckraker A name for a type of investigative newspaper or magazine journalist of the early 20th century. Muckrakers examined social problems, working conditions, environmental pollution, and other threats associated with the activity of large industry.

public opinion A collective indication or measurement of how the public feels about given issues. Usually measured using scientific random sampling techniques and opinion questionnaires or surveys. The term also refers to a more general, impressionistic perception of public sentiment on a given issue.

The mass media, especially newspapers, magazines, television, and movies, play a role in the portrayal of energy issues. Since the energy crisis of 1973, the attention of scholars has been turned to how media shape, frame, and influence audience perceptions of energy and the environment. During the period following the energy crisis, especially throughout the 1980s and early 1990s, issues of energy conservation were frequent topics of scholars' attention. Oil crises and the perceived dangers of nuclear power sensitized society to the potential importance of conserving energy. These issues were also frequently mentioned in the media. In these earlier days of the environmental movement, it was believed that mass media could be prominent tools to encourage conservation of energy, through adoption of energy-saving measures in the home, driving smaller and more fuel-efficient vehicles, and promoting alternative energy source use. The attitudes of this period highlighted the fact that media can play an important role in people's individual choices. Influences such as advertising, journalism, television programs, and other media need to be considered when determining how people make choices in energy use behavior.

1. INTRODUCTION

In general, the influence of media on energy use has been considered within the wider field of study of media effects on environmental concerns. This field of research has shown that media do have both direct and indirect impacts on how people develop conceptions of the environment. However, these effects are not always consistent; they do not always move in the same direction. Thus, it has been shown repeatedly that information derived from the media is an important factor in how people develop awareness about the environment. Because people directly experience only a small portion of the environment, knowledge about global environmental issues and problems must come from mediated sources. People who are more attentive to newspapers and other journalistic sources are more likely to be informed and knowledgeable about environmental issues and problems. Those who are particularly attentive to environment-specific media sources (such as environmental magazines or television programs) are better informed about environmental issues and are more concerned about them. On the

other hand, general media attention (especially to entertainment media) is associated with less knowledge and concern about environmental issues. Frequent viewers of television programs, for instance, are less concerned about environmental issues in general. Further, they are more supportive of materialist ideologies that tend to promote higher energy consumption.

These countervailing examples show that it can be dangerous to lump all "media" together under one umbrella. Sometimes media outlets promote conservation of energy and concern for the environment; specific campaigns aimed at reducing energy consumption are often studied with this as the goal. Meanwhile, a more general attitude of promotion of consumption seems to guide the overall media atmosphere, which is built on advertising-supported ideologies of material growth. Given these tendencies, it is necessary to try to disentangle the various media effects, in order to get some idea about the key questions of interest. The main question that is the focus in this article concerns how the media influence public conceptions of energy within an environmental framework.

2. *MEDIA COVERAGE OF ENERGY: HISTORY*

Before discussing current issues in media coverage of energy, some of the main historical aspects of how media have treated the energy issue are summarized. This discussion will be contexted within the wider theme of how the media treat the environment.

It is a common conception that environmentalism in the public mind and in the media frame is a phenomenon of the latter 20th century. However, there are clear examples of how the mass media provided a stage for a discussion of environment and energy issues well back into the 19th century. Preservationists such as John Muir, for example, were using the national media in their attempts to set aside lands for national parks. Muir's articles in magazines such as *Century* attracted the attention of Eastern elite audiences to issues that were mainly situated in the West. These strategies helped develop national attention for environmental issues in the context of a nationally emerging mass media structure. Though a national mass media system had emerged as early as the 1830s, especially with the development of mass newspapers in major cities served by wire services, this structure was most firmly cemented after the Civil War. How did this affect coverage of energy issues?

2.1 Coal and Oil

Attitudes about sources of energy such as coal and oil are recoverable from publications of the 19th century, which followed the development of new energy sources with close attention. However, as with media coverage of any major issue, it is not possible to determine a single prevailing attitude toward an energy source such as coal or oil. Certainly, many of the major media sources adhered to a generally nationalistic ideology, oriented toward goals such as economic progress, westward expansion, and even imperial aspirations. Within this context, fossil fuel sources obviously played an important role in the development of America as a world power. Thus, one major current of the media mainstream was oriented toward a view of fossil fuels as expanding the possibilities for America, without worrying too much about potential negative consequences.

But worrisome themes also appeared in the press. The economic booms and busts of oil discoveries were linked to boom-and-bust media cycles: high-hoped optimism followed by cautionary tales was a not uncommon cycle in the press. Stories told of those who made and lost fortunes were as characteristic of news coverage in the oil years as they were in the days following the Internet bubble. Oil was often presented as something ridiculously easy to obtain and sell, violating all previous rules of the marketplace. After a boom had gone bust, the national dailies turned to tales of woe and ghost towns in their coverage.

As oil became an industry, it attracted a different kind of attention, that of the "muckrakers." Muckrakers were the forerunners of today's "investigative journalist." Their reformist spirit led them to attack industry on issues ranging from child labor to food safety to environmental issues. Ida Tarbell (see Fig. 1), writing in the pages of *McClure's,* a national magazine, attacked the Standard Oil Company for its monopolistic and predatory practices. Her family life in the Pennsylvania oil patch had been disrupted by Rockefeller's South Improvement scheme. Published serially from 1902 to 1904, Tarbell's "History of Standard Oil" is considered a founding piece of investigative journalism. But not all media controversies resulted in immediate change. Concerns about ethyl leaded gasoline were covered fairly extensively, especially in the New York City area, from 1924 to 1926. Worker deaths from lead

FIGURE 1 Ida Tarbell (1857–1944).

poisoning led crusading scientists to point out that lead additives could be harmful to the public at large, due to risks from lead deposition in exhaust. Although a committee was formed by the Surgeon General to look at the issue, no action was taken, even with significant attention from newspapers such as the *New York World* and *The New York Times*. It was not until the 1970s that the Environmental Protection Agency (EPA) would take action to remove lead from gasoline. Still other themes were developed earlier than one might expect. Recognizing American dependence on oil led to journalistic calls for conservation and development of renewable energy sources long before the onset of the environmental era in the 1970s. The concern was not environmental in nature, but stemmed from a worry about maintaining America's preeminence despite dependence on oil.

Typically, media attention to environmental issues is driven by both journalistic cycles and events. Events are spectacular disasters or phenomena with widespread impact. A "killer smog" in Donora, Pennsylvania in 1948 drew enough media attention to catalyze the development of smoke-abatement programs in cities around the United States. This was an early precursor to the more far-reaching programs of air pollution control that were eventually enacted in the 1970s. Indeed, air pollution themes had received sporadic attention throughout the 20th century, but the atmospheric impacts of fossil fuel consumption began receiving a closer look in the media in the 1960s. This peaked with the passage of national environmental legislation (the National Environmental Protection Act) in 1970.

Fossil fuels and American industry in general came under further media scrutiny in the 1960s. Rachel Carson's *Silent Spring* (1962), though not focused directly on fuels or energy sources, drew attention to the chemical industry and its promotion of dangerous chemicals such as dichlorodiphenyl trichloethane (DDT). *Silent Spring* sensitized Americans to risks both known and unknown in and about the general environment. Carson arguably inaugurated the age of environmentalism, in which the media played an important role in turning people's attention to a variety of environmental issues, with fossil fuel consumption at or near the top of the list of problems. Carson's book, serialized in the *New Yorker* magazine, received wide media attention, building on the earlier model for journalistic crusading that had been successfully tested by both John Muir and Ida Tarbell.

This touched off a frenzy of popular publishing activity focused on energy consumption and environmental issues. Books such as *The Waste Makers* (Vance Packard, 1960), *The Quiet Crisis* (Stewart Udall, 1963), *The Population Bomb* (Paul Ehrlich, 1968), *The Closing Circle* (Barry Commoner, 1971), *The Limits to Growth* (Donella Meadows *et al*., 1972), *The Poverty of Power* (Barry Commoner, 1975), *The Eco-Spasm Report* (Alvin Toffler, 1975), and *The Fate of the Earth* (Jonathan Schell, 1985) are examples of popular publications that made some impact on public sensibilities and opinions about energy consumption problems. These efforts were strengthened by press attention to the oil crises of the 1970s, which caused a great deal of concern about energy dependence. With energy issues bouncing around the press throughout the 1970s, the issue was often at the top of the public agenda, particularly when gasoline prices were rising. With a cast of villainous characters [the Organization of Petroleum Exporting Countries (OPEC) oil sheiks] and an issue striking at the heart of the American economy, foreign oil was the biggest news item in 1973, and to a lesser extent in 1979. However, specific events also masked cycles of press concern about energy issues. These cycles are generated not by specific external motivating factors, but by tendencies to adhere to narrative structure embedded within journalistic practice. For instance, in the late 1980s and early 1990s, journalists in both newspapers and magazines

and on television turned their attention to a broad range of environmental issues. The attention was initially brought about by an extremely hot and dry summer in 1988. Scientists' claims about global warming suddenly found a foothold in the media, when James Hansen of the National Aeronautics and Space Administration (NASA) claimed that global warming could be definitively tied to human agency. Bill McKibben published a widely read book, *The End of Nature* (1989), which argued that climate change meant that human influence was suddenly spread throughout the entire environment, and there was no more pristine "nature" to be found. The book was also serialized in the *New Yorker*.

Suddenly, the press was covering a wide range of issues, from climate change to acid rain to radon gas to ozone depletion. The years 1988–1991 represented an unprecedented period of public concern and attention to environmental issues. The Exxon *Valdez* accident (1991) was yet another event that encouraged even more environmental debate in the media. It was during these years that the public and policy debate began to give more credence to the idea that the media could be a positive force for social change, especially in the big, important areas such as climate change. Environmental concern was so strongly present in the mediated discourse of the United States that companies such as McDonald's and Burger King adopted new forms of packaging to counter charges that styrofoam hamburger containers consumed too much energy in production and were persistent in the waste stream. Even entertainment television began to manifest signs of a green consciousness. Hollywood celebrities increasingly focused on environmental issues such as rain forest conservation. Public relations agencies with the purpose of placing environmental references in television programs and feature movies came into being. Movies with explicitly and implicitly environmental themes were more common. *Dances With Wolves* (1990) was a prototypical environmentally themed movie of the period, focusing on the connection of the Sioux Indians to the land. Movies with more directly energy-related themes include *The China Syndrome* (1979), about a nuclear disaster uncovered by an inquiring reporter; the *Mad Max* series of movies (1989–2000) about a postapocalyptic Australian outback gripped in wars for the dwindling supply of oil; *Waterworld* (1999), a story about a post-climate-change world that has been inundated with water; and *Ferngully* (1992), a children's story about a destroyed forest that threatens a race of environmentally conscious sprites. On television, children's shows such as *Captain Planet* (1990–1996) often focused on themes of energy conservation.

After 1991, however, general media attention began to subside (see Fig. 2). Vice President Al Gore published *Earth in the Balance* in 1992, but he missed the peak of media and public excitement. The eruption of Mount Pinatubo in the Philippines led to cooler temperatures globally, which also seemed to cool press interest. Indeed, research has shown that news attention to climate change issues varies with the actual temperature, such that journalists are less likely to cover climate change during cooler periods. In any case, coverage for all environmental issues was declining throughout the mid-1990s. The pattern was following that predicted by social scientist Anthony Downs, who argued that press attention to environmental issues would always be cyclical due to the inherent nature of the issues. Because environmental issues are difficult to solve, public attention will fade when the costs of achieving environmental gains are calculated. Also, the issues are seen as neither interesting nor fascinating from a journalistic standpoint. Other theorists also pointed out that the news agenda has a carrying capacity. When one issue rises in salience, others decline. The first Gulf War (1991), even though it had an important energy motivation, turned attention away from the environmental aspects of energy issues.

By 1995, environmental issues were neither as much in the media nor in the scope of public attention. The celebration of "Earth Day," which in 1990 had received a lot of media attention, went barely noticed in 1995. A strain of antienvironmental

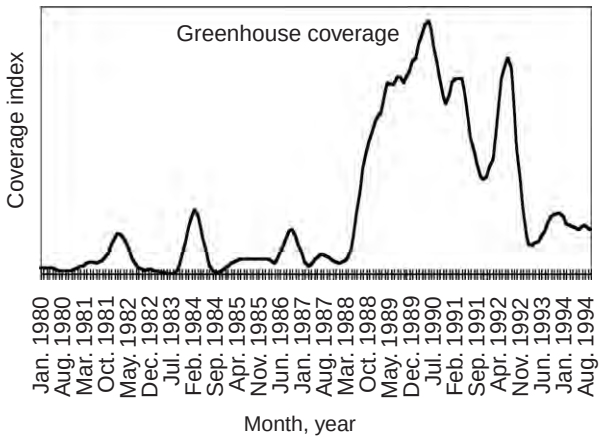

FIGURE 2 Coverage of climate change reported in *The New York Times*. From Shanahan and McComas (1999).

thinking was also becoming evident in the works of authors such as Julian Simon, who preached environmental optimism in works such as *The Ultimate Resource*. Readers of popular literature could see these ideas in books such as Greg Easterbrook's *A Moment on the Earth* (1995). Also, the energy industry was not at all inactive. Industry public relations groups such as the Western Fuels Association had engaged in active public communication campaigns to discredit the science associated with predictions about climate change. To some extent, these campaigns were successful, and public opinion eventually turned away from concern about climate change. Although the scientific community was not dissuaded in its opinions about climate change, lack of public resolve and media attention has made it difficult to develop stronger U.S. policies on climate change.

Since the mid-1990s, energy issues have struggled to receive major attention. Cheap oil has fueled the popularity of sport utility vehicles and trucks, which have been advertised heavily by car producers. Indeed, the reliance of the media on the automobile and energy-producing industries, through advertising revenues, is an important factor to consider when examining coverage of energy issues. Although the major media certainly did not shy away from criticism during disasters such as the Exxon *Valdez* incident, some critics have pointed out that mainstream news organizations are too reliant on funds from "Big Oil," or from Detroit.

Energy consumption, thus, is not currently viewed as a major issue on the American agenda, with the minor exception of concerns about dependence on oil and its relation to issues of susceptibility to terrorism. September 11, 2001 and the Iraq War (2003) activated certain sectors of society to begin thinking again about U.S. reliance on foreign oil. Slogans such as "No blood for oil" encapsulate the thinking of the social protest sectors that have sought to mobilize wider opposition to U.S. foreign policy in the Middle East. But the first Gulf War and the Iraq War were both very popular. The U.S. media sector assisted the war efforts in both cases by focusing on issues of patriotism and nationalism; their efforts were rewarded with strong opinion support. Energy issues were widely disregarded in both cases, except insofar as U.S. forces achieved successes in "protecting" energy resources such as the Iraqi oil fields. The media, having passed through a period of concern about environmental issues, revealed little of that concern in recent times.

2.2 Nuclear Energy

Nuclear energy, compared with traditional energy sources such as coal or oil, has received much different treatment in the media. Nuclear energy has always been portrayed in a more bipolar fashion, as offering either fantastic possibilities or horrifying risks. Coverage has tended to swing between these poles without resting much in the middle. As a consequence, public opinion has been more mistrustful.

After the detonation of atomic bombs at the end of World War II, there were attempts to promote peaceful uses of atomic energy. It would be fair to say that pro-atomic energy campaigns played a large role in shaping the media atmosphere. During the 1950s, the government encouraged a positive strain of thinking about nuclear energy that permeated the media. Dwight Eisenhower's "Atoms for Peace" speech of 1953 is one example of an attempt to create a rubric for public communication about nuclear energy that could escape from the dread perceptions engendered by its military history. But the fear brought about by the Cold War was made manifest in media coverage of various types. It was difficult for nuclear power to escape negative associations. Although many nuclear reactors were built and used, the attitude of the entertainment media in the 1960s toward nuclear power was focused either on science fiction or on doomsday scenarios. Movies such as *Failsafe* (1964: "It will have you sitting on the brink of eternity!") both informed and characterized the public fascination with and fear of nuclear weapons; also notable was Stanley Kubrick's *Dr. Strangelove* (1964), a satire of nuclear militarism based on *Failsafe*. Transfer of public fear from nuclear weapons to nuclear energy was probably inevitable. At a more quotidian level, nuclear energy had been portrayed as the source of horrific mutations and science-fiction accidents in more movies than can be recounted here [though they include *Attack of the Crab Monsters* (1957), *The Beast From 20,000 Fathoms* (1953), *The Creation of the Humanoids* (1962), *Godzilla, King of the Monsters!* (1956) and *Them!* (1954)]. And many movies (as well as television programs such as *The Twilight Zone* and *The Outer Limits*) used post-nuclear-holocaust scenarios as a standard setting or as a formulaic plot device.

Mediated public debate about nuclear energy as a power source emerged more strongly in the media in the 1970s. One major factor was the emergence of antinuclear activism. Media coverage of environmental activism can be a two-edged sword. Oftentimes,

specific stories about environmental issues present the environmental perspective as out of the mainstream. Activists and their causes are not at the core of public opinion concern. However, the salience derived from media coverage has been very beneficial to environmental causes. The nuclear activism issue is an excellent case in point.

Risk studies have shown that the risk from nuclear energy is perceived as an "imposed" risk. People are more likely to express concern about risks that they do not normally assume in the course of their daily lives. When such risks are covered heavily in the media, it may make little difference that actual risk ratios are relatively low. Such was certainly the case for nuclear power, which experienced negative attention from all sides, and never recovered from negative associations with the atomic bomb. The key media event that affected perceptions of nuclear power was Three Mile Island. Walter Cronkite ("the most trusted man in America") and other mainstream media were arguably quite alarmist in their coverage, making connections to the recently released movie *The China Syndrome*. Supporters of nuclear power have been extremely critical of the media model that was established with this incident; they blame it for the fact that citizens estimate risks from nuclear power as much higher than risks known in fact to be more dangerous, such as cigarette smoking.

With Chernobyl, a similar dynamic was introduced, although the media took a different tack given that the accident occurred within the Soviet Union. Studies showed that news agendas were dominated by the accident in the U.S. and especially in Europe. Though some coverage emphasized the relative safety of U.S. reactors compared to Soviet ones, this incident added yet another negative to the list of achievements of nuclear power. In the time between the two accidents at Three Mile Island and Chernobyl, the broadcast by the American Broadcasting Corporation (ABC) of *The Day After* (1983) was arguably the biggest entertainment media event of the 1980s that dealt with nuclear energy. It told the story of a U.S. city after a nuclear attack. It was watched by half of the U.S. population, and was seen as a feature film in many foreign countries. The Reagan White House was concerned about its antinuclear bias. The broadcast's effects on public opinion and knowledge about nuclear power were also studied, with inconclusive results, but undoubtedly few positive effects accrued for the nuclear energy industry, which was increasingly under fire.

3. PUBLIC OPINION ABOUT ENERGY

Public opinion polls have frequently asked citizens to comment on their thoughts, feelings, fears, and attitudes about energy sources. In terms of attitudes about energy in general, opinion and concern have varied. Through the 1970s and into the 1980s, in a variety of polls, about 80% of U.S. respondents said that the U.S. energy situation was "serious." This reflected general concern about energy prices and reliance on foreign oil. When assessing blame for the energy situation, respondents have been most likely to finger oil companies, although Arab states were often blamed as well. Oil companies, as is true of most energy institutions, receive very low levels of public support (nuclear power institutions receive the lowest ratings of all) in public opinion polls.

In the late 1980s and early 1990s, the U.S. moved beyond a debate on the energy supply, which was largely not an issue anymore. In the late 1980s, more consumers turned toward larger vehicles, and questions about greenhouse emissions and the role of fossil fuels in climate change moved to the front of the public agenda. These issues were foregrounded by the media, resulting in unprecedented levels of public concern about fossil fuels into the early 1990s. However, these concerns faded with the onset of the Gulf War and the economic downturn that followed. Coverage of climate change and other issues followed a classic cyclical pattern, as was noted above. How did this affect public opinion? One series of data showed that public concern about governmental spending on environmental issues was strongest during the time of peak media coverage. Concern was stronger among those who were heavier consumers of news media. In the late 1990s, concern about fossil fuels tended to drop, along with general concern about environmental issues. Although major international conferences on climate change, such as those held in Kyoto in 1997, did provide opportunity for new spates of energy-related coverage, these often focused on U.S. refusal to go along with world climate policy.

In general, as already noted, compared with fossil fuels, nuclear energy has sparked more negative feelings. In September of 1945, 93% of respondents to a National Opinion Research Center poll felt that there was a real danger of most people living on Earth being killed by nuclear bombs if a new world war broke out. But still, citizens generally strongly felt that it was acceptable to have used the bomb in 1945; they were also generally mixed on whether

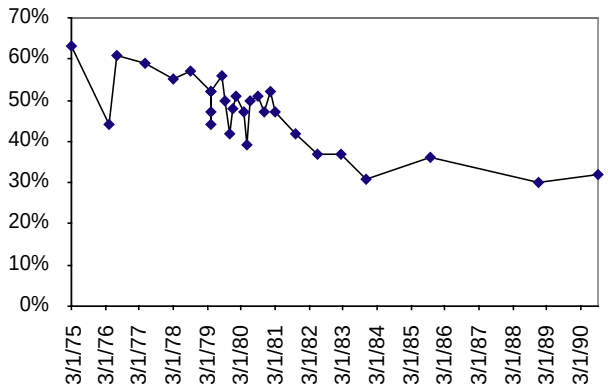

FIGURE 3 Percentage of poll respondents favoring building more nuclear plants in the United States (Harris poll data).

splitting the atom would turn out to be a net positive or negative for society.

In the 1970s, after the first oil shock, U.S. citizens felt that it was extremely important to develop alternative sources of energy. A 1976 Harris poll found that 80% of respondents favored developing nuclear energy sources, along with other sources such as solar energy and more oil exploration. But then, among other influences, news about nuclear power accidents in Three Mile Island and Chernobyl had effects on public opinion, though not initially as drastic as one might expect. Some researchers argued that nuclear power could "rebound" from the negative effects of such disasters. But over time, this proved not to be the case, as the public moved consistently toward negative views of nuclear power in the late 1980s and 1990s (Fig. 3). In addition to the perceived dangers evident in the disasters, other factors affecting support were antinuclear activism (often media based) and the perceived high expense associated with constructing nuclear plants. Also, the fictional portrayals mentioned above (*The China Syndrome* and *The Day After*) probably played a role.

4. MEDIA EFFECTS ON PUBLIC OPINION AND POLICY

To what degree do the media affect public attitudes about energy? Although many studies have examined relationships between media use and environmental attitudes, no clear finding has emerged. On a case-by-case basis, it is often difficult to show how specific media messages change public opinion, apart from extremely salient mass spectacles such as *The Day After.* For instance, studies of the effects of messages such as President Carter's "moral equivalent of war" speech on energy conservation showed minimal effects in terms of citizens actually conserving. Studies that attempted to tie proconservation media coverage or campaigns to specific energy consumption habits (such as lowering the thermostat) have also not shown much effect. At the micro level, it is clear that there are a myriad of forces that determine individual energy decisions, among which the media may play only a small role.

At a macro level, however, it is difficult to imagine a more powerful institution than the media for setting the social agenda and defining terms. Repeated exposure to messages favoring increased material consumption does play a role in actual consumption, as studies have shown. Viewers who spend a lot of time watching television ("heavy" viewers) are more likely to believe that the world is more affluent than it really is, they desire more material possessions, and they are less likely to be concerned about environmental issues. Such television viewers are even more likely to answer opinion questions about material wealth more quickly than "light" viewers; the implication drawn by psychologists is that heavy viewers work from a store of media-cultivated images that allow them to heuristically view the world as wealthier than it actually is. Media images also play a major role in determining people's risk perceptions and fears, particularly about nuclear energy. Thus, we can look at media effects at two levels. Environmental activists, energy producers, and other active participants in social policy focus most often on the day-to-day slate of messages that a citizen receives. These messages convey a welter of often conflicting impressions about the state of energy, what the polls refer to as the "energy situation." "Actors" with significant resources can play a major role in attempting to tip the balance of these conflicting messages. Issue-advertising models along the lines of those developed in the 1970s by Herbert Schmerz of Mobil Oil Company are one way that energy producers attempt to influence the policy discourse. As well, since the 1990s, most major energy producers have added environmental divisions to their corporate structure, in recognition of the increasing public relations importance of environmental issues. On the other hand, the incredible development and growth of environmental activist organizations have balanced out the claims and arguments of energy producers. Groups such as Greenpeace have been persistent and successful in developing media strategies. Groups with specific media missions include the Environmental Media Association, which strives to

make Hollywood productions more environmentally relevant.

Still, the fundamental tone of the media is oriented toward growth, toward what some sociologists called the "Dominant Social Paradigm." This paradigm values economic growth and encourages confidence in the ability of new technologies to fuel such growth. Scholars who have examined media from a broad cultural perspective have been most impressed with contributions of advertising to the creation and maintenance of this paradigm. Even though sociologists have detected the outlines of an emerging "New Environmental Paradigm," there is little doubt that the media system is still fundamentally structured to encourage growth in consumption.

Bill McKibben summed up these views in his *The Age of Missing Information* (1992), which dealt with a comparison of world views obtainable in the media versus those obtained in the real world. To McKibben, the power of television was not its specific messages, but rather the dizzying amount of content, most of which was focused on material consumption in one form or another. He complemented the views of scholars such as George Gerbner, who argued that the true effect of the media is the extent to which it cultivates perceptions of reality. The efforts of media researchers to document that the media do have an influence on perceptions of reality have not been in vain. In the energy sphere, consumption of media is tied to materialism, support for the dominant social paradigm, and less concern about environmental issues such as energy conservation.

Thus, the media have not changed much since the days of early coverage of oil booms. In the media, energy is the fuel of our technologically materialist culture. At the same time, media will sporadically play a watchdog role in suggesting environmental safeguards as far as our use of energy is concerned. Thus, even despite the various disasters, risks, problems, and accidents associated with fossil fuel consumption, the media do not fundamentally question our reliance on these fuels. Perhaps this is because everyone realizes we have no real alternative. On the other hand, with nuclear energy, we see the veto power of the media in action. In that nuclear power has not been an essential energy source, it has also been fair game for media criticism.

Glossary

coefficient of performance (COP) A figure of merit for cooling systems; it is defined here as the amount of thermal energy removed from a cooled space divided by the amount of work or heat supplied to the cooler to accomplish the heat removal.

fuel cell An electrochemical device for directly generating electricity by combining a fuel, such as hydrogen, with oxygen to form a reaction product, such as water; because theoretical performance is not tied to the thermodynamic Carnot efficiency, higher chemical-to-electrical energy conversion can occur.

fuel processor A chemical reactor specifically for converting a fuel from a complex mixture of hydrocarbons to a less complex, and often pure, form of usable fuel (e.g., hydrogen).

heat exchanger A device for transferring thermal energy from a hotter fluid to a colder one; heat exchangers come in a variety of configurations, including (but not limited to) parallel flow, counter-flow, cross-flow, compact, shell-and-tube, plate-and-frame, regenerative, recuperative, unmixed, and mixed streams.

logistics fuel Any number of liquid fuels widely used by the military for transportation and power generation; examples include JP-4, JP-6, diesel, gasoline, and kerosene.

microchannel array An array of channels with characteristic dimensions of less than 1 mm designed for conveying a heat and/or mass transfer fluid; when used as the basis for heat exchangers, boilers, and condensers, high rates of heat transfer result.

Micro Electro Mechanical Systems (MEMS) A class of devices typically made from silicon or employing it in the fabrication process; devices integrate electronics and mechanical devices onto a single substrate with typical feature sizes in the 1- to 50-μm range.

microreactor A miniaturized chemical reaction system characterized by small size (typically $<1\,cm^3$) and fabricated, at least partially, using methods of chemical or electrochemical etching, laser machining, electro discharge machining (EDM), or other microfabrication processes.

Microtechnology-Based Energy and Chemical Systems (MECS) A class of devices integrating heat and mass transfer components along with chemical reactor technology in a single integrated system; feature sizes are typically 50 μm to 1 cm.

nano-, micro-, and mesoscale Dimensional regimes for describing various levels of feature and/or device size; definitions vary, but a typical one would be nanoscale (10 nm to 1 μm), microscale (1–100 μm), and mesoscale (0.1–10.0 mm).

platelet architecture A fabrication scheme using a variety of micromachining techniques to place structural features in thin plates; several plates are then stacked together in a registered manner and bonded, producing a single part having an intricate array of embedded features.

process intensification The enhancement of heat and mass transfer rates as the characteristic length defining the process is decreased.

unit operation A process characterized by a single function; several unit operations can be combined together to produce, or generate, an end result.

The trend toward miniaturization has branched out into many fields of engineering. The area of Micro Electro Mechanical Systems (MEMS) has been established for well over a decade and is focused primarily on sensors and actuators, although other components such as gears, linkages, valves, and fluid mixers are common research and development topics. The energy area, including chemical processing, power generation, refrigeration, and heat

pumping, is in the nascent stages of process and systems miniaturization. The developing area of Microtechnology-Based Energy and Chemical Systems (MECS) holds great potential for spawning new commercial sectors to the economy. The primary aim of the MECS area is to miniaturize and integrate the components necessary for advanced energy and chemical systems. Miniaturization will be especially important in areas where portability, compactness, weight, reliability, and point application are the driving considerations.

1. INTRODUCTION AND OVERVIEW

At the beginning of the 21st century, the trend toward miniaturization has branched out into many fields of engineering. The area of MEMS has been established for well over a decade and is focused primarily on sensors and actuators, although other components, such as gears, linkages, valves, and fluid mixers, are common research and development (R&D) topics. MEMS have feature sizes between 1 and 50 μm, with development in the area being heavily dependent on fabrication processes common in the electronics industry. The energy area, including chemical processing, power generation, refrigeration, and heat pumping, is in the nascent stages of process and systems miniaturization. This developing area is called by many terms—Micro Systems or Micro Systems Technology (MST) in Europe and Micro Chemical and Thermal Systems (MicroCATS) or MECS in the United States—and holds great potential for spawning new commercial sectors to the economy. The primary aim of the MECS area is to miniaturize and integrate the components necessary for advanced energy and chemical systems. Researchers in the field view this idea as a way of improving traditional energy systems while addressing the challenges of new applications. Miniaturization will be especially important in areas where portability, compactness, weight, reliability, and point application are the driving considerations.

Systems based on this technology rely on the extraordinary rates of heat and mass transfer associated with microcomponent architecture. That is, as a system's characteristic heat transfer or mass transfer path is reduced, rates of transfer increase significantly. Depending on the type of system considered and the performance metric chosen, the increase can scale as $1/L$ or $1/L^2$, where L is the characteristic length defining the transfer path. An example is the fabrication of heat exchangers from microchannel arrays where the thermal diffusion path is very small and the total surface area per unit volume is high. Early work on microchannel heat exchangers demonstrated heat transfer rates of 20 kW/cm^3, albeit under extreme flow conditions. This is the rate of heating needed by an average home on a cold day in the northern latitudes.

Other important effects are present with a reduction in scale. As with heat transfer, microscale devices have high mass diffusion rates. This leads to very fast and complete mixing in small volumes. Another feature present in microsystems is precise control over chemical reactions and biological processes by rapidly controlling system temperature. With flow-through microscale devices, temperature gradients can be very large (on the order of 100,000 K over a distance of a few microns or a time period of a few microseconds). Finally, by virtue of scale, the stress in miniaturized structural devices is lower for a given operating pressure. Therefore, it is practical to operate at higher pressures than in conventional processing situations. This can increase efficiency substantially or skew a chemical reaction to higher yields of a desirable product.

Enhancement of the primary transport processes by scale reduction is responsible for what researchers in the area call process intensification. This term captures the idea of using microscale structures in mesoscopic devices to enhance performance in small or miniaturized systems. However, size reduction cannot go on indefinitely. This is due to the increasing difficulty of transporting fluids and maintaining temperature differences within a miniaturized system. Excessive pressure drops, parasitic internal heat conduction, and mechanical friction are just a few of the existing problems when miniature energy systems are developed.

Integration is also a central issue in MECS research. To take advantage of mass production techniques leading to economical devices, it is desirable to have most if not all of the critical components of a system integrated together and fabricated simultaneously. Realistic implementation of this concept will probably rely on a number of additional steps, such as "pick and place" (common in the electronics industry), to complete the device. Aside from lowering production costs for single systems, additional capability and functionality can result from processing multiple devices at once. For

example, integrated arrays of components open up new approaches to solving challenging problems in the energy and chemical processing fields. In high-capacity applications such as chemical plants, production schemes based on massively paralleled arrays could be used. The principal advantage to this approach is the higher production efficiency associated with microscale processing and the inherent reliability of parallel architecture where the failure of one or even several individual devices would have a small effect on the overall production rate. If a few individual components required replacement, they can be isolated from the array, removed, and then replaced without shutting down the overall system.

A clear definition of an energy system must be given to elucidate the application areas for this new technology. In the context used here, the term "energy systems" generally involves energy generation, use, distribution, or conversion from one form to another. Furthermore, microtechnology-based energy systems involve the concept of microfabricated internal features providing process intensification over standard practices in common use today. Component and system size spans the mesoscale/microscale regime, as shown in Fig. 1. Nanoscale features may be important to this field during the coming decades but are beyond the scope of this discussion.

Intermediate size applications are the most likely to be commercially attractive in the short term, especially where MECS technology makes possible previously impractical activity. For instance, a MECS reformer to strip hydrogen atoms from hydrocarbon-based fuels will allow use of fuel cells in automobiles (with higher efficiencies and lower pollution). For this idea to work, high-temperature steam reformers and membrane separation are needed in small package configurations. Thermal management will also be critical to the development of practical systems. Heat loss from palm-sized reformers must be minimized through use of high-performance insulation, and heat exchangers are necessary to conserve thermal energy in the various internal gas streams. With the process intensification afforded by MECS technology, palm-sized fuel reformers for fuel cell-powered automobiles become feasible.

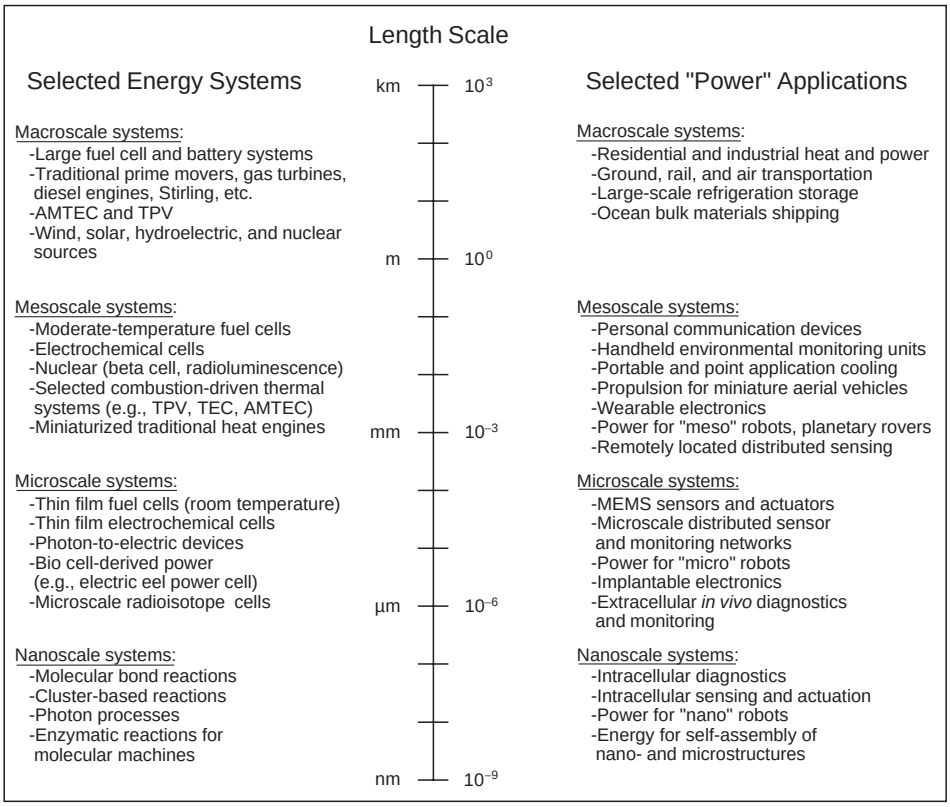

FIGURE 1 Length scales important to the energy area.

Two other areas where this technology can make an impact are small-scale power production and resource processing. As an example of the first application area, consider the chemical energy stored in a liquid hydrocarbon fuel. When burned with oxygen from the surrounding air, the heat generated can be two orders of magnitude higher than the energy contained in an electrochemical battery. If the heat can be converted to electricity with 20% or higher efficiency, stored energy densities for portable power generation can be 5 to 20 times those of current battery technology. This would require miniaturized and integrated components to achieve practical implementation in small-scale packages, but no fundamental limitations exist in developing a battery replacement operating from hydrocarbon fuels. Another application area would involve resource processing at remote locations such as on the surface of Mars. If human exploration of Mars is to take place, it makes sense to process native materials for fuel, oxygen, and water. This type of resource processing would be accomplished most reliably by large numbers of small devices working to generate the necessary power and performing the required chemical processing of the indigenous materials.

Other application areas are possible and include decentralization of heating, ventilation, and air-conditioning (HVAC) systems (super zoning), cooling of protective suits for hazardous environments, and micropropulsion of miniaturized air, land, and sea vehicles. Although the true value of MECS will become known only during the next few decades, the vision of bringing about both evolutionary and revolutionary changes to the energy area is one of the driving forces in this developing field.

2. *UNIT OPERATIONS*

A unit operation is a single process critical to the functioning of a larger integrated system. Several unit operations are typically joined together, either sequentially or in parallel, to accomplish the overall system function. For MECS, this overall function could include (but is not limited to) heat generation through combustion, heat-activated heat pumping, or power generation. The unit operations terminology derives from chemical engineering where filtration, evaporation, distillation, and batch reaction processing are relevant. In this work, a broadening of the term is implied to include other elementary operations important for the generation and conversion of energy.

2.1 Heat Exchangers, Evaporators, and Condensers

The most fundamental process from an energy systems standpoint is heat transfer to (or from) a working fluid. This unit operation typically occurs in small channels, the characteristic diameter of which is less than 1 mm. Other heat transfer configurations, such as fluid flowing through a network of posts or through a mesh, are also possible. Specific examples of this fundamental unit operation include phase change occurring in boilers, evaporators, and condensers. Single-phase systems where the fluid undergoes a temperature change only also falls into this category.

A slightly more complicated arrangement for transferring thermal energy from one fluid to another occurs in a heat exchanger. Many different configurations exist for this type of device. Classifications include parallel flow, counter-flow, and cross-flow for the primary arrangement of the flow as well as shell-and-tube, plate-and-frame, single pass, multiple pass, and other terminology specifying the physical arrangement. Regardless of the type and configuration, heat exchangers are designed to recover thermal energy from one fluid and deliver it to another to enhance the overall performance of a system (by way of conserving thermal energy).

Use of engineered microstructures in heat and mass transfer has the potential of enhancing transfer rates, thus leading to process intensification in thermal/mass diffusion limited situations. The typical microstructure used is the microchannel array. Characteristic dimensions of these structures are small enough so that laminar conditions exist throughout. Consequently, diffusional processes are responsible for thermal and species mixing and result in a time for process completion proportional to d^2/α, where d is the channel dimension (the diameter if circular) and α is the thermal diffusivity (for thermal mixing) of the fluid. Thus, smaller channels lead to higher rates of thermal and mass transfer, resulting in process intensification. Surface area per unit volume can also be increased in these devices. If special design accommodations are not made in microchannel systems, the penalty for enhanced transfer rates is often higher pressure drops across the device. One of these accommodations would be to array a larger number of parallel microchannels so that a shorter length of fluid channel results in a lower pressure drop, whereas the increased number of parallel paths maintains the required throughput. It is not uncommon for heat fluxes exceeding $100\,W/cm^2$ to be achieved with water flowing through microchannel arrays.

2.2 Valves

Microvalves have been developed for a variety of applications suitable for MECS. Valve classification can be divided into passive and active categories. The passive type is the most fundamental and is configured as a basic check valve where a thin flapper plate covers an orifice. Microvalves of this type have been fabricated using a variety of techniques, including lithography and etching, laser micromachining, and electro-discharge machining. Materials have included metal on metal, metal on polymers, and silicon with photoresists such as PMMA and polyimides. Soft lithography has also been used to create check valves. Work in this area has resulted in miniature peristaltic pumps driven by compressed air. Sizes of these microvalves vary from the 50-μm range (for orifice diameters) up to 1 mm. Larger sizes are typically classified as conventional macroscale devices.

Active valves have designs that rely on electric actuation in some specific form. Direct actuation by a piezoelectric element has been achieved where the sealing element in the valve is a simple piezoelectric bending element, or the so-called bimorph, in place of a passive flapper in the check valves discussed previously. Electromagnetic solenoid actuation has also been developed, but this activity borders on conventional solenoid valves found commercially. A new development in the electromagnetic actuation area is arrays of active valves with characteristic sizes of a few millimeters and integrated together on substrates containing manifolding and sensor placement. This level of sophistication is only beginning to emerge from laboratory work in the commercial sector.

Secondary electrical effects using heating of bimetallic strips or shape memory alloy elements are being used for actuating valves. Electrical current passing through the active element (a metal strip) itself, or through a nearby resistor for I^2R heating, is the most common way of actuating valves of this type. For the bimetallic valves, heating causes a differential thermal expansion of the two metals, leading to a bending or distorting in a suitably designed element. Shape memory elements can also be designed as a composite actuator to provide an active opening and closing of an orifice on electrical current flow. Thermopneumatic forces have also been harnessed for valve actuation. This method relies on the expansion of a material, often through phase change, on heating. A common problem with all valve designs is leakage in the adverse direction, that is, the direction opposite to the desired flow when closed. Due to scaling of the sealing area, which goes as the characteristic length of the valve squared, valves become progressively more leaky as the overall scale is reduced. This can be mitigated somewhat by design; however, effective low-leakage valves at the microscale remain problematic.

2.3 Pumps and Expanders

Many small-scale energy systems require effective miniaturized pumps and expanders. These devices are responsible for conveying a working fluid through various components to execute a cycle that may result in power production, heat pumping, or refrigeration. As an example, a pump is required for pressurizing the working fluid in Rankine power cycles. Miniaturized pumps could also cycle a heat transfer fluid through a cooling loop for heat rejection purposes. On the other hand, expanders are necessary for any cycle employing a working fluid to generate power. Specific examples include microturbines, miniaturized piston-based machines, and roots-type expanders.

Most candidate techniques for pumping and expanding are ineffective for MECS applications. However, there are a number of ongoing projects concerned with development of pumps, compressors, and expanders. Micro turbo machinery has been the focus of one such project. Its targeted application is to develop a gas turbine engine the size of a shirt button. Many spinoff applications will result if the project is successful, including compressors, pumps, and expanders—all based on high-speed rotating machinery. Note that scaling turbo machinery down to the several millimeter size regime requires careful attention to machining tolerances, heat transfer effects, and operating speed. It is anticipated that rotational rates of up to 2 million revolutions per minute (rpm) will be needed in such devices. Various piston-based expander and compressor configurations can also be miniaturized at least down to the several millimeter range, but sub-millimeter devices will be a challenge. Seals, friction, and heat transfer effects all have adverse scaling characteristics; hence, novel design and fabrication methods are needed.

Pumps in the true microscale regime can be fabricated using photolithographic techniques where flexible diaphragms are used and electrostatic or electrothermal mechanisms are used for driving the diaphragms. Simple check valves of the flapper kind can be used to control the flow. Current state-of-the-art pumps of this type have low pumping speeds and limited pressure increases. Other microscale pumps working with weak electro–fluid interaction, such as

electrohydrodynamic and even magnetohydrodynamic effects, have also been evaluated. Low pumping speeds and minimal pressure rises have been observed. Until effective designs are developed, mesoscale pumps, compressors, and expanders may have to be coupled with many parallel flow microscale components to be effective. Hybrid mesoscale/microscale devices would result from this. Recent developments in the actuator area could help to bring about practical mesoscale/microscale pumps and compressors. New polymer-based electro-active materials and magnetic shape memory actuators are now becoming available to MECS researchers.

2.4 Mixers

Mixing is a process where two or more liquids or gas phase components are brought together and combined to form a uniform composition. Both turbulent and diffusive processes are typically employed to achieve the mixing action. As the scale of the process is reduced, diffusion becomes dominant. Microtechnology mixers are designed to bring together individual components for mixing with the smallest diffusional scales possible. Mixing is an important unit operation in the chemical and energy industry and can be found in combustors, microreactors, and adsorbing processes.

Micromixing technology has been developed in several different directions, but the common theme with most concepts is to rapidly bring together the constituents where a very small diffusive length scale exists for the final mixing step. Mixing in microchannel geometries has been studied in "Tee" sections, opposed microjets, channel flow through arrays of posts, and various interdigited designs. Mixing in converging channels and jet-in-cross-flow geometries has also been studied. Practical micromixers have been developed and proven out using deep-etch photolithography (in silicon) where an interdigited arrangement yielded a length scale of 100 μm (distance between two streams). Note that the time for diffusional mixing is proportional to L^2/D, where L is the distance between two mixing streams and D is the diffusion coefficient. Hence, it is important to reduce the device size to achieve rapid and complete mixing.

2.5 Separation Units

Separation is a unit operation used in absorption heat pumps and chemical processing applications such as solvent extraction and product separations. A typical separation process in a heat pump application involves the desorption of ammonia from a water–ammonia solution. Although a number of configurations have been studied for this process at the macroscale, most are based on gravity and have relatively low rates of desorption. For developing small heat-activated absorption heat pumps, microtechnology can be applied through the use of thin "sheet" channels where desorption of ammonia is accompanied by heat addition. As the sheet film in the channel is made thinner ($<100\,\mu m$), diffusional processes become exceedingly fast and high rates of desorption can be achieved.

Practical implementation of the thin sheet geometry for desorption has taken the form of mechanical membrane gas–liquid contactors. This approach has been dictated by the consequences of capillary forces present at small-length scales. Surface tension and flow in the "lubrication" regime of fluid dynamics conspire to prevent unconstrained films from flattening out to the dimensions necessary for rapid desorption. With the use of a mechanically constrained liquid film, progress on desorber units has progressed to the point of making miniature heat-activated heat pumps feasible. To realize the potential of the concept, an integrated approach to the design of a thin film desorber must be used. Thus, combining a microchannel heat exchanger with a mechanically constrained thin film desorber has resulted in high-performance units ideal for small-scale systems.

2.6 Microreactors and Combustors

MECS will most likely employ combustion for driving processes such as vapor generation, endothermic chemical reactions, and (most notably) fuel reforming. Both fuel reformers and combustors will be of a miniature design relying on embedded catalysts for promoting chemical reactions at moderate temperatures (350–750°C). Many potential configurations exist depending on the application and constraints on the design. Microchannel arrays are a potential configuration; mesh and post architecture is another to achieve the desired surface area and small diffusional lengths necessary.

Small-scale fuel reforming is an important area of research in the microreactor area. Hydrogen production for fuel cells is the main driver for this activity. Fuels such as methanol, ammonia, and gaseous hydrocarbons have been tested in laboratory settings with reaction volumes on the order of $1\,mm^3$. These devices are constructed using several different

techniques, but etched silicon and platelet technology (described later) are two methods being explored. Note that thermal management of microreformers is exceedingly important given that heat loss can represent a significant fraction of the energy transfer rates present in the device. Consequently, small reformers will require both high-performance insulation and gas stream configurations that recover thermal energy in the exiting flows. A systems approach to design optimization incorporating thermal management, flow pressure drops, and component interfacing will be necessary for practical systems to emerge from the laboratory.

A heat source is required to drive endothermic reactions of fuel reforming and shift reactions. Evaporators and boilers also require a heat source. Of all the conventional sources of heat, combustion of liquid hydrocarbons has the highest stored energy densities. Compared with electrochemical cells, liquid fuels have energy densities 35 to 300 times greater than current battery technology. This assumes that the fuel has an energy density of 42 kJ/g (with air coming from the surroundings) compared with a zinc–air battery at 1.2 kJ/g or a lead–acid battery at 0.125 kJ/g. The development of moderate-temperature (450–1000°C depending on the type of fuel) combustors in a miniaturized form has led to a practical method of releasing this energy in a small overall component size. Microcombustors have been developed in a size range of a few cubic millimeters where a platinum catalyst has been used to promote reactions. Catalytic operation is a necessity because miniature and microscale devices have much larger surface/volume ratios, and hence a high degree of heterogeneous reactivity, compared with conventional macroscopic combustors. Also, true microscale operation typically takes place at length scales much smaller than the quench distance associated with the fuel being burned. However, high-temperature operation can mitigate the need for catalytic surfaces in some cases.

As the characteristic size of combustors is reduced from mesoscale to microscale, thermal management plays an increasingly important role in efficient combustor operation. Work currently taking place in miniaturized combustors includes development of small excess enthalpy burners fabricated using a three-dimensional printing process by stacking hundreds of individually patterned layers. A toroidal combustor has been developed in the form of a "Swiss roll" where the hot region of the burner is isolated from the surroundings by the inward spiral of reactants and the outward flow of products. Excellent heat recovery can be achieved with this design. There has also been work accomplished on the development of microscale combustors based on a bayonet-style counterflow heat exchanger where the outside surface of the combustor is insulated by either vacuum conditions or high-performance insulation. Hydrogen and propane have been catalytically burned in volumes of less than 0.5 mm^3 (Fig. 2) at temperatures in excess of 650°C. Other work has also taken place on small-scale diffusion flames and insulated burners. The current technology offers validation of the ability to construct small-scale heat sources for integration with other components to build miniaturized energy systems.

2.7 Balance of Plant

A critical issue with MECS development is the size and complexity of the "balance of plant." This includes subcomponents such as air movers, fuel delivery components, sensors, valves, and other associative concerns (e.g., power for start-up). These issues are being explored by a few researchers concerned with the development of total systems, but all too often this aspect of energy systems developed is relegated to a minor consideration when in fact it can be the deciding factor for practical systems. The balance of plant problem must be explored in detail and resolved for each specific case being examined. Over the coming years, solutions may begin to emerge through ongoing efforts in related microtechnology development.

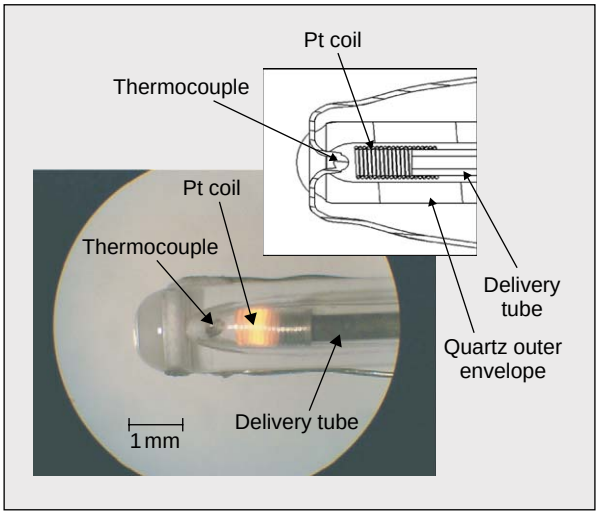

FIGURE 2 Example of catalytically promoted microcombustor. (Courtesy of Oregon State University.)

Specifically, microscale engineering and MEMS-type fabrication techniques may offer effective balance-of-plant solutions in an integrated packaging scheme.

3. SYSTEMS

Applications abound for microtechnology-based energy systems. Although not exhaustive, Fig. 1 conveys important developmental areas and provides a listing of technologies important in each size class. The current topic is concerned with the mesoscale/microscale size regime; overall systems of palm size or smaller are the main focus here. These systems are based on subcomponents that have microscale elements for process intensification but can fall into either the mesoscale or microscale regime. The focus here is concerned with power generation and cooling. These two applications will be the main areas for MECS during the coming years and could represent multi-billion-dollar industries by the end of the first decade of the new century.

3.1 Power Generation

Power generation can take the form of shaft work, electricity, or a propulsive effect (for applications involving flight or submersibles). Electrical power generation using fuel cells or microengines will become a direct competitor to batteries as the technology in MECS is developed into reliable systems. As mentioned earlier, stored liquid hydrocarbons have a large advantage over electrochemical storage in terms of energy density. However, batteries enjoy significant advantages in ease of use and reliability. Once MECS are developed to their full potential, they should provide portable applications capability with substantial benefits for both military and commercial uses.

3.1.1 Fuel Cells and Fuel Processing

Fuel cells are direct energy conversion devices that combine two reactants to produce electrical power. The reactants are typically a fuel such as hydrogen, or methanol, and oxygen from the air. Fuel cells require an electrolyte capable of passing an ionic charge carrier across an electronic conduction barrier where the ions are driven by a concentration gradient. Fuel cells also need a catalytic-based anode and cathode for reactant preparation. For mesoscale/microscale systems, fuel cells are best fabricated in thin film form. Depending on the desired power output of the system, the "footprint" may well be relatively large to supply the required power. Systems arranged in this manner are referred to as mixed scale systems on the basis that one critical dimension is small (the thickness), whereas the extent of the device (its footprint) can be the requisite size to satisfy a particular power application.

Thin film fuel cells operate across a broad range of temperatures. Proton exchange membrane (PEM) cells based on Nafion or similar material can operate at room conditions but provide better performance at elevated temperatures. The upper practical temperature limit for Nafion is approximately 100°C, although pressurized systems can go higher. The reason for this limitation is the requirement for keeping the membrane saturated with water to promote ion passage. Fuels for PEM cells include hydrogen and methanol as well as other fuels if reforming takes place. Direct methanol fuel cells have received much attention recently as a possible power source for portable electronics. Developments in PEM cells have resulted in new membrane materials operating near 200°C, where power densities can be higher and where catalysts on the fuel side (the anode) have less susceptibility to carbon monoxide poisoning. This is critical for cells consuming a reformer gas because carbon monoxide in low concentrations is usually present even after filtering.

Higher temperature systems are also a possible choice for mesoscale power systems. Solid oxide fuel cells (SOFCs) have traditionally been made with electrolytes of yittria-stabilized zirconia having a thickness greater than 100 μm. This has dictated operating temperatures approaching 1000°C due to low ion mobility through the electrolytes. Research on thin film SOFCs over the past decade or so has shown the possibility of operating at temperatures as low as 500°C. This makes them attractive for small-scale systems. Attributes of the thin film SOFCs at these lower temperatures include tolerance to many types of fuels (including carbon monoxide), no water management issues, and the possibility of operating with either internal reforming or direct fuel oxidation. If the power density of the thin film devices can be maintained at the lower temperatures, practical small-scale systems may result.

As mentioned earlier, practical PEM fuel cells require hydrogen to operate (with the exception being the work on direct methanol fuel cells). However, to carry sufficient quantities of hydrogen gas for cell operation, high-pressure canisters are required. This can be a safety hazard, especially if pressures greater than 100 atm are needed. An alternative is to extract hydrogen from a fuel rich

in this constituent (e.g., methanol, ammonia, hydrocarbons). Fuel reforming is the process by which this extraction occurs and has recently been the focus of much research. Note that other hydrogen sources have been considered, such as the so-called hydrogen-on-demand systems using borohydrides, but are not examined here.

Reforming takes place at temperatures from approximately 350°C for methanol to over 750°C for hydrocarbons and ammonia. The reactions are endothermic and require a source of heat to drive them to near completion. Small-scale reformers are configured so that fuel with water vapor passes over a catalyst within a microchannel array. The fuel molecules are "reformed" so that hydrogen, carbon dioxide, carbon monoxide, and excess water emerge from the device. Trace amounts of unreacted hydrocarbons can also contaminate the exit stream. The consequence of not having a pure hydrogen stream from the reformer is severe; if small amounts of carbon monoxide are present in the hydrogen supplied to a PEM fuel cell, poisoning of the anode catalyst results. Hence, reformers require a rigorous cleanup and filtering of the fuel stream. Nevertheless, mesoscale/microscale reformers with metallic membrane filters having internal volumes of less than a few cubic millimeters are being developed. As with all mesoscale/microscale devices operating at elevated temperatures, thermal management is important for conserving the energy of the process.

3.1.2 Miniature and Microscale Heat Engines

Many characteristics of traditional engines make them attractive for use in power generation and propulsion. They tend to be self-aspirating and rely on combustion, which at the macroscale is a very robust form of heat generation. Fuel is plentiful and inexpensive, with storage easily realized. The energy density of the fuel (or fuel plus container), when compared with electrochemical sources, is high. Along with these advantages come a number of drawbacks, especially where miniaturization is concerned. For example, an engine is thermodynamically restricted (by the Carnot efficiency) in its conversion of chemical energy to work due to the intermediate heat-generating step. This is in contrast to the direct energy conversion of fuel cells. However, conversion efficiency is respectable in macroscopic engines and can approach the 30 to 40% range at design speed and power output. Note that the overall conversion efficiency of fuel cells rarely exceeds 50% because of the cell's internal electrochemical irreversibilities and losses due to power conversion electronics, fuel use, and reforming. Thus, thermal engines provide a practical and reliable way of extracting chemical energy bound up in hydrocarbon fuels.

Most common thermal engines rely on compressing a cooler, condensed working fluid and expanding a hot, volume-expanded fluid. This is often accomplished through mechanisms that have rubbing or clearance seals, hot regions separated from cold structures, and bearings to allow differential motion between parts. All three of these defining characteristics suffer from adverse scaling effects. Although scaling laws are not discussed here, consider the case of maintaining the required temperature difference for the Brayton cycle (gas turbine). By its very nature, this engine exploits a difference in temperature to generate work from heat. This temperature difference is the driving force for engine operation, and as the temperature difference increases, better thermal efficiency results. However, as the size of the engine is reduced, its internal structure acts as a thermal pathway shunting a portion of the usable heat through two unproductive pathways. First, some of the heat is transferred to the surroundings without producing work. Second, heat is conducted through the connection between the turbine and the compressor, heating the inlet air stream. At smaller sizes, it becomes progressively harder to insulate the hot section of the engine to prevent heat flow through the two leakage paths. Simple calculations for palm-sized gas turbines having a 300 K inlet temperature and a turbine operating at 1800 K show the parasitic heat loss to be comparable to the overall power output. The parasitic effects become more pronounced as the engine is further miniaturized until no practical conventional design is possible.

Microthermal engines, as characterized by miniature Wankel engines, Stirling engines, and micro gas turbines, all are practical macroscopic engines but suffer from significant sealing problems, reduced subcomponent efficiency, friction, and thermal management issues when scaled to the mesoscopic size regime. To date, significant work has been invested in micro gas turbines and Wankel engines. The former is contemplated to have a rotor diameter of approximately 5 to 10 mm, a combustor temperature in excess of 1200°C, and rotation rates of up to 2 million rpm. Wankel engines and compressors have received considerable interest recently. The particular design features making this approach attractive are a simple overall design and no valves. Furthermore, a near two-dimensional layout of the engine (Fig. 3) would permit MEMS-type fabrication (in silicon or other suitable material) if workable designs emerge

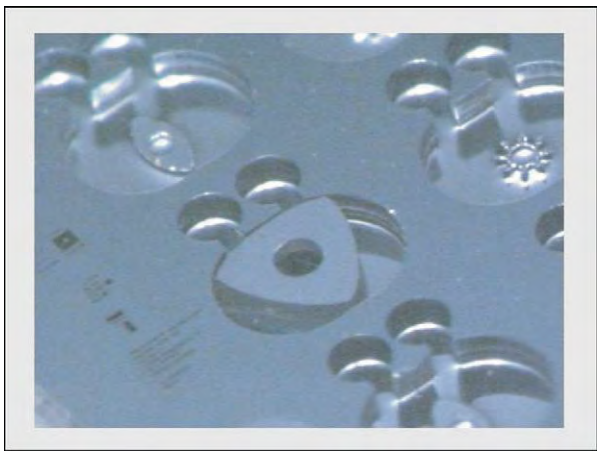

FIGURE 3 Lithographically deined 1-mm Wankel rotor in its housing. (Courtesy of University of California, Berkeley.)

from the laboratory. As with most miniature internal combustion engines, the Wankel presents serious questions regarding seals, internal heat transfer, and combustion in small spaces.

3.2 Cooling

An important technological application for MECS is small-scale systems cooling. As mentioned previously, an advantage will be realized in areas where portability, compactness, weight, and point application are the driving considerations. Many specific cases that meet these criteria exist. For example, cooling protective suits used in chemical and biological "hot spots" represent one important application. Super zoning in residential buildings for heating and cooling is another. At the smallest length scales, electronic chips would benefit from onboard and integrated cooling mechanisms. The following is a brief overview of some of the work being done in this area.

3.2.1 Refrigeration and Cryocooling

Microtechnology can be employed to produce miniaturized refrigeration and cryocooling systems. Although process intensification is typically the route used for miniaturization, microtechnology can also be used for reducing the size of mechanical components that are necessary for operation. For example, to create a small-scale vapor compression refrigerator, the heat transfer components comprising the condenser and evaporator can be made in a microchannel configuration for enhanced heat transfer rates. However, the mechanical compressor will often be the determining factor for overall size and weight. Advanced compressor designs can be developed by replacing existing components with micromachined ones, or entirely new types of compressors can be developed. In the former area, valve heads and drive mechanisms can be redesigned to take advantage of layered manufacturing techniques so that integrated components result. In the latter area, work has been under way focusing on electrostatically operated compressors micromachined out of silicon. Other approaches using thermopneumatic operation, electroactive polymers, and magnetic shape memory alloys have been pursued.

Cryocoolers can benefit from miniature components as well, but fundamental heat transfer issues must be considered. For example, counterflow heat exchangers or regenerators are necessary for cryocooler operation. This is due to thermal isolation requirements of the cold space from ambient temperature. The working fluid must pass relatively unimpeded (i.e., low pressure drop) through the heat exchanger while thermal energy is exchanged between the incoming and outgoing flows. To reduce the size of the overall cooler, each component (including the heat exchanger or regenerator) must be reduced in scale. However, this presents a heat transfer problem in the form of heat leakage into the cold space. As the size, and hence the length, is reduced, the temperature gradient along the heat exchanger increases, leading to enhanced heat transfer rates to the cold section. On further size reduction, a point is reached where the cooler load is entirely from this leakage and no useful heat lift takes place. Thus, there exists a limit, based on fundamental heat transfer principles, to which coolers can be reduced in size.

With these considerations, several of the techniques used at the macroscale for cryocooling have been investigated for miniaturization. For instance, both pulse tube and Stirling cycle devices have been studied for miniaturization. Conduction through the regenerators and heat exchangers limits the ultimate size of the system, but cryocoolers that are approximately a centimeter in length appear to be practical. Miniaturization of the cyclic compressors needed for cryocoolers is also an important need in this area. Typically, piston-based compressors are used; reducing their size involves all of the challenges as does the microengine area discussed earlier. Another possible approach to cryocooling uses a reverse Brayton cycle. Miniaturized turbo machinery could be effectively employed for this application. However, the performance of any Brayton cycle, whether

power producing or in cooling applications, is strongly influenced by the efficiency of the individual components. Thus, compressor and turbine elements in a reverse Brayton cycle machine must be relatively efficient for the cycle to be practical. Although this section has not covered solid-state coolers or refrigerators, much work has been under way for producing efficient small-scale devices (e.g., thermoelectric coolers). If high "figure-of-merit" materials become available for thermoelectric cooling, they will play an important role in miniaturized cooling applications.

3.2.2 Heat-Actuated Heat Pumps

Heat-actuated heat pumps are cooling systems requiring no electricity for operation. Rather, a heat source is used, avoiding the need for batteries. This consideration is critical for portable applications because on a weight basis, a stored liquid fuel has anywhere from 35 to 300 times the energy content of batteries, depending on the battery technology considered. Thus, although the simple solution of combining an electric motor, a battery package, and a vapor compression refrigerator may sound appealing, it actually suffers a severe volume and weight disadvantage when compared with a heat-actuated system. An efficient heat-actuated cooler, perhaps based on combustion of butane or a logistics fuel, can be especially applicable to cooling protective suits and vehicle interiors. In general, the coefficient of performance (COP) for a heat-actuated cooling system needs to be in the range of unity for effective systems to be fielded.

Two types of heat-activated cooling systems are considered viable for miniaturized systems. Both would rely on microtechnology for operation of critical components, and both would use combustion of a storable fuel to drive the process. The first is an absorption cycle heat pump with a working fluid of lithium bromide and water or ammonia and water. The key components of the cycle are shown schematically in Fig. 4. The feature of this device making it a possible choice for palm-sized cooling is the use of microtechnology in the absorber, desorber, and evaporator. As shown in the diagram, a small amount of electrical power is needed for pumping the two-component liquid to a higher pressure. However, more than 90% of the energy used in the device would come from combustion of the stored fuel.

Significant developmental challenges exist for miniature absorption coolers intended for protection suits. The absorber and desorber rely on thin,

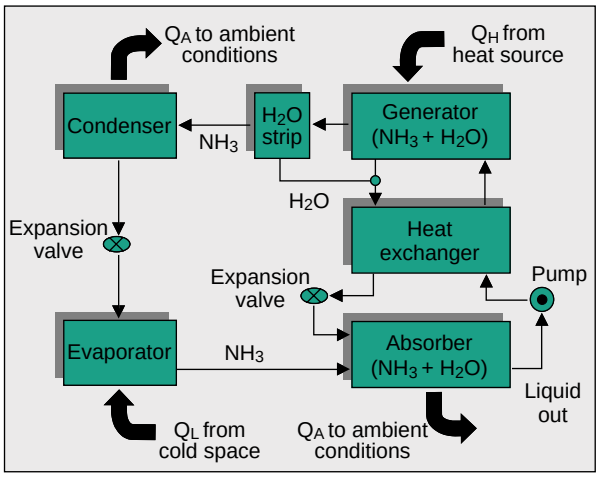

FIGURE 4 Schematic diagram of an ammonia/water absorption heat pump.

mechanically constrained membranes that mediate the separation of the two-component system. For practical use, orientation independence is required so that fieldable units can operate whether the wearer is standing upright or lying down. Finally, an integrated approach for the main components of the cooler, as well as for the balance of plant, must be developed so that economical fabrication is possible.

The second possible system for miniaturized heat pumps takes the form of an engine-driven vapor compression refrigerator. Microtechnology would be used throughout, but especially in the refrigerator components such as the compressor, evaporator, and condenser. The miniature engine for this type of heat pump has yet to be developed. Candidates are the aforementioned small-scale turbines and Wankel engines as well as other engine concepts using external combustion. High efficiency in a small package will be a key aspect to this heat pump concept. Furthermore, thermal management, including insulation around hot engine parts and energy recovery in the exhaust stream, will be critical if the engine-driven vapor compression cycle is to be realized.

4. MATERIALS, FABRICATION, AND COSTS

4.1 Criteria for Materials in the Energy Area

In fabricating microscale energy systems, a number of operating conditions must first be taken into account. Foremost are the operating temperatures throughout

the device. Often with mesoscale/microscale energy systems, two closely spaced parts of the same device have a large temperature difference between them; hence, a large gradient can be present. A primary constraint is to have the material withstand the maximum temperatures existing in the system, but the gradients and thermal expansion must also be tolerated. This is especially true if more than one material is used for construction where transitions must be made between material sets. Corrosion and oxidation are also important considerations when extended operating lifetime is required. Materials must be chosen for compatibility with the working fluid being used, especially at the temperature extremes of operation. The various materials comprising all wetted parts must not catalyze decomposition reactions at the fluid–surface interface—not even slightly—or else extended operation cannot be ensured. Furthermore, the materials must retain sufficient strength at the operating temperature and should have a low thermal conductivity. This latter criterion stems from the requirement of minimizing conductive heat loss throughout the device. Finally, cost, ease of machining, and material joining factors (e.g., brazing, diffusion bonding, soldering compatibility) must also be considered when selecting the materials of construction. With all of these criteria and constraints, the engineer must have a versatile material set to work with when designing and constructing MECS.

Other considerations come into play when selecting thermal insulation for isolating the elevated temperature (or cold) sections of the device from ambient conditions. Several potential material sets are available for this task, but operating temperature is one of the deciding factors in using a particular material or technique. For example, silica-based aerogel material has a very low effective thermal conductivity and can be used throughout the temperature range from cryogenic to elevated temperatures of up to 800°C. The aerogel can be either infiltrated with a gas or evacuated for very low thermal conductivity. However, radiation heat transfer in the infrared (IR) region must be effectively blocked at high and low temperatures. To accomplish this, carbon black is typically used as a dispersant. But because of oxidation of the carbon, this formulation is incompatible with air at temperatures above approximately 350°C. Other insulating systems, such as multifoil vacuum insulation and simple vacuum gaps, can be used. For long-term service, vacuum conditions must be maintained and might require gettering.

4.2 Types of Engineering Materials Available

Silicon is the material of choice for most MEMS due to (1) the feature size often being in the range of less than 20 μm requiring single crystalline material and (2) the dependence on fabrication techniques developed by the electronics industry for processing this material. However, it is a particularly poor choice for the larger thermally based devices that characterize MECS. The room temperature thermal conductivity of silicon is approximately 150 (W/mK). Use of this material leads to high rates of heat transfer across the short distances where temperature gradients occur. The thermal conductivity of silicon above 1000°C falls to below 25 W/mK, but the average value can still be high. Various metallic alloys and intermetallics, including common stainless steels, are potential fabrication materials for small-scale heat engines and coolers. Most stainless steels have a room temperature thermal conductivity between 11 and 15 W/mK. In contrast to silicon, the thermal conductivity of metals increases with increasing temperature. It is interesting to note that between approximately 1000 and 1200°C, the thermal conductivities of silicon and stainless steel are similar. However, heat loss through each material will depend on average thermal conductivities, and silicon will still have the higher average value. From a heat loss point of view, the best materials will probably turn out to be ceramics and glasses with amorphous structures. Fused silica is at the low end of the thermal conductivity range, with a room temperature value of 1.4 W/mK. This climbs to approximately 4 W/mK at 1200°C. It is also highly resistant to thermal shock due to its low thermal expansion coefficient. A class of material not known for elevated temperature use is polymers. However, polyimide (and other similar polymers) can be used up to approximately 400°C, and this could make these polymers attractive in certain applications.

In most MECS concepts, internal structures will be engineered to reduce internal thermal conduction, which implies thin sections. However, these same sections often contain a working fluid at elevated pressures and must be hermetic. Furthermore, they must support the stress due to the operation of the device and must not fail catastrophically. Single crystal silicon and other pure semiconductors (most notably silicon carbide) can be excellent structural material for microtechnology components. But they are brittle and unforgiving in a yield mode. The so-called engineering materials, including steels and

other metals, ceramics, and plastics, will probably be applied to the construction of larger microscale and mesoscale devices due to a wide selection of both properties and bonding techniques available. Material costs are reasonable for most of the engineering materials, and various forms such as thin sheets are commercially available. Another deciding factor, as discussed in the next subsection, is the availability of lower cost manufacturing techniques. In this respect, silicon requires a wide suite of expensive equipment for bulk and/or surface machining the material.

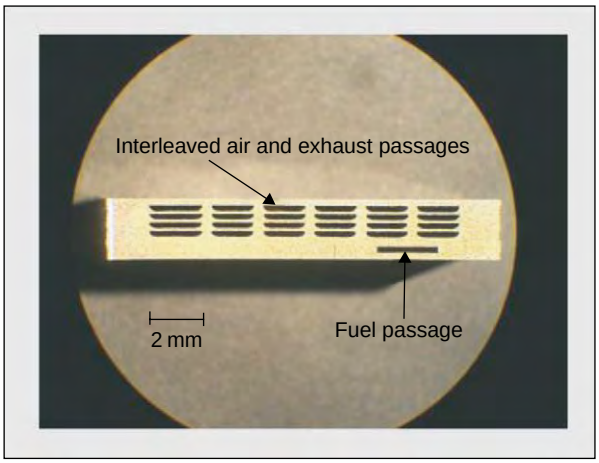

FIGURE 5 A three-stream counterflow heat exchanger fabricated using platelet technology. (Courtesy of Oregon State University.)

4.3 Microfabrication Techniques for Engineering Materials

Fabrication techniques developed for integrated circuit (IC) production have been refined to the extent of supporting a multi-billion-dollar industry. Chip manufacturing relies on silicon-based processing where micron-sized features are routinely used in production. MECS do not require the extremely small "line widths" needed for IC fabrication. Furthermore, in many energy applications, silicon is not the favored material, as discussed previously. Other fabrication techniques, such as LIGA, have been specifically developed for MEMS. Although many rely heavily on silicon processing, others can produce very small structures in metals electrodeposited on a surface or within a micromold. Again, for MECS applications, the feature size of these MEMS fabrication techniques is usually much smaller than what is needed.

Because MECS are fundamentally different from traditional ICs and MEMS, they require different materials and fabrication processes. One important fabrication method for microenergy applications is called microlamination or platelet technology (Fig. 5). Although its history dates back to the 1970s, when it was developed for liquid rocket engine injectors, it is now being pursued by a number of groups for fabricating MECS. The method is based on microlamination of metals, ceramics, and polymers. The process begins by surface machining, or cutting, a single lamina with a pattern containing the desired structure. The lamina is often a shim of a material having desirable mechanical and thermal properties important to the functioning of the final device. Once the pattern is cut, the shims are surface treated and precisely stacked in a prearranged order. The stack is then bonded together, forming a single block of material. For the platelet architecture to have utility, a machining method capable of fabricating structures in the laminating material is needed. The method must be versatile, easy to use, and capable of rapid machining (with through-cuts and surface texturing) in a wide variety of materials. One of the most general techniques is laser numerically controlled micromachining. It is most useful for prototype runs and can be used on metals and polymers. Other useful techniques specific to only one class of material can also be used. For example, chemical etching through a photographically defined mask (photolithography) can be used on most metals. The process is commercially available and can be employed for high-volume production runs. Another machining technique applicable to most metals is wire-based electrodischarge machining (wire EDM). Current machines on the market are numerically controlled and have wire diameters as small as 50 μm. The cutting of metal platelets with this technique is primarily a two-dimensional operation and can be as precise at 5 μm. Note that conventional high-speed milling, with end mills as small as 100 μm, can be achieved with most modern equipment and can be applied to both metals and plastics. Although wire EDM and conventional milling with small tools have been described in the context of platelet fabrication, their precision and speed can also be applied to a wide range of small mechanical components needed for MECS.

The properties of ceramics (and of materials such as quartz) are desirable from an energy systems point of view, but this class of material is difficult to machine and form. Relatively few techniques are available for cutting the requisite structures in ceramics. However, work is progressing on various

additive techniques for making small components out of both plastics and ceramics. Some of these techniques go by the name stereolithography and often employ a laser to selectively fuse a particle bed of the starting material into a desired shape.

Glossary

β-oxidation Metabolic process whereby fatty acids are oxidized to produce energy for locomotor activity.
fatty acid Major energy source for many migrants; part of triglycerides.
glycogen Carbohydrate formed by the union of two glucose molecules.
homeotherm Animals that are insulated and regulate their body temperature, typically with the assistance of physiological heat production by shivering.
hyperlipogenesis Excessive production of lipid stores brought about by hyperphagia and increased enzyme activity.
Krebs cycle The tricarboxylic acid cycle; chemical process whereby metabolic substrate provides energy for utilization and storage by the organism.
metabolizable energy Energy obtained from food; the basic amount of energy available for all activities.
passerine Birds belonging to the order Passeriformes; relatively small perching birds, including sparrows, thrushes, and swallows.
poikilotherm Animals that do not regulate their body temperature with precision; typically, they get heat from external sources.
triglyceride Molecular form of storage lipid; a glycerine backbone to which three fatty acid molecules are attached.

Migration is defined as the periodic, regular (usually annual) movement of animals between breeding sites and wintering or feeding–maturation areas. Numerous species of animals migrate, but the majority making trips of significant distance include swimming (fish, sea turtles, sea snakes, cetaceans, and pinnipeds) or flying (insects, birds, and bats) species. The energetic cost of locomotion has been measured in numerous animals, large and small, as well as the energetic costs of locomotion (the latter in kJ/kg km).

1. IMPORTANCE OF MIGRATION

Because costs of transport of terrestrial migrants are high, and risks of predation severe, there are few species of small animals that migrate by walking or running, and all animals making terrestrial migrations of more than a few kilometers are relatively large mammals, such as wildebeest (*Connochaetes taurinus*), caribou (*Rangifer tarandus*), and bison (*Bos bison*).

In insects, migration occurs fairly frequently among species in the orders Lepidoptera (butterflies and moths) and Diptera (flies) and occasionally in Orthoptera (grasshoppers and locusts), Colleoptera (beetles), and Odonata (dragonflies). Many fish are migratory—so many so that migrants have been classified into three groups; anadromous, catadromous, and oceanic species. Anadromous fishes are those that are born in freshwater, mature in the ocean, and make spawning runs back in freshwater (salmon, herring, and lampreys). Catadromous fishes are those that are born in the ocean, then move up into freshwater habitats to mature, and finally make trips to spawning grounds back in the ocean. Oceanic species (sharks, tuna, and swordfish) migrate much like whales, following food, often with the assistance of currents such as the Gulf Stream. Like terrestrial mammals, migration is limited to larger fishes. Most small fish cannot swim rapidly and cannot store sufficient energy to travel long distances. Young eels are an exception. They are able to make much of their

 © 2004 Elsevier Inc. All rights reserved.

migration by drifting with the current. Among birds, many migrants are members of the order Passeriformes (perching birds) or belong to the various groups of waterfowl (ducks, swans, cranes, storks, grebes, and loons). However, just about every order within the class Aves includes at least a few migratory species. For example, nearly all temperate zone swifts, hummingbirds, and goatsuckers are migratory and some of the pelagic seabirds (shearwaters, albatrosses, and jaegers) are remarkable travelers that wander over huge expanses of ocean. Among mammals, cetaceans (whales), pinnipeds (seals), and bats include many migratory species.

Because the risks of migration are great, it is axiomatic that migrants must derive significant selective advantages from changing location. The focus of this article is on the balance of costs and benefits that affect the ultimate reproductive success of migrants. Although many of the advantages are potentially related to reduced competition and lower predation rates, some of the justification discovered by investigators of the phenomenon has involved energy acquisition and use. Without doubt, natural selection favors animals that minimize energy expenditure during migration, either to increase their potential range over barren habitat or to reduce the amount of foraging necessary after shorter trips.

Although we often think of poikilotherms (cold-blooded animals) as lethargic organisms less active than homeotherms (warm-blooded), it is significant that migration is fairly common in both groups. There is a relatively large amount of information regarding the physiology and ecology of migration of insects and fishes, but little attention has been given to similar aspects of terrestrial migrants. Furthermore, the information regarding the ecophysiology of flying migrants, primarily birds, far exceeds all other sources and this article reflects that bias.

2. MIGRATION PATTERNS AND RANGES

Migration, strictly defined, can be as restricted as a trip of a few hundred meters or as much as thousands of kilometers. Some salamanders (e.g., mole salamanders and newts) and many species of frogs (particularly tree frogs) emerge from the soil and travel to temporary ponds to breed. They then return to their subterranean hiding places, where they may remain for the next 6–11 months. The distance involved may be only a few meters.

The most extensive migration may be that of the Arctic tern (*Sterna paradisaea*), which literally spends its lifetime in migration, traveling 40,000 km or more, its trip interrupted only by an annual period of reproduction. Note, however, that this trip is not nonstop and the tern feeds along the way, can drink seawater, and rests on the surface of the ocean. The migration of the blackpoll warbler (*Dendroica striata*) may be viewed as even more remarkable because it may fly more than 80 h nonstop from New England to Bermuda or the Caribbean Islands with no food or rest. However, the monarch butterfly (*Danaus plexippus*), which travels more than 3000 km, or dragonflies, which apparently fly across the Gulf of Mexico, are no less striking in their abilities to migrate.

Patterns of migration vary among different groups of migrants. Migrants may travel exclusively during the day (diurnal), at night (nocturnal), or up and down mountainsides (altitudinal). Some insects and mammals (e.g., lemmings) said to be migratory actually are not because their movements are emigrations from population centers to food sources. Their return to their site of birth is not predictable and often does not happen at all. Most migrants travel in groups that either are loosely formed (insects and small birds) or are in distinct flocks (waterfowl and cranes). Onset of migration is usually controlled by weather conditions. For example, individuals of migratory fishes typically gather in schools (e.g., salmon, eels, and shad) before setting out. In some fish species, the number of migrants passing a point pulses in correlation with environmental conditions such as water temperature. Migratory insects may incorporate several generations in one annual circuit (e.g., monarch butterfly), during which time adults survive long enough to get to the next stopover and lay eggs, which develop into the adults covering the next leg of the migration. Birds, particularly small passerine species, are the icons of migration. They annually depart from wintering grounds in spring and from breeding grounds in autumn at fairly precise dates, take similar routes from year to year, and make extensive preparations for the trips. Migratory birds and some insects (e.g., dragonflies) must cross great expanses in which there is no suitable habitat to land or refuel. Birds crossing the Gulf of Mexico number in the millions, and in the spring their passage (together with numerous insects also in migration) may be readily seen on radar screens.

Birds crossing more hospitable terrain typically alternate one or more days of flight followed by

longer stopover periods, during which energy for the next flight period is accumulated. Short flights require relatively small energy reserves, whereas long flights depend on large fuel loads. The total amount of energy reserve is a compromise among the effects of loading on energetics, risks of the trip, and necessary duration of the flight. Furthermore, a key factor in acquiring the birds' optimal fuel reserves and for their resulting migration speed is the rate of fuel deposition at stopover sites. In small birds, metabolizable energy and intake rates are very high, particularly 1 day after reaching stopover (feeding) areas. This may indicate an increase in the capacity of the digestive tract after many hours of fasting during flight.

Some fish have similar adaptations for migration. Sockeye salmon (*Oncorhynchus nerka*) accumulate large fat reserves that are largely consumed during swimming over long migratory trips to upstream breeding sites (as much as 1200 km). In the course of their migration, they may use 91–96% of their lipid (possibly all of the lipid that can be mobilized) and more than 50% of the protein content of their flesh.

The general timing of migration is under the control of circannian (endogenous annual) physiological rhythms more finely tuned by changes in photoperiod. Increasing day length stimulates spring migration in a number of species, and decreasing day length stimulates fall migration. This is especially evident in birds. Day length is the most accurate environmental indicator of time of the year, but many species begin subtle preparation for migration before the photoperiod changes greatly. Timing also varies with age of the migrant, body size, distance of the migration, and rate of accumulation of energy stores.

Many migratory species routinely return to the site of their birth with precision. This is called philopatry or site fidelity. Philopatry has long been known for birds, but it has also been recognized in sea turtles, bats, cetaceans, and other species. Returning to specific locations, especially if breeding has been successful, is of obvious importance and may be related to the ability of the organism to accumulate sufficient energy in its previous breeding attempt. However, such precise migration requires special skills. The navigation of long-range migrant birds depends on their striking sense of location, including their ability to detect magnetic fields. Some species correct their direction of movement by integrating information from star patterns with these fields. Wintering site fidelity is less well-known, but there are examples of species (passerine birds) that appear to return to specific sites on the wintering grounds and this is especially true for nonpasserine birds, such as waterfowl and cranes, that travel in specific flyways and winter on the same refuges year after year.

No other single event in the life history of migratory organisms requires more energy than that expended in travel during this period. Indeed, within the span of a few days, some small passerine birds may spend a significant proportion of their total annual energy budget in spring and fall migration. The majority of this energy is expended in two activities: accumulation of energy stores for their journey and the locomotor costs of movement between starting points and ultimate destinations. Much of the evolution of migration centers on the amount and nature of the energy stores and on reduction of the costs of travel.

3. MOLECULAR NATURE OF ENERGY STORES

Several fuels have been shown to support the energetic demands of muscular activity of migrating animals. Among these are carbohydrates, lipids, and some amino acids. Not all animals use the same fuel and some may even use different substrates during different stages of a prolonged trip, particularly if feeding is not possible. Glycogen and trehalose, a disaccharide that hydrolyzes to glucose, may be used in metabolic pathways of some migrant Diptera (flies) and Lepidoptera (butterflies and moths). Other species typically store glycogen, which is transformed to glucose (a simple sugar) for use in the Krebs cycle. In birds, glucose and glycogen are used for muscular activity, but accumulation of lipid for migration has been observed widely; it has been demonstrated in at least 40 families of birds. Some insects and birds use large proportions of glycogen early in migration but begin to use lipid as glycogen stores are depleted. Protein can be used in cases of extreme exertion, but this usually is indicative of an animal near its limits of survival.

In many birds, some insects, and perhaps other animals, nonesterified fatty acids provide fuel for avian exercise, particularly as activity is prolonged. Declines in lipid reserves and downward shifts of respiratory quotients (carbon dioxide produced/oxygen consumed) during prolonged locomotion under controlled conditions in the laboratory support these observations. Premigratory fat deposits are generally

TABLE I

Energy Content of Common Fuels Used in Migration

Material	J/g
Carbohydrates	16.7–18.8
Proteins	~18.0
Lipids	37.7–39.7

composed of triglycerides containing a mixture of fatty acids of various chain lengths and degrees of saturation. The metabolic pathway in which these lipids are used as fuel in many insects, fishes, birds, and mammals is β-oxidation. In this process, fatty acids are broken down into two-carbon units, converted to acetyl-CoA, which then enters the Krebs cycle. A great deal of energy (38 ATP) may be generated for every two-carbon unit going through the biochemical pathway.

Lipid is superior to carbohydrate as an energy reserve because lipid contains more energy than carbohydrate (Table I), and storage of carbohydrate is typically accompanied by storage of water, which increases body mass but contributes no energy. The water may amount to approximately 3 g per gram of glycogen. In birds, the net result is that 1 g of lipid potentially provides more than 37 J, whereas 1 g of glycogen (including water) provides only approximately 5 J. It is obvious that lipid is superior to glucose or glycogen as a intrinsic fuel source for long-range migration, especially in flying animals.

Lipid depots are mostly in the form of triglycerides (triacylglycerols), which consist of three fatty acid molecules attached to a glycerol moiety. The triglyceride content of adipose tissue may exceed 80% in some species, particularly birds. The fatty acids can be released metabolically from the glycerol molecule either entirely or partially and are then carried to the mitochondria within muscle cells, where they are transformed to produce substrate for oxidative metabolism. They are converted to two-carbon (acetyl) fragments that are oxidized in the Krebs cycle, producing relatively large numbers of ATP molecules. The amount of energy produced depends on the carbon chain length of the fatty acid (Table II). Although fatty acids may vary from 10 to 24 carbon atoms (chain length), the most common fatty acids have chain lengths of 16 and 18 carbons. Triglyceride composition may vary seasonally, geographically, and with diet of the migrant. The most energy-rich forms of triglyceride are those with greatest chain length that are least saturated (more double bonds). Unfortunately, these have higher melting points and may be less easily mobilized for use. Migratory birds tend to have flight muscles that are largely "red" fibers with many mitochondria, a good blood supply, and the metabolic capacity for sustained exercise fueled by lipids.

TABLE II

Common Names, Melting Points, and Energy Content of Common Fatty Acids

Common name	c:d[a]	J/g	Melting point (°C)
Saturated fatty acids			
Caparic	10:0	35.3	32
Lauric	12:0	36.8	45
Myristic	14:0	38.0	54
Palmitic	16:0	38.9	63
Stearic	18:0	39.7	70

Nervonic	24:1	—	43

[a] Ratio of carbon atoms (c) to double bonds (d).

4. MAGNITUDE OF ENERGY STORES

The amount of fuel stored for migratory trips is extensive in some species. For example, the blackpoll warbler, a bird that flies more than 80 h nonstop during fall migration, may add 10 g of lipid to its body mass of 11 g shortly before its fall migration. Hummingbirds that cross the Gulf of Mexico during migration may be even more obese. These birds arguably have the largest energy stores of any animal in the world, rivaled only by some mammals in their prehibernation period and some cetaceans and pinnipeds outside of migration periods. Insects and bats that migrate over fairly large distances also deposit substantial amounts of fat.

In general, the mass of energy stores varies with size of the migrant, the distance to be covered, and barriers to be crossed (Table III). For example, small

TABLE III

Lipid Reserves in Some Migrants

Blackpoll warbler	342
Bobolink	273

[a] Percentage of total dry mass.

birds have relatively larger premigratory energy stores than large birds, everything else being equal. Transoceanic migrants must have large fuel supplies, especially if they are not able to land on the water or forage en route. Accumulating such reserves may be done by any or all of the following: hyperphagia (excessive eating) in the period prior to departure, increased efficiency of nutrient utilization, reduction of energy expenditure in activities not related to preparation for migration, and selection of food items high in energy. In most species, only hyperphagia seems to be important. Some migrants, particularly small birds, can fatten significantly in a short period of time, perhaps 1 or several days. Premigratory hyperphagia is best known in birds, but relatively little evidence of the phenomenon exists for insect, bats, or other forms. In birds, hyperphagia results in hyperlipogenesis and lipid deposition may rapidly occur. Some investigators have not been convinced that all of the fattening occurs as a result of hyperphagia, but there is little evidence of increased efficiency of assimilation, decreased activity, or decreases in standard metabolism in the premigratory period. In fact, small birds demonstrate intensive nocturnal activity under caged conditions (Zugunruhe) during the premigratory period that is not shown at any other time. This paradoxical behavior would be wasteful of energy but probably represents a stereotyped behavior that replaces actual migration. There have been several observations of animals making dietary shifts to items containing more energy during the period just prior to migration.

Accumulation of sufficient reserves in a short period of time has a number of advantages. First, the time of arrival of some birds on their breeding grounds may be affected by their ability to accumulate sufficient reserves on the wintering rounds (or v.v.). It appears that arrival dates are extremely important in gaining advantage on competitors, exploiting food resources that are only temporarily abundant, and avoiding inclement weather. Second, heavy fuel loads may increase wing loading in flying animals, thus making them vulnerable to predators, so rapid accumulation and use is adaptive.

5. ANATOMICAL STORAGE SITES FOR ENERGY RESERVES

Energy deposits are basically stored at two general locations within the migrant's body. Poikiolothermic animals tend to store lipids in discrete fat bodies that are located within the body cavity. (Fat bodies in the thorax and abdomen are the major sites of storage in insects.) This is also generally true for short-distance migrants, such as frogs and some salamanders, but may vary widely in other poikilotherms. For example, in migratory fish, lipid storage sites are in connective tissue, mesenteries of intestines, skeletal muscle, liver, or the head, skin, and tail. Homeotherms also deposit lipids within the body cavity but usually store large amounts of fat at subcutaneous sites. Whales are obvious examples. Their subcutaneous fat deposits were the foundation of the whaling industry. The difference between the spatial patterns of poikilotherms (fish, amphibians, and reptiles) and homeotherm (birds and mammals) may be due to heat conservation by the latter through the increased insulation provided by the subcutaneous fat. In birds, fat deposition may be done in a fairly discrete sequence in which the lipid is placed at fairly specific sites, beginning in the body cavity and ending at several subcutaneous sites. For example, the white-crowned sparrow (*Zonotrichia albicollis*) deposits lipid in 15 recognizable regions. In birds, subcutaneous layers of fat associated with feather tracts appear first. Subsequent fattening is manifested as greater amounts of subcutaneous fat plus some abdominal storage. In the final stages of fattening, intraabdominal deposits become extreme. When fat is deposited at both abdominal and subcutaneous sites, it is usually used in the opposite sequence as its deposition (i.e., abdominal fat is used first and subcutaneous fat last). It is logical that lipid nearest sites of utilization would be easiest to mobilize, but there is evidence that the molecular nature of the fatty acids

may differ with the location of the depot. Long-chain, saturated fatty acids have higher melting points than short-chain, unsaturated ones and are presumed to be more easily mobilized. Subcutaneous sites are cooler than abdominal sites, so long-chain, saturated fatty acids may be less easily used.

6. PATTERNS OF ENERGY STORAGE

The storage of energy in the depot fats that fuel most of the migratory trip may play a dominant role in the species' behavior for short periods. Some animals spend the majority of their lives in transit in a way that requires little energy storage for travel (e.g., tuna and seabirds). Storing huge reserves by cetaceans may reflect food availability on opposite ends of the their migratory pathway more than the energy demands of migration. Most other species have life histories that involve annual sequences of breeding and wintering, punctuated with two annual migrations. This pattern usually involves periods of energy accumulation and storage immediately prior to migration, the magnitude of which may be remarkable. In migrants that cross large areas in which food is unavailable, fuel storage is more pronounced. For example, transoceanic migrant passerines deposit large amounts of fat; intracontinental migrants stop periodically, never fattening extensively. Swimming migrants (fish and cetaceans) may likewise pass through areas in which food is scarce and thus must store large amounts of fuel (typically lipid). Terrestrial, short-range migrants either make very short trips, after which they feed for a few days, or feed as they go, stopping only during part of the day. In both instances, they have relatively small energy depots in comparison with long-range migrants.

In some cases, the temporal pattern of energy storage differs between spring and autumn migration. The difference may be a response to availability of food resources but also may be due to the benefits of precise timing of migrants traveling to breeding sites. In some small birds, fattening in spring occurs during a shorter period of time than does lipid acquisition in the fall, and nonmigrants show little seasonal variation in fattening, especially if they live in tropical habitats (Fig. 1). Precision in spring is beneficial because the earliest arrivals tend to obtain better territories and are more prone to reproduce successfully.

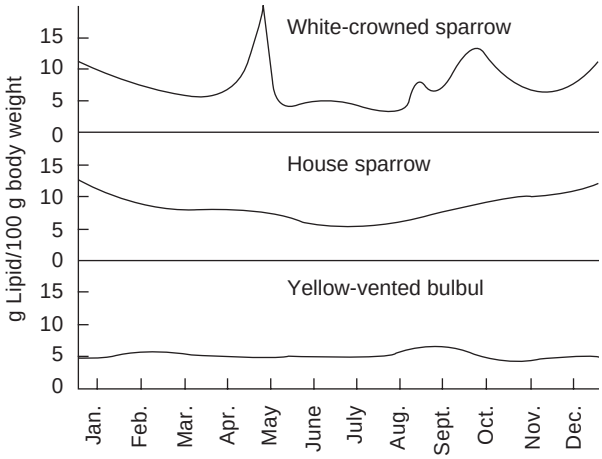

FIGURE 1 Annual cycles of lipid deposition in three passerine birds. The white-crowned sparrow (*Zonotrichia albicollis*) is a temperate zone migrant, the house sparrow (*Passer domesticus*) is a temperature zone nonmigrant, and the yellow-vented bulbul (*Pycnonotus goiavier*) is a tropical nonmigrant. From Blem (1990).

7. ENERGETIC COSTS OF MIGRATION AND FLIGHT RANGES

The energetic cost of migration, although striking in the short term, typically is not a great part of the annual budget of most animals. In long-range migrants such as some passerine birds, less than 1% of their annual energy is expended in migratory flight. In more leisurely migrants, this is similar, but the necessary energy can be collected as the migrant travels and thus the process is less demanding.

Long-range migrants typically have high rates of metabolism, great endurance, and a large metabolic scope (ratio of peak metabolic rate to standard or resting metabolic rate). Other factors affecting the ability of migrants to travel long distances include speed of travel and the mass of the migrant.

Migration is least costly for swimming organisms, more energetically expensive for flying organisms, and most costly for animals traveling terrestrially. Large animals have relatively low costs of transport and small animals have large costs (Table IV).

In flying migrants, flight range depends largely on the amount (and possibly chemical composition) of fuel stored prior to migration. The amount of fuel and the style of flight are a compromise among the costs of transportation of reserves, the risks of migration, and the nature of the migration (i.e., short-range intracontinental hops versus long-range transoceanic flights). However, energy demands of flight can be reduced by soaring, which is relatively inexpensive, and by flying with aid of favorable

TABLE IV

Costs of Transport of Some Species

Species	Mass (g)	Energy (J/kg km)
Mosquito	0.0082	0.033

Lemming[a]	61.0	164.0
Sockeye salmon	3.0	2.0
Sockeye salmon	1500.0	4.5

[a] Not really migratory.

winds. Insects fly low within the boundary layers of shelter, use updrafts, or fly with the wind. Birds sometimes use soaring, flying information, or fly with the wind to reduce costs of migration. The monarch butterfly, however, has been observed flying into winds up to 12 km/h. In fact, the volume of migration of insects and birds is often a function of weather patterns. Migrant birds in eastern North America are usually associated with southerly winds in spring and north/northwest winds in autumn and often follow fronts. In some species of birds, migration only occurs over part of the range. In such species, the migratory birds may have longer wings, apparently reducing increased wing loading brought about by fuel loads. Empirical studies indicate that avian metabolic rates increase less rapidly with body mass than does the ability to store and carry lipid reserves, thus providing longer ranges for larger birds.

In birds and insects that cross large distances where refueling is difficult (deserts) or impossible (oceans), mass of reserve is important in several ways. Theoretical and empirical studies both suggest that there is an optimal flight velocity with regard to fuel use. Low speeds (near hovering) are expensive, as are very great speeds (Fig. 2). Furthermore, large flying objects travel less expensively at higher velocities than small ones at lower speeds. This results in greater flight ranges for large birds, even though their energy reserves are not proportionately greater (Fig. 3). Additionally, as travel progresses and body mass decreases as fuel is utilized, the optimal speed becomes lower. Some researchers have observed that migrants travel more slowly as they reach their destination. However, untested assumptions about physiology and aerodynamics may greatly affect estimated flight ranges. In the earliest studies of

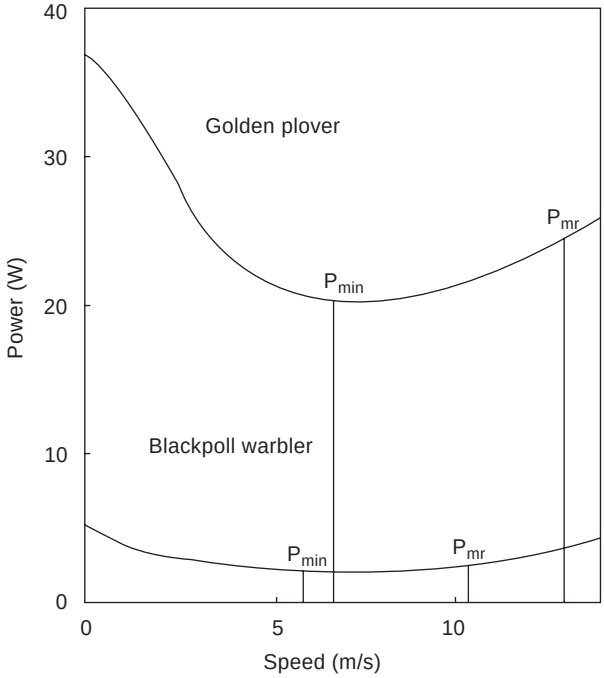

FIGURE 2 Theoretical power curves of two long-range migrants. Lines for minimum power required for flight extend to minimum energy costs (P_{min}); lines for power producing maximum ranges extend to velocities that produce these maximum migratory ranges (P_{mr}). From Blem (1980).

ruby-throated hummingbird migration (*Archilochus colubris*) across the Gulf of Mexico, some investigators doubted that potential flight ranges of hummingbirds were not sufficient to complete the trip. Subsequent measurements of hummingbird flight metabolism indicated that a 4.5-g hummingbird (containing 2 g of fat) could fly nonstop for 26 h (at a cost of approximately 3 J/h). At 40 km/h, its range was estimated at 1050 km, and it is now believed that a trans-Gulf flight is possible by these birds and the available field data support this observation.

8. ENERGETIC BENEFITS OF MIGRATION

Migration is a risky activity. For example, during migration there is a high potential for mortality from predation, and there are predators that appear to seek out migrant insects, birds, and fish. Small birds that are exclusively diurnal throughout their lives migrate at night, ostensibly to avoid predation. Inclement weather may take a toll. There are numerous records of mass mortality caused by storms during passage over large bodies of water.

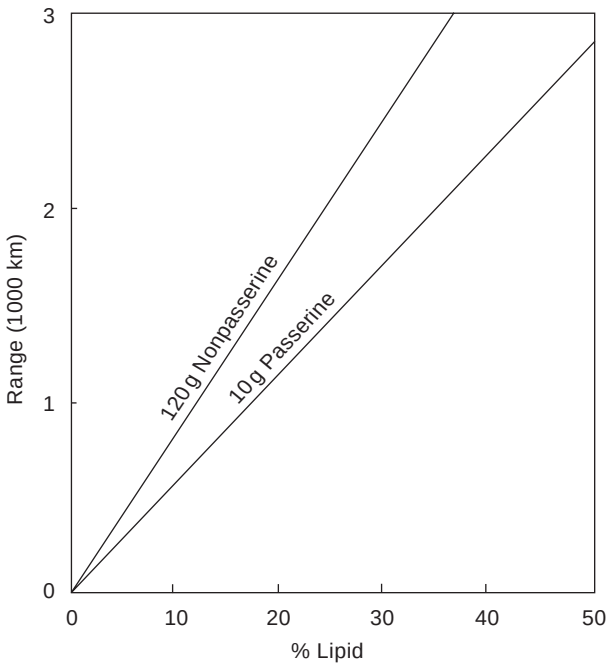

FIGURE 3 Nonstop flight ranges for two avian migrants as a function of their lipid reserves. These curves are often slightly to noticeably concave, which is not apparent here because of the narrow scale of the figure. Lipid content of the migrants is expressed as percentage of total wet body mass. From Blem (1980).

Rafts of dead birds, including kinglets, hummingbirds, and passenger pigeons (many years ago), and several species of insects have been found floating on seacoasts or along the shores of the Great Lakes following violent storms.

Starvation is a real possibility, particularly if the migrant flies or swims in opposing wind/water currents. At some locations, migrant birds are commonly seen in severely emaciated condition. They have little or no lipid, are greatly dehydrated, and are little more than "flying skeletons." They may rapidly perish if they do not quickly find food and water. Finally, simple accidents occur at high rates. In recent years, accidental death from striking towers, buildings, and other man-made structures has become a major source of mortality, estimated to amount to millions of birds each year in North America alone.

There are several possible benefits of migration that offset the risks that accompany extensive travel, including avoidance of predation and parasitism on the breeding grounds and reduced competition at more distant breeding sites. Many migrants appear to obtain energetic benefits from migration because periodic, heterogeneous food resources become available to them. In fact, some of these species literally never experience winter. They obtain the benefits of spring/summer throughout their lives. Some species (e.g., pinnipeds and cetaceans) may migrate only because of rich food sources at one or both ends of the journey. Longer day length on northern breeding grounds may provide energetic benefits for species whose foraging time would otherwise be limited. Tests of the hypothesis that birds or other migrants benefit energetically from the environment of the breeding area have provided both positive and neutral results. For example, the dickcissel (*Spiza americana*), a long-range neotropical migrant, attains a positive energy balance during the breeding season because of the longer photoperiod to which it is exposed in the north. American robins (*Turdus migratorius*) appear to obtain similar benefits. On the other hand, tests of field sparrows (*Spizella pusilla*) and tree sparrows (*Spizella arborea*) indicated no such benefits.

It is worth noting that reproductive output in some species increases with distance of migration. At distant breeding grounds, food may be more available as a result of the presence of fewer competitors. This not only provides obvious energetic benefits but also reduces risks of predation if the migrant needs to forage less during the breeding season. Foraging activity usually makes the animal more vulnerable to predation because its attention is directed elsewhere and it sometimes must move out of seclusion to find food sources. Long day length provides more time for foraging of diurnal animals (many insects and birds) and should provide energetic benefits, but these might be partially offset by relatively low environmental temperatures at northern breeding sites.

The energetic benefits of extended day length and higher ambient temperature at southern latitudes in winter may be a selective factor for fall migration in a variety of animals but are best understood in insects and birds. Furthermore, some species of birds appear to become distributed on their wintering grounds in a manner related to energetics. For example, in several species of small birds, sex ratios vary geographically, apparently because of differences in size and the metabolic requirements of the sexes. Males winter farther north and have larger body masses. Bergmann's rule, an ecogeographic principle used to describe ecotypic variation in vertebrates, suggests that body size increases with latitude in such a way that it provides energetic benefits. Larger individuals may have greater endurance of periods of fasting caused by inclement weather.

Glossary

autonomous energy efficiency improvement An exogenous technical change that is unrelated to energy prices or other variables predicted by the model.

foresight The ability of producers or consumers to anticipate future changes in market conditions. Perfect foresight means that they correctly anticipate the future (as predicted by the model); myopic foresight assumes that the conditions tomorrow will be like today's.

general equilibrium The joint solution to the market price for multiple energy and economic sectors.

induced technological change An endogenous technical change, usually resulting from price-induced behavior.

interindustry interactions The relationships between industries that reveal which sectors buy from and which sectors sell to each industry.

process analysis An engineering concept that refers to discrete technologies, each often requiring fixed input combinations.

production function A relationship that links inputs to output and specifies the rate at which each input can be substituted for each other input in response to shifts in input prices.

putty–clay capital stock malleability The assumption that original equipment cannot be modified once installed.

putty–putty capital stock malleability The assumption that both old and new capital can be reconfigured once installed, to fit the current price situation in each time period.

vintage Identifying equipment and its energy and other key characteristics by the year when it is introduced.

Various economic models of energy supply and demand have been used for global climate change policy analysis. Although these models are quite diverse in their structure and focus, all systems determine market-clearing equilibrium prices that balance production and consumption levels for different fuel types. On energy demand, these models (except for MARKAL-Macro) are "top-down" in that they seek to establish aggregate or sectoral relationships between consumption, prices, and economic activity, as opposed to the "bottom-up" assessments that focus on specific equipment and their energy use. This comparison focuses on the energy supply and demand adjustments that significantly influence the costs of various strategies for limiting carbon emissions, although the models also incorporate reduced-form representation of the climatic effects that determine the benefits of abatement.

1. ALTERNATIVE MODELING APPROACHES

A number of different economic models has been applied to the global climate change problem; the focus here is on 16 modeling systems by teams, most of whom have recently participated in model-comparison studies conducted by Stanford University's Energy Modeling Forum. The models are identified in Table I along with their principal investigators and sponsoring organization. Half of these teams are based in the United States and half outside of it. The model structures discussed herein appear to be most important for determining the effects of climate policies. Weyant has provided comprehensive discussions of the many major findings or insights from applying these models to this issue.

Although each model has unique characteristics and has proved to be extremely valuable for studying certain types of issues, the structures of the models can be described in terms of five basic categories shown in Table II. Many of the models now employ combinations of traditional modeling paradigms. One category of models focuses on carbon as a key input to the economy. These models do not distinguish between energy types and therefore are similar to models of aggregate energy use. Trends toward less carbon-intensive fuels are incorporated into their projections for carbon. They consider the cost of reducing carbon emissions from an unconstrained baseline by using an aggregate cost function in each country/region. This approach uses a simple vintaging structure to incorporate the time lags in reducing carbon intensity in response to increases in the price of carbon. In these models, all industries are aggregated together, and gross domestic product (GDP) is determined by an aggregate production function with capital, labor, and carbon inputs. These models generally omit interindustry interactions, include trade in carbon and carbon emissions rights but not in other goods and services, and assume full employment of capital and labor. The Regional Integrated Climate and Economy (RICE) and Framework for Uncertainty, Negotiation, and Distribution (FUND) models are examples of this category of models.

Another closely related category of models focuses heavily on the energy sector of the economy. These models consider the consumption and supplies of fossil fuels, renewable energy sources, and electric power generation technologies, as well as energy prices and transitions to future energy technologies. In general, they explicitly represent capital stock turnover and new technology introduction rate constraints in the energy industries, but take a more

[a] Models combine multisector general equilibrium with multisector macroeconometric approaches.

aggregated approach in representing the rest of the economy. In these models, all industries are aggregated together, and GDP is determined by an aggregate production function with capital, labor, and energy inputs. These models generally omit interindustry interactions and assume full employment of capital and labor. The Model for Evaluating Regional and Global Effects (MERGE 3.0), Carbon Emissions Trajectory Assessment (CETA), MARKAL-Macro, National Energy Modeling System (NEMS), and Global Relationship Assessment to Protect the Environment (GRAPE) paradigms are examples of this category of models. MERGE 3.0 and CETA have the same basic structure, with nine and four regions, respectively. GRAPE includes a somewhat broader set of technology options, including especially carbon sequestration technologies.

A third category of models is those that include multiple economic sectors within a general equilibrium framework. They focus on the interactions of the firms and consumers in various sectors and industries, allowing for interindustry interactions and international trade in nonenergy goods. In these models, adjustments in energy use result from changes in the prices of energy fuels produced by the energy industries included in the interindustry structure of the model (e.g., coal, oil, gas, and electricity). Explicit energy sector capital stock dynamics are generally omitted. These multisector general equilibrium models tend to ignore unemployment and financial market effects. The Intertemporal General Equilibrium Model (IGEM), the Massachusetts Institute of Technology Emissions Projection and Policy Analysis (MIT-EPPA) model, and the WorldScan model are examples of this type of model. The Global General Equilibrium Growth (G-Cubed) model does consider some unemployment and financial effects and is, therefore, a hybrid general equilibrium/macroeconometric model. G-Cubed, MIT-EPPA, and WorldScan all include trade in nonenergy goods.

A fourth basic class of models combines elements of the first two categories. They are multisector, multiregion economic models with explicit energy sector detail on capital stock turnover, energy efficiency, and fuel-switching possibilities. Examples of this type of hybrid model are the Asian–Pacific Integrated Model (AIM), Australian Bureau of Agriculture and Resources Economics–Global Trade Environment Model (ABARE–GTEM), Second Generation Model (SGM), and Multi-Sector–Multi-Region Trade (MS–MRT) model. These models include trade in nonenergy goods, with AIM including energy end-use detail, GTEM and MS–MRT including some energy supply detail, and the SGM considering five separate supply subsectors to the electric power industry.

By including unemployment, financial markets, international capital flows, and monetary policy, the Oxford model is the only model included here that is fundamentally macroeconomic in orientation. However, as shown in Table II, the G-Cubed and IGEM models do consider some unemployment and financial effects, as well as international capital flows.

2. THE KEY ROLE OF ENERGY PRICES

Economic models assign an important role to the price of energy in determining the economy's adjustment to climate change policies. The models compute the price of carbon that would be required to keep emissions levels controlled at some predetermined level. Although it is easiest to think about these scenarios as carbon taxes or permits (which may or may not be tradable), the additional carbon

costs also reveal important information about any program that seeks to reduce carbon emissions.

Most economic models solve a set of mathematical equations to obtain the prices of goods and services and key inputs, including different forms of energy. The simultaneous solution of these equations represents an equilibrium in which supply equals demand among consumers and producers. In this sense, these models generally determine fuel prices endogenously by searching for those prices that will balance the supply and demand for each fuel. This approach is very valuable for policy analysis of control strategies that will affect the supply and consumption of different fuels. In this framework, an energy price increase can be either the motivation for, or the result of, greenhouse gas (GHG) emissions reductions. For example, governments may impose emissions taxes to motivate GHG reductions. Emissions taxes increase the costs of fuels directly, and economies will adjust to reduce the use of those higher cost fuels, substituting goods and services that result in fewer GHG emissions. On the other hand, governments may cap the total amount of emissions, distribute or sell emissions "allowances," and let the market determine the price and distribution of these allowances. Such a "cap and trade" system will induce changes in prices that are difficult to predict. Because a cap would essentially restrict the supply of carbon-based fuels, GHG consumers would bid up the price until demand for such fuels no longer exceeded supply. In this way, the higher prices reduce emissions, but also allocate the GHGs to their highest value uses.

The effects of higher fossil fuel prices would diffuse throughout the economy. Prices of secondary energy sources, such as electricity and oil products, would rise as the higher primary fuel costs are passed through into electricity rates, fuel oil, and gasoline prices. Higher fuel costs would also increase operating costs in transportation, agriculture, and especially industry. Although energy costs make up only 2.2% of the total costs in U.S. industries, they constitute up to 25% of the total costs in the most energy-intensive sectors (e.g., iron and steel, aluminum, papermaking, and chemicals). Each industry's ability to pass these cost increases along to customers through higher product prices would depend on the strength of the demand for its products and on the severity of international competition. Because many of the major trading partners of the United States would also be implementing similar climate policies, it is likely that the energy cost increase would result in higher prices for a broad range of consumer products. Households could also be affected through increased heating, transportation, and utility bills and, to a lesser degree, food bills and other costs of living.

A host of adjustments by producers and consumers in the economy would take place in parallel with the price increases, and, in fact, these substitutions would also serve to limit the extent of the price increases that would ultimately result. Higher energy costs would induce firms to accelerate the replacement of coal-based or obsolete plants with more energy-efficient or less carbon-intensive equipment. Utilities and their customers would seek alternatives to carbon-intensive coal-fired power plants, stimulating the market for hydro, nuclear, gas-fired, and renewable electricity sources. As coal prices rise relative to natural gas prices, modern gas-fired combined-cycle power plants would become even more competitive. Older, less efficient coal-fired plants would probably be retired from service or reserved for intermittent operations. Energy-intensive industries would also face a number of adjustment decisions: whether to retire obsolete facilities and concentrate production at more modern, low-cost facilities; whether to modify their furnaces to burn gas instead of coal; whether to generate their own electricity; whether to invest in a wide variety of energy-conserving process changes; whether to redesign products to save energy; and whether to alter their product mix. Ultimately, there would be an effective diminution in the value of the existing stock of plant and equipment because it is optimized for the set of input prices that prevailed when it was installed and would be suboptimal for the new price regime.

In the short run, consumers and producers would reduce their energy consumption by either consuming less energy services (for example, turning their thermostats down or driving their automobiles less) or producing less output. Consumers and producers may also, potentially, reduce energy use without reducing output by identifying energy efficiency measures previously believed to be uneconomic. In the intermediate time frame, there might be opportunities for fuel switching (or substitutions between other inputs) that would not involve substantial outlays for new equipment or infrastructure (for example, switching the fuel used in a multi-fuel-capable boiler from oil or coal to gas). In addition, consumers may be able to substitute goods that require less energy to produce (which would become relatively less expensive) for more energy-intensive ones (which would become relatively more expensive). In the long term, new technologies would be purchased that either use less GHG-intensive fuel or are more fuel efficient. In addition, new, less GHG-intensive technologies might become available over

time as a result of research and development expenditures or cumulative experience. The emergence of these new technologies might be related to the energy price increases, the base case trend of all other prices, or simply the passage of time.

Higher energy prices would lead to less energy use, and less energy use would decrease the productivity of capital and labor. These productivity changes would, in turn, generally result in a slowdown in the accumulation of capital equipment and infrastructure, and in lower wages for workers. Ultimately, even after all the adjustments have been made, consumers would have somewhat less income, which might cause them to adjust the amount of time they spend on work rather than leisure. The resulting adjustment in labor depends on two opposing effects. Workers would want to work more to make up for their loss in real income, but the lower wage would make working worth less relative to leisure. Replacing work with leisure would involve an additional change in welfare. Offsetting these welfare losses would be the benefits of reduced climate change and the benefit of making those responsible for GHG emissions pay for the damages they cause.

The complicated web of economic adjustments that would take place in response to rising prices of energy, or energy scarcity, makes the task of projecting the costs of GHG mitigation a challenge. Interpreting the results they produce is further complicated because different modeling systems emphasize different dimensions of the adjustment process. Also, different policymakers may be interested in different policy regimes, and in different impacts of climate change and climate change policies.

3. FACTORS INFLUENCING THE RESPONSE TO CLIMATE POLICIES

Baseline economic, technological, and political conditions, the opportunities to substitute away from fossil fuels, the nature of the capital stock turnover process, and the dynamics of technological progress are four very important factors that determine a model's response to climate change policies.

3.1 Baseline Conditions

One set of important issues is the base case emissions and climate impact scenarios, against which the costs and benefits of GHG mitigation policies are assessed. They are largely the product of assumptions that are external to the analysis. Each GHG mitigation cost analysis relies on input assumptions in three areas:

- Population and economic activity.
- Energy resource availability and prices.
- Technology availability and costs.

Most of the researchers projecting the cost of reducing carbon emissions have relied on worldwide population growth projections made by others (e.g., the World Bank or the United Nations). These external projections are generally based on results from very simple demographic models. There is less uncertainty about projections for the developed countries, where population is expected to peak very soon, than for the developing countries, where population is typically assumed to peak somewhere around the middle of this century. Very few of the researchers analyzing GHG emissions reductions make their own projections of economic growth. Most rely on economic growth projections made by others, or on external assumptions about labor force participation and productivity growth.

Another key set of assumptions concerns the price and/or availability of energy resources. The prices of fossil fuels (oil, natural gas, and coal) are important because producers and consumers generally need to substitute away from these fuels when carbon emissions are restricted. Optimistic assumptions about natural gas availability and/or substitutability can make carbon emissions reductions easier to achieve in the short run. Natural gas plays an important role because its carbon emissions are about 60% of those from coal, and 80% of those from oil, per unit of energy consumed. In addition, the amount of unconventional oil and gas production that will ultimately be technically and economically feasible is highly uncertain. It depends on future economic incentives for oil and gas exploration and production, which could (absent climate policies) retard the development of carbon-free renewable and higher efficiency end-use energy technologies. How oil exporters would react to a climate policy that would reduce the demand for oil imports is another key dimension of the energy supply picture.

A final set of key assumptions includes those made about the costs and efficiencies of current and future energy-supply and energy-using technologies. These factors tend to be critical determinants of energy use in both the base case and control scenarios. Most analysts use a combination of statistical analysis of historical data on the demand for individual fuels and process analysis of individual technologies in use or under development, in order to represent trends in

learning by doing (past experience with the technology) and its effect on reducing costs as well as other characteristics of energy technologies. Particularly important, but difficult, is projecting technological progress within the energy sector. Jorgenson and Wilcoxen have attempted to estimate systematically and empirically future trends in energy productivity at a national level, but such efforts are rare. Typically, analysts take one of two approaches: (1) the costs and efficiencies of energy-using and energy-producing technologies are projected based on process analysis, and the characteristics of these technologies are extrapolated into the future, or (2) the trend in energy demand per unit of economic activity, independent of future price increases, is assumed. Some recent analyses have attempted to blend the two approaches. At some point, these two approaches tend to converge, because the end-use process analyst usually runs out of new technologies to predict. It is then assumed that the efficiency of the most efficient technologies for which there is an actual proposed design will continue to improve as time goes on.

Projections of the benefits of reductions in GHG emissions are also highly dependent on the base case scenario employed. The greater the base case damages (i.e., the damages that would occur in the absence of any new climate policies), the greater the benefits of a specific emissions target. The magnitude of the benefits from emissions reductions depends not only on the base case level of impacts, but also on where they occur, and on what sectors are being considered. In fact, a number of additional socioeconomic inputs (e.g., income by economic class and region; infrastructure and institutional capability to adapt to changes) are required because they determine how well the affected populations can cope with any changes that occur. The task of projecting base case climate change impacts is particularly challenging because (1) most assessments project that serious impacts resulting from climate change will not begin for several decades and (2) most of the impacts are projected to occur in developing countries, where future conditions are highly uncertain. How well developing countries can cope with future climate change will depend largely on their rate of economic development.

3.2 Representation of Substitution Possibilities

As efforts are made to reduce GHG emissions, fossil fuel combustion and other GHG-generating activities become more expensive. Producers adjust to these price increases by substituting inputs (i.e., switching to inputs that generate fewer GHG emissions in manufacturing any particular product) and by changing their product mix (i.e., producing different products that require less GHG emissions to make). The extent to which inputs can be shifted depends on the availability and cost of appropriate technologies as well as on the turnover rate of capital equipment and infrastructure. These two factors, as well as consumer preferences, determine an industry's ability to produce and sell alternative mixes of products. Increases in the costs of fossil fuels and products that depend on fossil fuel combustion will reduce consumers' real incomes. Consumers will simultaneously decide (1) the extent to which they wish to adjust their mix of purchases toward less carbon-intensive products and (2) how to adjust their mix of work and leisure time to compensate for the reduction in their real income.

3.2.1 Short-Term vs. Long-Term Substitution

If businesses and households have several decades to complete the substitution process, the current stocks of energy equipment and associated infrastructure do not constrain the substitutions that they may make. Businesses and households are limited primarily by the available technologies and by their own preferences regarding how much of each available product they would buy at the prevailing prices.

If climate policy is long term, the transition to a lower carbon energy system can be relatively smooth and the costs relatively moderate. To reach such an outcome, economic incentives should be designed to motivate producers and consumers to invest in more energy-efficient and less carbon-intensive equipment when their existing equipment has reached the end of its useful life. Useful life is an economic concept that compares the costs of operating existing equipment with the costs of purchasing and operating new equipment. A new and better computer may be purchased after 3 years, even though the old computer could be "useful" for 10 years, because the new one has superior cost and performance characteristics. Or an old car may be kept running because the performance advantage of the new car is not worth the cost.

Over shorter time spans, however, existing plant and equipment can significantly constrain the behavior of firms and households, adding transition costs to the long-run costs of GHG control policies. Policies implemented on this time scale (i.e., within 10 years) will lead to reductions in energy services

(e.g., industrial process heat and home heating and cooling), some easy fuel switching, and an increase in the purchase and use of available energy-efficient products and services. They will also influence the rate of retirement and replacement of existing equipment. Energy-producing and energy-using goods are relatively expensive and long-lived. Thus, it will generally take a substantial increase in energy prices to induce those who own such equipment to replace any of it before the end of its useful life.

The importance of capital stock dynamics creates a formidable challenge for the analytical community. Some data on the characteristics of the energy-producing and energy-using capital stock are available. It would be ideal to have information on the costs of operating and maintaining every piece of equipment currently in use. This would enable analysts to calculate all the trade-offs between retiring equipment early and using other strategies to achieve the specified targets. Unfortunately, the data that are available are generally aggregated across large classes of consumers and generally include all existing capacity without regard to when it was installed. An important exception is power plant data, which are very disaggregated and include the age of the equipment. However, even these data are generally not sufficient to ascertain precisely the point at which the carbon price incentives will influence the rate of replacement of plant and equipment. Limitations on data require the analyst to make a number of assumptions regarding the aggregation and interpretation of the available data.

3.2.2 Two Approaches to Representing Substitution Possibilities

In many models, technologies are represented with "production functions" that specify what combinations of inputs are needed to produce particular outputs. The production function specifies the rate at which each input can be substituted for each other input in response to shifts in input prices. As new capital investment occurs and older capital is retired, the technology mix within the model will change.

Two basic types of production functions may be specified: aggregate production functions and technology-by-technology production functions, also known as process analysis. Some models (e.g., G-Cubed, SGM, and EPPA; see Table I for model identification) use smooth and continuous aggregate production functions that allow incremental input substitutions as prices change, even if the resulting input configuration does not correspond to a known technology. These models do not represent individual technologies. Such models often assume "nested" production functions. For example, at one level, substitutions are possible between energy, capital, and labor in producing final commodities; at a second level, substitutions are possible between electricity and fuel oil in producing energy; and, at a third level, substitutions are possible between coal and natural gas in producing electricity. Models employing continuous aggregate production functions do not account for individual technologies.

In contrast, other models (e.g., MARKAL-Macro and NEMS) draw from a menu of discrete technologies, each requiring fixed input combinations—i.e., each technology is essentially represented with its own production function. This approach is often referred to as "process analysis." These combinations correspond to those employed in actual, or anticipated, technologies that the modeler specifies. The technology-rich MARKAL-Macro model specifies over 200 separate technologies. For discrete technology models, different technologies become cost-effective as input prices change. Modelers then assume that these technologies are selected and used to produce outputs. Process analysis represents capital stock turnover on a technology-by-technology basis. The data and analysis requirements for this type of model can be substantial.

A number of systems use a process analysis approach within the energy sector and an aggregate production approach for the remainder of the economy (e.g., MERGE, MARKAL-Macro). When using either approach, it is important to be able to distinguish between the causes of changes in the selections the models make among the existing technologies. Sometimes the technology choice changes because prices change, and sometimes it changes because new technologies become available.

Some models represent both individual energy supply technologies and individual energy consumption technologies, and do not represent the remainder of the economy explicitly. With these models, however, the analyst must either (1) assume that "end-use" energy demands (such as the demand for home heating and automotive transport) do not respond to changes in the prices of those services or (2) employ a complex statistical estimation technique (which requires some historical data on the cost of end-use energy equipment) to estimate the price responsiveness. The choice of production function depends, in part, on the time frame under consideration and the level of technological disaggregation. Short-term models intended to shed light on precise technology choices specify production functions for

large numbers of separate technologies. In contrast, models concerned with longer term effects can safely characterize technological trends using aggregate production functions. Many models blend the two approaches. Although they allow for smooth input substitution in determining new capital investment, they fix input proportions for all equipment installed in a certain year (sometimes called a "vintage"). Similarly, a model may have smooth production functions for conventional fuels, yet stipulate discrete technologies for a particular noncarbon fuel (e.g., EPPA).

3.2.3 Capital Stock Turnover and Malleability

In modeling capital investment in plant and equipment and turnover, each system must use assumptions about the flexibility the investor has in choosing technologies and in changing their characteristics after installation. Data availability and computational considerations limit the choice of modeling assumptions that can be employed. Fortunately, there are some simple formulations that seem to give plausible results in most circumstances.

In almost all models, it is assumed that in making decisions about new capital investment, the decision maker (firm, individual, or government entity) has complete flexibility (particularly in the mix of capital and energy inputs required) in choosing among available technologies before their purchase. The models differ, however, in their assumptions about how much the characteristics of the capital equipment can be changed after it has been installed. These adjustments may be desirable if changes in input prices occur, but retrofitting to a certain set of characteristics is generally more expensive than installing equipment with the same characteristics initially. On the other hand, technological improvements may reduce the costs of the retrofitting over time.

Most models make one of two polar assumptions about this process. To describe these assumptions, the metaphor of soft putty and hardened clay has proved useful ("putty" representing a flexible scenario and "clay" representing a hardened or inflexible scenario). In a putty–clay or putty–putty formulation, the first term refers to the assumption about the degree of flexibility in original capital investment, and the second term refers to the assumption about the degree of flexibility in modifying that capital after it is installed.

- In a putty–clay formulation, it is assumed that the original equipment cannot be modified once installed. Putty–clay assumptions are more realistic in cases in which relative prices are changing rapidly. Here, new capital investments embody state-of-the-art technology and use input mixes that are appropriate for the price expectations that exist at the time of the investment. These characteristics then remain with that vintage until it is scrapped.
- In a putty–putty formulation, it is assumed that capital—old or new—can be reconfigured once installed to fit the current price situation in each time period. Under the so-called putty–putty assumption, the capital stock is a single entity that is neither broken down into separate vintages nor constrained to retain its initial technology and input mix. The term "putty–putty" is used to indicate that capital can be continuously reshaped both before and after investment has taken place. The inherited capital stock adjusts to changes in prices and technology as fully as brand new capital. In effect, the entire capital stock continually adapts itself to reflect current technologies and prices.

The precise details of the capital adjustment process differ from model to model. In some, there is a composite stock of old capital that reflects some average mix of inputs. In others, each vintage is identified and depreciated separately. In many models, the old capital stock cannot be altered. In others (e.g., NEMS), it can be retrofitted if doing so is more profitable than making brand new investments, or if it is required by regulation.

Modelers are just starting to experiment with various hybrids of the two formulations, i.e., putty–semiputty formulations, in which some retrofitting is allowed at some additional cost. One type of putty–semiputty specification allows plant and equipment to be retired before the end of its useful life if the operating cost of the old equipment is greater than the operating plus capital costs of replacement equipment. In this case, the remaining capital costs of the old equipment would have to be written off, so the changes in prices or new technologies would have to be quite significant for this to occur. Prices do rise to these levels in some models in Kyoto Protocol simulations in which the flexibility mechanisms are severely restricted.

3.3 Capital Stock Adjustment Process

Jacoby and Wing have described three characteristics of these models that are important in analyzing the time horizon for meeting the Kyoto targets: the time frame, the level of detail about capital stock and

production structure, and the specification of economic foresight. The first and most obvious attribute is the time interval over which a model solves its equations. If a model uses a 10-year time interval, the relatively long time period limits the model's ability to be used in analyzing phenomena occurring within a decade, such as the consequences of accepting a 2008–2012 Kyoto target after the year 2000. The results of such models may thus obscure important short-run dynamics of adjustment. The second important attribute of the models is the level of aggregation in the capital stock and the production structure. The level of aggregation affects how models represent the sources of rigidity in the production sectors of the economy. For example, the choice about whether to aggregate output and capital by sector or by technology determines the degree of substitution that is possible within the model's structure. Within a specific aggregate, substitutions are, by construction, assumed to be costless. Additional capital stock produces outputs using a combination of inputs that reflects (1) current and expected input prices and (2) the constraints and limits of existing technologies.

Models capture the aging of capital in different ways. In evaluating short-term adjustment to climate policies, the distinction between putty–putty and putty–clay specifications is critical. In the face of a stringent near-term policy, the putty–putty assumption may produce unrealistic results because this specification implies that large parts of the current capital stock can be transformed into more efficient and less carbon-intensive alternatives. However, for analysis of the long run, after fuel prices have settled at a new equilibrium level relative to other goods and services, the distinction is less important. In this postadjustment phase, the inherited capital stock will be increasingly fuel efficient and competitive under prevailing conditions, because those conditions will more closely match the conditions in place at the time the investments were made.

The third important characteristic of models of the capital stock turnover process is the way they treat foresight. Models may specify economic behavior as forward-looking or myopic. Forward-looking models assume that agents with perfect foresight find the path of emissions reductions that minimize discounted costs over the entire modeling horizon, choosing the timing and stringency of control measures so as to smooth optimally the costs of adjustment. In contrast, myopic models assume that economic agents seek to minimize the costs of policy on a period-by-period basis, and take little or no action in advance of the onset of carbon constraints. Model results can be very sensitive to assumptions about investor foresight. Models that assume perfect foresight allow emissions targets to be met at lower costs because investment decisions are made in the full certainty that emissions limits will be set and achieved. Models that assume some degree of myopia generate higher costs because investors must scramble to alter the capital stock as the target period approaches, prematurely scrapping existing capital (e.g., coal-fired power stations) and quickly investing in less carbon-intensive alternatives.

Of the models reviewed here, a great majority assume perfect foresight, whereas only one is constrained to be myopic (EPPA). Some models (e.g., G-Cubed) allow alternative assumptions under different runs and/or can set expectations differently for different sectors. The NEMS and SGM models can allow industrial or utility investors to give greater consideration to future conditions than individual consumers do.

In practice, investors do not have perfect foresight, nor do they suffer from complete myopia. Although there is inevitable uncertainty regarding future economic conditions, policymakers can reduce uncertainties by making credible commitments to meet targets or to initiate market-based policies. Model results clearly demonstrate that the more convinced investors are that emissions targets will become binding, the less costly the transition to lower carbon emissions.

3.4 Technological Change

How these opportunities will change with time and with people's experience with new technologies also have important effects. Technological change can be thought of as increasing the amount of a product that can be produced from a given amount of inputs, or as expanding the universe of opportunities for substitution of inputs and products that were described in the last section. Technological change is discussed separately from input and product substitution here because the underlying determinants are somewhat different, because technological change is less well understood, and because of the opportunities for synergy between public support and private investment in stimulating new technology development.

In 1942, Schumpeter identified three distinct types of technological change that take place continually in modern economies: (1) invention of completely new ways of satisfying human needs and wants, or the creation of new needs not previously identified or

satisfied, (2) innovation, which takes place through continual improvement and refinement of existing ways of doing things, and (3) diffusion of new technologies throughout and across economies. These processes are all important for climate policy. It often takes decades for innovation and invention to pay off. Even diffusion may be difficult to accelerate over a decade, though, because it takes time to distribute information, analysis, and experience from one user to another.

New technologies can allow firms to produce a particular product using a mix of inputs not previously available, including, for example, less energy. In addition, new technologies can lead to new products. These new products compete with existing products, with further implications for carbon emissions reduction policies. If these new technologies and new products produce less carbon, then carbon emissions will be lower, fewer emissions reductions will be needed, and/or emissions reductions will be less expensive. Projecting how technological change might progress over time, both with and without climate policies, is challenging. The processes by which technological change occurs are very complex and the data required to estimate how these changes have been made in the past are generally not available. However, there are several ways economic models represent technological change.

3.4.1 Induced Technological Change

Inventions of productive technologies or processes are, by their very nature, hard to predict. However, past experience has shown that they can be revolutionary enough to justify large expenditures in basic research in strategic areas. Innovations could be of great help in lowering the costs of reducing GHG emissions. Thus, it would be worthwhile to find an appropriate combination of government interventions and private sector incentives that encourage innovation. Thus far, however, most of the policy debate on the influence of technological change on climate change policy has focused not on technology policy options, but rather on how restrictions on GHG emissions reduce aggregate mitigation costs over time. This latter effect has been labeled "induced technological change" (or ITC for short). ITC has to do with price-induced behavior—i.e., what private firms will do in response to higher prices. It does not incorporate what firms will do anyway in trying to become more competitive through investing in research and development, or what they would do in response to government sponsorship of research and development or other direct government technology policies. There has been a good deal of discussion about the potential for induced technological change to substantially lower, and perhaps even eliminate, the costs of CO_2 abatement policies. These discussions have exposed very divergent views as to whether technological change can be induced at no cost, or at some cost.

Every ITC model must represent some incentive to induce technical change in one or more ways, such as the following examples:

1. The form of profits from innovations, as in the top-down models, which focus on the behavior of economic aggregates rather than the behavior of individual actors or the use of individual technologies.
2. At a more aggregate and abstract level, by means of cost-functions, research and development production functions, or empirical estimates. Similarly, the decision maker(s) considered may be either decentralized industries, representative firms, or a central planner.
3. By the inclusion of intrasectoral knowledge spillovers that are advances that individual firms within a sector cannot keep to themselves. For example, the level of investment may be determined by the rate of return the firm expects to earn on the research and development investment as compared with other available investment opportunities. However, the rate of innovation may far exceed that implied by the rate of return alone because other firms in the industry may be able to replicate the innovation.
4. By the dimension in which technological change is assumed to progress (i.e., new products or processes, substitution of inputs, or reorganization of production and distribution arrangements).

Some ITC models are based on empirical observations of past responses to energy price and policy changes. One advantage of this type of model is that different sectors may exhibit different rates of technological progress. However, only one model, IGEM, estimates all these parameters simultaneously because of the large amount of data necessary and the heavy computational burdens of such estimations. Another advantage is that this type of model implicitly takes into account real-world factors that are relevant to technological change and that are difficult to incorporate into conventional economic frameworks. Thus, this model relies on empirical observations of real events, not on a simplified representation of the phenomenon. All types and sources of short-term technical change are included. One disadvantage of this aggregation,

though, is that the approach may omit specific known technologies that are beginning to be introduced but that are not yet revealed in the available data. In addition, information about the underlying costs of research and development is lost. Also missing is explicit attention to how firms determine their research and development investments. Firms take into account both the cost of engaging in research and development and the expected benefits in terms of future profitability. Thus, models are unable to evaluate optimal policies with full consideration of the costs of research and development. Another disadvantage is that the model is as limited as the data set from which it is constructed. Only one historical path can be observed, and it is assumed that tomorrow's economy will respond to energy price changes in the same way as yesterday's economy. Thus, long-term technological change is beyond the feasible reach of this type of model. "Long-term" here refers to periods over which substantial technological development and major inventions may occur.

Nonetheless, empirical modeling of ITC may be valuable for short- to medium-term projections, or for estimating the short- to medium-term cost of policies on the economy. Empirical models may also be valuable in comparing or calibrating short-term projections from other types of ITC models. Also, the consideration of ITC helps clarify two key matters of debate: (1) whether prior studies (without ITC) have overstated the cost of achieving given emissions reduction targets and (2) the optimal size and timing of a carbon tax.

3.4.2 Autonomous Energy Efficiency Improvement

In contrast to the ITC models, many models include exogenous technical change. ("exogenous" can mean external to the model, or independent of price, or both.) A simple characterization of technological improvement, employed in many of the models, is a single scaling factor—the autonomous energy efficiency improvement (AEEI)—that makes aggregate energy use per unit of output decline over time, independent of any changes in energy prices. (Many modelers specify the AEEI as a percentage of gross domestic product growth, so that the value changes over time.) Although the definition of the AEEI varies from model to model, in all models it implicitly represents the effect of technological progress. In some models, it also represents one or both of two additional trends: (1) changes in the structure of the economy, resulting in a shift in the relative contribution of energy-intensive industry output to total economic output, and (2) an improvement in energy efficiency over time, reflecting the gradual removal of market barriers that prevent some energy consumers from choosing more efficient energy technologies.

Although the AEEI approach allows for energy improvements over time, it is limited in two respects. First, using the AEEI approach to represent technological change ignores price-induced technological progress (ITC). In reality, higher prices do spur greater innovation and more rapid diffusion of energy-saving technologies. Second, it is not clear what an appropriate rate for AEEI should be. This is important, especially for longer term projections, which are very sensitive to differences in assumed rates. More sophisticated specifications (often used in conjunction with an AEEI parameter) attempt to paint a more detailed picture of technological change by incorporating some degree of price sensitivity, distinguishing different sectors, and assessing changes to specific technologies.

3.4.3 Learning by Doing

In practice, much technological advance comes from learning by doing (LBD), which is the incremental improvement of processes through small modifications and adjustments. It is not until a technology is actually used that important lessons are learned that can be applied to its subsequent development. LBD is an integral part of the innovation process. Observations of past technological innovations show that initial installations are quite expensive, but that costs drop significantly the more the technology is used, and the more lessons are learned from using it. This type of learning may be the result of either exogenous or endogenous (induced) technological change.

The LBD approach does not reveal how learning occurs and whether the learning is associated with invention, innovation, or diffusion. Thus, it cannot evaluate which policies might be appropriate for increasing the learning associated with a technology. The approach also suffers from its inability to establish whether future cost reductions result from increased cumulative experience with the technology or whether they occur with the passage of time, which is closely associated with cumulative experience.

Although most models do not attempt to capture LBD, two models do mimic the process. MERGE assumes endogenous diffusion rates: the more investment there is in advanced technologies in the early years of the projection, the greater is the rate of

adoption in the later years. In the NEMS model, learning by doing is represented in the electricity generation sector, where the capital costs of particular types of new plants decline as more such plants are built.

4. CONCLUSIONS

As long as climate change policies are geared toward keeping a dynamic economy tied to some historical benchmark emissions level, projections of baseline economic and emissions conditions will dominate the costs of emissions control strategies. An equally important consideration is the adopted policy regime, such as the extent to which international emissions trading is permitted. In general, the more flexibility permitted as to where, when, and which GHG reductions may be used to satisfy a commitment, the smaller the economic impacts. In addition to these baseline and policy assumptions, the model structures also influence the cost estimates associated with climate change actions. Especially important are how each model's structure accounts for the rate and extent to which available inputs and products can be substituted for one another and the rate of improvement in the substitution possibilities over time (i.e., technological change). The representation of the substitution possibilities depends both on the available technologies and on how the retirement of existing equipment and the introduction of new technologies are represented. The more flexibility the model includes in the choice of technologies, retirement of old equipment, and introduction of new technologies, the lower the economic impacts of emissions reductions.

Technological change occurs when new technologies allow a particular good or service to be produced with fewer inputs, or when a new product is developed. Most models used to project GHG emissions and mitigation costs assume that technological change takes place steadily over time, but does not depend on changes in prices or the implementation of government policy options. Thus, different technologies are selected as prices change, but no new technologies are added to the menu. Analysts have recently started developing ways by which price-induced technological change and price-induced increases in the rate of diffusion of new technologies can be included.

The technological change that occurs over time, and that is included in most of the models, reduces the costs of mitigating carbon emissions because it decreases the base case trajectory of GHG emissions. However, it is probably unrealistic to assume that changes in energy prices will not alter the course of technological progress. In the short run, price increases should encourage the diffusion of new technologies. In the intermediate term, they should lead to a more rapid rate of increase in the rate of improvement of existing technologies and earlier remodeling or replacement of other facilities and equipment. In the long run, they should stimulate the development of brand new technologies. Both kinds of changes should reduce the average rates of GHG emissions per unit of output.

time-series data Composed of a repeated number of observations of a variable over time.

Walras's Law Often wrongly considered an equilibrium condition, a law stating simply that consumers fully expend their wealth.

After the first modeling efforts investigating the relationships between energy and economics emerged during the 1970s, two broad classes of modeling approaches appeared: the economic or top-down models and the technical/engineering or bottom-up models. The top-down models adopted a general perspective and described the economic linkages between energy demand and supply and the rest of the economic system, with the main goal of analyzing energy or wider economic policies. The bottom-up models adopted a focused view of the energy sectors and explored the various technological options, with the main goal of highlighting low-cost energy production opportunities.

1. AN INTRODUCTION AND A SHORT HISTORICAL OVERVIEW

The first modeling efforts investigating the relationships between energy and economics date back to the 1970s. Since the beginning, two broad classes of modeling approaches appeared: the economic or top-down models and the technical/engineering or bottom-up models. The first approach, adopting a general perspective, described the economic linkages between energy demand and supply and the rest of the economic system, with the main goal of analyzing energy or wider economic policies. The second approach, adopting a focused view of the energy sectors, explored the various technological options, with the main goal of highlighting low-cost energy production opportunities. During the same period, natural scientists became interested in energy modeling as well. To assess the role of anthropogenic

greenhouse gas (GHG) emissions in determining global warming, they developed pioneering models consisting at that stage in simple extrapolations based on a restricted number of parameters where qualitative/quantitative experts' opinions were predominant with respect to direct estimation or calibration procedures. Simulation of energy and climate policies was well beyond the capacity of these first mathematical tools.

Interestingly, it was mainly environmental concerns that stimulated both bottom-up and top-down modeling efforts during the subsequent decade. In this respect, a particularly important event was the 1988 Toronto Conference on Climate that spurred a real boom in modelization. One of the outcomes of the conference was to establish a first preliminary limit for carbon dioxide (CO_2) emissions in the measure of a cut of 20% with respect to the 1988 level. This fostered immediate and great interest in the scientific and political communities to assess costs and benefits of such a target, its implications for the economic systems, and the feasible strategies for its accomplishment. Moreover, the need to analyse three different dimensions—energy, economics, and environment—encouraged a fruitful and unprecedented exchange of knowledge among disciplines.

Nowadays, bottom-up and top-down models are being used extensively to investigate climate change issues and the costs of the related policies. Moreover, it is a fact that even when these models are used to investigate energy policies and reforms not directly related to climate, they nevertheless take into account some environmental implications (e.g., GHG emissions are commonly considered a strategic variable to monitor anyway).

It could be said that the points in common between the two approaches end here. In fact, they have led to very different model properties and results. A striking example is again given by the case of determining the costs of climate change policies where top-down and bottom-up studies wound up producing opposite results. This induced two opposing views in the scientific community: one claiming the necessity to integrate the two methodologies so as to exploit the comparative advantages of both techniques and the other considering the two methodologies totally incompatible.

Recently, also due to the development of new flexible software packages and to the improvement in computers' computational capacity, the first view seemingly has prevailed, and a large number of "hybrid" models sharing top-down and bottom-up features is being developed. Still, the integration techniques are far from reaching an uncontroversial standard and securing full validation from the scientific community; bridging the gap between the two approaches developed for different purposes and permitting different analyses designed to answer different questions remain a difficult and complex task. Yet despite efforts to merge characteristics in the hybrid models, and despite convergence between model categories, the distinction remains an important one that is essential to understanding the policy conclusions of influential studies and to avoiding misinterpretation of model results.

In light of this, the aim of this article is to describe the main technical and theoretical features of bottom-up and top-down modeling approaches, presenting their results, highlighting their respective strengths and weaknesses, and discussing the main issues that have arisen due to a possible integration.

In what follows, this article presents the technical characteristics of the two modeling approaches. It then compares and comments on the theoretical rationales shaping the models' use and results. Subsequently, it describes possible ways in which the two approaches could be and have been reconciled. The final section concludes the article.

2. TOP-DOWN AND BOTTOM-UP MODELS: COMPARING TECHNICAL FEATURES

2.1 Top-Down Modeling: Technical Features

Top-down models are considered economic, general equilibrium, or aggregated models; they aim to giving a comprehensive picture of the functioning of an economic system, including the relationship between energy markets and the rest of the economy, based on the behavior of representative and rational economic agents maximizing an objective function. The information used to build top-down models "comes from the past"; usually, historical data describing energy–economic interactions are used to shape present and future market behavior. With respect to this, two broad parameterization techniques can be identified: calibration (originating models in which the key parameters forging agents' behavior are based on the information stemming from a given point in time, i.e., the base year) and estimation (originating econometrically estimated models in which the parameterization is obtained extracting information from longer time periods, i.e.,

through time-series or panel econometric techniques). In fact, it is common for both approaches to coexist within a model, especially due to constraints imposed by data availability.

Traditionally the economic modeling literature has divided between general equilibrium models (GEMs), whether static or dynamic (on their turn, classifiable in recursive dynamic and growth models), and macroeconometric models. The view of GEMs is "Walrasian"; that is, optimizing producers and households demand and supply goods and factors, perfectly flexible prices adjust excess demand and supply in all markets that clear, and profit maximization under perfect competition and free market entrance guarantee zero profits and the optimal distribution of resources. Macroeconometric models are "neo-Keynesian" in the sense that the economic system is demand driven; moreover, perfect competition is abandoned, especially in energy and labor markets where market power and bargaining processes determine price settings.

Notwithstanding the great heterogeneity within the top-down model family, the explicit aim of comprehensiveness, the focus on agents' decisions, and the idea that the past can describe the future consistently allow one to identify some important common features in the various modeling efforts.

2.1.1 Key Parameters and Variables

Usually, the most important parameters and variables constituting the main drivers of internal processes and results are the elasticity of energy demand in response to gross domestic product (GDP) or income changes; the elasticity of price substitution among capital, labor, and energy; the indicators of technical progress, usually assuming the form of non-price-induced decreases in energy use per unit of GDP (the so-called autonomous energy efficiency improvement [AEEI]) and/or of a more general autonomous factor-augmenting productivity (generally "Hicks-neutral" technical progress); the cost and availability of existing and future energy supplies; and the availability, conversion efficiencies, and costs of existing and future energy generation technologies, including "backstops" (discussed later). Together with the GDP growth rate, all of these elements determine future energy demand and the economic cost of a technological switch.

2.1.2 Disaggregation

It is a recognized fact that estimated econometric relationships among aggregated variables are generally more reliable than those among disaggregated variables; as a consequence, the behavior of the models is more stable using such variables. Thus, it is common to adopt a high level of aggregation for top-down models when they are applied to long time frames. An additional constraint on the level of disaggregation attainable is imposed by computational burdens. This is true in particular for dynamic top-down models in which the process of intertemporal optimization used to find the equilibrium path for the economic variables taking into account strategic behavior among various agents (countries or sectors) requires the solution of huge nonlinear systems. In practice, although a static top-down model can reach a good degree of sectoral disaggregation (e.g., the 57 sectors of the GTAP model), a dynamic top-down model usually presents fewer than 10 to 15 sectors (e.g., the G-cubed model) or even no sectoral disaggregation (e.g., the RICE '96 and RICE '99 models).

2.1.3 Technology

Being concerned with the feedback between energy and other sectors, and between macroeconomic impacts of given policies (e.g., energy or climate change policies), on the national or even global scale, top-down models tend to propose minimal details of the energy-consuming side of the economy. More specifically, technology is usually represented by the shares of the purchase of a given input in intermediate consumption in the production function, as well as in labor, capital, and other inputs, and by the previously mentioned AEEI and/or the factor accounting for Hicks-neutral technical change. Depending on the functional form of the production function, these parameters describe the degree of substitutability among inputs and the evolution of their productivity. In other words, they shape economically a technology that finally determines energy (and other input) demands for the various energy types. This reflects the idea that it is mainly the characteristics of the specific energy type, such as its price, that govern demand developments. It is important to highlight that shares are usually constant and that parameters of technological progress are usually exogenous, being represented by some kind of time trend. This implies, on the one hand, that the approach to technology is inherently static, somehow "freezing" substitutability relationships among various inputs to what has already been observed (in a given year or a given "past") and, on the other, that non-price-induced technological progress is not agents' decision. In other words, agents can decide where to place themselves along the

production frontier, but they cannot determine the shape and shift of that frontier. More recently, the issue of endogenizing technological change was tackled by several researchers. Again the perspective is intrinsically economic. Put simply, the point here is to endow agents with an additional decision variable, usually the amount of investment in research and development (R&D), competing with the others, the stock of which determines, according to some functional form, the productivity and energy efficiency of the input bundle. In this case, AEEI and technical progress do depend on agents' decisions.

2.1.4 The Supply Side

Another key aspect that top-down modeling studies have to consider is the availability of primary inputs, in particular of energy sources and their cost. The majority of top-down models distinguish between carbon-emitting and non-carbon-emitting energy supplies. Usually, fossil fuels (coal, oil, and natural gas) provide energy and produce GHGs as by-products, whereas electricity use is considered carbon free. Some models explicitly consider the possibility of accessing alternative forms of renewable energy supplies with low or zero carbon content. This is done mainly following the so-called "backstop approach," a rather common technique. Alternative energy sources are already technologically feasible and available, but they are not economically viable due to their high costs. As time passes, extracting energy from traditional energy sources becomes more costly due to reserve exhaustion. Accordingly, at a given point in time, new energy sources and technologies become competitive and enter into the market, determining a total or partial shift away from carbon-emitting sources. Thus, the assumed cost and availability of backstop technologies are key determinants of the long-term marginal cost of supply in top-down models.

2.2 Bottom-Up Modeling: Technical Features

Bottom-up models are considered engineering, partial equilibrium, or disaggregated models. Their original aim was to find least cost opportunities to meet an exogenous demand for specific energy services. More recently, following environmental concerns, they have been used to devise least cost opportunities to achieve a given energy efficiency or carbon emission reduction. Bottom-up models are based on technological and economic data that describe in great detail past, present, and future technological options that are used, or that can be used, for harnessing energy resources and convert them into energy services.

Bottom-up models can be grouped into two broad categories: spreadsheet models (which solve a simultaneous set of equations to describe the way in which a given set of technologies is or could be adopted) and simulation or optimization models (which simulate investment decisions endogenously). Again within the heterogeneity of bottom-up modeling, some common features can be devised.

2.2.1 Key Parameters and Variables

In a bottom-up model, the fundamental parameterization concerns the costs and initial values of installed capacities of technologies currently in use and of their alternatives, their residual lives, fuel and electricity costs, and the potential rates and limits of alternative technology penetration.

2.2.2 Disaggregation

As mentioned previously, a typical feature of bottom-up models is the high degree of detail or disaggregation in the representation of the energy sector. But note that disaggregation in bottom-up models has a different meaning with respect to top-down terminology. Most bottom-up models interconnect conversion and consumption of energy via energy carriers. Usually, energy carriers are disaggregated according to their involvement with primary supplies (e.g., mining, petroleum extraction), conversion and processing (e.g., power plants, refineries), and end use demand for energy services (e.g., boilers, automobiles, residential space conditioning). Demand for energy may, on its turn, be disaggregated by sector (e.g., residential, manufacturing, transportation) and by specific functions within a sector (e.g., air conditioning, heating, lighting).

2.2.3 Technology, Supply, and Demand

Bottom-up models capture technology in the engineering sense. This means, for instance, that technology A, with a given performance X determined by a whole set of parameters accessible at the direct cost C(A), on its turn determined by a whole set of parameters, is compared with technology B with a given performance Y accessible at the direct cost C(B). As an outcome, individual measures are ranked in order of increasing net cost to form "packets of options" represented as marginal cost or curves. These are called "conservation supply curves" (CSCs). More specifically, CSCs can be obtained through a three-step procedure: (1) energy-saving

potential and costs of all possible "packets" of options are evaluated, (2) the total "cost of conservation" curve is obtained as the lower convex bound of all conservation packets that may be justifiable at some energy price level, and (3) the CSC is obtained by plotting the slopes of each straight line segment of the total cost of conservation curve. Demand in these models is usually exogenous but can also be determined endogenously. The "typical" focus is on end use energy demand (for heating, lighting, ventilation etc.). This endorses the view that the evolution of energy demand is driven mainly by the various purposes for which energy is made use of. Household energy demands are typically specified by vintage models of a large number of end use technologies whose penetration rates follow a time profile with saturation levels. Penetration ratios could be specified to follow a logistic function, and in some cases parameters of these logistic functions are estimated for each type of appliance.

All of the descriptions in this section are summarized in Table I and Fig. 1.

3. TOP-DOWN AND BOTTOM-UP MODELS: COMPARING THE METHODOLOGIES

It should not be surprising that the different technical characteristics of the two modeling approaches, peculiar to two different disciplines adopting different perspectives, determine a difference both in the kind of questions the specific models can address and in the qualitative and quantitative results they can produce.

TABLE I

Main Features of Top-Down and Bottom-Up Modeling Approaches

Criterion	Top-down	Bottom-up
Level of disaggregation	• Usually low: 1–10 sectors or activities; can be high in some CGE static models	• High: a wide range of energy end uses represented
Behavior representation	• Comprehensive (general equilibrium approach = full economic feedback effects) but few energy-relevant details	• Detailed (at end use level) but not comprehensive (partial equilibrium approach, "no rebounds")
Representation of technologies	• Based on macro, input/output, or econometric analysis • Production functions determine substitution possibilities	• Based on engineering and cost data • Description of physical flows
Technological change	• Price and income effects • Usually exogenous technical progress (Hicks-neutral + AEEI); some models consider R&D and learning-by-doing-driven endogenous technical progress	• Assumptions on market shares or optimization • Projections of technological efficiency • Learning curves
Methodological approach	• Time-series/panel econometrics or calibration based on a single year • Economic growth estimated or exogenous	• Spreadsheet analysis (for descriptive reasons) • Simulation/optimization models
Efficiency gap	• No energy efficiency gap except in case of energy subsidies • Usually markets are fully competitive in CGE models; market power (oligopoly/monopolistic competition) in energy markets in Keynesian macroeconometric models	• Energy markets are not efficient (functioning inside the production frontier) • Potential for cost-effective energy savings
Assumptions about market barriers and hidden costs of new technologies	• Costs of adopting new technologies are reflected in observed behavior	• Significant market barriers prevent adoption of new technologies • Hidden costs tend to be low
Transaction costs of removing market barriers and imperfections	• High	• Low

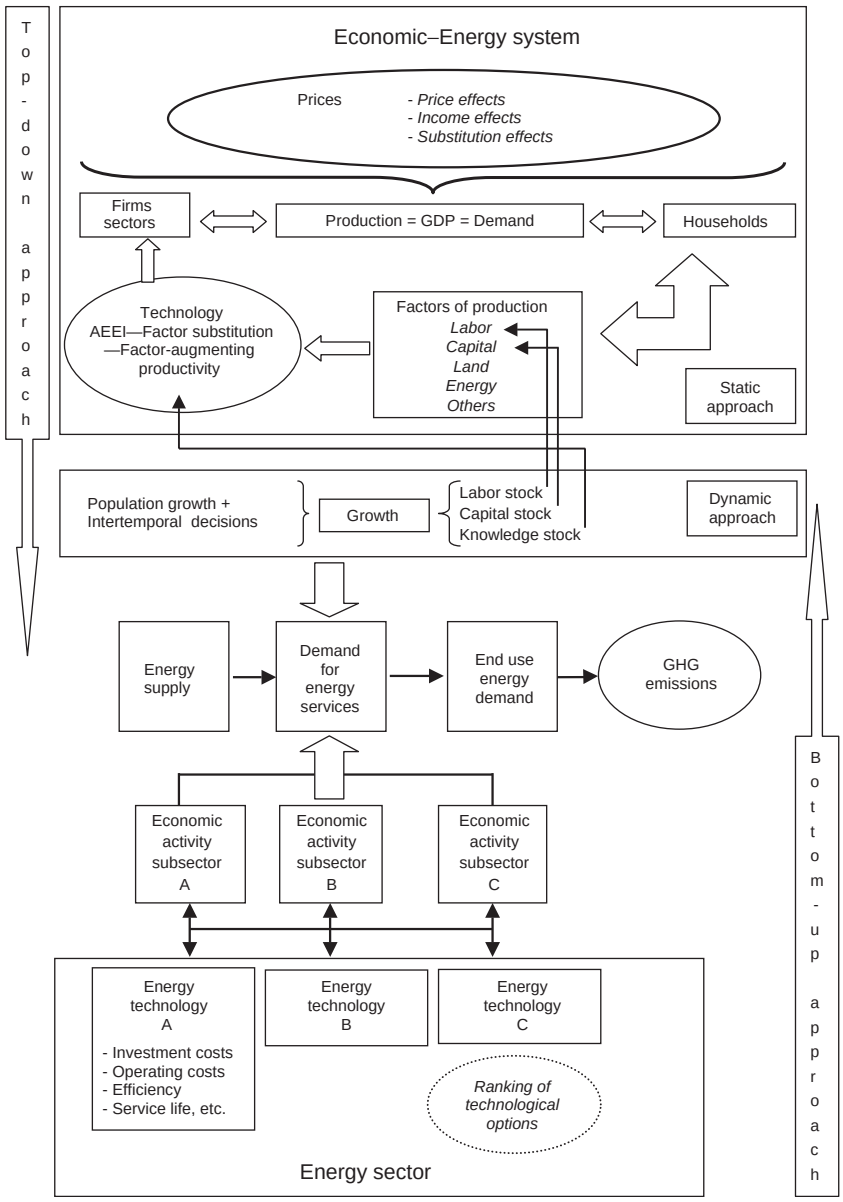

FIGURE 1 Schematic diagram illustrating the structural features of bottom-up and top-down modeling exercises. Top-down approaches are highlighted by the downward arrow, and bottom-up approaches are highlighted by the upward arrow.

A problem can arise when, using both tools to investigate the same issue with the explicit aim of providing policy advice, the two approaches end up with opposite answers. This is the specific case of climate change and climate change policies where both top-down and bottom-up models have been widely used to assess costs and benefits of various control options to decide how much, and according to which strategies (if any), to intervene. Unfortunately, top-down models generally conclude that mitigating global warming entails substantive costs for the economic systems, whereas bottom-up models demonstrate that potential costs are negligible.

Understanding the reason for this discrepancy offers the opportunity to present and compare the different methodologies. Basically, a top-down model can perform two kinds of investigations that are strongly market oriented: the so-called "if-then" or simulation analysis and the optimization analysis. In the first case, the question answered is of the following type: "what are the economic consequences (in terms of international/intersectoral

trade, GDP, welfare, etc.) of a specific perturbation (e.g., a tax levied on the production or consumption of a given good, a change in factor productivity and endowment) imposed on a system?" or "what is the tax or subsidy required to accomplish a given policy target?" In the second case, the question answered is of the following type: "what is the path of a given control variable (e.g., the tax, the investment, the abatement rate) allowing a given target minimizing cost or maximizing welfare to be reached?" The perspective of top-down models is "wide" or "general"; that is, in describing the effect of the perturbation imposed on the system, they try to describe and measure all of the (macro)economic implications and feedback originated within the system. The technological part is necessarily simple, embodied in a small number of parameters.

Conversely, bottom-up models focus on problem solving and are solution oriented. They identify least energy and/or least cost strategies to providing energy services or to accomplish given GHG emissions reduction targets. Basically, the user of a bottom-up model can specify a given set of constraints (e.g., on technology or on demand but also derived from policy variables as emissions limits or taxes), and the model will produce the least cost "technological" solution that meets the provided set of constraints. The outcome of the procedure allows various future technology configurations, the paths of their adoption, and the optimal allocations of their investment flows to be described and compared. Bottom-up models are focused on the energy sector that they describe in great detail but leave the general macroeconomic picture outside the model.

This illustrates two important differentiations. First, top-down models can consider new technological options only marginally. This implies that top-down models, unlike bottom-up models, observe that an important part of the emissions reduction potential of the energy sector is missing. Second, the global perspective of top-down models takes into account the so-called rebound effects that usually escape from bottom-up analyses. Said simply, under an engineering perspective, the possibility of accessing a new "clean" technology at low cost directly implies a cheap decrease in the polluting potential of an economic sector. In a top-down framework, lower prices imply savings and/or an increase in demand for that technology. Both of these elements—an increase in demand and additional savings that can be expended somewhere—usually lead to an increase in energy consumption or consumption tout court ("rebound") that, on its turn, may lead to an increase or a lower decrease in emissions.

Another basic difference is more "philosophical": top-down models adopt the perspective of markets led by rational agents. The direct consequence is that in a top-down world, new and low-cost technologies are hardly accessible because rational agents should have already exploited all of the best available options. Another consequence is that in top-down models, all physical and technological resources for supplying energy services are constrained to quantities available at the current time. A practical example is given by the previously mentioned treatment of backstop technologies. The possibility of obtaining energy from new sources is indeed accounted for, but notwithstanding technological progress, it is accounted for only at an increasing cost over time. Bottom-up models consider the future as "changeable"; they observe that technological progress can improve supply- and demand-side technologies, whose price can then decline. This is why bottom-up models usually highlight the potential for low-cost or even negative cost energy or emissions-saving opportunities.

In light of this, which approach is more reliable? Can the two approaches be reconciled or integrated? Regarding the first question, it must be recognized that both approaches present strengths and weaknesses. The strength of top-down models is their comprehensiveness; basically, these models point out that the energy sector cannot be considered in isolation from the whole economic system and, more important, that economic elements shaping and shaped by agents' behavior are very important in determining the technological quality and performance of a production system. The main limitation is top-down models' inherently "fixed" nature; they can offer valuable insights about the future so long as the relations obtained from the past remain unaltered and can be projected into the future. The main consequence is that a true analysis of impacts of technological innovation over time is precluded because these models implicitly neglect the fact that information, policy, or institutional changes can increase the availability of cost-effective technologies. Conversely, bottom-up models do highlight the possibility of low-cost options but suffer from their technology- and sector-specific focus. This neglects two important facts. On the one hand, even assuming that a technological option were available, it could be neither developed (due to, e.g., the huge investment necessary) nor diffused through the whole production system (due to, e.g., the existence of

transaction costs and other barriers imposed by investment planning). On the other hand, bottom-up models neglect rebounds or feedback that can counterbalance (sometimes dramatically) initial efficiency improvements.

These considerations could also shed some light on the issue of reconciling results. The basic point is to recognize that the two approaches are different. Additional confusion derives from the fact that sometimes the same terminology is used in the two fields but with different meanings. Top-down models are useful for describing macroeconomic (general equilibrium) effects and transmission channels related to taxes, various economic scenarios on energy and environment, and changes in the energy system. The subsequent quantification could be reliable so long as technical progress and cost-effective efficiency opportunities are limited and, more generally, the relationship among energy, economics, and the environment does not change over time. Conversely, bottom-up models are valuable tools for analyzing regulation and energy planning, restructuring of the energy supply sector, and introduction of technological standards and the technological development so as to quantify the aggregated development in energy efficiency, but they cannot be used generally, for example, to provide estimates of the costs of reducing GHGs on a global scale.

4. TOP-DOWN AND BOTTOM-UP MODELS: POSSIBLE INTEGRATION

As pointed out by some authors, it seems not only desirable but also natural to integrate the two approaches. Engineering data on technical potential and costs can offer valuable input to economic market investigations analyzing the effects of a given energy policy, whereas information about the economic intersectoral and international relationships described by top-down models can enrich the cost assessments of bottom-up research with the crucial dimensions of market effects.

Indeed, numerous attempts have been made to coherently and consistently exploit the benefits of both methodologies. One straightforward procedure is to use the results of bottom-up models as an input in macroeconomic models. This is the so-called soft link. An example derives from the MARKAL–MACRO model. MARKAL is a national system optimization model that determines the "best" energy technology solutions and provides marginal abatement costs, energy prices, and rates of technical change as input for MACRO, a simple production and utility function for the economy.

A "harder" link among bottom-up and top-down rationales is obtained when bottom-up and top-down modules can work interdependently. An example derives from the Hybris model, developed by Jacobsen, in which the macroeconomic top-down model ADAM for Denmark is linked to three different bottom-up energy modules: energy supply, demand for heat, and demand for electricity. Basically, the bottom-up modules aggregate or disaggregate variables to fit the specification of the macro model. The model can run different scenarios for bottom-up and top-down initiatives separately and then compare them to scenarios with "combination of reduction" initiatives to highlight the interdependencies among them.

Another notable example is given by the AIM Asian–Pacific model documented by Fujino and colleagues. A set of bottom-up modules that can reproduce detailed processes of energy consumption, industrial production, land use changes, and waste management, as well as technology development and social demand changes, is linked to top-down modules to compute GHG emissions and their general equilibrium relationship with international trade and via an aggregation computable general equilibrium (CGE) interface to assess country and global sustainable development paths considering the feedback among energy, economics, and the environment.

As claimed by several authors, a soft link methodology suffers from the major limitation of failing an effective reconciliation between the logic of the two approaches. In particular, the separation between technological choices at the bottom-up level and economic choices at the top-down level is not observed in the reality where the two decisions are indeed taken simultaneously. Moreover, the top-down part of the model usually is built following the "neoclassical" investment theory that does not allow distinguishing between investment decisions related to the "quality" of the capital stock (e.g., its energy-saving potential) and those related to the "quantity" of the capital stock (e.g., its productive capacity). The consequence is that energy-saving investment is necessarily ill modeled.

This has led to the development of so-called hard link models that attempt a full fusion between top-down and bottom-up features. One possibility is to add a qualitative dimension to the capital stock. An interesting example derives from the WARM model for the European economy, developed by Carraro and

Galeotti, in which economic agents decide not only the quantity but also the quality of the total capital stock. This is done assuming the existence of two kinds of capital: a polluting one and an environmentally friendly one (with the latter allowing for energy savings). Each year, a new capital vintage enters into use, and its quality is determined by the relative weight of the "dirty" and "clean" components endogenously chosen by agents. This composition determines a quality index of the total capital stock that is crucial in determining energy demand responses to environmental and/or energy policies.

Alternatively, Bohringer proposed a hybrid approach that can be applied to a static CGE framework in which energy sectors are represented by bottom-up activity analysis and the other production sectors are characterized by top-down production functions. What is interesting is that the model is solved as a unique equilibrium. Although the technicality of the argument is beyond the scope of this article, this is intuitively possible by observing that equilibrium conditions stemming from the bottom-up representation of a sector are compatible with the equilibrium conditions implied by the standard Arrow–Debreu framework constituting the basis for CGE static top-down models when they are stated in their most general form. The treatment of this kind of problem requires the use of the so-called complementary format proposed by Cottle and Pang. The model is formulated as a nonlinear system of inequalities satisfying the usual Arrow–Debreu general equilibrium conditions (non-negativity of supply minus demand for every commodity, zero profit condition, and Walras's Law). In top-down sectors, substitution is described by nested separable constant elasticity of substitution (CES) functions, whereas in bottom-up sectors, it is represented by a bundle of discrete Leontief technologies.

A possible integration procedure in a dynamic environment was instead proposed by Muller. The basic idea is to consider capital goods as heterogeneous, being characterized by both different production capacity and different energy efficiency. The representative firm chooses quality and quantity of new capital equipment simultaneously to minimize present and discounted future costs. Basically, this intertemporal optimization procedure is constrained by two laws of motion: one for capital stock and one for its quality. This last factor cannot be adjusted to the desired level immediately; rather, it can be improved only by replacing old inefficient vintages with new, more energy-efficient equipment. In this way, the model can take into account the double role of investment. One is the top-down motivation of giving up one unit of consumption today in exchange for increasing productive capacity and consumption tomorrow, and the other is the bottom-up motivation of sustaining higher costs today by buying an efficient capital stock in exchange for gaining energy savings due to this higher efficiency tomorrow.

5. CONCLUDING COMMENTS

A model can be defined as a simplified but sufficiently representative picture of reality. Thus, the very first task of a model is to describe reality—or some aspects of it—that should appear clearer and more understandable with the imposed simplification of the model than without it. In the case of energy modeling, it is unquestionable that both top-down and bottom-up approaches contributed greatly to improving the knowledge of the respective economic and technological dynamics related to the energy system. Nevertheless the different foci of the two methodologies—one economic the other technological—usually leads them to different forecasts and prescriptions. Moreover, it must be recognized that, notwithstanding numerous promising attempts to bridge the gap between the two views, this difference still remains. Under a scientific perspective, this is not dramatic. The process of gaining knowledge takes time, and accordingly, a difference in results can be expected, and the consequent debate can constitute a major driver for scientific improvements. For scientists, it is a strong push to develop finer bottom-up and top-down methodologies and more appropriate integration techniques. On the contrary, under a policy perspective, the difference is problematic. On the one hand, it may lower the trust of policymakers regarding both approaches; on the other hand, it may leave policymakers without a sure framework for their decision making. This issue is very concrete insofar as although a full recognized and accomplished scientific reconciliation is missing, the choice between top-down and bottom-up modeling has to be made on political grounds. What science can do, while working on improvements, is present the results of the two approaches and state clearly under which conditions, and according to which hypotheses, these results could be expected to hold. Symmetrically, policymakers should make clear which vision of the world has endorsed their strategies, in any case bearing in mind that tackling energy policies adopting a bottom-up or top-down angle in isolation is misleading.

Glossary

annualized (amortized) cost An initial or up-front payment for an asset converted to an economically equivalent stream of regular payments over the life of an asset; conversion depends on the interest rate.

average cost The total cost of a given total quantity divided by the total quantity (e.g., the total cost of 4 billion barrels of oil divided by 4 billion barrels) (cf. marginal cost).

bundled cost A cost, such as the cost of parking, that is not explicitly and separately priced, but rather is included in the cost of other items that together are explicitly priced as a "bundle."

cost–benefit analysis A method of analysis in which the economic impacts of a proposed plan, policy, or project are identified, quantified, and valued in dollars for the purpose of comparing the total value of the negative impacts (costs) with the positive (benefits).

external cost The incidental cost of an economic transaction to persons who are not formally part of the transaction (see Section 4.5 for a more formal definition).

marginal cost The cost of an additional or incremental unit of consumption (e.g., the cost of the four-billionth barrel of oil) (cf. average cost). The marginal cost will exceed the average cost if the cost of producing each additional unit increases continually because of increasing scarcity of resources.

monetary cost A cost, such as the cost of gasoline, that is expressed in monetary terms (e.g., dollars) in market transactions. A nonmonetary cost is a cost, such as the cost of travel time, that is not expressed directly in money terms.

opportunity cost In economics, the opportunities or alternative resource uses given up as a result of a particular use of a resource.

optimal price A price on a good or service that incorporates all of the marginal costs to society of using the good or service.

private cost The opportunity cost of an action to a private individual, usually as part of a market transaction.

social cost The opportunity cost of an action to society as a whole; generally equal to the private cost plus the external cost.

The social cost of motor vehicle use—the all-inclusive economic cost to society of using motor vehicles—comprises explicitly priced private-sector costs, bundled private-sector costs, public-sector costs, external costs, and personal nonmonetary costs. Estimates of the social cost can be used for a variety of purposes, including analyses of efficient pricing of motor vehicle goods and services, cost–benefit analysis of motor vehicle projects and plans, and general policy analysis related to motor vehicle use. This article focuses on the classification, uses, and magnitude of estimates of the social cost of motor vehicle use.

1. BACKGROUND

Every year, American drivers spend hundreds of billions of dollars on highway transportation. They pay for vehicles, maintenance, repair, fuel, lubricants, tires, parts, insurance, parking, tolls, registration, fees, and other items. These expenditures buy Americans considerable personal mobility and economic productivity. But the use of motor vehicles costs society more than the hundreds of billions of dollars spent on explicitly priced transportation goods and services. There also are bundled costs, i.e., those goods and services that are not explicitly priced, but rather are bundled in the prices of

 © 2004 Elsevier Inc. All rights reserved.

nontransportation goods and services. For example, "free" parking at a shopping mall is unpriced, but it is not costless; its cost is included—bundled—in the price of goods and services sold at the mall.

In addition to these priced or bundled private-sector costs, there are public-sector costs, of tens of billions of dollars per year, to build and maintain roads and to provide a wide range of services that partly support motor vehicle use. These costs include those for police protection, the judicial and legal systems, corrections, fire protection, environmental regulation, energy research and regulation, military protection of oil supplies, and more. Finally, beyond these monetary public and private-sector costs, are the nonmonetary costs of motor vehicle use, which, by definition, are not valued in dollars in normal market transactions. A wide variety of nonmonetary costs exist, including the health effects of air pollution, pain and suffering due to accidents, and travel time. Some of these nonmonetary costs, such as air pollution, are externalities, whereas others, such as travel time in uncongested conditions, are what may be called "personal nonmonetary costs."

The social cost of motor vehicle use—the all-inclusive economic cost to society of using motor vehicles—is the sum of all of the costs just mentioned: explicitly priced private-sector costs, bundled private-sector costs, public-sector costs, external costs, and personal nonmonetary costs. These costs are listed in complete detail and classified more rigorously, in Table I. Over the past decade, a number of researchers have been doing detailed and comprehensive analyses of the social cost of motor vehicle use. In the following sections, the purpose of estimating the total social cost of motor vehicle use is explained, a conceptual framework and a cost classification are delineated, and recent cost estimates are presented and discussed.

2. *RELEVANCE OF ANALYSES OF THE SOCIAL COST OF MOTOR VEHICLE USE*

Researchers have performed social-cost analyses for a variety reasons and have used them in a variety of ways to support a wide range of policy positions. Some researchers have used social-cost analyses to argue that motor vehicles and gasoline are terrifically underpriced, whereas others have used them to downplay the need for drastic policy intervention in the transportation sector. In any case, social-cost analyses usually excite considerable interest, if only because nearly everyone uses motor vehicles. By itself, however, a total social-cost analysis does not determine whether motor vehicle use on balance is good or bad, or better or worse than some alternative, or whether it is wise to tax gasoline or restrict automobile use or encourage travel in trains. Rather, a social-cost analysis is but one of many pieces of information that might be useful to transportation policymakers. Specifically, a social-cost analysis can help in the following ways:

1. To establish efficient prices for transportation resources, such as roads or automobile emissions. A social-cost analysis can give some idea of the magnitude of the gap between current prices (which might be zero, as in the case of emissions) and theoretically optimal prices, and can inform discussions of the types of policies that might narrow the gaps and make people use transportation resources more efficiently. However, unless it is done with extraordinary specificity and explicitly with an eye to pricing, a social-cost analysis cannot tell us optimal prices for roads or emissions or anything else.
2. To evaluate all of the costs and benefits of alternative transportation investments in order to find the alternative that will provide the highest net benefit to society. A social-cost analysis, as is presented here, is conceptually one-half of the full social-cost-benefit analysis that must be performed in order to invest society's resources efficiently. At a minimum, a broad but detailed social-cost analysis can be a source of data and methods for evaluations of specific projects.
3. To prioritize efforts to reduce the costs of transportation. A detailed comparison of costs can help decide how to fund research and development to improve the performance and reduce the costs of transportation. For example, when considering funding research into the sources, effects, and mitigation of pollution, it might be useful to know that emissions of road dust might be an order of magnitude more costly than are emissions of ozone precursors, which in turn might be an order of magnitude more costly than are emissions of toxic air pollutants.

The analysis and estimates are presented here with these relatively modest informational purposes in mind, not to promote any policies regarding motor vehicle use. There is no declamation, for example, about the correct price of gasoline or the correct level of investment in the highway infrastructure.

3. A CONCEPTUAL FRAMEWORK

In speaking of the social cost of motor vehicle use, what is meant is the annualized social cost of motor vehicle use. The annualized cost of motor vehicle use is equal to the sum of periodic or operating costs (such as fuel, vehicle maintenance, highway maintenance, salaries of police officers, travel time, noise, injuries from accidents, and disease from air pollution) plus the value of all capital (such as highways, parking lots, and residential garages; items that provide a stream of services), converted (annualized) into an equivalent stream of annual costs over the life of the capital. This annualization approach essentially is an investment analysis, or project evaluation, in which the project, in this case, is the entire motor vehicle and use system. Of course, it is awkward to treat the entire motor vehicle system—every car, every gallon of gasoline, every mile of highway—as a "project" up for evaluation, but endeavoring to generate data and methods that will be generally useful in analyses of pricing, investment, and research will not avoid the scale and its awkwardness.

3.1 What Counts as a Cost of Motor Vehicle Use or Infrastructure?

In economic analysis, "cost" means "opportunity cost." The opportunity cost of action A is the opportunity that is foregone—what is given up, or used, or consumed—as a result of doing A. For some resource R to count as a cost of motor vehicle use, it must be true that a change in motor vehicle use will result in a change in use of R. Thus, gasoline is a cost of motor vehicle use because a change in motor vehicle use will result in a change in gasoline use, all else equal. But general spending on national health and education is not a cost of motor vehicle use because a change in motor vehicle use will not result in a change in the resources devoted to national health and education.

For the purposes of planning, evaluating, or pricing, it is of concern not only whether something is a cost of motor vehicle use, but, if it is a cost, exactly how it is related to motor vehicle use. For example, pollution is a direct, immediate cost of motor vehicle use: if motor vehicle use is changed a little, pollution is immediately changed a little. But defense expenditures in the Persian Gulf, if they are a cost of motor vehicle use at all, are an indirect, long-term, and tenuous cost (via congressional decisions about military needs, which might be informed by concerns about the security of oil supply for transportation). This sort of distinction is important because the more tenuously linked costs are harder to estimate, often delayed considerably with respect to the causal changes in motor vehicle use, and often highly dependent on the specific characteristics and amount of the change in motor vehicle use.

3.2 Costs versus Benefits

In this discussion, the dollar social cost but not the dollar social benefit of motor vehicle use is considered. Of course, it is not forgotten that there are benefits of motor vehicle use (a charge occasionally leveled against social-cost analysts) and there is certainly no presumption here that the benefits somehow are less important than the costs of motor vehicle use. Rather, because there is no credible way to estimate all of the benefits of motor vehicle use, there is no attempt to do so here. The emphasis here, however, is that not only does motor vehicle use provide enormous social benefit, but that this benefit, if it could be expressed in dollars, almost certainly would greatly exceed the full social cost.

Nevertheless, because this is a cost analysis only, it is not possible to say much about net dollar benefits or cost–benefit ratios, or whether a particular transportation system is worthwhile, or better or worse than another system. For example, this analysis indicates that motor vehicle use might cost more than is realized (i.e., that the total social cost appreciably exceeds the commonly recognized private costs, such as for fuel, vehicles, and maintenance and repair). But even if this is so, it does not mean that motor vehicle use costs more than it is worth, or that there should be a preference for any transportation option that might have near-zero external costs, or even any transportation option that might have lower total social costs. To make these evaluations, the dollar value of all the benefits as well as the dollar value of all the costs must be estimated.

3.3 Average Cost as a Proxy for Marginal Cost

To be relevant, a social-cost estimate must apply to a potential (realistic) context or policy. Given this, the question might asked: Is an estimate of the social cost of all motor vehicle use, which reveals what would be saved without a motor vehicle system and no motor vehicle use at all, of practical interest? Certainly an estimate of the total dollar cost of all motor vehicle use, by itself, is useful only for research purposes, not for evaluating any policy, because a policy requiring the elimination of motor vehicle use

TABLE I

Classification of the Social Costs of Motor Vehicle Use[a]

	Private sector monetary costs			External costs of motor vehicle use		
Personal non-monetary costs	**Goods and services produced and priced in the private sector (estimated net of producer surplus and taxes and fees)**	**Goods bundled in the private sector**	**Goods and services provided by government**	**Monetary externalities**	**Nonmonetary externalities**	**Nonmonetary impacts of the motor vehicle infrastructure**[b]
Travel time (excluding travel delay imposed by others) that displaces unpaid activities	Costs usually included in GNP-type accounts:	Annualized cost of nonresidential, offstreet parking included in the price of goods and services or offered as an employee benefit	Annualized cost of public highways (including on-street parking and off-street private investment)	Monetary costs of travel delay imposed by others (extra consumption of fuel, and foregone paid work)	Accidental pain, suffering, death, and lost nonmarket productivity, not accounted for by the economically responsible party	Land-use damage: habitat, species loss due to highways, MV infrastructure
Accidental pain, suffering, death, and lost nonmarket productivity inflicted on oneself	Annualized cost of the fleet (excluding vehicles replaced as a result of motor vehicle accidents)	Annualized cost of residential, offstreet parking included in the price of housing	Annualized cost of municipal and institutional off-street parking	Accident costs not accounted for by the economically responsible party (property damage, medical, productivity, and legal and administrative costs)	Travel delay (imposed by other drivers) that displaces unpaid activities	The socially divisive effect of roads as physical barriers in communities
Personal time spent working on MVs and garages, refueling MVs, and buying and disposing of MVs and parts	Cost of transactions for used cars	Annualized cost of roads provided or paid for by the private sector and recovered in the price of structures, goods, or services	Highway law enforcement and safety	Expected loss of GNP due to sudden changes in oil prices	Air pollution: effects on human health, crops, materials, and visibility[d]	Esthetics of highways and vehicle and service establishments
	Parts, supplies, maintenance, repair, cleaning, storage, renting, towing, etc. (excluding parts and services in the repair of vehicles damaged in accidents)		Regulation and control of MV air, water, and solid waste pollution	Price effect of using petroleum fuels for motor vehicles: increased payments to foreign countries	Global warming due to fuel cycle emissions of greenhouse gases (U.S. damages only)	
	Motor fuel and lubricating oil (excluding cost of fuel use attributable to delay)		MV and fuel technology R&D		Noise from motor vehicles	
	Motor vehicle insurance (administrative and management costs)				Water pollution: effects of leaking	

MV noise and air pollution inflicted on oneself	Priced private commercial and residential parking (excluding parking taxes) Costs not included in GNP-type accounts: Travel time (excluding travel delay imposed by others) that displaces paid work Overhead expenses of business and government fleets Private monetary costs of motor vehicle accidents (including user payments for cost of motor vehicle accidents inflicted on others, but excluding insurance administration costs)	for oil used in other sectors (not an external cost internationally) Monetary, non-public-sector costs of fires and net crimes[c] related to using or having MV goods, services, or infrastructure Police protection (excluding highway patrol); court and corrections system (net of cost of substitute crimes) Fire protection Motor-vehicle-related costs of other agencies Military expenditures related to the use of Persian Gulf oil by motor vehicles Annualized cost of the Strategic Petroleum Reserve	storage tanks, oil spills, urban runoff, road deicing Nonmonetary costs of fires and net crimes[c] related to using or having MV goods, services, or infrastructure Air pollution damages to ecosystems other than forests, costs of motor vehicle waste, vibration damages, fear of MVs and MV-related crime

[a] Abbreviations: MV, motor vehicle; GNP, gross national product; R&D, research and development.

[b] Although these are nonmonetary environmental and social costs of total motor vehicle use, they are not costs of marginal motor vehicle use, and hence technically are not externalities.

[c] These should be classified not as external costs, within an economic framework, but rather as costs of illegal or immoral behavior, within a framework that encompasses more than just economic criteria. However, regardless of how these are classified, they in fact are related to using or having motor vehicle goods, services, or infrastructure.

[d] The cost of crop loss, and some of the components of other costs of air pollution (e.g., the cost of medical treatment of sickness caused by motor vehicle air pollution), probably should be classified as monetary externalities.

is highly unlikely. However, an estimate of the cost of all motor vehicle use (i.e., as explained previously, an estimate of the annualized cost of the entire system) will be useful as a starting point to the extent that it accurately can be scaled down to an estimate of the cost of a more realistic "project size." That is, if the true cost of a proposal to increase the motor vehicle system and its use by 10% is approximately 10% of the cost of the entire motor vehicle system as estimated here, then the estimate of the cost of the entire system will be a useful starting point for evaluating the proposal.

Do social costs of motor vehicle use in fact scale linearly with output? In economic terms, the question can be stated as follows: Is the total cost function linear, so that marginal (or incremental) cost per unit is constant and equal to average cost per unit (where the average cost per unit is equal to the total cost divided by the total number of units)? In most cases, the answer is "not exactly," because most types of costs probably are not strictly a linear function of output. For example, it is known that the nonmarket costs of air pollution are a nonlinear function of motor vehicle pollution, and that congestion delay costs are a nonlinear function of motor vehicle travel. Still, even though most costs of motor vehicle use are not strictly a continuous linear function of motor vehicle use, down to the mile or gram or decibel or minute, in at least some scenarios of relatively large changes in motor vehicle use, the average cost ratio might be a serviceable approximation of the actual long-run marginal ratio of interest. At a minimum, some of the data and methods used in an analysis of total cost will be useful in an analysis of marginal cost.

3.4 Classification of Components of the Total Social Cost

In any social-cost analysis, the individual cost components, or cost items, should be identified and classified in consonance with how the cost estimates will be used. As discussed previously, estimates of the total social cost of motor vehicle use legitimately can be applied toward three ends: to ensure that motor vehicles are used efficiently, to evaluate transportation investments, and to prioritize efforts to reduce costs. Of these uses, only the first one, efficiency of use, comes with a set of widely accepted organizing principles. That is, when estimating costs in order to help policymakers improve the efficiency of the use of the transportation system, then costs should be organized into groups with similar characteristics with respect to this purpose of understanding the economic efficiency of motor vehicle use (for example, costs that are priced and efficiently allocated, unpriced but efficiently allocated, or unpriced and inefficiently allocated). Therefore, in Table I, the costs of motor vehicle use are grouped with respect to efficiency of use. However, there is an additional criterion that has nothing to do with efficiency per se: whether a cost is monetary, which means "valued in dollars in real markets." (For example, gasoline and parking are monetary costs, but air pollution is nonmonetary cost.) The distinction between monetary and nonmonetary costs is important methodologically, because it is much harder to estimate the nonmonetary costs. These distinctions result in the six categories of Table I. These are reviewed briefly next.

4. COMPONENTS OF THE SOCIAL COST OF MOTOR VEHICLE USE

The discussions that follow are based on the classification set forth in Table I.

4.1 Column 1: Personal Nonmonetary Costs

Personal nonmonetary costs are those unpriced costs of motor vehicle use that a person self-imposes as a result of the decision to travel. The largest personal costs of motor vehicle use are personal travel time in uncongested conditions and the risk of getting into an accident that involves nobody else. With respect to economic efficiency, the particular issue in the case of personal nonmonetary costs is whether drivers fully recognize the personal nonmarket costs that they face. If a person does not correctly assess these costs (that is, if the true value to the user does not equal the true cost to the user), then the person will drive more or less than would be the case if he or she were fully informed and rational. For example, people who, on account of ignorance or poor judgment, underestimate their risk of falling asleep at the wheel, once in a while will make trips for which the real but underestimated risk-cost exceeds the value, and which, consequently, in principle, should not be made.

4.2 Column 2: Priced Private-Sector Motor Vehicle Goods and Services, Net of Producer Surplus and Taxes and Fees

Priced private-sector costs are related to goods and services that are explicitly priced in private markets:

motor vehicles, motor fuel, maintenance and repair, insurance, and so on. Because these goods and services are bought and sold by private individuals, they are the most familiar components of the total social cost. Also, a portion of these goods and services constitute the "transportation" subaccounts of the gross national product (GNP) accounting.

The social cost of motor vehicle goods and services supplied in private markets can be calculated by starting with known prices and quantities sold, but is not equal to prices multiplied by quantities. Rather, the social (economic) cost is the area under what is called the private supply curve: the dollar value of the resources that a private market allocates to supplying vehicles, fuel, parts, insurance, and so on. To estimate this area, two items must be subtracted from total price-times-quantity revenues, i.e., producer surplus, and taxes and fees. (It is appropriate to start with revenues because prices and quantities can be observed, but not supply curves.) The producer surplus is deducted because it is defined as revenue ("profit," in lay terms) in excess of economic cost, and hence is a noncost wealth transfer from consumers to producers. Taxes and fees assessed on producers and consumers are deducted because they either are transfers from producers and consumers to government, or else are economically inefficient government charges for government services.

The deduction of producer surplus is not merely a theoretical aside: it bears directly on comparisons of alternatives. For example, in comparing the cost of motor fuel with the cost of alternative energy sources, it will not do to count the revenues received by oil producers as the cost, because a large portion of the revenues received by oil producers is extra "profit," far in excess of costs and "normal" profit (which is why major oil-producing countries are so wealthy). It also is important to note that the prices and quantities are realized in private markets rarely if ever are optimal in economic terms, not only because of taxes and fees, which cause economic distortions, but because of imperfect competition (e.g., monopoly), standards and regulations that affect production and consumption, externalities (discussed later), and poor information. Put another way, there is no simple dichotomous world in which private-sector prices are perfect and can be left alone and all other prices (or nonprices) need to be fixed. Rather, there are a variety of market imperfections in every sector of the economy, including the most competitive, unregulated private sectors, and a corresponding range of issues pertaining to pricing, taxation, regulation, and so on. In some cases, there may be as much concern about the market price of tires as there is about the best way to charge motor vehicle users for roads or about the complete lack of a price on motor vehicle emissions.

4.3 Column 3: Bundled Private-Sector Costs

Some very large costs of motor vehicle use are not explicitly priced as separate costs of motor vehicle use. Foremost among these are the cost of free, nonresidential parking, the cost of home garages, and the cost of local roads provided by private developers. However, all of these costs are included in the price of "packages" (such as houses and goods) that are explicitly priced. This bundling is not necessarily economically inefficient; in principle, a producer will bundle a cost and not price it separately if the administrative, operational, and customer (or employee) costs of collecting a separate price exceed the benefits. In a perfect market, it can be presumed that any observed bundling is economically efficient and that it would be economically undesirable to actually mandate unbundling. As concerns economic efficiency, then, the question is whether taxes or regulations (such as requirements that office buildings have a certain number of parking spaces, regardless of what the building owners think) and the like distort the decision to bundle and whether a supplier is correct in his assessment of the costs and benefits of bundling. To the extent that taxes and standards are distorting the market for parking, the ideal remedy is to eliminate the inefficient taxes and standards, not to force parking costs to be unbundled.

4.4 Column 4: Motor Vehicle Goods and Services Provided by the Public Sector

Government provides a wide range of infrastructure and services in support of motor vehicle use. The most costly of these is the capital of the highway infrastructure. Government costs are categorized separately because generally they either are not priced, or else are priced but not in the most efficient manner. Note that, whereas all government expenditures on highways and the highway patrol are a cost of motor vehicle use, only a portion of total government expenditures on local police, fire, corrections, jails, and so on is a cost of motor vehicle use. The portion of these expenditures that is a cost—a long-run or average cost, anyway—of motor

vehicle use has been estimated. This sort of allocation is valid for expenditures (such as for police protection) that arguably are economic costs of motor vehicle use, in the sense of "cost" as used previously. (For example, motor vehicle use results in motor vehicle-related crime, which consumes police-protection services, and motor vehicle fires, which consume fire-protection services.) Publicly provided goods and services that are not priced at all are arguably also monetary externalities, which are shown in column 5 of Table I and are discussed next. Those items that might be both a publicly provided good or service and a monetary externality are shown to straddle columns 4 and 5 in Table I.

4.5 Columns 5–7: Monetary and Nonmonetary Externalities

An externality is a cost or benefit that an action of person A imposes on person B, but that person A does not account for in his or her deliberations regarding the utility (usefulness) of the action. Environmental pollution, traffic delay, pain and suffering due to accidents, and the loss of GNP due to sudden changes in the price of oil are common examples of externalities. Some analysts distinguish "monetary externalities," which are valued in dollars in markets, from "nonmonetary externalities," which are not valued in any markets, even indirectly. Although monetary external costs are valued in markets, they are completely unpriced from the perspective of the responsible motor vehicle user and hence are externalities. The clearest example, shown in column 5 of Table I, is accident costs that are paid for in dollars by those who are not responsible for the accident. For example, vehicular repair costs inflicted by uninsured motorists are valued explicitly in dollars in private markets, but are unpriced from the perspective of the uninsured motorist responsible for the accident.

With respect to economic efficiency, the concern here, as with any external cost, is that the costs are not priced at all, and hence are associated with consumption that is larger than is socially desirable. The intuition behind this is straightforward: if people pay a price that is less than the full cost to society, they will consume more than they would if the price were raised to reflect the external costs. The largest monetary externalities (and hence the largest potential sources of economic efficiency) are those resulting from motor vehicle accidents and congestion on the highways.

Most environmental damages are nonmonetary externalities. Environmental costs include those related to air pollution, global warming, water pollution, and noise due to motor vehicles. To estimate these costs, complex physical processes and biological responses must be modeled and the dollar value of the responses must then be estimated. (The valuation step, which often is quite difficult, is required for nonmonetary but not for monetary externalities; hence the distinction between monetary and nonmonetary costs.) By far the largest environmental externality of motor vehicle use is the cost of particulate air pollution. Interestingly, a typically overlooked and completely unregulated emissions source, particulate matter kicked up from the road bed by passing vehicles, may be one of the largest sources of pollution damages—much larger than damage from ozone.

5. RESULTS OF AN ANALYSIS

The results of a comprehensive analysis of most of the costs of Table I are summarized by aggregate cost category in Table II. Note that the aggregated totals are shown here in order to provide a sense of magnitudes, not because such aggregated totals are inherently useful. Indeed, as discussed next, care must be taken to avoid misusing estimates of the total social cost of motor vehicle use. Table II also shows two subtotals of interest: all monetary costs (those that are valued in dollars in markets) and costs that normally are included in GNP-type accounts of the economic value of transportation. Costs normally included in GNP-type accounts are of interest because they are the explicitly priced private-sector costs and hence represent what most people readily identify as "costs of motor vehicle use." It can be seen that these are a small fraction of the total social costs of motor vehicle use.

An estimate of user payments for public highway and services is shown at the bottom of Table II. An important caveat regarding the use of this estimate is discussed in the next section.

5.1 Allocation of Costs to Individual Vehicle Categories

All of the costs shown in Table II pertain to all motor vehicles (autos, trucks, and buses). Although it can be interesting to estimate the cost of all motor vehicle use, it typically will be more useful to estimate the

TABLE II

Summary of the Social Costs of Motor Vehicle Use in the United States, 1990–1991

	Total cost ($10^9$$)		Percentage of total	
Cost item	Low	High	Low	High
Personal nonmonetary costs of motor vehicle use	527	968	32	29
Motor vehicle goods and services produced and priced in the private sector (estimated net of producer surplus, taxes, and fees)	827	980	49	30
Motor vehicle goods and services bundled in the private sector	76	279	5	8
Motor vehicle infrastructure and services provided by the public sector[a]	131	247	8	7
Monetary externalities of motor vehicle use	43	104	3	3
Nonmonetary externalities of motor vehicle use[b]	68	730	4	22
Grand total social cost of highway transportation	1673	3308	100	100
Subtotal: costs of usually included in GNP-type accounts	559	674	33	20
(2) + (3) + (5) subtotal: monetary cost only	1077	1610	64	49
Item: payments by motor vehicle users for the use of public infrastructure and services	114	206		

[a] Includes items in Table I that straddle columns 4 and 5.

[b] Includes motor vehicle noise and air pollution inflicted on oneself (from column 1 of Table I). Excludes nonmonetary impacts of the motor vehicle infrastructure (column 7 in Table I) and air pollution damages to ecosystems other than forests, costs of motor vehicle waste, vibration damages, and fear of motor vehicles and motor-vehicle-related crime (last item in column 6 of Table I).

cost of different classes of vehicles or of different fuel types, because analysts, policymakers, and regulators typically are interested in specific classes of vehicles and specific fuels, rather than all motor vehicles as a group. (For example, pollution regulations are set for individual classes of vehicles, not for all motor vehicles as a class.) For some cost items, such as the some of the costs of air pollution, analysts have estimated marginal costs as a function of vehicle type and other specific characteristics of motor vehicles and their use. For example, noise costs are estimated as a function of vehicle type, vehicle speed, distance from the road, the presence of sound barriers, housing values, and many other parameters. Air pollution costs are estimated as a function of vehicle characteristics, urban population, weather variables, and other parameters. Road maintenance and repair costs are estimated as a function of vehicle weight, traffic volume, and other factors.

If marginal cost functions are not available, total costs can be allocated to particular vehicle classes or uses on the basis of general cost-allocation factors. A cost-allocation factor shows the share of a particular vehicle class of some general measure of motor vehicle use. For example, it shows the share of light-duty gasoline autos of total vehicle miles of travel, or the share of heavy-duty diesel vehicles of total motor vehicle expenditures for maintenance and repair. The use of these allocation factors is straightforward. For example, the heavy-duty diesel vehicle fraction of total vehicle ton-miles per axle, multiplied by any total motor vehicle cost that is a function of vehicle ton-miles per axle, yields the amount of that cost that is assignable to heavy-duty diesel vehicles. Thus, if total expenditures for highway repair are known, and it is believed that highway repair costs are related to ton-miles of travel per axle, the ton-mile/axle allocation factors can be used to allocate the total expenditures to individual vehicle classes.

5.2 How the Results of a Social-Cost Analysis Should Not Be Used

The legitimate uses of estimates were discussed in previous section. Caution against several common misuses of these estimates is necessary, however. First, the temptation to add up all of the imperfectly priced costs and to express the total per gallon of gasoline, as if the optimal strategy for remedying every inefficiency of motor vehicle use was simply to raise the tax on gasoline, should be resisted. The economically optimal strategy for dealing with imperfect prices is considerably more complex than this. In the first place, some sources of economic

inefficiency, such as imperfect competition and a distortionary income tax policy, are not externalities, and hence are not properly addressed by taxation at all. Taxation can be an appropriate remedy for external costs, but it is a particular kind of taxation that is appropriate (one in which the tax is equal to the actual marginal external cost), and it turns out that there is not a single external cost, with the possible exception of CO_2 emissions from vehicles, that in principle is best addressed by a gasoline tax. For example, an optimal air pollution tax would be a function of the amounts and types of emissions, the ambient conditions, and the size of the exposed population; it would not be proportional to gasoline consumption.

Second, it might be misleading to compare the total social cost of motor vehicle use with the GNP of the United States, because the GNP accounting is quite different from and generally more restricted than social-cost accounting. Most importantly, the GNP does not include nonmarket items. Third, the considerable uncertainty in most social-cost estimates should be represented properly. With regard to the estimates of Table II, the uncertainty actually is greater than is implied by the low and high ranges, even where the high is much higher than the low, because the estimates shown do not include every conceivable component or effect of every cost, and do not always accommodate the entire span of data or opinions in the literature. (Also, the costs "not estimated" in column 6 of Table I should not be assumed to be trivial.) Fourth, although Table II shows highway user tax and fee payments and the government-provided motor vehicle goods and services to which the user payments nominally apply, it may not be economically meaningful to compare the user payments with the government expenditures. Most emphatically, it is not true that any difference between user payments and government expenditures is a source of economic inefficiency that must be eliminated in order to have efficient resource use. This is because economic efficiency does not require that the government collect from users revenues sufficient to cover costs; rather, efficiency results from following certain pricing rules, which when applied to goods such as highways need not result in user revenues covering costs. An efficient pricing scheme for government goods and services would look nothing like the present tax and fee system. Consequently, a comparison of current user tax and fee payments with current government expenditures reveals little, if anything, quantitative about economic efficiency. However, such comparisons may be of use in analyses of equity (questions of who pays for what), which is not addressed here.

Finally, estimates of *the total social* cost of motor vehicle use may be of use in the analysis of a particular policy or investment decision only if it is believed that the marginal costs associated with the particular policy or decision are reasonably close to average costs, which can be calculated easily from total costs. In this respect, average cost estimates derived from the results of Table II will be less and less applicable as times and places increasingly different from the United States in 1990 and 1991 (the basis of the estimates of Table II) are considered. However, even if total-cost estimates per se are irrelevant, the underlying data, methods, and concepts (which are presented in the sources listed in the reading list at the end of this article) might be useful in an analysis of specific pricing policies or investments.

6. SUMMARY

The social costs of motor vehicle use in the United States have been classified, discussed, and estimated. The analyses, which present some first-cut estimates of some of the costs, are meant to inform general decisions about pricing, investment, and research, providing a conceptual framework for analyzing social costs and developing analytical methods and data sources.

It should be clear that a social-cost analysis cannot describe precisely what should be done to improve the transportation system in the United States. There are several kinds of inefficiencies in the motor vehicle system, and hence several kinds of economically optimal measures. The magnitude of these inefficiencies is difficult to estimate accurately. Moreover, society cares at least as much about equity, opportunity, and justice as it does about efficiency. In sum, a total social-cost analysis contributes only modestly to one of several societal objectives regarding transportation.

Glossary

alternative One of several things or courses of action to be chosen by the decision maker. It is the most fundamental entity in a multicriteria decision-making model. Alternatives are also called solutions, especially when dealing with continuous variables, in the mathematical programming context.

attribute A surrogate measure of performance used to represent a criterion. Usually quantified, using some measurable unit, to identify the consequences arising from implementation of any particular decision alternative. Thus, whereas warmth is a criterion, temperature, measured in a suitable (say Celsius or Fahrenheit) scale, is an attribute.

criterion A tool allowing comparison of alternatives according to a particular significance axis or point of view.

decision maker (DM) The individual whose subjective opinions are considered in arriving at a solution for a decision problem.

decision problem A decision-making problem is characterized by the need to choose one or a few from among a number of alternatives.

group decision making (GDM) A situation in which the opinions of more than one decision maker need to be considered in arriving at a solution for a decision problem.

multiattribute decision making (MADM) Involves cases in which the set of alternatives is defined explicitly by a finite list from which one or a few alternatives should be chosen that reflect the DM's preference structure.

multicriteria decision making (MCDM) Making decisions in the face of multiple conflicting criteria. MCDM situations are also referred to herein as multicriteria analysis (MCA) decision situations.

multiobjective decision making (MODM) Involves cases in which the set of alternatives is defined implicitly by a mathematical programming structure with objective functions. Such alternatives are usually defined in terms of continuous variables, which results in an infinite number of alternatives. Multiobjective decision making is also referred to in the literature as multiobjective mathematical programming, multiobjective optimization, vector optimization, or simply multiobjective programming.

nondominated alternative An alternative that is clearly superior to others with respect to at least one criterion. The nondominated alternative is also called an efficient alternative, a noninferior alternative, or a Pareto-optimal alternative.

objective Usually represents the direction of improvement of the attributes; mainly used in mathematical programming problems. A maximizing objective refers to the case in which "more is better," whereas a minimizing objective refers to the case in which "less is better." For example, profit is an attribute, whereas maximizing profit is an objective.

preemptive priorities A situation in which it is assumed that a higher ranked objective is infinitely more important than any of the lower ranked objectives.

stakeholders People who affect and are affected by the decision under consideration.

The field of energy includes a number of issues that require analysis considering several criteria. For example, decisions on almost all energy projects require consideration of several, mostly conflicting, criteria related to economic development arising out of increased energy use, and environmental degradation arising out of increased energy production. Accordingly, multicriteria analysis has been applied to a number of energy-related problems.

1. INTRODUCTION

Multicriteria analysis (MCA), or multicriteria decision making (MCDM) as it is more often called, is a subfield of operations research. It is a special case of the so-called decision-making problems. A decision-making problem is characterized by the need to choose one or a few from among a number of alternatives. The person who is to choose the alternatives is normally called the decision maker (DM). The preferences of the DM will have to be considered in choosing the right alternative(s). In MCDM, the decision maker chooses the most preferred alternative(s) on the basis of two or more criteria.

2. WHY IS MULTICRITERIA ANALYSIS NECESSARY FOR ENERGY ISSUES?

Actually, single-objective programming can be considered as a specific case of MCA. Though some problems have been considered with a single criterion (which is captured by the single-objective function of the linear programming models), many of the issues often have impact on more than one criterion. When it can be safely assumed that only one criterion is overridingly important, linear programming approaches that use the single-objective function should be employed. However, if impacts should be considered in terms of several criteria, the MCA methods should be employed. Further, note that MCA is much more general, involving not only multiobjective programming models, but also non-programming-based models.

2.1 Need for Multiple Criteria

The issues of the energy sector that can be tackled by quantitative methods (including single-criterion linear programming and MCA methods) abound, from the location of power plants, to transmission and distribution systems, to the choice of demand-side management programs, to the choice of options that mitigate global warming. Financial criteria are the most dominant considerations usually evaluated in single-criterion analysis of energy issues. However, the growing importance of environmental impacts of decisions in the field of energy has increased the importance assigned to environment-related criteria such as air pollution (emission of sulfur dioxide, nitrogen oxides, etc.), water pollution, human health, global warming, acid rain, oil spills, preservation of biodiversity, etc., increasing the need for multicriteria analysis of energy-related decision problems. Of course, other criteria, such as quality and reliability, are also relevant for specific problems.

Multicriteria analysis of energy problems encompasses technological, economic, social, environmental, risk, and financial criteria in making energy decisions. Multicriteria decisions require certain approaches that are not normally used in single-criterion decision-making situations. For example, it is necessary to carry out a trade-off analysis when distinctive characteristics in terms of cost, environmental emissions, human health, etc. are compared and weighed against each other. These comparisons equate to comparing apples and oranges, but are the necessary ingredient of any multicriteria analysis. The trade-off analysis is necessary only when the criteria employed are conflicting, i.e., when there is no alternative that performs well in terms of all the criteria. In some situations, such trade-offs may not be necessary. For example, in the power sector, there may be alternatives that have beneficial impacts on both environmental and economic objectives—most energy-efficient investments that are economically justifiable also bring about a reduction in emissions, and thus they score well in terms of both the criteria, i.e., environmental quality and economic efficiency. The two criteria are said to be not conflicting in this case. However, in most of the energy-related problems, alternatives are often evaluated in terms of conflicting criteria. For example, wind power plants score well in terms of environmental criteria but are more expensive than many other power generation options.

2.2 Group Decision Making

Another feature of multicriteria analysis is group decision making. Invariably, multiple criteria have to be considered to arrive at a decision, because different criteria are important to different people, who both affect and are affected by the decision under consideration. These people are normally referred to as the stakeholders. There may be different groups of stakeholders for a decision-making situation. For example, government and local authorities are normally stakeholders for most energy-related decisions because they would like to ensure that the resulting decision follows legal guidelines and is socially acceptable. A company, entrepreneurs, or potential investors are also stakeholders; here the greater interest is in the economic

and finance-related criteria. For a utility company, for example, the decision made about the problem of siting a power plant would have an economic impact. Environmentalists, public pressure groups (such as nongovernmental organizations and local media), and the local public, also stakeholders, may wish to ensure that the environment is not adversely affected. In some cases, opinions of experts and academia may also be important. Hence, involvement of all the stakeholders is important in arriving at a large-scale energy-related decision. And, the opinion of a stakeholder group should be synthesized from the opinions expressed by individual members of the group (such as individual local people, when the stakeholder group is the local public). MCA has been considered a valuable tool for facilitating early involvement of all stakeholders in the decision-making process, and enhances the fairness and transparency of the procedures for complex decision situations, including energy-related decision situations.

Ideally, the final decision of a stakeholder group should be arrived at by consensus. However, due to the conflicting nature of the criteria adopted by different people (or groups of people), especially in energy-related decision situations, it may not be possible to arrive at a consensus decision. In such cases, special procedures are required to estimate the most preferred solution for the group as a whole, from the opinions expressed by the group members. Most of the multicriteria methods provide such special procedures. Due to the need to consider the subjective opinions of a number of people, most of the MCA methods have been designed to be interactive.

3. MCDM: TERMINOLOGIES, CLASSIFICATION, AND SOME GENERAL CHARACTERISTICS

The field of multicriteria decision making has been succinctly defined as making decisions in the face of multiple conflicting criteria. Some special issues of journals have been devoted to the field of MCDM, including *Management Science* (Vol. 30, No. 1, 1984), *Interfaces* (Vol. 22, No. 6, 1992) (devoted to decision and risk analysis), and *Computers and Operations Research* (Vol. 19, No. 7, 1994). The *Journal of Multi-Criteria Decision Analysis*, since 1992, has published articles entirely devoted to MCDM. Special issues of the *Journal of the Operational Research Society* (April, 1982), and of *Interfaces* (November–December, 1991) provide a range of applications. Issue No. 2, Volume 133 (January 2001) of the *European Journal of Operational Research* is a special issue on goal programming.

3.1 MCDM Terminologies

Several terminologies are normally used when dealing with a decision problem that has multiple criteria. The terms "goals," "objectives," "criteria," and "attributes" are commonly found in the MCDM literature and can be used with interchangeable ease. The general meaning of these words is similar in most cases.

Alternatives are the most fundamental entities in a MCDM model. They are normally compared with each other in terms of criteria. Identification of criteria for a particular problem is subjective, i.e., varies for each problem. Criteria are normally developed in a hierarchical fashion, starting from the broadest sense (usually called the goal of the problem) and refined into more and more precise sub-goals and sub-sub-goals. In general, some rules should be followed in identifying criteria for any decision problem. They have to be mutually exclusive or independent, collectively exhaustive, and should have operational clarity of definition.

The criteria of a decision problem are usually very general, abstract, and often ambiguous, and it can be impossible to associate criteria directly with alternatives. Attributes are objective and measurable features of the alternatives, and are sometimes used to describe criteria. Objectives, used mainly in mathematical programming problems, represent directions of improvement of the attributes. The term "criterion" is a general term comprising the concepts of attributes and objectives. It can represent either attribute or objective, depending on the nature of the problem. Due to this, MCDM is considered to encompass two distinct fields, namely multiattribute decision making and multiobjective decision making. These fields are discussed in the next section.

3.2 A Classification of Different MCDM Approaches

The broad area of MCDM can be divided into two general categories, multiattribute decision making (MADM) and multiobjective decision making (MODM). MADM involves cases in which the set of alternatives is defined explicitly by a finite list

from which one or a few alternatives should be chosen that reflect the decision maker's preference structure. MODM involves cases in which the set of alternatives is defined implicitly by a mathematical programming structure with objective functions. Such alternatives are usually defined in terms of continuous variables, which results in an infinite number of alternatives.

3.3 Multiobjective Decision Making—Some Basic Concepts

In this section, a comparison of a multiobjective decision making problem with a single-objective decision-making problem is used to introduce certain key concepts frequently used in MCDM literature. Note that many of the concepts introduced in this section are also applicable to MADM problems.

A single-objective decision-making (SODM) problem is generally written in the following form:

$$\begin{aligned} &\text{maximize/minimize } Z = CX \\ &\text{subject to } AX = b,\ X \geq 0, \end{aligned} \tag{1}$$

where Z is the objective function. The set of equations, $AX = b,\ X \geq 0$, represents the constraint set of the problem. Methods for solving single-objective mathematical programming problems have been studied extensively for the past 40 years. However, almost every important real-world problem involves more than one objective. A general multiobjective decision-making (MODM) problem has the following form:

$$\begin{aligned} \text{maximize/minimize } Z_1 &= C_1 X \\ \text{maximize/minimize } Z_2 &= C_2 X \\ \text{maximize/minimize } Z_n &= C_n X \\ &\vdots \\ \text{subject to } AX &= b,\ X \geq 0, \end{aligned} \tag{2}$$

where the values Z_i, $i = 1, 2, \ldots, n$, represent the n objective functions. The set of equations, $AX = b$, $X \geq 0$, represents the constraint set of the MODM problem. Thus the MODM problem is similar to a SODM problem, except that it has a stack of objective functions instead of only one.

Let us consider a simplified example involving choice of a coal technology for electric power generation. Let the objectives be as follows:

$$\begin{aligned} \text{Minimize } Z_c &= \text{investment cost.} \\ \text{Maximize } Z_G &= \text{savings of emissions of global pollutants } (CO_2 \text{ here}) \\ \text{Maximize } Z_L &= \text{savings of emissions of local pollutants } (SO_2 \text{ here}) \\ \text{Subject to some constraints.} & \end{aligned} \tag{3}$$

Let us assume that we have some technologies (normally called alternatives of the decision problem), say pulverized fuel (PULV) technology, pressurized fluidized bed combustor (PFBC) technology, and integrated coal gasification combined cycle (IGCC) technology, that satisfy the constraints. This means that these are the three feasible technologies (or alternatives). The performance of the technologies in terms of the three criteria is shown in Table I. Note that the savings of emissions of CO_2 and SO_2 are lower and investment costs higher for PFBC technology compared to IGCC technology. Thus PFBC technology fares, on all the three objectives, worse than IGCC technology and hence it should not be considered any more. In MCDM terminology, PFBC technology is said to be inferior to (or dominated by) IGCC technology. Technologies PULV and IGCC are incomparable, as neither of them is at least as good as the other in terms of all the objectives. Although PULV is cheaper in terms of the investment cost compared to IGCC, it results in smaller savings of the environmental emissions. Hence, PULV and IGCC are said to be noninferior technologies and PFBC is called an inferior technology. (Please note that, in practice, comparisons of the

TABLE I

Some Characteristics of Coal Technologies for Power Generation in India[a]

Technology	CO_2 savings (g/kWh)	SO_2 savings (g/kWh)	Investment cost ($/kW)
Pulverized fuel (PULV)	220	3.30	1202
Pressurized fluidized bed combustor (PFBC)	240	3.32	1894
Integrated coal gasification combined cycle (IGCC)	590	3.75	1578

[a] Values estimated by the author from miscellaneous sources.

different coal technologies will not be so simple. For example, PFBC technology may fare better than other technologies if some other criteria are considered.) Thus a noninferior alternative is one that is clearly superior with respect to at least one criterion. The noninferior alternative is also called an efficient alternative, nondominated alternative, or Pareto-optimal alternative. In any MODM exercise, the first task is to identify the noninferior options. Note that there may be more than one noninferior option for any multiobjective programming (MOP) problem.

Once the noninferior alternatives are identified, it is necessary to evaluate them so as to arrive at the best alternative. Because none of the noninferior alternatives will optimize (i.e., maximize/minimize) all the objective functions, it is necessary to identify those alternatives that best satisfy all the objective functions (in the opinion of the decision-maker). This has to be contrasted with single-objective optimization problems that are concerned with arriving at one or more optimal solutions. Thus, although the underlying philosophy in SODM problems is in optimizing solutions, MODM aims at identifying one or more satisficing solutions. One way of reducing the number of Pareto-optimal alternatives is by providing performance targets for each of the objectives. For example, if the DM specifies no interest in those technologies that cost more than \$1500/kW, then IGCC technology is automatically excluded from the DM preference set, and PULV technology now remains the only choice. This is a satisficing solution because it satisfies all the performance targets, but obviously it need not be an optimal solution. This is the basic idea of goal programming (discussed later). In general, identification of alternatives (technologies here) that are considered best by the decision maker requires additional information on the preference structure among the objectives, which is not necessary for SODM problems.

The preference structure can be ordinal or cardinal. This essentially involves identifying the "importance parameters" or "weights" associated with the objectives. Suppose it is possible for the DM to provide weights (w) to the three objectives as follows: $w_C = 5$, $w_S = 2$, $w_I = 8$, where the subscripts C, S, and I represent CO_2 savings, SO_2 savings, and investment cost, respectively. These weights may be specified exogenously before attempting to analyze the MOP problem. They imply the trade-offs between the objectives that the DM is willing to consider. It is necessary to have a trade-off because the objectives are conflicting: given the nondominated options, it is not possible to maximize one objective without getting reduction in the performance of other objective. The information as to how much of reduction in one objective can be tolerated to improve performance in another objective is called the trade-off information. Note that this trade-off information is subjective and depends on the particular DM for whom the MODM problem is being analyzed. The given structure means, in the opinion of the DM, that the objective Z_S (SO_2 savings) is the least important objective, a reduction in investment cost by \$1/kW is considered by the DM to be equivalent to an increase of $8/2 = 4$ g/kWh in SO_2 savings, an increase in CO_2 savings by 1 g/kWh is considered by the DM to be equivalent to an increase of 2.5 g/kWh in SO_2 savings, etc.

Given such cardinal weights, the MODM problem reduces to the SODM problem, with the single objective of minimizing $Z = \sum w_i Z_i$ subject to the constraints. In this case, IGCC technology has an aggregate score of about 15,582, and is preferable to PULV (which has an aggregate score of about 10,723). Thus, the MODM can be reduced to a SODM problem if such cardinal weights can be unambiguously specified. However, in practice, many DMs find it difficult to specify a precise set of weights. Imprecision occurs also because the different objectives have different performance measures or they are measured in incommensurable units. In situations when specification of cardinal weights is difficult, it may be easier to provide ordinal rankings or provide simple ranks of the objectives. For example, given the weight structure, even if the weights cannot be specified exactly, the ranking pattern may remain the same, i.e., Z_I is the most important of all the three objectives, followed in importance by Z_C, and Z_S is the least important objective, or

$$Z_I \succ Z_C \succ Z_S. \tag{4}$$

Here, the symbol $\succ$ stands for "is preferred to." Thus, $Z_I \succ Z_C$ means that Z_I is preferred to Z_C.

When it is assumed that no further trade-off is possible, this may be considered as a case of preemptive priorities, i.e., the higher ranked objective is assumed to be infinitely more important than any of the lower ranked objectives, or $w_I \ggg w_C \ggg w_S$. Preemptive priorities are more commonly denoted by P, i.e., $P_I > P_C > P_S$. Under these preemptive priorities, PULV technology is preferable to IGCC technology. In fact, PULV technology will be preferred even if we have a hypothetical technology with CO_2 savings of 500 g/kWh, SO_2 savings of

9 g/kWh, and investment cost of $1203/kW. This is because, under the assumptions of the preceding preemptive priorities, a reduction of $1/kW is worth infinitely more than any amount of CO_2 savings or SO_2 savings. This is the basic principle behind a version of goal programming, called preemptive goal programming.

3.4 Multiattribute Decision-Making Methods—Some Common Characteristics

In general, MADM methods have some common characteristics:

1. The persons or organizations that are the stakeholders of the decision problem being considered have to be identified. These people will act as the decision makers whose opinions will be elicited by the MCDM methods. This stage is equally applicable to MODM methods, especially while eliciting the preference information for choosing one or a few from the set of all nondominated alternatives (solutions).
2. A model of the decision problem has to be constructed. Typically, the model will consider the main goal of the problem, relevant criteria, attributes, and alternatives. For example, if it is desired to evaluate some selected technologies, it is important to identify the key criteria that distinguish the characteristics of technologies, and all the relevant technologies to be considered as alternatives in the model. The model is called a hierarchical model in some MCDM methods, because it represents a hierarchy of decisions—the goal of the exercise (say, selection of the most important energy technologies), the criteria (economic significance, social significance, etc.), and alternatives (the technologies to be evaluated).
3. Ideally speaking, criteria have to be mutually exclusive and collectively exhaustive. Collective exhaustivity is critical in some methods, such as in the analytic hierarchy process, because final rankings could change for the addition or deletion of alternatives at a later stage.
4. The relative importance of criteria, which are implicit trade-off data (see previous section) used in identification of the best alternative(s), has to be assessed. Although assessment of the relative importance of criteria forms an important step in many MCDM methods, some methods do not use this information (e.g., data envelopment analysis). The procedure for this assessment differs for each method and forms generally the single most important distinguishing feature of each method. The procedures will be described in more detail in the next section for some important MCDM methods, along with some prominent applications of the methods in the field of energy. The assessment can be performed either by an individual, or by representatives of conflicting values acting separately, or by those representatives acting as a group. Again, some methods have special procedures to aggregate the opinions of individuals to form a group opinion, though in general the group members should be encouraged to arrive at a single unanimous assessment.
5. Assessment of alternatives with respect to different criteria.
6. Aggregation of performance of alternatives with respect to all criteria to provide the overall performance measures of alternatives. Simple additive or multiplicative aggregation is used in many methods, but can also be more sophisticated (e.g., data envelopment analysis uses linear programming). The overall performance measures could also be considered as the rankings of the alternatives.

Note that many of these characteristics are also valid for the MODM problems, especially when the preferences of the DM are elicited.

4. AN OVERVIEW OF SOME MCDM METHODS AND THEIR ENERGY APPLICATIONS

Several surveys are available that describe many of the MCDM methods suggested in the literature. In the following discussion, four selected MCDM methods that have been applied to a number of problems in the field of energy will be briefly described. Due to space limitations, additional methods cannot be discussed here, but are available in the references listed at the end of this article. Software packages are available for facilitating the implementation of most of the methods, but, again owing to space limitations, they will not be discussed here.

4.1 MADM Methods

4.1.1 Multiattribute Utility Theory

Utility measures the subjective "worth" of an outcome, even one that is not a monetary value. Traditionally, utility functions are defined for stochastic problems that involve uncertainty. In the case

of deterministic problems, the term "value functions" is more commonly used. The utility or value functions may be thought of as evaluative mechanisms that can be used to measure the value of a particular solution.

Utility functions are defined in terms of uncertainty and thus tie in the decision maker's preferences under uncertainty, revealing the DM's risk preference for an attribute. An uncertain situation faced by a decision maker can be considered similar to a lottery—the DM can earn $\$X$ with a probability p, and earn $\$Y$ with probability $(1-p)$. In these situations, a rational decision maker is expected to maximize *the expected utility*, given by $\$[pX+(1-p)Y]$. Utility functions are assessed by giving the DM a sequence of choice between alternatives or between alternative lotteries. The responses are used to generate functions.

Multiattribute utility theory (MAUT) consists of assessing and fitting utility functions and probabilities for each attribute, and then using the functions and probabilities to come up with rankings of alternatives. The utility functions for each attribute are aggregated to get the overall utility function. At least two methods of aggregation are used in MAUT, additive and multiplicative. The additive aggregation is

$$\begin{aligned} U(A) &= \textstyle\sum_i w_i u_i(a_i) \\ \textstyle\sum_i w_i &= 1,\ w_i \geq 0, \end{aligned} \tag{5}$$

where $0 \leq u_i(a_i) \leq 1$; $u(a_i)$ is the utility function describing preferences with respect to the attribute i, a_i represents the performance of the alternative A in terms of the attribute i, the scaling factors w_i define acceptable trade-offs between different attributes, and $U(A)$ represents the overall utility function of the alternative A when all the attributes are considered together. This form of additive aggregation is valid if and only if the decision maker's preferences satisfy the mutual preferential independence. Suppose that there is a set of attributes, X. Let Y be a subset of X, and let Z be its complement, i.e., $Z = X–Y$. The subset Y is said to be preferentially independent of Z, if preferences relating to the attributes contained in Y do not depend on the level of attributes in Z.

Under certain assumptions, the multiplicative aggregation can be written as $U(A) = \Pi_i\ u_i(a_i)$. This multiplicative utility function requires stronger assumptions such as the Utility independence. The utility functions may be used as objective functions for solving mathematical programming problems. Utility theory has been criticized because of its "strict" assumptions, which are usually not empirically valid. Because of the strict assumptions, practical applications of MAUT are relatively difficult, though there are several practical successful applications of MAUT. This has led to some simplifications of the MAUT concepts. For example, the multiattribute value theory is a simplification of MAUT without uncertainty and risk. The simple multiattribute rating technique is another simplification that makes weaker assumptions while eliciting utilities. These are described in the next few subsections.

4.1.1.1 Multiattribute Value Theory Multiattribute value theory (MAVT) is a simplification of MAUT: MAVT does not seek to model the decision maker's attitude to risk. As a result, MAVT is considered to be easier to implement. Value theory assumes that it is possible to represent a decision maker's preferences in a defined context by a value function, $V()$, such that if alternative A is preferred to alternative B, then $V(A) > V(B)$. For this representation to be possible, the decision maker's preferences should satisfy two properties: the transitivity property (if A is preferred to B, B is preferred to C, then A should be preferred to C) and comparability (given two alternatives A and B, the decision maker must be able to indicate whether A is preferred to B, or B is preferred to A, or there is no difference between the two).

Note that the value function is an ordinal function, i.e., it can be used only to rank alternatives. In contrast, utility function is cardinal, i.e., it can be used to measure the strength of preference among alternatives. Multiattribute value theory explicitly recognizes that the decision maker will use many attributes (criteria) when evaluating a set of alternatives. For each attribute i, a partial value function $v_i(a_i)$ describing preferences with respect to the attribute i is assessed by the decision maker, where a_i represents the performance of the alternative A in terms of the attribute i. Then, the overall value function $V(A)$ of the alternative when all the attributes are considered together is normally obtained using the additive form: $V(A) = \Sigma_i\ v_i(a_i)$. This is more generally expressed as follows:

$$\begin{aligned} V(A) &= \textstyle\sum_i w_i v_i(a_i) \\ \textstyle\sum_i w_i &= 1,\ w_i \geq 0, \end{aligned} \tag{6}$$

where $0 \leq v_i(a_i) \leq 1$. As mentioned above, the scaling factors w_i define acceptable trade-offs between

different attributes. Again, this additive value function is appropriate if and only if the decision maker's preferences satisfy the so-called mutual preferential independence discussed earlier.

4.1.1.2 Simple Multiattribute Rating Technique The simple multiattribute rating technique (SMART) follows the steps described in the previous section for modeling a decision problem. It uses the simple weighting technique for the assessment of importance of criteria, and for the assessment of alternatives with respect to criteria. To rate (i.e., assess the importance of) criteria, the DM is asked to start by assigning the least important criterion an importance of 10. Then, the DM has to consider the next-least-important criterion, and ask how much more important (if at all) is it compared to the least important criterion, and assign a number that reflects that ratio. This procedure is continued till all the criteria are assessed, checking each set of implied ratios as each new judgement is made. The DM will be given the opportunity to revise previous judgments to make them consistent. Once the numbers are assigned, the relative importance of criteria is obtained by summing the importance weights, and dividing each by the sum. Thus, the relative importance of the criterion $j(w_j)$ is the ratio of importance weight of this criterion to the sum. Note that $\sum_j w_j = 1$ by definition.

Alternatives are rated with respect to each criterion in a similar fashion. Though MAUT requires the development of complex utility functions for each criteria, SMART prefers to produce the rating using a more straightforward approach: the DM is asked to estimate the position of the alternative of a criterion on a scale of 0 to 100, where 0 is defined as the minimum plausible value and 100 is defined as the maximum plausible value. Once the two measures are available, the overall performance of an alternative i can be aggregated using the simple weighted average,

$$U_i = \sum_j w_i u_{ij}, \tag{7}$$

where U_i is the overall performance rating of alternative i, w_j is the relative importance of criterion j, and u_{ij} is the rating of the alternative i with respect to the criterion j. The alternative that has the maximum U_i is the most preferred alternative to achieve the goal of the decision problem. The values of U_i can be used to provide the overall rankings of the alternatives.

MAUT, or its simplified versions MAVT or SMART, has been used for several practical applications. Siting and licensing of nuclear power facilities is an interesting application of these methods in the field of energy. Siting of nuclear power facilities is an extremely complex task because there are many interest groups with their own set of multiple objectives. Five categories of objectives were considered in the study: environmental, human safety, consumer well being, economic, and national interest. Note that each category has one or more objectives. For example, the economic category comprises objectives such as maximize economic benefits to local community, maximize utility company profits, and improve balance of payments. Similarly, the consumer well-being category comprises two objectives: provide necessary power and minimize consumer power costs. There are many interest groups (stakeholders) for this problem. The power company is one of the interest groups. Objectives of interest to the company are maximizing company profits, satisfying consumer preferences for energy, minimizing the detrimental environmental impact of its facilities, and maximizing the net benefits of its facilities on the local communities. Hence, it is important to assess a utility function from the company that is a function of these four objectives. Eliciting the utility functions involves assessing the trade-off information among the four objectives. More detailed discussion of this application is available in the literature cited in the reading list at the end of this article.

Additive or multiplicative utility or value functions have been employed to handle multiple criteria in many applications in the field of energy: to integrate socioeconomic, environmental, and cost criteria in siting a power plant and routing its transmission lines; for the weighting of environmental and economic benefits in demand-side management programs; for the amalgamation of energy, controllability, flexibility, viability, and other related attributes of new resources in bidding procedures; and combining measures of air, water, land, visual, noise, and solid waste effects into an index of environmental impact for use in resource bidding and screening. Other energy-related applications of utility or value theory include air pollution control problems, transporting hazardous wastes, refueling a nuclear power plant, climate change analysis, the study of UK energy policy, selection of a portfolio for a solar energy project, selection of a technology for the disposition of surplus weapons-grade plutonium, performing "as low as reasonably practicable"

(ALARP) assessments in the nuclear industry, identifying appropriate technological alternatives to implement treatment of industrial solid residuals, and risk analysis in nuclear emergency management.

4.1.2 The Analytic Hierarchy Process

The analytic hierarchy process (AHP) is one of the most popular and widely employed multicriteria methods. In this technique, the processes of rating alternatives and aggregating to find the most relevant alternatives are integrated. The technique is employed for ranking a set of alternatives or for the selection of the best in a set of alternatives. The ranking/selection is done with respect to an overall goal, which is broken down into a set of criteria.

The application of the methodology consists of establishing the importance weights to be associated to the criteria in defining the overall goal. This is done by comparing the criteria pairwise. Let us consider two criteria, C_j and C_k. The DM is asked to express a graded comparative judgment about the pair in terms of the relative importance of C_j over C_k with respect to the goal. The comparative judgement is captured on a semantic scale (equally important/moderately more important/strongly important and so on) and is converted into a numerical integer value a_{jk}. The relative importance of C_k over C_j is defined as its reciprocal, i.e., $a_{kj} = 1/a_{jk}$. A reciprocal pairwise comparison matrix A is then formed using a_{jk}, for all j and k. Note that $a_{jj} = 1$. It has been generally agreed that the weights of criteria can be estimated by finding the principal eigenvector w of the matrix A:

$$AW = \lambda_{\max} w. \tag{8}$$

When the vector w is normalized, it becomes the vector of priorities of the criteria with respect to the goal; $\lambda_{\max}$ is the largest eigenvalue of the matrix A and the corresponding eigenvector w contains only positive entries. The methodology also incorporates established procedures for checking the consistency of the judgments provided by the decision maker.

Using similar procedures, the weights of alternatives with respect to each criterion are computed. Then, the overall weights of alternatives are computed using the weighted summation

$$\begin{pmatrix} \text{Overall weight} \\ \text{of alternative } i \end{pmatrix} = \sum_j \begin{pmatrix} \text{Weight of alternative } i \text{ with} \\ \text{respect to } C_j \times \text{weight of } C_j \\ \text{with respect to the goal} \end{pmatrix} \tag{9}$$

The popularity of AHP stems from its simplicity, flexibility, intuitive appeal, and ability to mix quantitative and qualitative criteria in the same decision framework. Despite its popularity, several shortcomings of AHP have been reported in the literature, which have limited its applicability. However, several modifications have been suggested to the original AHP, such as the multiplicative AHP (MAHP), to overcome these limitations. Some of the prominent shortcomings of AHP include the following limitations:

- Rank reversal: The ranking of alternatives determined by the original AHP may be altered by the addition of another alternative for consideration. For example, when AHP is used for a technology selection problem, it is possible that the rankings of the technologies get reversed when a new technology is added to the list of technologies. One way to overcome this problem is to include all possible technologies and criteria at the beginning of the AHP exercise, and not to add or remove technologies while or after completing the exercise. Some variants, such as MAHP, do not suffer from this type of rank reversal.
- Number of comparisons: AHP uses redundant judgments for checking consistency, and this can exponentially increase the number of judgments to be elicited from DMs. For example, to compare eight alternatives on the basis of one criterion, 28 judgments are needed. If there are n criteria, then the total number of judgments for comparing alternatives on the basis of all these criteria will be $28n$. This is often a tiresome exercise for the decision maker. Some methods have been developed to reduce the number of judgments needed.

AHP has been applied to a variety of decision problems in the literature. Several detailed annotated bibliographies of AHP applications are available. In an illustrative application of AHP for the selection of greenhouse gas mitigation options, there are three criteria—namely, cost-effectiveness, feasibility, and other national benefits—to rank five demand-side management options (variable speed drives, good housekeeping, energy-efficient motors, compact fluorescent lamps, and cogeneration). Some other energy-related applications of AHP include solar energy utilization, energy resource allocation, integrated resource planning, climate change negotiations, environmental impact assessment, energy choices for the United States and for members of the Organization of Petroleum Exporting Countries (OPEC), choice of an appropriate of energy mix for

the United States, and, options for high-level nuclear waste management. In some of the applications, AHP has been combined with other MCA methods, such as goal programming and compromise programming. In an application of AHP for global negotiations on climate change, the method has been used to compare the preferences of nations of the world to decide about the extent of reduction of greenhouse gases. In another application in utility planning, AHP has been applied to evaluate the best bids from private parties using criteria such as flexibility in starting date, fuel diversity, reputation of the bidder, and environmental impacts during generation and transmission.

4.2 MODM Methods

As discussed earlier, most of the MODM problems start with the following mathematical programming problem:

$$\begin{aligned} \text{maximize/minimize } Z_1 &= C_1X \\ \text{maximize/minimize } Z_2 &= C_2X \\ \text{maximize/minimize } Z_n &= C_nX \\ &\vdots \\ \text{subject to } AX &= b, \quad X \geq 0 \end{aligned} \tag{10}$$

where the values Z_i, $i = 1, 2, \ldots, n$, represent the n objective functions.

4.2.1 Goal programming

Goal programming (GP), likely the oldest school of MCDM approaches, was developed in the 1950s as an extension of linear programming. In its simplest form, the method of GP assigns so-called aspiration levels (also called targets or goals) for the achievement of different objective functions, and minimizes the deviations of actual achievement from the aspiration levels. It is important to stress here that that the term "goal" has the connotation of target when used in goal programming, whereas in the general MCDM context, the term "goal" is taken to represent a generalization of all criteria.

Consider Problem (10). Suppose T_i is the aspiration level for the objective function Z_i. This means that the decision maker expects to achieve around T_i for the objective function Z_i as given by the approximate equation, $Z_i \approx T_i$, which can be further written as $Z_i + d_i^- - d_I^+ = T_i$, where d_i^- and d_I^+ are deviational variables measuring deviations of actual achievement below and above the aspiration level. They are usually called underachievement and overachievement deviational variables, respectively. Because it is expected that the actual achievement will be as close to the aspiration levels as possible, the deviational variables are minimized in goal programming. Weights, reflecting the relative importance of the objective functions, can also be associated with the deviational variables during the minimization. Thus, one simple form of the goal programming objective function is given by the following relationship:

$$\min \sum_{i=1}^{n} \left(w_{in} d_i^- + w_{ip} d_i^+ \right), \tag{11}$$

where the values w_i are the weight given to minimizing the selected deviational variable from the aspiration level T_i. This objective has to be minimized subject to the original constraints of Problem (1).

Here are two major approaches in goal programming: minimizing the weighted function of goals (discussed previously) and preemptive goal programming that avoids the weighted summation in the goal programming objective function. In preemptive GP, the weights used in the objective function are preemptive weights as defined in Section 3.4. Other mathematical forms, such as minimizing the maximum deviation, fractional goal programming, and nonlinear GP, are also available in the literature. GP has been criticized by several authors. For example, it can, in some circumstances, choose the dominated solution. The criticisms can be overcome by careful applications of the method. In one application, GP has been used to provide energy resource allocation for the city of Madras in India. The minimum energy requirements for cooking, water pumping, lighting, and using electrical appliances form the main constraints of the model. The objective functions pertain mainly to the needs for minimizing cost, maximizing efficiency, minimizing consumption of petroleum products, maximizing employment generation, maximizing the use of locally available resources, minimizing emissions of oxides of carbon, sulfur and nitrogen, and maximizing convenience and safety. The trade-off information about the relative importance of these objectives has been obtained using the AHP.

4.2.2 Compromise Programming

The multiple objective functions Z_i in Problem (10) are often conflicting. Compromise among the multiple conflicting objective functions is defined as deviation or "distance" from the ideal solution. The compromise programming approach minimizes the

distance from the ideal solution. The distance is defined as

$$d_p = \left\{ \sum_{i=1}^{n} w_i^p \left[\frac{Z_i(x^*) - Z_i(x)}{Z_i(x^*)} \right]^p \right\}^{1/p}, \quad (12)$$

where x is the vector of decision variables in the optimization exercise, the values $Z_i(x)$, $i = 1, 2, \ldots, n$, are the n objective functions, $Z_i(x^*)$ represents the ideal solution [when the objective function $Z_i(x)$ is optimized separately without considering the other objective functions], w_i represents the weights to be provided to the objective function $Z_i(x)$, and the parameter p can range from 1 to ∞.

Note that the deviations of all of the objective functions, $Z_i(x^*) - Z_i(x)$, are divided by the respective ideal values. This is done because the objectives are measured in different units and are not comparable in absolute terms. In the literature, p has been interpreted as a degree of noncompensation among the objectives. The case $p = 1$ refers to when the objectives are perfectly compensatory, i.e., an increase in one can compensate for a decrease in the value of the other. The case of $p = \infty$, on the other hand, corresponds to absolute noncompensation, i.e., the objectives are of completely different natures, and improvement in one does not compensate for worsening of the others. Thus, when compromise programming is used, one will have to minimize d_p subject to the original constraints, $AX = b$, $X \geq 0$.

Compromise programming has received some energy applications, especially related to utility planning and environmental economics. In an application, the method has been used to aid the utility planners to select the best bids for generation capacity addition. Bids from independent power producers have been evaluated using multiple objectives—minimizing cost, minimizing emissions, and maximizing qualitative measures such as flexibility, fuel diversity, reputation, etc., subject to constraints representing demands, capacity limits for individual generator and transmission projects, budget constraints, hydro energy availability, fuel production and transportation capacity limits, and minimum utilization of generation capacity. Note that the first two objectives are quantifiable whereas the remaining objectives are not directly quantifiable. Although the compromise programming model has used the first two objectives directly, other qualitative objectives have been handled using AHP.

4.3 Other Methods

The field of MCDM features many more techniques for solving MCA problems. Only a few were described in the previous section. Other techniques include ELECTRE, PROMETHEE, an aspiration-level interactive method, TOPSIS, the reference point approach, multiobjective linear programming, and data envelopment analysis. A technique named preference ratios through intervals in multiattribute evaluation (PRIME) is a relatively recent method that deals with incomplete information about the preferences of the decision makers. An approach involving measuring attractiveness by a categorical-based evaluation technique (MACBETH) was developed in Europe in the 1990s. It is an interactive approach for cardinal measurement of judgments about the degrees of attractiveness in decision processes. Other methods based on an outranking approach (the approach initially used in the ELECTRE methods) include the QUALIFLEX method, the ORESTE method, and the TACTIC method. There are more methods, such as the utilitiés additives UTA) method, the ZAPROS method, and the NIMBUS method. Most of these methods are described in the literature mentioned in the list of suggestions for further reading.

Glossary

coefficient of performance The ratio of energy transferred out of a system (e.g., an air conditioner or heat pump transfers heat from inside a house to outside the house) to the energy input to the system.

competitive market Pertains to the degree that energy prices and supply are influenced or set by any particular group in the market; if energy prices and supplies are set by many market participants (no monopoly or monopsony power) and not by regulatory bodies, the market is said to be competitive.

corporate average fuel efficiency (CAFE) For new cars, a standard by which the average of all cars sold in the United States by a manufacturer must achieve 27.5 miles per gallon.

dynamic linear programming model A multiperiod linear programming model that is composed of multiple smaller linear program models (one for each time period) that are linked with intertemporal constraints; a dynamic linear programming model provides the optimal value of the objective over all time periods—decision making with perfect foresight.

efficiency The ratio of the energy output by an energy system to the energy content of the fuel input to the energy system.

exajoule (EJ) A unit of energy equal to 10^{18} joules; 1.0556 EJ is approximately 1 quadrillion Btu.

Gauss–Seidel convergence algorithm An iterative method for solving large linear or nonlinear models; in the National Energy Modeling System (NEMS), the algorithm finds where supply equals demand and the delivered prices for which this happens.

greenhouse gases Gases that have the property of absorbing or trapping energy in the earth's atmosphere; such gases include carbon dioxide, methane, and a number of manmade chemicals used in refrigeration and manufacturing, with the latter group being collectively known as "high global warming potential" gases.

intermittent technologies Pertain to technologies whose energy production is intermittent (e.g., wind, photovoltaics); for intermittent technologies, energy production depends on factors other than the availability of the technology (e.g., availability of wind and sunlight).

learning factor Pertains to the rate by which manufacturing costs decline for every doubling of capacity.

linear programming model A mathematical model with a linear objective function and linear constraints.

load shape Pertains to the time profile of energy consumption.

logit function A function form that often includes exponential functions in the denominator and numerator; it is typically used to determine market shares.

market diffusion Pertains to the adoption of a new technology or features into the market.

merit order dispatch Pertains to the order in which power plants are brought online and used to satisfy electricity demand; a merit order dispatch requires that plants be brought online in order of increasing operating plus fuel costs.

overnight capital cost Usually pertains to the costs quoted for electric power generation plants; overnight costs include all manufacturing costs, including owners' costs

 © 2004 Elsevier Inc. All rights reserved.

and project contingency but not interest during construction.

reference energy system A schematic representation of energy flows in an energy system, from energy production, to intermediate conversions and transformations, to delivery at end use.

renewable portfolio standard Pertains to a potential policy requiring that a minimum percentage of all generation be provided from renewable energy sources such as wood, wind, other biomass, and geothermal.

Residential Energy Consumption Survey (RECS) A survey that was developed and is published periodically by the Energy Information Administration.

technological change Pertains to changes in the development, adoption, and characteristics of technologies, including innovations, efficiency improvements, cost reductions, and the addition of new qualitative features such as variable speed fans.

technological optimism Pertains to cost and performance (mis)estimates for technologies that have not been commercialized. Prior to commercialization, manufacturing costs tend to be underestimated and performance tends to be overestimated.

unit energy consumption (UEC) A surrogate term used to measure efficiency in a process that combines structures and energy conversion systems.

The development and introduction of new technologies to the market, relative costs and performance of technologies, physical lifetimes of installed equipment (which influence the natural turnover rate), and consumer preferences are key factors that determine the rate of market diffusion of technologies and how quickly energy use patterns, energy efficiency, and energy-related environmental emissions in a society can change. Estimates of the costs and benefits of new energy policies, such as those that may be implemented to constrain carbon dioxide or other greenhouse gas emissions, will depend on estimates of how rapidly advanced technologies are accepted in the market and how quickly existing end use equipment reaches the end of its useful life (i.e., wears out). Consequently, the representation of technological change, market diffusion, and other economic flexibility embodied in any energy–economy modeling system will be major determinants of the projected energy–economy adjustments or responses to policy/price changes. This article provides an overview of the National Energy Modeling System (NEMS), which was developed and used by the Energy Information Administration (EIA) to address energy–economic–environmental policy questions for the U.S. government—typically Congress and the executive branch of government. A brief example of a recent NEMS application in assessing the potential impact of a 20%, nonhydroelectric, renewable portfolio standard (RPS) by 2020 on U.S. energy markets is also provided. The second national energy modeling system described in this article is the Canadian MARKAL model, one of the numerous variants of the market allocation (MARKAL) model, a dynamic linear programming formulation of the Canadian energy markets.

1. INTRODUCTION

The purpose of this article is to provide an overview of arguably two of the most prominent and influential national energy modeling systems used over the past decade or so: the National Energy Modeling System (NEMS) and the MARKAL model. NEMS was developed by the Energy Information Administration (EIA) during the early 1990s to analyze U.S. energy markets and is important because it is the primary analytical and projection tool used by the U.S. Department of Energy to analyze the energy, economic, and environmental impacts of proposed energy policies for the U.S. government. MARKAL is important because it has been used by more than 50 countries and 70 regional governments to analyze the impact of energy strategies and is supported by an international group of experts and the International Energy Agency (IEA).

The persistence of and refinements to these models over the past decade or so reflect both the increasing complexities of proposed energy–environmental policies and the recognition that energy policy has important impacts on an economy, even though energy's share of gross domestic product (GDP) may be less than 10%.

The next section of this article provides an overview of NEMS with more detailed descriptions of the residential and electricity generation markets to illustrate how two representative energy sectors are modeled in the system. This is followed by an example of the use of NEMS in policy analysis—a renewable portfolio study. The subsequent section provides an overview of MARKAL. The final section provides an example of policy analysis using the MARKAL model.

2. OVERVIEW OF NEMS

This section provides a brief overview of NEMS. A more extensive treatment of the NEMS model is

provided on the EIA's Web site (www.eia.doe.gov). NEMS is a large, technology-rich, regional, computer-based energy–economy model of U.S. energy markets for the midterm period through 2025.

In 1990, the secretary of the U.S. Department of Energy (DOE) directed that NEMS be developed. NEMS was designed and developed to support energy policy analysis and strategic planning, based on recommendations from the National Research Council (NRC) of the National Academy of Sciences.

Key features implemented in NEMS included (1) regional outputs of energy, economic, and environmental activity of the U.S. economy; (2) use of a modular modeling structure to facilitate and enable the model builders to work with particular aspects of the model independently; (3) integration of engineering and economic approaches to represent actual producer and consumer behavior; (4) use of a projection period spanning 20 to 25 years; and (5) incorporation of the broader energy analysis community and outside peer groups in the design and update of NEMS.

NEMS was completed at the end of 1993 and was used for the first time to develop the *Annual Energy Outlook 1994, with Projections to 2010*. More recently, NEMS has been extended to 2025 and further revised to address electricity restructuring and carbon mitigation issues and numerous other multipollutant policy studies.

NEMS is used to develop baseline projections that are published annually in the *Annual Energy Outlook* (*AEO*). NEMS is also used by analysts to prepare special studies that are requested by the U.S. Congress, the DOE Office of Policy, other DOE offices, and other government agencies. In accordance with the requirement that the EIA remain policy neutral, the *AEO* projections assume that all existing legislation, regulations, and policies remain unchanged. Furthermore, these projections depend on additional uncertain assumptions, including the estimated size of the economically recoverable resource base of fossil fuels, changes in world energy supply and demand, the rate at which new energy technologies are developed, and the rate and extent of their adoption and penetration. Consequently, the *AEO* projections are not meant to be predictions about the future. This article describes an updated version of NEMS used for the *AEO 2000*.

2.1 Purpose of NEMS

The primary purpose of NEMS is to analyze the energy-related consequences for the United States of alternative energy policies or pertinent economic or energy market influences. The policy questions of interest have determined the level of detail required within the structure of NEMS. For example, environmental issues relating to energy production and consumption have taken on new importance with the implementation of the Clean Air Act Amendments (CAAA) of 1990 and the proposed Kyoto Protocol on greenhouse gases (GHGs) in 1997. Accordingly, NEMS is designed to measure seven emissions (sulfur oxides [SO_x], nitrogen oxides [NO_x], carbon, carbon monoxide [CO], carbon dioxide [CO_2], volatile organic compounds, and mercury) released in the use of energy products to generate electricity and, in the case of carbon (or CO_2), to constrain national emissions using a pricing mechanism. The technology representation in NEMS is particularly helpful in the analysis of national carbon mitigation policies and utility sector SO_x, NO_x, and mercury mitigation policies due to its explicit representation of vintage (time-dependent) energy equipment and structures (e.g., building shells) and the careful tracking of vintage capital stock turnover rates. For similar reasons, NEMS contains sufficient detail in the transportation sector to project the use of alternative or reformulated fuels such as compressed natural gas, ethanol, and methanol. In addition to environmental concerns, NEMS is designed to account for existing and emerging government regulations (e.g., electricity restructuring), the potential for the development and use of new energy-related technologies, the increased use of renewable sources of energy (especially intermittent technologies), and the potential for demand-side management, conservation, and increases in the efficiency of energy use. These topics reflect the expected scope of current and future government policy.

The NEMS representation of energy markets focuses on four important interrelationships: (1) interactions among the energy supply, conversion, and consumption sectors; (2) interactions between the domestic energy system and the general domestic economy; (3) interactions between the U.S. energy system and world energy markets; and (4) interactions between current production and consumption decisions and expectations about the future.

2.1.1 Domestic Energy System/Economy Interactions

The general level of economic activity in sectoral and regional detail has traditionally been used as an explanatory variable or "driver" for projections of energy consumption and prices. In reality, energy prices and other energy system activities themselves

influence the level of economic activity. NEMS is designed to capture this "feedback" between the domestic economy and the energy system. Thus, energy price changes are capable of affecting macroeconomic variables such as GDP.

2.1.2 Domestic and World Oil Market Interactions

The world oil price (WOP) is a key variable in domestic energy supply and demand decision making. As a result, WOP assumptions have been a key starting point in the development of energy system projections. In fact, the U.S. energy system itself exerts a significant influence on world oil markets, and this in turn influences the WOP—another example of a feedback effect. World energy market supply and demand are first specified outside of NEMS. Given this, NEMS models the interactions between the U.S. and world oil markets, with changes in U.S. oil markets affecting world supply and demand. As a result, domestic energy system projections and the WOP are made internally consistent.

2.1.3 Economic Decision Making over Time

The production and consumption of energy products today are influenced by past decisions to develop energy resources and acquire energy using capital. Similarly, the production and consumption of energy at a future time are influenced by decisions made today and in the past. Current investment decisions depend on expectations about future market circumstances. For example, the propensity to invest now to develop alternative energy sources is greater when it is expected that future energy prices will be higher. NEMS allows the application of different kinds of foresight assumptions to be applied differentially to its individual submodules. This feature allows the consequences of different kinds of planning horizons to be incorporated into NEMS projections.

2.2 System Design of NEMS

Like its predecessor models (e.g., the Intermediate Future Forecasting System [IFFS]), NEMS incorporates a market-based approach to energy analysis. NEMS balances the supply of and demand for energy for each fuel and consuming sector, taking into account the economic competition between energy sources.

NEMS is partitioned into a modular system, which is solved by applying the Gauss–Seidel convergence method with successive overrelaxation. The modules of NEMS represent each of the fuel supply markets, conversion sectors, and end use consumption sectors and also include interactive macroeconomic and international modules. The primary flows between these modules are the delivered prices of energy and the energy quantities consumed by product, region, and sector but also include other information such as economic activity and technology characteristics. The delivered prices of fuels incorporate all of the activities necessary to produce, import, and transport fuels to the end users. Figure 1 provides a system overview of NEMS.

The integrating methodology controls the independent execution of the component modules. The modules are executed from the integrating module. To facilitate modularity, the components do not pass information to each other directly but instead communicate through a central data file. This modular design provides the capability of executing modules individually or to alternative modules, thereby allowing decentralized development of the system and independent substitute analysis and testing of individual modules. Furthermore, this modularity allows the flexibility of using the methodology and level of detail that is most appropriate to represent each energy sector.

A solution is achieved by equilibrating on the delivered prices and quantities of energy demanded, thereby ensuring an economic equilibrium of supply and demand in the consuming sectors. Each fuel supply, conversion, or end use demand module is called in sequence by the integrating module and solved, assuming that all other variables in the other energy markets are fixed. For example, when solving for the quantities of fuels demanded in the residential sector for an input set of energy product prices, all other sectors of the economy are held fixed. The modules are called iteratively until successive end use prices and quantities remain constant within a specified tolerance. This equilibration is achieved annually through the midterm period to 2025. Table I provides a summary of NEMS products and regional details. NEMS reflects market economics, industry structure, and energy policies and regulations that influence market behavior.

NEMS consists of four supply modules (oil and gas, natural gas transmission and distribution, coal, and renewable fuels), two conversion modules (electricity and petroleum refineries), four demand modules (residential, commercial, transportation, and industrial), one module to simulate energy–economy interactions (macroeconomic activity), one module to simulate world energy–domestic energy interactions (international energy activity), and one module to provide the mechanism for achieving a

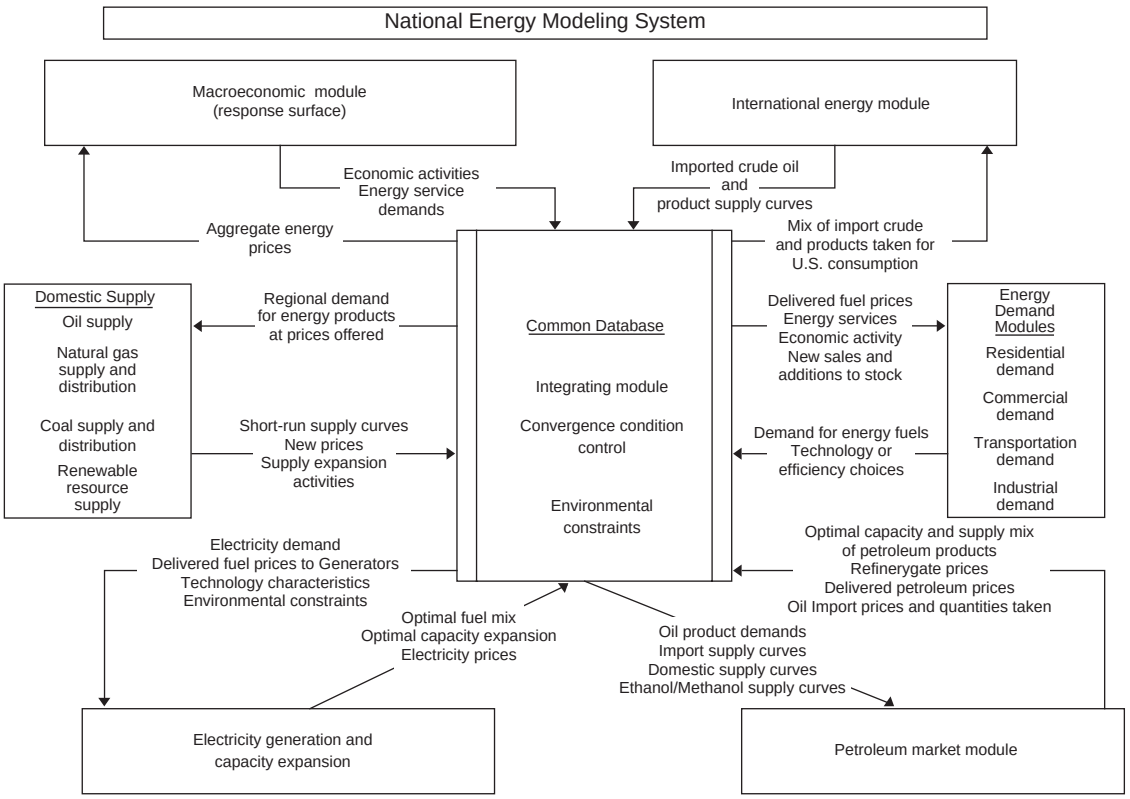

FIGURE 1 NEMS systems view.

general market equilibrium among all of the modules (the integrating module).

2.3 Foresight

All of the NEMS supply modules require assumptions of future energy prices and demands for energy so as to make capacity expansion decisions. Recognizing that there is valid evidence that decision making varies by sector, one implementation of foresight in NEMS allows each sector to use those foresight and behavioral assumptions deemed most appropriate for that sector. Two alternative decentralized options that have been implemented for foresight are myopic (i.e., assuming, within any forecast year, that the current prices will remain constant into the future for capacity expansion decisions) and extrapolative (i.e., assuming, within any forecast year, that expected prices, demands, and supplies are a function of historical trends and other critical assumptions regarding behavior). In the simplest case, the extrapolation may be a growth rate applied to the current forecast year.

Perfect foresight has been implemented using a recursive process where the previous run's prices are used as the expectations.

2.4 Emissions

Recognizing the importance of environmental issues associated with the use of energy, an environmental accounting capability has been incorporated within NEMS. Seven emissions are accounted for in the electricity generation sector: sulfur dioxide (SO_2), NO_x, CO, CO_2, carbon, volatile organic compounds, and (most recently) mercury emissions from power plants. A subset of these emissions is computed for energy production activities and fuel combustion. In addition, NEMS is designed to represent all current environmental regulations (e.g., CAAA of 1990) as well as other mandated costs for controlling toxic substances.

NEMS also incorporates the capability of constraining systemwide CO_2 emissions as well as SO_2 emissions, NO_x, and mercury emissions in the utility market—important features for policy analysis. One option for achieving a prescribed level of systemwide CO_2 emissions is accomplished by raising the cost of producing emissions until the total system emissions are reduced to the level of the constraint. Another approach used in the utility market for SO_2 is to incorporate the constraint directly into a linear program. This is

TABLE I

Summary of NEMS Modeling Details

Energy system activity	Categories	Regions
Primary supply		
Oil	Conventional	Six lower 48 onshore
	Enhanced	Three lower 48 offshore
	Heavy oil	Three Alaska
	Shale oil	
Gas	Conventional nonassociated	Six lower 48 onshore
	Conventional associated	Three lower 48 offshore
	Coalbed methane	Three Alaska
	Three other types	
Natural gas transmission and distribution	Residential, commercial, industrial, utility firm versus interruptible Peak versus offpeak	12: nine census divisions, with further subdivisions for key transportation issues
Coal	Four sulfur categories	16 supply regions
	Four thermal categories	
	Deep and surface mining types	
Renewables	Hydropower, wind, geothermal, solar thermal, photovoltaic, municipal solid waste, biomass	Natural Environment Research Council/ Refining/Census
Conversion		
Electricity (including uranium for nuclear)	Utilities, independent power cogeneration	13 supply regions Nine census demand regions
Refining	Five crude categories 19 products	Three petroleum allocation for defense districts
Energy demand		
Residential	Eight end use services	Nine census divisions
	Three housing types	
Commercial	Eight end use service	Nine census divisions
	11 building types	
Transportation	Six vehicle size categories	Nine census divisions
	10 vehicle age categories	
Industrial	35 industries	Four census regions shared to nine census divisions
	Nine primary industries	

the method used by the electric market module to constrain SO_2 emissions as mandated by the CAAA of 1990.

2.5 Policy Analysis Capability with NEMS

The following list illustrates the main analytical capabilities available with NEMS:

• *Federal tax policies/fees:* impacts of energy tax policies on the economy and energy system; impacts of Btu or carbon taxes; revenue recycling options (how portions of taxes are recycled through the economy: all to consumers, all to deficit reduction, or some other combination); federal reaction to rising unemployment (accommodating or not)

• *Emissions caps/restrictions:* carbon emissions cap (cap and trade impacts) from all sectors; national sulfur cap from electricity generation; NO_x cap from electricity generation; mercury emissions cap from electricity generation; other emissions caps

• *Effects of existing and proposed government laws and regulations related to energy production and use:* impacts of electricity restructuring on prices and treatment of stranded costs; impacts of renewable portfolio standards (RPSs); impacts of

increased use of renewable energy sources; potential savings from increased efficiency of energy use; changes in emission levels due to environmental policies; effects of appliance efficiency and building shell standards on energy consumption; impacts of fuel use restrictions (e.g., required use of oxygenated and reformulated gasoline, mandated use of alternative-fueled vehicles) on emissions, energy supply, prices, and economic growth; changes in natural gas prices and pipeline and import capacity in response to regulatory initiatives; impacts of automobile CAFE standards

- *Impacts of advanced/alternative technology menus/cost/performance:* potential impacts of new and advanced energy production, conversion, and consumption technologies; impact on technology learning of accelerated demonstration plants for utilities (government-funded/mandated capacity additions to accelerate learning and reduce capital and/or operating and maintenance [O&M] costs); impacts of new technologies on consumption and production patterns and emissions; impacts on the production of crude oil and natural gas resulting from improvements in exploration and production technologies
- *Oil market assessment:* responses of the energy and economic systems to changes in world oil market conditions as a result of changing levels of foreign production and demand in the developing countries.

2.6 NEMS Residential Sector

The residential demand module forecasts fuel consumption and energy equipment choices in the residential sector for 9 census divisions, 3 housing types (single-family, multifamily, and mobile homes), and 10 end uses of which 8 (space heating, space cooling, water heating, refrigerators, freezers, lighting, clothes dryers, and cooking) have equipment choices associated with them.

2.6.1 Important Interactions with NEMS

NEMS is initialized with information about the state of the U.S. energy system for a recent historical year. With respect to the residential demand module, this includes base year housing stock and retirement rates, appliance stocks and life expectancies, new appliances to be made available in current and future years with their costs and efficiencies, housing shell integrity (efficiency index), unit energy consumption per end use and household, and square footage per household and housing type. In addition, assumptions about population and associated demographics developed by the U.S. Department of Commerce are provided as inputs to the projection.

NEMS provides to the residential modules forecasts of residential energy product prices and new housing starts (Fig. 2). The housing stock submodule begins by adjusting the previous year's housing stock by adding new construction (new housing starts) and

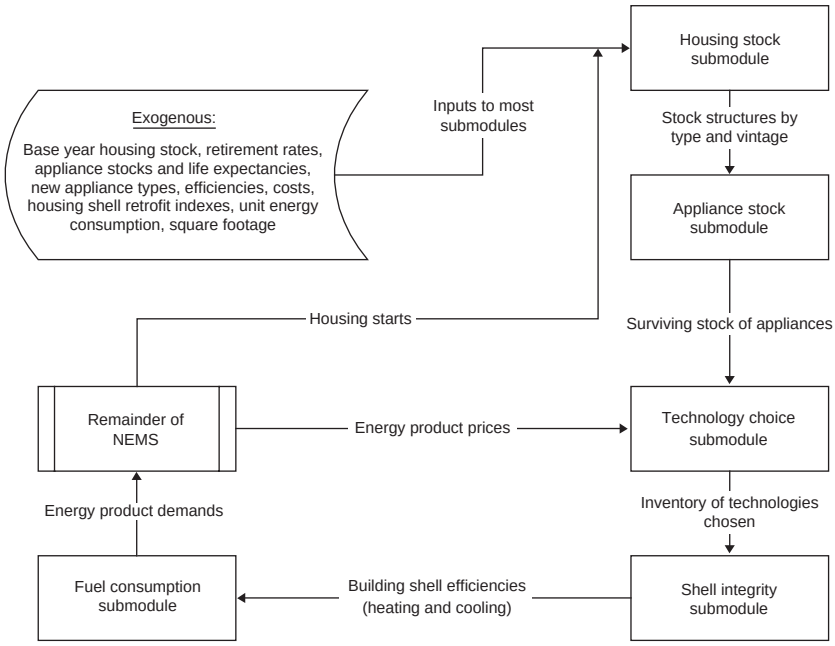

FIGURE 2 Residential demand module.

subtracting housing retirements. The new housing stock is allocated to each of the three housing types based on a combination of historical shares and income distribution and demographic changes. Control is then transferred to the appliance stock module, which (1) retires appliances in homes that were retired, (2) retires appliances that have reached the end of their useful lives, and (3) prepares the menu of technology choices with their associated cost and performance characteristics. Control is then transferred to the technology choice submodule. This submodule, using equipment cost and performance data with estimated consumer preference functions, selects appliances to replace retired appliances and appliances needed for new housing. Control is then passed to the shell integrity submodule, which adjusts the heating and cooling requirements of each building type based on an autonomous change to shell efficiency (improvements that are independent of price) and price-induced changes to building efficiency.

Once the appliances have been selected for each end use and end use energy intensities have been adjusted for changes to shell integrity and lifestyle changes such as increasing floor space per household, the energy consumption module computes energy consumption by fuel and census division, and this is passed back to NEMS for response. Figure 3 provides an overview of the residential demand module with an emphasis on the appliance and fuel choice components.

2.6.2 Equipment Characterizations and Choice Methodology

2.6.2.1 Technology Characterizations Residential sector energy technologies are characterized by (1) retail cost of equipment plus installation, (2) efficiency of the equipment, (3) dates available for purchase (efficiency standards may limit availability during future years), and (4) technological evolution, that is, either projected efficiency increases or projected cost declines. Cost reductions can be discrete

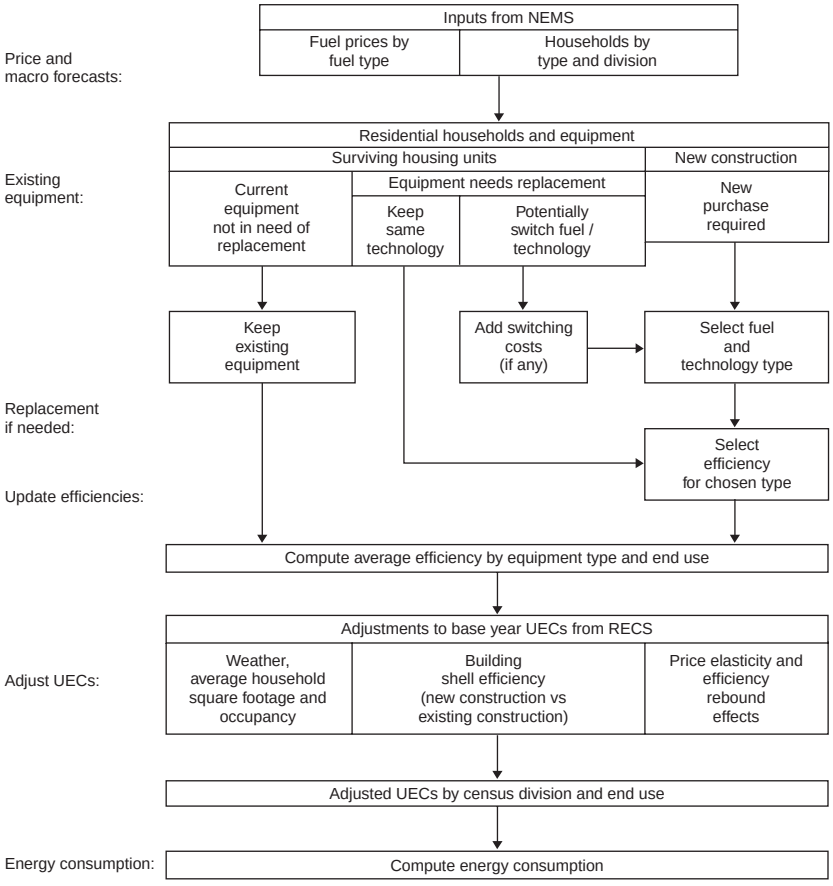

FIGURE 3 NEMS residential model overview. UECs, units energy consumption; RECS, Residential Energy Consumption Survey.

(e.g., a new characterization of a technology in a given year) or continuous (e.g., annually declining costs modeled for new heating technologies).

2.6.2.2 Market Penetration/Consumer Choice Algorithm The choice of equipment in the residential demand sector is made using a two-step selection process that incorporates the following important residential market attributes: (1) the inclination not to replace equipment until it fails (i.e., "if it isn't broken, don't fix it"), (2) the predisposition to stay with the same technology when equipment needs to be replaced, and (3) the incorporation of switching costs ("real and perceived") when changing to a different fuel is contemplated.

Technology choice/penetration is a two-step process in the NEMS residential energy model. Equipment choices are segmented by new and replacement equipment. For equipment decisions in new homes or for replacement decisions that consider fuel switching as an option, the first step is to decide on what fuel and general equipment type will be used for each end use (e.g., natural gas furnace for space heating). The second step is to select the efficiency of the equipment (e.g., the furnace). For replacement decisions that do not consider fuel switching or technology switching, the only decision made is to select the efficiency of the technology. NEMS uses a logit function to represent the decisions made in each of these two steps.

In the residential sector, technologies compete on the basis of relative importance of installed cost and operating cost for each technology. Equipment choices are segmented by new and replacement equipment for each of nine census divisions and each of three building types.

2.6.2.3 Fuel–Technology Class Choice The following calculation is performed as the first step in determining the fuel–technology class combination in new homes and when considering fuel switching when replacing worn equipment. When fuel switching is considered for replacement decisions, a matrix of switching costs from one equipment/fuel type to another is added to the installed capital costs before computing life cycle costs. Life cycle costs are based on the implicit hurdle rate for each end use and technology combination using 7 years as the time horizon over which discounted costs are calculated. These hurdle rates combine not only financial aspects (the cost of money) but also nonfinancial aspects (institutional and physical obstacles and perceived risks). The implicit discount rates range from 15 to more than 100%. The time horizon of 7 years reflects the fact that the average time between moves for homeowners in the United States is less than 7 years, and a longer time horizon for calculating discounted costs seems inappropriate for simulation purposes.

If LC_i is the life cycle cost of the representative technology for each fuel–technology class i, the share allocated to fuel–technology class i is given by the logit function

$$S_i = \frac{\exp(a_i + b_i LC_i)}{\sum \exp(a_j + b_j\, Lc_j)};\ \ j = 1,\ n.$$

2.6.2.4 Efficiency–Technology Decision Each efficiency choice function is calibrated to historical shipment efficiency data; that is, the model replicates efficiency choices for historical years. The efficiency–technology decision is based on a three-parameter logit function of the form

$$S_i = \frac{\exp(a_i + b_i\, FC_i + c_i\, O\&M_i)}{\sum \exp(a_j + b_j\, FC_j + c_j\, O\&M_j)};\ \ j = 1,\ k_i,$$

where FC_i is the first cost of technology i, $O\&M_i$ is the O&M cost of technology i, and k_i is the number of technologies that use fuel i.

2.7 Electricity Market Module

The electricity market module (EMM) represents the capacity planning, generation, transmission and distribution, and pricing of electricity subject to delivered prices for coal, petroleum products, and natural gas; O&M costs for existing and new generation equipment; the costs of renewable fuels for generation; the capital costs of power generation investments; and electricity load shapes and demand. The submodules consist of capacity planning, fuel dispatching, finance and pricing, and load and demand-side management (Fig. 4). In addition, nonutility supply and electricity trade are represented in the fuel dispatching and capacity planning submodules. Nonutility generation from cogenerators and other facilities whose primary business is not electricity generation is represented in the demand and fuel supply modules. All other nonutility generation is represented in EMM. The generation of electricity is accounted for in 13 supply regions, whereas consumption is satisfied in the 9 census divisions.

Operating (dispatch) decisions are provided by the cost-minimizing mix of fuel and variable O&M costs, subject to environmental constraints. Capacity expansion is determined by the least cost mix of all

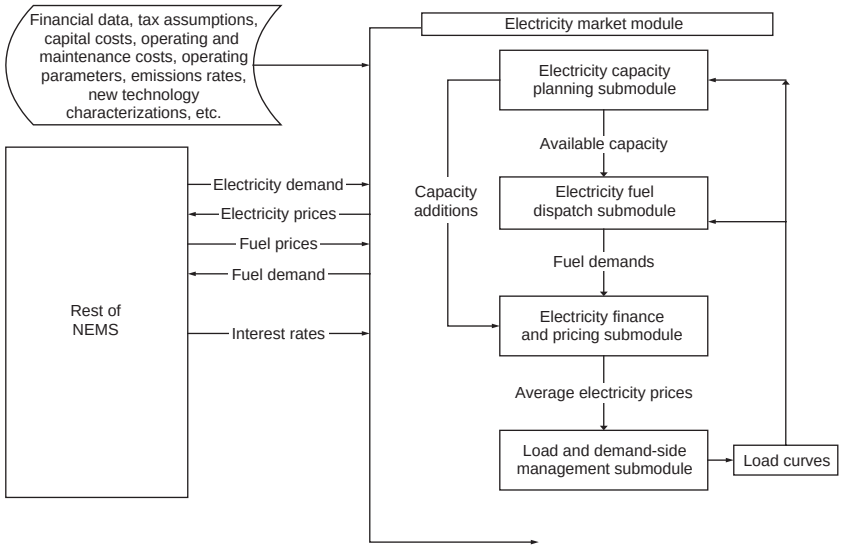

FIGURE 4 Electricity market module overview.

expected costs, including capital, O&M, and fuel, subject to meeting environmental restrictions and expected electricity demand. Construction of generating plants with long lead times is selected with planning horizons up to six periods into the future; the planning horizon can change with respect to the generating technology being considered. Electricity demand is represented by load curves, which vary by region, season, and time of day.

The solution to the submodules of EMM is simultaneous in that, directly or indirectly, the solution for each submodule depends on the solution to every other submodule. A solution sequence through the submodules can be viewed as follows:

- The load and demand-side management (LDSM) submodule processes electricity demand to construct load curves.
- The electricity capacity planning (ECP) submodule projects the construction of new utility and nonutility plants, the level of firm power trades, and the addition of scrubbers for environmental compliance.
- The electricity fuel dispatch (EFD) submodule dispatches the available generating units, both utility and nonutility, allowing surplus capacity in select regions to be dispatched for another region's needs (economy trade).
- The electricity finance and pricing (EFP) submodule calculates total revenue requirements for each operation and computes average and marginal cost-based electricity prices.

2.7.1 Load and Demand-Side Management Submodule

The LDSM submodule generates load curves representing the demand for electricity. The demand for electricity varies over the course of a day. Many different technologies and end uses, each requiring a different level of capacity for different lengths of time, are powered by electricity. For operational and planning analysis, an annual load duration curve, which represents the aggregated hourly demands, is constructed. Because demand varies by geographic area and time of year, the LDSM submodule generates load curves for each region and season.

2.7.2 Electricity Capacity Planning Submodule

The ECP submodule, a dynamic linear programming formulation of capacity expansion decision making, determines how best to meet expected growth in electricity demand given available resources, expected load shapes, expected demands and fuel prices, environmental constraints, and costs for utility and nonutility technologies. When new capacity is required to meet electricity demand, the timing of the demand increase, the expected use of the new capacity, the operating efficiencies, and the construction and operating costs of available technologies determine what technology is chosen.

The timing of the demand increase is important because the construction lead times of technologies differ. The ECP submodule looks up to six periods into the future when identifying new capacity needs. A multiperiod optimization is performed, whereby

capacity choices in each year are made by looking at several years in the future rather than at only a single year. Construction lead times also contribute to uncertainty about investment decisions. Technologies with long lead times are subject to greater financial risk. Compared with plants with shorter lead times, they are more sensitive to market changes in interest and inflation rates and are more vulnerable to uncertain demand projections that determine the need for new capacity. To capture these factors, the discount rate for each technology can be adjusted using risk premiums based on the construction lead time. The risk-adjusted discount rate results in the perception that a technology with a long lead time is less economically attractive than another technology with similar costs but a shorter lead time.

Uncertainty about investment costs for new technologies is captured in the ECP submodule using technological optimism and learning factors. The technological optimism factor reflects the inherent tendency to underestimate costs for new technologies.

The degree of technological optimism depends on the complexity of the engineering design and the stage of development. As development proceeds and more data become available, cost estimates become more accurate and the technological optimism factor declines. Learning factors represent reductions in capital costs due to "learning-by-doing." For new technologies, cost reductions due to learning also account for international experience in building generating capacity.

The decrease in overnight capital costs due to learning depends on the stage of technological development. The costs of a "revolutionary" technology are assumed to decrease much faster than the costs of mature technologies, ranging from 10% for every doubling of capacity for advanced technologies to 1% for every doubling of capacity for mature technologies.

Capital costs for all new electricity generating technologies (fossil, nuclear, and renewable) decrease in response to foreign and domestic experience. Foreign units of new technologies are assumed to contribute to reductions in capital costs for units that are installed in the United States to the extent that (1) the technology characteristics are similar to those used in U.S. markets, (2) the design and construction firms and key personnel compete in the U.S. market, (3) the owning and operating firm competes actively in the United States, and (4) there exists relatively complete information about the status of the associated facilities. If the new foreign units do not satisfy one or more of these requirements, they are given a reduced weight or are not included in the learning effects calculation.

Initially, investment decisions are determined in the ECP submodule using cost and performance characteristics that are represented as single-point estimates corresponding to the average (expected) cost. However, these parameters are also subject to uncertainty and are better represented by distributions. If the distributions of two or more options overlap, the option with the lowest average cost is not likely to capture the entire market. Therefore, ECP uses a market-sharing algorithm to adjust the initial solution and reallocate some of the capacity expansion decisions to technologies that are "competitive" but do not have the lowest average cost.

Fossil-fired steam plant retirements are calculated endogenously within the model. Fossil plants are retired if the market price of electricity is not sufficient to support continued operation. The expected revenues from these plants are compared with the annual going-forward costs, which are mainly fuel and O&M costs. A plant is retired if these costs exceed the revenues and the overall cost of electricity can be reduced by building replacement capacity.

Retirement decisions for nuclear capacity are also determined by the model. Four options for the operating license are considered. A unit (1) can be retired early (10 years prior to the end of the operation license), (2) can be retired when the license expires, or can be operated (3) an additional 10 years or (4) an additional 20 years by renewing the license. At each stage, the assumed aging-related expenditures due to capital additions, increased maintenance, and/or performance declines are compared with the cost of replacement capacity. A unit is retired if the aging costs, which are recovered over 10 years, exceed the cost of building new capacity.

The ECP submodule also determines whether to contract for unplanned firm power imports from Canada and from neighboring electricity supply regions. Imports from Canada are computed using supply curves developed from cost estimates for potential hydroelectric projects in Canada. Imports from neighboring electricity supply regions are computed in ECP based on the cost of the unit in the exporting region plus the additional cost of transmitting the power. Transmission costs are computed as a fraction of revenue. After building new capacity, the submodule passes total available capacity to the electricity fuel dispatch submodule and new capacity expenses to the electricity finance and pricing submodule.

2.7.3 Electricity Fuel Dispatch Submodule

Given available capacity, firm purchased power agreements, fuel prices, and load curves, the EFD submodule minimizes variable costs as it solves for generation facility use and economy power exchanges to satisfy demand during each time period and in each region. The submodule uses merit order dispatching; that is, utility, independent power producer, and small power producer plants are dispatched until demand is met in a sequence based on their operating costs, with least cost plants being operated first. Limits on emissions of SO_2 and NO_x (and mercury and CO_2 if such policies are requested) from generating units and the engineering characteristics of units serve as constraints. Coal-fired capacity can cofire with biomass to lower operating costs and/or emissions. During off-peak periods, the submodule institutes load following, which is the practice of running plants near their minimum operating levels rather than shutting them down and incurring shut-off and start-up costs. In addition, to account for scheduled and unscheduled maintenance, the capacity of each plant is derated (lowered) to the expected availability level. Finally, the operation of utility and nonutility plants for each region is simulated over six seasons to reflect the seasonal variation in electricity demand.

Interregional economy trade is also represented in the EFD submodule by allowing surplus generation in one region to satisfy electricity demand in an importing region, resulting in a cost savings. Economy trade with Canada is determined in a manner similar to that of interregional economy trade. Surplus Canadian energy is allowed to displace energy in an importing region if doing so results in a cost savings. After dispatching, fuel use is reported back to the fuel supply modules, and operating expenses and revenues from trade are reported to the EFP submodule.

2.7.4 Electricity Finance and Pricing Submodule

The costs of building capacity, buying power, and generating electricity are tallied in the EFP submodule, which simulates the cost-of-service method often used by state regulators to determine the price of electricity. Revenue requirements shared over sales by customer class yield the price of electricity for each class. Electricity prices are returned to the demand modules. In addition, the submodule generates detailed financial statements.

The EFP submodule also determines "competitive" prices for electricity generation. Unlike cost-of-service prices, which are based on average costs, competitive prices are based on marginal costs. Marginal costs are primarily the operating costs of the most expensive plant required to meet demand. The competitive price also includes a "reliability price adjustment," which represents the value consumers place on reliability of service when demands are high and available capacity is limited. Prices for transmission and distribution are assumed to remain regulated, so the delivered electricity price under competition is the sum of the marginal price of generation and the average price of transmission and distribution.

2.7.5 Emissions

The EMM tracks emission levels for SO_2, NO_x, and mercury. Facility development, retrofitting, and dispatch are constrained to comply with the pollution constraints of the CAAA of 1990 and other pollution constraints. An innovative feature of this legislation is a system of trading emissions allowances. The trading system allows a utility with a relatively low cost of compliance to sell its excess compliance (i.e., the degree to which its emissions per unit of power generated are below the maximum allowable levels) to utilities with a relatively high cost of compliance. The trading of emissions allowances does not change the national aggregate emissions level set by the CAAA, but it does tend to minimize the overall cost of compliance.

3. ANALYSIS OF A 20% NON-HYDROELECTRIC PORTFOLIO STANDARD

Concerns over the possibility that climate change may be caused by anthropogenic activities, particularly the combustion of fossil fuels, have raised interest in examining a series of policy options that may inhibit or reverse the growth of energy-related carbon emissions. Recently, a number of bills have been introduced by the U.S. Congress that would simultaneously reduce emissions of NO_x, SO_2, mercury, and CO_2 from power generators. Two of the more recent policy proposals include Senate bill S. 1766 and House bill H.R. 4. These analyses were developed using the *AEO 2002* version of the NEMS. Other related analyses have been performed at the request of the House Committee on Government Reform and the Senate Committee on Environment and Public Works. These may be viewed or downloaded from the EIA Web site.

The policy considered in this article is a 20% non-hydroelectric RPS. A typical RPS requires that a share of the power sold must come from qualifying renewable facilities. Companies that generate power from qualifying renewable facilities are issued credits that they can hold for their own use or sell to others. To meet the RPS requirement, each individual electricity seller must hold credits—issued to qualifying renewable facilities or purchased from others—equal to the share required each year. For example, a supplier of 10 TWh of retail electricity sales during a year with a 10% RPS requirement would have to hold 1 TWh of renewable credits. In a competitive market, the price of renewable credits would increase to the level needed to meet the RPS requirement. The RPS provides a subsidy to renewable generators (from nuclear, coal, natural gas, oil, and hydroelectric generators) to make them competitive with other resource options while allowing the market to determine the most economical renewable options to develop.

3.1 Assumptions of the RPS

In the 20% RPS case, we assumed the *AEO 2002* reference case assumptions in all areas except the following:

- A non-hydroelectric RPS of 20% by 2020 was assumed, growing linearly from approximately 2.5% in 2003 to 20% by 2020. A renewable credit trading system was assumed. Sellers of electricity must hold renewable credits that are equal to the minimum renewable portfolio fraction of generation assumed for each year.
- Because a renewable portfolio policy implies greater public acceptance and, as a consequence, lower legal and other preparation costs, the RPS incorporates the assumption that wind system costs will be lower, and the maximum allowable generation from intermittent technologies (e.g., wind, photovoltaics [PV]) was raised from 15 to 20% of total generation in the RPS case. (Many electricity market experts assert that even 15% intermittent power generation is too high without backup due to reliability. As a rough rule of thumb, intermittent power cannot exceed the reserve margin of the power control center.)
- All existing state and federal programs or mandates for renewable power generation are assumed to adhere to existing legislation and are not included in the costs attributed to federal RPS programs.

3.2 Results

In 2003, 12 states had RPSs, targets, or other incentive programs. Without the current federal and state wind programs, grid-connected wind systems or other intermittent renewable generation technologies are not expected to be economical in the United States over the midterm through 2020. Niche markets are another matter because electricity options are often quite limited.

Approximately 4.8 GW of capacity is expected to result from state RPS programs, and 2.2 GW is expected to result from other state-sponsored stimulus programs, over the 2001–2020 time frame. However, because of these capacity additions, technological learning is expected to result in cost reductions for wind; the projected lower wind costs become competitive with conventional fossil-fueled technologies in some regions of the United States during the 2015–2020 period. Renewable capacity built under these programs reduces the incremental quantity of renewable generation needed to comply with the federal RPS program.

3.3 Fossil Fuel Use and Electricity Market Impacts of the RPS

The penetration of renewable generation technologies reduces the construction of the more efficient gas combined cycle and coal gasification generation technologies that would have been built in the reference case, thereby reducing the overall stock efficiency of fossil-fueled electricity generation plants. In 2020, the RPS case is projected to build approximately 70 GW less combined cycle and 26.8 GW fewer new advanced coal units. Renewable generation capacity is projected to increase by approximately 166 GW, much of which is intermittent wind capacity ($\sim$99 GW above the reference case) (Fig. 5).

Fossil fuel consumption in 2020 is expected to be approximately 5.6% lower in the RPS case than in the *AEO 2002* reference case—down from 120.9 to 114.2 EJ. For electricity generation in 2020, fossil fuel consumption is expected to be approximately 19% lower than in the reference case—down from 37.7 to 30.4 EJ.

The RPS electricity production is expected to be slightly lower in 2020 than in the reference case ($\sim$30 TWh or 0.6%) due to the higher electricity prices that result from the RPS. However, electricity generation from non-hydroelectric renewables is expected to increase from approximately 160 TWh

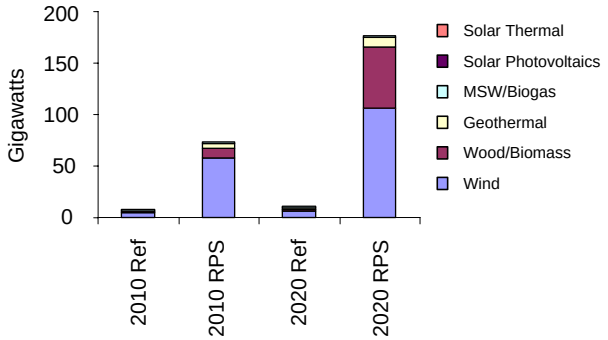

FIGURE 5 Renewable capacity additions: Reference versus RPS case. MSW, municipal solid waste; Ref, reference.

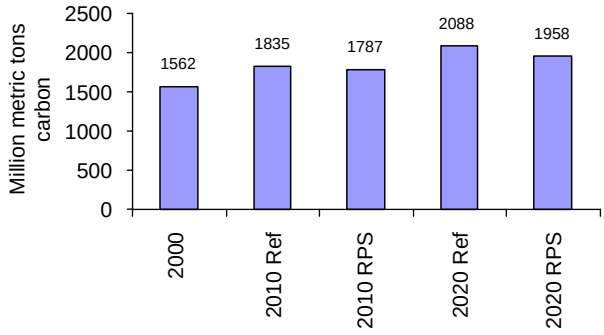

FIGURE 7 Carbon emissions: Reference versus RPS. Ref, reference.

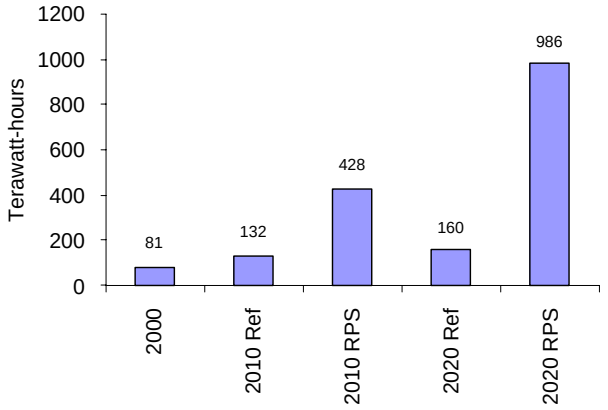

FIGURE 6 Non-hydroelectric renewable generation. Ref, reference.

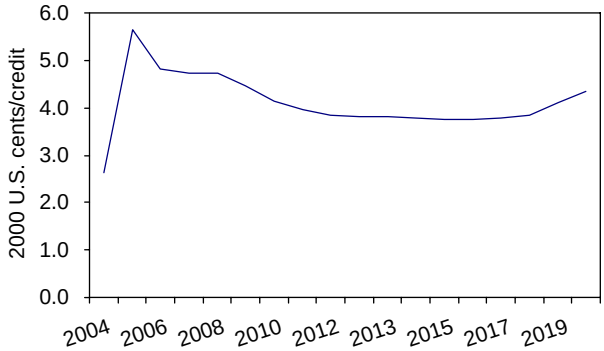

FIGURE 8 Renewable generation credit prices.

in the reference case in 2020 to approximately 986 TWh in the RPS case (Fig. 6). The primary contributors to non-hydroelectric renewable generation in the RPS case in 2020 are expected to be biomass generation from both dedicated plants and cofiring with coal (~476 TWh), wind systems (~335 TWh), and geothermal (~82.5 TWh).

3.4 GHG Emissions

NEMS projects only CO_2 emissions on a systemwide basis for the United States. In 2020, carbon emissions are projected to be approximately 6% lower in the RPS case than in the *AEO 2002* reference case (Fig. 7). However, carbon emissions from electricity generation are expected to be approximately 16.8% lower in the 20% RPS case than in the reference case despite meeting the 20% RPS target in 2020. Consequently, per capita carbon emissions are projected to decline by 0.4 metric tons (~5.5%).

3.5 Costs of the 20% Renewable Policy

Imposition of an RPS on the U.S. generation markets is projected to have a relatively mild adverse affect on delivered electricity prices but at a significant cost to the electricity industry. Electricity prices in 2020 in the RPS case are projected to be approximately 3% higher than in the reference case as a result of the costs that were added to electricity prices to conform to the RPS. The reduction in natural gas prices in the RPS case in 2020 relative to the reference case mitigates against the price increases that would otherwise have occurred due to the renewable credit prices paid and the additional capital invested in renewable generation technologies. However, the cost to the electricity industry over the next 18 years ranges between $38 billion and $59 billion (in 2000 U.S. dollars), using a discount rate ranging from 0 to 10%.

As the industry ratchets up its use of renewables to 20% by 2020, significant issues emerge regarding the ability of the U.S. renewable resources to continue to expand as evidenced by the rising renewable credit prices and the slowing expansion rate of wind and geothermal capacity (Fig. 8). For

example, geothermal resources are projected to have used more than 50% of all remotely competitive sites, although an additional 10 GW of capacity is possible at significantly inferior and costlier sites. Wind expansion in 2020 is expected to begin to be limited by the amounts of cost competitive wind resources remaining in regions that are sufficiently close to demand and transmission centers to allow further expansion. Although wind capacity is projected to reach 109 GW by 2020 under a 20% RPS, expansion beyond 150 GW is likely to be very expensive. The rapid growth in biomass generation eventually is likely to be limited by the competition between agricultural uses and the generation of an energy feedstock for biomass power generators. Furthermore, dedicated biomass gasification plants must be built within a 50-mile radius of their resources to be cost-effective; otherwise, transportation costs are likely to make biomass generation very expensive (by raising renewable credit prices).

3.6 Conclusions

A 20% renewable portfolio standard for the United States is expected to increase total consumer costs of electricity by approximately 3%. Although this does not appear to be significant on a national level, the regional distributional price effects can be quite significant. For example, producers in regions rich in coal- or gas-based generation are likely to experience much larger revenue reductions than will those that are rich in renewable resources. The RPS is likely to significantly increase the costs to the power generation industry, from $38 billion to $59 billion, for the period ending in 2020.

Whether the benefits of a 20% RPS outweigh the costs is a matter of considerable policy debate within the United States. The answer clearly depends on how costs and benefits are perceived and whether they can be measured at all.

4. OVERVIEW OF MARKAL

4.1 Purpose of MARKAL

MARKAL stands for market allocation. The model's original purpose was to evaluate energy technologies in a comprehensive and integrated framework. Since its initial implementation during the early 1980s, MARKAL has undergone several significant enhancements that have extended its scope to the computation of a competitive, dynamic, energy supply–demand equilibrium. The model represents all stages in the energy market—extraction, trade, conversion, and end use consumption—with each sector selecting from an array of technologies that produce and/or consume energy forms. The technologies, together with their input and output energy carriers, constitute a reference energy system (RES) of the regional energy system being modeled (local regions, countries, or provinces).

MARKAL's original capabilities as a tool for an economic assessment of technologies has been enhanced by the addition of new features to the model, including the ability to simulate endogenous technological learning, the inclusion of interregional trade variables, and the capability to represent major uncertainties.

MARKAL evaluates the economics of a technology in the context of the configuration of the entire energy system. This fact renders it difficult, if not impossible, to evaluate a single technology in isolation because its profitability depends on the presence or absence of competing technologies in all parts of the energy system.

MARKAL may be used in two distinct modes. In the first mode, a perfectly competitive energy market is simulated, where all economic agents (suppliers and producers) make their investment and operating decisions under perfect information and perfect foresight and minimize long-term energy system costs using a single discount rate. This mode is particularly useful for revealing the socially optimal set of technologies and for identifying those technologies that should be targeted to achieve the optimal technological mix over the long run. In the second mode, several market imperfections may be introduced to bring the model closer to a short- to medium-term forecasting tool. For instance, the assumptions of perfect information and of perfect foresight may be replaced by the introduction of uncertainty via stochastic programming or by using the model in a time-stepped fashion to simulate decision making with imperfect foresight. In addition, different discount rates may be assumed for different sectors (and even different technologies), thereby simulating the observed differences in behavior among economic agents. This forecasting mode is better suited to the short to medium term when simulating energy market agents under imperfect information.

4.2 MARKAL Model Structure

The MARKAL model minimizes energy system costs over a specific time horizon, subject to satisfying all of

the energy service demands and environmental or fuel use restrictions. This objective can also be viewed as minimizing the net social cost (or maximizing the social surplus) of the energy system, while satisfying a number of constraints, over the horizon.

We now proceed to flesh out several terms in the preceding description. To configure means to decide which technologies to invest in (and/or abandon) at different dates, which ones to operate (and at what level), how much of each energy form to produce during each period, how much of each energy form to buy and/or sell to other regions, and so on. In addition to time periods (which are usually 5 or 10 years long), MARKAL divides electricity demand into three seasons (winter, summer, and spring/fall) and two diurnal divisions (day and night). These time divisions result in six so-called time slices. These time slices are recognized only for technologies producing electricity or low-temperature heat, neither of which may be easily stored and so require a finer time disaggregation than do other energy forms. As a result, these two energy forms are disaggregated into time slices for each time period.

The energy system of a region includes energy supply sources such as mining, imports, and exports as well as processing, conversion of the various energy forms, and their transport (including interregional transport), distribution, and end use consumption by all sectors of the economy. These activities are represented in MARKAL by means of technologies, which consume and/or produce energy forms and/or materials (collectively termed commodities).

The end use technologies produce special kinds of commodities that are physical products or services for which demands are specified.

The set of technologies, demands, sources, and commodities determine the topology of the "reference energy system" of the region modeled. Figure 9 is a simplified representation of a typical MARKAL RES showing the five broad components usually recognized in each model instance: primary energy resources (SRC), energy conversion into electricity or low-temperature heat (CON), other energy processing (PRC), and energy end uses (DMD), with the right-most oval in the figure representing the demands (DM) for energy services and products.

Each "region" may be a country, a group of countries, or a province/state within a country. Multiregional MARKAL models have been created with a wide variety of geographical scopes, going from a relatively small community to the whole world divided into 15 regions. The regions are

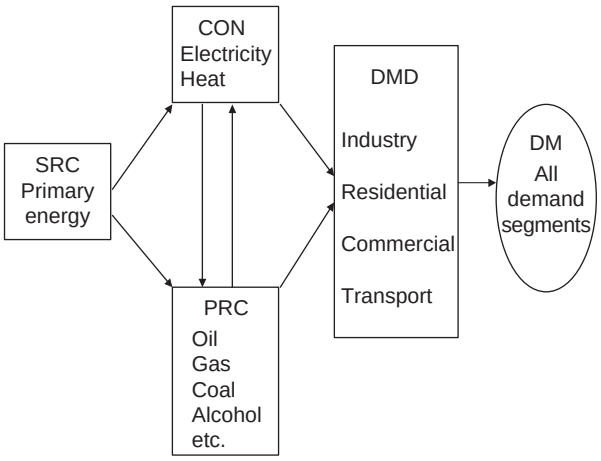

FIGURE 9 Simplified reference energy system. See text for abbreviations.

interconnected by technologies that transport energy forms (e.g., transmission lines, pipelines).

The "horizon" comprises at most nine periods, each having equal duration (usually 5 or 10 years, as chosen by the modeler). At least one of the initial periods is a historical period over which the model has no freedom and for which all of the quantities of interest are fixed to their historical values. This calibration to an initial period is one of the important tasks required for setting up a MARKAL model for a given region. The main variables that must be fixed are the capacity and operating levels of all technologies as well as extraction, exports, and imports for all energy forms and materials. Note that the initial period's calibration also influences the model's decisions over several future periods because the "profile of residual capacities" (i.e., capacities inherited from a historical period) is fully specified over the remaining lives of the technologies existing at the start of the model forecast horizon.

MARKAL minimizes the "total energy system cost," which includes the following elements: investments, fixed and variable annual O&M costs, commodity import costs, minus export revenues, and demand losses incurred from reduced product and service demands. To correctly account for the remaining value of all equipment that is still operating at the end of the horizon, a salvage value (i.e., residual value) of all such equipments is computed and subtracted from the total cost. This is an important feature; without salvage value, the investment decisions made by the model would be severely distorted, especially toward the end of

the planning horizon. Optionally, the user may also specify taxes and subsidies on some commodities (e.g., an emission tax on some pollutant). Because the various costs are incurred at different times over the horizon, each cost is first discounted to a fixed year before being added to the total cost. The same or different discount rates may be used for the various sectors and regions.

The constraints imposed by MARKAL are many. The main ones are as follows:

- *Satisfaction of demands*. A reference demand scenario is provided by the user, specifying the reference demand trajectories in all subsectors. These demands are set for the reference case but may later be modified by MARKAL if some alternate scenario is such that it alters the prices of end use demands (demands can be price elastic in MARKAL). Note also that prices are computed endogenously by MARKAL for all commodities and end use demands.
- *Conservation of investments*. If the model decides to invest in a piece of equipment at a certain period, the capacity is increased accordingly for the life of the equipment. At the end of that life, the capacity is decreased by the same amount (unless the model decides to extend the life of the equipment by investing in a life extension technology). While computing the available capacity at some time period, the model takes into account the capacity resulting from all surviving (unretired) investments up to that period. Some of those investments may have been made prior to the initial period and remain in operating condition (embodied by the residual capacity of the equipment), whereas other investments may have been made by the model at or after the initial period. However, the model is not forced to use all of the available capacity.
- *Use of capacity*. At each period, the model may use some or all of the available capacity in that period times the availability factor of the technology. In some cases, the model may decide to use less than the available capacity at certain time slices or even throughout the whole period. In other words, some capacity may be inactive during some time periods. Of course, this will occur only if such a decision contributes to minimizing the overall cost. Optionally, there is a provision for the modeler to force specific technologies to use their capacity.
- *Electricity balance*. At each period, during each time slice, and in each region, electricity produced plus electricity imported (from other regions) must be at least as much as electricity consumed plus electricity exported (to other regions) plus grid losses. A similar balance exists for low-temperature heat.
- *Balance for other energy forms*. This is the same as for electricity, but because time slice plays no role, there is only an annual balance equation.
- *Electricity peaking reserve constraint*. This constraint requires that at each time period and for each region, total available capacity exceeds the average load of the peaking time slice by a certain percentage. This percentage is called the peak reserve factor and is chosen to reflect the extra load at peak as well as uncertainties regarding electricity supply that may decrease capacity in an unpredictable way (e.g., water availability in a reservoir, unplanned equipment downtime). The peak reserve factor is typically set between 0.20 and 0.50. The peaking time slice is defined as the time slice when load is heaviest (it may be winter day in cold countries, summer day in warm countries, etc.).
- *Emissions constraint(s)*. The user may impose on the whole system upper limits on emissions of one or more pollutants. The limits may be set for each time period separately to simulate a particular emissions profile (also called emission target).
- *Base load (electricity generation only)*. The user may identify which technologies should be considered as base load technologies by MARKAL, that is, those whose operation must not fluctuate from day to night during a given season. The user may also specify what is the maximum fraction of night production that may be supplied from all base load technologies.
- *Seasonal availability factors (electricity sector only)*. The user may specify seasonal and even day/night limitations on the use of the installed capacity of some equipment. This is especially needed when the operation of the equipment depends on the availability of a resource that cannot be stored, such as wind or sun, or that can be partially stored, such as water in a reservoir.

The Canadian incarnation of MARKAL has the following specific features:

- It is composed of 14 linked MARKAL modules, one for each Canadian province and territory plus a U.S. model. All 14 modules are linked by a large number of energy trade variables as well as permit trading variables when required.
- Each provincial module contains full technological descriptions of energy extraction, electricity production, oil and gas processing, coal extraction, industrial processes of all energy-intensive industries, transportation, and residential and commercial end

uses. A typical provincial module contains more than 2000 technologies.

• The demand segments number more than 50 in each provincial module.

• There are more than 500 energy trade links among the 13 Canadian jurisdictions and the U.S. module, encompassing detailed representation of the oil and gas pipelines, electricity interties, and coal and refined petroleum products trading.

4.3 Representation of Energy Market Interactions

MARKAL maximizes the long-term net energy-related social surplus (i.e., the sum of energy-related producers and consumers surpluses) of a state, province, country, or group of countries. Equivalently, the model computes a least cost partial equilibrium on energy markets (i.e., the prices and quantities such that all quantities produced are consumed at the computed market clearing prices). In MARKAL, all energy forms (quantities by fuel type) and their prices are endogenous (computed by the model) and result from the optimization. The demands for products and services are also endogenous but in a different fashion; their price elasticities are chosen by the user, and these choices in turn determine the demand levels.

Mathematically, MARKAL optimizes a linear objective function subject to various constraints. The economic significance of the result of the optimization is twofold. First, the primal solution consists of the investment levels, capacities, and operating levels for all technologies as well as the amounts of each energy form extracted, traded, produced, and consumed by each technology. Second, the dual solution provides shadow prices for all constraints. Three types of shadow prices are of particular practical interest: those of the energy balance constraints (which provide prices for all energy forms), those of the emissions constraints (which provide the price of each pollutant whose emissions are capped), and those of the demand constraints (which provide a price for each demand for a good or service).

4.4 Technology Representation

Each technology is explicitly represented by its technical and economic parameters as follows:

- Nature and quantities of inputs and outputs per unit of technology
- Emission of each pollutant per unit of technology
- Annual availability factor of the technology
- Seasonal availability factors (electricity- and heat-producing technologies only)
- Technical life duration
- First period of availability
- Time profile of existing capacity (residual capacity at initial period)
- Investment cost per unit of capacity
- Fixed O&M cost per unit of capacity
- Variable O&M cost per unit of capacity
- Delivery cost per unit of each input into the technology
- Upper and/or lower bounds on capacity, on investment, and on operating level

Note that each parameter, except life duration and period of first availability, may be specified for each time period desired.

5. EXAMPLE APPLICATION OF THE CANADIAN MARKAL MODEL

In 1999, the Canadian government embarked on a systematic study of all aspects of climate change in Canada. This multistage process, named National Climate Change Implementation Process (NCCIP), directly involved a large number of stakeholders regrouped in 15 issue tables, charged with proposing a large array of measures and actions to reduce GHG emissions. The output from these issue tables was collected by the Analysis and Modeling Group (AMG), which was responsible for integrating the issue tables' proposals into a set of coherent strategies using several energy–economy models, including MARKAL. The MARKAL model was selected as one of two energy technology models to provide an integrated analysis of several paths to Kyoto, that is, to analyze the economic impacts on the Canadian economy of various ways of reducing GHG emissions. The results of the two energy technology models were then injected into the macroeconometric model TIM/RIM to complete the economic analysis with macroeconomic indicators.

The NCCIP was divided into two phases. During phase I, several paths to Kyoto were examined under fairly general economic instruments. During phase II, a restricted number of paths were examined more closely and the market instruments were made more precise.

5.1 Scenarios and Paths to Kyoto

5.1.1 Phase I of the AMG

Three scenarios were considered in addition to the baseline:

- *Canada acts alone (CA) scenario*. In this scenario, only Canada implements GHG reduction strategies, whereas the rest of the world does not. Therefore, the oil price remains the same as in the base case, and energy trade with the United States is negatively affected by Canada's GHG policies.
- *Kyoto–loose (KL) scenario*. Annex I countries (including the United States) implement Kyoto-like GHG reductions, and an international permit trading system is in place. The permit price is low ($25/metric ton [tonne] CO_2). Canadian electricity and gas trade is positively affected, but oil trade is negatively affected.
- *Kyoto–tight (KT) scenario*. The situation is the same as in the KL scenario except that the permit price is high ($50/tonne CO_2). Gas and electricity trade is positively affected, and oil trade is negatively affected but to different degrees than in the KL scenario.

A path describes the components of a GHG reduction strategy. Five paths were defined and simulated in the AMG phase I:

- *Path 0*. Force in all of the issue tables' measures without any imposed emissions target.
- *Path 1*. Impose a 1990−4.33% cap on each sector separately.
- *Path 2*. Impose a 1990−4.33% cap on the entire Canadian economy.
- *Path 3*. This is a variant of path 2 where the cap is imposed on approximately 90% of the Canadian emission sources, with the rest being treated via dedicated measures and actions.
- *Path 4*. This is a variant of path 3 where only approximately 40% of the GHG sources are covered by the cap, with the rest being treated via dedicated measures.

Path 0 is not really a path to Kyoto given that there is no guarantee that the desired target will be reached. The issue tables' measures are made available to the model but are not imposed in paths 1 to 4. In paths 1 to 4, only the sectors covered by permits could buy or sell permits from the international market. Path 2 is a 100% efficient path that achieves the target at minimum cost.

TABLE II

Cases Treated during Phase I

	Path 0	Path 1	Path 2	Path 3	Path 4
Scenario					
Canada acts alone	Y	Y	Y	Y	Y
Kyoto-tight			Y		Y
Kyoto-loose			Y		Y

Note. Y, yes.

The scenarios and paths potentially create 15 combinations. Of these, 9 were simulated during phase I plus the base case, as shown in Table II.

5.1.2 Phase II of the AMG

The CA scenario was dropped, and it was assumed that the Kyoto treaty was in effect and ratified by all industrialized countries except the United States.

Two carbon price scenarios were considered (high and low prices for permits). The paths considered (now called cases) were as follows:

- *Case 1*. This is similar to path 3 (maximum coverage of the economy). Permits were not allocated at all. Emitters must buy them at the prevailing carbon price.
- *Case 2a*. This is similar to path 4 (partial coverage of the economy). Permits were allocated gratis to covered industries in proportion to their emissions in 1990. The proportionality coefficient is calculated to achieve the Kyoto target.
- *Case 2*. This is similar to path 4 (partial coverage of the economy). Permits were allocated gratis but proportionally to the output of each industry in 2010.
- *Case 3*. This is similar to path 4 (partial coverage of the economy). Permits were allocated gratis according to a so-called triptych formula by sector and by province. The multiple-criteria formula was devised to favor development of some sectors and provinces while taking into account each sector/province's endowment in energy forms.

In addition to these, two sensitivity scenarios were simulated, both with case 2 only: one with an intermediate CO_2 price and the other with a supplementarity condition imposing a limit on the amounts of international permits that Canada was allowed to purchase. Table III shows the resulting 10 combinations that were simulated during phase II.

TABLE III

Cases Treated during Phase II

Carbon price	Case 1	Case 2	Case 2a	Case 3
High ($50)	Y	Y	Y	Y
Intermediate ($25)		Y		
Low ($10)	Y	Y	Y	Y
Supplementarity constraint		Y		

Note. Y, yes.

5.2 Some Results from the Analysis

5.2.1 Main Conclusions for Phase I

5.2.1.1 CA Paths

- Path 0 did not achieve the Kyoto target (fell short by more than 40%), and its total cost was quite large.
- Path 1 nearly achieved the Kyoto target (shortfall of 10%), with a total cost 2.5 times that of path 2.
- Path 2 (efficient path) achieved the Kyoto target at a net present value cost equal to $25 billion (the smallest of all paths).
- Path 3 (broad coverage) achieved the Kyoto target at a cost reasonably close to that of path 2. Because path 3 is more likely to be implementable in practice, it becomes a good candidate for further analysis and potential implementation.
- Path 4 (large final emitters coverage) achieved the Kyoto target at a cost closer to that of path 1 than to that of path 2. Therefore, narrow permit coverage is much less efficient than broad coverage.

5.2.1.2 KT and KL Paths When international permits are available, the overall Kyoto costs are significantly smaller than when Canada acts alone. In the KT path, Canada actually incurs negative costs when implementing the Kyoto GHG reductions. This is due to the increased energy trade with the United States (gas and electricity). In the KL path, overall costs for Canada are close to zero.

5.2.2 Main Conclusions for Phase II

- The overall cost for Canada of achieving the Kyoto target is very sensitive to the price of carbon rights, but it is much less sensitive to the case considered. For instance, for the high carbon price, the net present value varies from $+$12 billion to $+$18 billion, depending on the case analyzed. For the low carbon price, the net present value stays in the range of –$1 billion to –$2 billion.
- However, the sectoral and provincial detailed costs vary quite a bit from case to case. Cases 1 and 2a show heavy burdens on industries, whereas cases 2 and 3 succeed in smoothing the costs better across sectors. This is due to the output-based allocation of permits adopted in these two cases.
- The imposition of a 50% limit on permit acquisition proves to be quite costly for Canada. In the low carbon price (case 2), Canadian costs jump from –$2 billion to $+$5 billion.
- The triptych formula partially succeeds in alleviating the burden for the targeted provinces. It is inferred that some additional refinements of the formula would achieve a better repartition of the Kyoto burden than in case 2.

Glossary

cogeneration The simultaneous production of power (either electrical or mechanical) and useful heat (e.g., process steam) using a single fuel source.

energy service company A business that implements energy conservation measures for its customers and is paid by them part of the corresponding cost savings.

firm power Continually available power, or power that is available for a large, prespecified, part of the time.

"free" electricity or gas consumer A consumer free to choose a supplier of electricity or gas, in contrast to a "captive" consumer.

independent power producer An electrical power producer that is not a generation utility, i.e., does not have a concession contract and is not regulated. Independent producers compete, at their own risk, with other producers and, sometimes, with generation utilities in a power supply market.

indicative forward planning Prospective studies, carried out or contracted by government bodies, indicating possible expansion paths and providing guidance about future investment needs to interested agents.

Some of the current national energy policies in Brazil were adopted during the two terms of President Fernando Henrique Cardoso, from 1995 to 2002. Other policies that were set up earlier have evolved over time to their present form. Since the middle of 2003, under the government of President Luis Inácio Lula da Silva, who took office in January 2003, there have been proposals to change some of these energy policies. Potential shifts that may impact the national energy policy of Brazil include institutional and managerial changes in the country's energy supply industry; the fostering of some types of energy supply development and demand-side management programs; the formulation of energy price regulations; tariff making, with cross-subsidies for some large consumers; the granting of subsidies to the poor for fuel and electricity purchases; increasing the cross-links between energy and environmental policies; and integrating the approach to energy policymaking and forward planning. In this latter matter, the roles of the Ministry of Mines and Energy and the National Council for Energy Policy are of paramount importance.

1. ORGANIZATION OF THE BRAZILIAN ENERGY SUPPLY INDUSTRY

From the 1940s and through the 1950s and 1960s, the federal government of Brazil, with the help of the state governments, undertook the charge of assuring, through state-owned companies, the supply of most of the electricity, oil, and gas consumed in the country. A state monopoly for the production, importation, processing (with the exception of private refineries existing at that time), and transportation of oil and gas was defined by the 1953 mandate, Law No. 2004, and was granted to Petrobras, a federal-government-owned company created for the purpose. Distribution and retail trade of oil products were kept out of the monopoly, instead being shared between BR, a subsidiary of Petrobras, and large transnational oil supply companies such as Shell, Exxon, and Texaco. Some Brazilian states formed state-owned companies to distribute and trade initially town gas and later natural gas.

 © 2004 Elsevier Inc. All rights reserved.

The Brazilian government created Eletrosul, Furnas, Chesf, and Eletronorte to generate and transmit electricity for, respectively, the southern, southeastern/midwestern, northeastern, and northern regions of the country, putting all of these entities under the control of a holding company called Eletrobras. Chesf also sells electricity for some very large consumers in the northeastern region, and Eletronorte, besides doing the same in the northern region, also provides distribution services in the capitals of the northern states. All of the state governments formed electrical energy distribution and retail supply companies; some of them, such as Cesp (in the state of São Paulo), Cemig (in the state of Minas Gerais), and Copel (in the state of Parana), also generate and transmit power. At a later stage, the federal government acquired control of two large electricity distribution utilities, Light and Escelsa, which supply areas located in the states of Rio de Janeiro and Espírito Santo, respectively.

Petrobras and Eletrobras, the latter with the cooperation of all of the large state-owned electricity supply utilities in the country, did the required forward (expansion) and operation planning exercises for the oil and gas and electrical power supply industries, respectively, and proposed the associated energy policies for the Ministry of Mines and Energy. This scheme, of having state-owned companies as the main operators in the Brazilian energy supply industry, involving both federal and state governments, succeeded up to the mid-1980s, when a number of policy positions cast shadows on the adequacy of the scheme for the future. The missteps included (1) the artificially low tariffs for electricity (mirroring most public service tariffs imposed by the federal government, in often vain efforts to control high inflation rates) and (2) the political misuse of electricity supply and gas distribution utilities (involving incompetent and often corrupt management and the initiation of construction of several plants, particularly electric power stations, primarily to reap political benefits to some politicians, but without the necessary funding to finish them on schedule), coupled with the desire of the federal government to have substantial and fast increases in domestic production of oil and gas. Discussions about what institutional changes should be made to correct the problems dragged along through several governments and lasted nearly a decade, up to the time when a deep financial crisis in the electricity supply industry required urgent action. President Fernando Henrique Cardoso, in the beginning of his first term in office, decided to sell all of the federally owned electrical power utilities to private investors and also to exert political and economic pressure on state governments to do the same. At the same time, two amendments to the Brazilian Constitution were passed in congress, ending the legal monopoly of Petrobras and allowing the state governments to grant concessions to investor-owned gas distribution utilities and not just to state-owned ones, as was the case before this change. The control of Petrobras continued to be in the hands of the federal government, but Petrobras was expected to compete with private companies in the production, importation, processing, and transportation of oil and gas, allowing, according to the government's wishes, lower prices in the market and substantial increases in the domestic production of these commodities.

At the end of President Cardoso's second term (December 2002), some competition was achieved in domestic exploration; four bidding rounds were carried out to grant exploration and production (EP) licenses, but no licenses have been granted for production of oil and gas (no large findings have occurred outside of Petrobras' EP areas) and few licenses were granted for importation of natural gas. No competition has occurred in the processing and transportation of oil and gas. Several transnational companies operating in this industry have preferred so far to set up joint ventures with Petrobras, rather than to challenge a competitor with such market power as Petrobras still has in Brazil.

Privatization in the electricity supply industry has occurred to a much more limited extent than was planned initially by the government. Around 70% of the distribution capacity was actually privatized but less than 30% of the generation capacity went to private ownership (the large-scale generation and transmission utilities Furnas, Chesf, Eletronorte, Cemig, and Copel continue to be state owned). This partial failure of President Cardoso's government plans was caused by strong political opposition to the privatization of these utilities, not just from opposition parties but also from the government's own rank and file, particularly after the electricity supply shortage of 2001. Rolling blackouts were avoided due to a power rationing program, in effect from June 2001 through March 2002; also, several short-construction-time generating plants were built, to provide reserve capacity, and some generation and transmission facilities were brought online ahead of schedule.

Big changes, however, were made in the Brazilian electrical power supply industry. A regulated third-party access system was mandated for both transmission and distribution networks. An independent

regulatory agency (ANEEL), a national system operator (ONS), and a wholesale market (MAE) were created; because of legal disputes among some utilities, the latter did not settle the short-term transactions (spot market) up to the end of 2002. The distribution and trade activities of the distribution utilities now have separate accounting systems, and for some utilities, the generation and transmission businesses were split into different companies during the privatization process. Some new agents in the electricity market were created, such as the independent power producers (IPPs), the "free" consumers (who, as opposed to the traditional "captive" consumers, can choose their electricity suppliers), and the pure traders (who do not own any generation, transmission, or distribution assets).

In the oil and gas supply industry, a negotiated third-party access scheme was defined by Law No. 9478, which detailed, in 1997, the new "rules of the game," to promote competition in the industry. The same law created the National Petroleum Agency (ANP), an independent agency that regulates the whole oil supply chain and the upstream activities of the natural gas supply chain.

The opening up of the Brazilian energy supply industry to private investors, in order to redirect public investments to other areas and to introduce competition in the industry, in line with what is happening in several other countries, was the main energy policy of President Fernando Henrique Cardoso. As a result of this policy, there are now both private and state-owned large companies in both main branches of the industry (oil/gas and electricity supply). Electricity tariffs, rising much faster than the country's inflation rates, represent a big problem facing the new federal administration. This has been exacerbated in the past few years by growing marginal costs (particularly for generation), by clauses in concession contracts linking the annual tariff updates to an inflation index (which has been overvaluing the strong devaluation of the local currency, the real, since 1999), and by the perception among private investors in the industry of a high-risk business environment, which, in the short term, either increases profit expectations or decreases investments.

In order to solve this problem, by making some changes in the current institutional model of the Brazilian electric power supply industry, the government of President Luis Inácio Lula da Silva intends to negotiate with the utilities the inflation index issue and to pursue programs to reduce the perceptions of high risk. The main changes proposed by the Ministry of Mines and Energy in July 2003 and, after discussions with the interested parties, reaffirmed with minor modifications in December 2003, are as follows:

1. The electricity supply market will be divided into two parts, one comprising the free consumers and the other comprising the captive consumers. Free consumers choose their suppliers among independent power producers, or traders, and buy from them their energy requirements, through freely negotiated bilateral contracts; the captive consumers deal with a distribution utility, through a pool managed by a new entity, the Administrator of Electricity Contracts (ACEE), which will replace the current electricity wholesale market (MAE) organization.
2. The tasks of ACEE will be management of long-term bilateral contracts among generators and distribution utilities and settlement of contractual differences for all market agents.
3. A new state-owned company, the energy research company (EPE) will be created to carry out the long-term (20 years ahead) and medium-term (10 years ahead) expansion planning exercises for the Ministry of Mines and Energy (MME); the resulting plans will be publicly discussed and eventually modified before final approval and implementation by the Ministry.
4. The plan for 10 years ahead will define the hydropower plant projects, the predefined energy and capacity generation blocks for thermal power plants, the regional constraints, and the transmission lines that should be auctioned by MME (no longer ANEEL), in addition to the required commissioning dates, to meet the forecasted demand of the pool consumers.
5. The bidding process referred to previously will allow proposals, by interested agents, of alternative projects to fulfill the energy supply or transmission needs as outlined in the plan. The proposal requiring the least revenue during the concession period will be the winning bid.
6. Preference will be given to public service generation utilities, instead of independent power producers, to supply the pool. Such utilities will sign a concession contract with MME and will have their firm power shared among all distribution utilities of the national interconnected grid, through compulsory long-term bilateral power purchase contracts.
7. Meeting the forecasted demand of the distribution utilities for the next 5 years should be fully assured through these long-term power purchase contracts. Special contractual arrangements are proposed for additional power purchases, in association with nonpredicted demand requirements.

8. EPE, ONS, ACEE, and ANEEL will help MME to oversee the supply conditions over the next 5 years, proposing corrective measures whenever necessary, which includes setting up generation reserve margins.

These changes were brought to the Brazilian Congress in December 2003, in the form of proposals of two new laws, to be enacted in the first half of 2004.

President Silva has emphasized that no further privatizations in the electricity supply industry will take place during his presidency. The partial deverticalization process carried out in this industry under the previous administration will continue in the new administration; vertically integrated utilities will form separate companies to carry out generation, distribution, and trade activities with free consumers, whereas separate accounting systems will suffice in the case of generation and transmission.

2. THE NATIONAL COUNCIL FOR ENERGY POLICY

The National Council for Energy Policy (CNPE) was created in 1997 by Law No. 9478, but was not actually installed until October 2000. According to a report issued in 2001 by a commission formed by the government to search for the causes of that year's electricity supply shortage, earlier activation of the council would have helped to avert or, at least, to minimize the effects of the shortage.

The National Council of Energy Policy consists of ten members, seven ministers of state bureaus (Mines and Energy, Planning, Economy, Environment, Industry and Trade, Civil House, and Science and Technology), one representative of the state governments, one representative of the universities, and one citizen expert on energy policy issues; the President of the Republic appoints the latter two members. The CNPE is headed by the Minister of Mines and Energy, who forwards proposals of energy policy resolutions to the President of the Republic; once approved, the proposals have the power of a presidential decree. Thus, CNPE is the most important forum for setting energy policies in the country. At the end of President Cardoso's second term, three technical committees were lending support for the council activities: one committee addressed the activities of the electrical power sector, another dealt with fuel supply chains, and the third focused on activities concerning required changes in the institutional model of the Brazilian electrical power supply industry.

3. FOSTERING ENERGY SUPPLY

Most of the national energy policies aiming to foster various forms of energy supply in Brazil were conceived in the 1970s. Policy development focused on medium- and large-scale hydroelectricity plants, coal-fired power plants, nuclear power stations, large-scale petroleum and gas production from offshore wells located in deep waters, and fuel alcohol production from sugarcane. Policies to boost the generation of electricity from gas-fired power plants, small hydropower stations, wind power, and biomass resulted from decisions made during President Cardoso's government. All of these policies are briefly reviewed in the following sections.

3.1 Hydroelectricity

Brazil has a large hydroelectric potential, i.e., 258,420 MW, of which just 23.9% corresponded to plants in operation in 2002 and 4.3% represented hydropower stations under construction at that time. Since the middle of the 20th century, particularly after the 1960s, the federal and state governments have made large-scale efforts to tap this valuable and comparatively cheap resource, building the plants themselves through state-owned utilities or, more recently, providing credit facilities for private investors, through the National Bank for Economic and Social Development (BNDES).

Of the total installed capacity of electrical power plants in Brazil as of December 2001, the share of hydropower stations was 82.25%; the corresponding figure for public supply plants at that time was 84.92%. During President Cardoso's government, there was a policy guideline establishing that investments in new hydroelectric power plants should be carried out preferentially by private entrepreneurs, with possible minority participation of state-owned utilities in the case of projects of strategic interest for the federal administration. Spokesmen from the new government have declared recently that state-owned utilities will have more opportunity to invest in hydroelectricity than they had in the previous administration.

3.2 Coal-Fired Power Plants

Brazil's recoverable coal reserves as of December 2001 were estimated at 32.4 billion tons, the largest coal reserves in Latin America; the mines are located in the southern states of Rio Grande do Sul, Santa

Catarina, and Parana. The coal's high content of ash and, in most of the mines, sulfur severely limits the use of Brazilian coal in the iron and steel industries, and the remoteness of the mines necessitates great transport distances; in the year 2001, 99.9% of the coal consumed in Brazil's iron and steel plants was imported. The lack of appropriate railway networks in the mining regions also adds a further difficulty to the transportation problem. The Brazilian coal-mining industry has therefore always depended on the construction of new coal-fired power plants to survive. However, these plants have never been competitive with hydropower stations in Brazil, and have thus required subsidies to be built and operated.

Under the old rules of the Brazilian electricity supply industry, state-owned utilities had been building coal-fired power stations in the southern states of the country, close to the mines, for strategic reasons (diversification of the fuel mix for power generation and, as a result of an industrial policy, aiming to increase the domestic production of components for such plants); a fund (CCC) created by an electricity surcharge was formed to subsidize the operation of these plants when required, i.e., during years and seasons of low inflows to the hydro plant reservoirs. A minimum capacity factor for the plants, however, has been fixed, because of minimum annual consumption levels specified in the coal supply contracts, required to keep the mines running.

The new rules of the game in the Brazilian electricity supply industry, aiming to foster industry competition, cast shadows on the future of the coal mining industry in the country; the CCC fund, for instance, will be downsized from 2003 to 2005 and eliminated in 2006, according to 1997 legislation (Law No. 9648). Law No. 10,438, passed by the Brazilian Congress on April 26, 2002, however, opened a new door for the coal producers; the resources of a new fund (CDE), created by this law for the electricity supply industry, can, among other uses, be employed to finance both old stations (for operating expenses, replacing the cash flows from the CCC fund) and new coal-fired power stations. The amount of the CDE fund to be made available for such purposes will be defined on a regular basis by the National Council for Energy Policy.

3.3 Nuclear Power Stations

President Cardoso's administration created Eletronuclear, a subsidiary of Eletrobras, to assume responsibility for the nuclear plants in Brazil. Brazil has two operational nuclear power plants, Angra-1 (675 MW) and Angra-2 (1.3 GW), both located at the town of Angra dos Reis, in the state of Rio de Janeiro. Angra-1 was bought from the U.S. company Westinghouse in 1969. The Angra-2 plant came online in 2000, 23 years and $10 billion (U.S. dollars) after construction began; it was the single outcome, in terms of power plant building, of a very ambitious nuclear power agreement signed between the Brazilian and German governments in 1975, which envisaged the construction, by Siemens of Germany, of eight nuclear power stations in Brazil; the agreement also specified the transfer of German technology related to fuel cycle activities (mining, processing, fuel enrichment, fuel element manufacturing, and reprocessing), and the joint development of a new uranium enrichment process.

The construction of a second nuclear plant (Angra-3, with an installed capacity of 1.3 GW), included in the Brazilian/German agreement, was started in 1981, involving foundation works and the acquisition of German equipment. Due to budget cuts and to some opposition from environmental groups, the construction was stalled and the equipment for the plant has been mothballed. However, the electricity supply crisis of 2001 bolstered interest in bringing the Angra-3 plant into service. Those in favor focus on the need of the country to diversify its sources of power generation and to take advantage of its substantial uranium reserves (the world sixth largest: 309,370 t of U_3O_8 as of December 2001); furthermore, there is the fact that about $750 million (U.S. dollars) has already been spent on the plant, including the purchase of about 60% of the required equipment. These resources will be lost if the project is abandoned and Eletronuclear will be unable to develop sufficient scale to become competitive. On the other hand, those against Angra-3 point out that the project will require around an additional $1.7 billion (U.S. dollars) and will take at least 5 years to be completed; it is also emphasized that the population still views nuclear energy with suspicion, because issues surrounding safety and the final disposal of the radioactive residues have not yet been resolved.

CNPE authorized Eletronuclear in 2001 to carry out the necessary economic and environmental feasibility studies (Resolution No. 05, approved in December 2001). In August 2002, the Council voted in favor of Eletronuclear resuming the construction of Angra-3 after the necessary environmental licenses have been granted, if the new government does not decide to halt the process (a CNPE meeting was

scheduled for May 2003 via Resolution No. 8, of September 17, 2002; major outlays in the project will occur only after that meeting). This decision was postponed for 2004 by the new federal administration, in part because of current surplus power supplies in MAE and in part because of urgent cash problems at Eletronuclear, requiring a tariff revision by ANEEL.

Apart from Angra-3, no other new nuclear plants are planned for Brazil. Such plants may be built in the future, but only if safer and less expensive new technologies, still at the research and development stage, succeed on an international scale.

3.4 Oil and Gas Production from Offshore Deepwater Fields

Brazil has the second largest proved oil reserves in South America (after Venezuela), at 1.35 billion m^3, or 8.48 billion barrels, as of December 2001; 88% of the total is in offshore basins and 80% is at depths above 400 m. The natural gas proved reserves as of December 2001 stood at 219.84 billion m^3, or 7.76 trillion ft^3, the fifth largest in South America behind Venezuela, Argentina, Bolivia, and Peru; 60% of the total is in offshore basins and 40% is at depths above 400 m.

The production of both petroleum and natural gas has been rising steadily in Brazil since the early 1990s, reaching, in 2001, 75.22 million m^3, or 1.3 barrels per day (bbl/d) of petroleum, which met 79.3% of the consumption in that year, and 14.04 billion m^3, or 1.36 billion ft^3 per day of gas. Imports of gas from Bolivia started in 1999 and imports from Argentina started in the next year, totaling 4.61 billion m^3, or 0.45 billion ft^3 per day in 2001. The offshore Campos Basin, north of Rio de Janeiro, is the country's most prolific production area for both oil and gas, containing around 80% of the national reserves. The Santos Basin also holds large gas fields. Brazil's oil imports come mostly from Venezuela and Argentina.

As was the case with many other national oil companies, Petrobras initially concentrated on building up its downstream infrastructure, particularly from 1965 to 1974. In the wake of the first oil price shock, in the middle 1970s, the Brazilian government ordered the management of Petrobras to implement three new policies aiming to decrease the effects of the oil price rises on the national balance of payments: (1) international expansion of the company in upstream activities, through a subsidiary, Petrobras International (Braspetro); (2) signature of service contracts, with a risk clause, with private oil companies in regions not yet under exploration; and (3) an increase in the national production of oil and gas through exploitation of offshore, mainly deepwater, fields, which make up most of the Brazilian reserves. The first two strategies failed, but the last one has been highly successful. Petrobras' accomplishments in deepwater production have been internationally acknowledged and the Campos Basin's success at proving giant reserves at great depths has attracted attention worldwide. Many companies have been encouraged to come to Brazil to participate in ANP's promoted bidding rounds, in order to develop upstream exploration, some of them without partnering with Petrobras.

In 1986, Petrobras began the first of the Procap programs (the Petrobras technological development program on deepwater production systems, or Procap 1000). The main objective of this program was to improve the company's expertise in oil and gas production in water as deep as 1000 m. It also consolidated Petrobras' production concept based on floating production systems. Petrobras' Procap 2000, launched in 1993, emphasized the development of technologies aimed at reducing investment and operational costs as well as improving efficiency and extending the working life of equipment at water depths of 1000–2000 m. Procap 3000, implemented in 2000, goes even further, seeking to develop technologies that will make oil and gas production in ultradeep waters, below 2000 m, technically and economically feasible. In 2000, the U.S. Geological Survey published new estimates of global oil reserves suggesting that Brazil might still have some 47 billion barrels of undiscovered oil, almost all in offshore fields, with about 35% in the Campos Basin.

Apart from the second half of the 1980s, when Petrobras' management became involved in a long battle with the Ministry of Economy, which decided to cut back the company's expenditures and investments, the rest of the time the federal administration has supported the company's effort to boost oil and gas production from offshore deepwater fields, striving in the medium term for self-sufficiency in oil production. This is likely to continue with the new administration.

3.5 Fuel Alcohol from Sugarcane

Since 1975, with the creation of the National Alcohol Program (Proalcool) by Federal Government Decree No. 76,593, Brazil has produced anhydrous alcohol from sugarcane; this alcohol is blended with

gasoline in Otto cycle car engines in proportions of up to 25%. With the second phase of Proalcool, which started in 1979 (Federal Government Decree No. 83,700), hydrated alcohol has also been produced for use in Otto cycle engines modified to run on 100% ethanol, or neat alcohol.

Currently, Brazil is the world's largest producer of sugarcane, with crops often yielding over 300 million tonnes of crushed cane per harvest season. Prior to Proalcool, the Brazilian share was less than 15% of worldwide production. During the 1970s, many ethanol distilleries were installed in the country, either as new plants or as distilleries annexed to existing sugar mills. The main alcohol-producing states are São Paulo (contributing over two-thirds of the total), Rio de Janeiro, Alagoas, and Pernambuco. Since Proalcool was created, two main products have been obtained from sugarcane: sugar and fuel ethanol. The former has been an important component of the basket of commodities exported by the country since the time when Brazil was a colony of Portugal; in contrast, exports of fuel ethanol have been sporadic and have faced many protectionist barriers abroad.

The production rate of fuel ethanol has varied according to the relative prices of both sugar, particularly in the export markets, and alcohol, which are the main factors affecting production, besides climatic and environmental variables. When sugar prices are high, the production of alcohol decreases, and vice versa. Up to the beginning of the current decade, the price of fuel ethanol was fixed by the government, tracking with the controlled price of gasoline; now both prices are determined by market forces, although they will eventually be subject to government pressures on Petrobras and on the alcohol producers when price increases are considered too high.

The main objective of Proalcool, rapid growth of the alcohol industry, in conjunction with subsidies that increased alcohol production capacity in the 1970s and early 1980s, has facilitated the building of a large alcohol industry. Within the industry, there is still considerable need for increasing energy efficiency and reducing production costs; government policies for this industry have so far failed to address the important issue of cost-effectiveness. The Proalcool program was discontinued in the early 1990s during President Collor de Mello's term in office. The federal government, however, continues to foster the production of fuel ethanol by maintaining the requirement of a mandatory blend of anhydrous alcohol with gasoline. The blend formulation set by the government is between 18 and 25% ethanol, depending on the annual production of ethanol, which, as already pointed out, is strongly affected by sugar prices abroad.

In support of the fuel ethanol program, there are discounts on federal taxes applied to alcohol-fueled cars (the IPI tax) and to fuel ethanol (the recently created CIDE tax). The share of alcohol-fueled cars in total sales of new cars dropped from 96% in 1985 to 1.15% in 2001, after a low of 0.07% in 1997. At the end of 2001, there was an aging fleet of neat alcohol-fueled cars, estimated at about 2.5 million vehicles. New policies have been considered by the federal government to boost the production of hydrated ethanol once more. The most important measures that have been envisaged are the compulsory addition of ethanol to diesel oil in buses and lorries and the establishment of government "green fleets" that will run on neat ethanol. None of these measures, however, has yet been adopted, and the outlook for hydrated ethanol production in Brazil is not promising. On the other hand, the prospects for future growth in the production of anhydrous alcohol to blend with gasoline are bright, not only because of the environmental benefits of such blends, in terms of reduction of air pollution, particularly in large cities, but also because of the good prospects for "flexible fuel" vehicles. These vehicles employ electronic fuel management technologies that allow use of any blend of anhydrous alcohol with ethanol. Some flexible fuel models are already available in the Brazilian market. Because the prices for these vehicles are higher than the prices for the low-ethanol-blend counterparts, the government is evaluating the adoption of financial incentives to help boost sales.

A rapid hydrolysis process to produce ethanol from sugarcane bagasse (crushed cane) is being developed in the state of São Paulo. A demonstration plant should be operating soon. If this technology proves economically feasible, it will allow an increase of around 30% in alcohol production with the use of 50% of the currently available sugarcane waste (tops and leaves, or "barbojo"), without any additional contribution from sugarcane plantations. There have been significant improvements in the productivity of both sugarcane agriculture and the ethanol-based industrial sector. These gains have been due to a combination of factors, including (1) introduction of new and improved sugarcane varieties, (2) better economies of scale from larger and more efficient new plants, and (3) technological improvements and energy conservation measures in old plants. However,

there is still room for further cost reductions. Finding better uses for the sugar and alcohol by-products, such as sugarcane bagasse, barbojo, and vinasse (organic wastewater), is certainly an excellent route to improving the economic performance of these plants. The prospects to increase the current generation of surplus electricity in cogeneration plants located in sugar mills and alcohol distilleries are also promising.

3.6 Gas-Fired Thermal Power Plants

Brazil has a large natural gas pipeline network to transport the gas produced in the Campos and Santos basins to the cities of Rio de Janeiro, São Paulo, and Belo Horizonte. There is also a long pipeline for collecting and transporting the output of gas fields located in the northeastern region of the country to the local capitals and industrial areas; there are plans to interconnect the two pipeline systems. There are also smaller transportation networks to receive the production from the offshore Espirito Santo Basin and from the onshore field of Urucu; the former delivers gas to Vitoria, the capital of the state of Espirito Santo, and to industrial areas in the northern part of that state, and should be connected soon to the Campos/Santos network. Commissioning of the onshore field of Urucu awaits completion of pipelines that will supply Manaus and Porto Velho, the capitals of the states of Amazonas and Rondonia, respectively. All of these gas pipelines are owned by Petrobras.

There are two international gas pipeline connections in the country. The first pipeline to connect Brazil to foreign gas sources was the Bolivia-to-Brazil pipeline, tapping Bolivia's Rio Grande sources and servicing the states of Mato Grosso do Sul, São Paulo, Parana, Santa Catarina, and Rio Grande do Sul; this pipeline came onstream in July 1999. In the Bolivian part of the pipeline, there is a diversion to supply a power plant and other consumers in Cuiaba, the capital of the state of Mato Grosso. Partners in the Brazilian section of the pipeline include Petrobras, which is the major shareholder, Enron, Shell, and BBPP Holdings. The second international pipeline links the city of Parana, in Argentina, to Uruguaiana, in the state of Rio Grande do Sul, Brazil, where it supplies gas to a 600-MW power plant. Transportadora de Gas del Mercosur is the pipeline's operator. Service began in July 2000. An extension of the pipeline, which will connect Uruguaiana to Porto Alegre, the capital of the State of Rio Grande do Sul, to service a new power plant in Porto Alegre, was planned but has been postponed. Additional Argentina–Brazil pipelines are in various stages of planning, although recent natural gas discoveries in Bolivia and Brazil could discourage the development of these projects. It is also possible that a second Bolivia–Brazil pipeline will be built.

The primary motivation behind the projects of most of the recently built or planned pipelines has been the hope for a fast buildup of natural gas demand in Brazil, in conjunction with expectations that there will be construction of a large number of gas-fired thermal power plants. The source of these expectations was the belief of President Cardoso's government that the private investors, under the new rules of the Brazilian electrical power supply industry, would prefer to build efficient, combined cycle, gas-fired power plants, as has been the case in many developed and developing countries, instead of new hydro plants, as has been the Brazilian practice in past decades. Some initial uncertainties among the potential investors caused the Brazilian government to step in; in September 1999, the Gas-Fired Thermal Power Plants Priority Plan, or simply PPT, was announced. The first version of the PPT identified 15 projects, totaling 12 GW, expected to be online by 2003. Specific regulations were established for these projects, such as a specific value for the upper limit pass-through that the electricity distribution companies are allowed to pass on to their "captive" consumers' tariffs. To reassure investors concerned about fluctuations in gas prices, which were in U.S. dollars and were indexed to a basket of fuel oils, the government, through Petrobras, set price ceilings on 20-year fuel supply contracts. There was just one gas price, revised quarterly, regardless of the power plants' location. In addition, the national development bank, BNDES, offered a special loan program.

Uncertainty among the investors remained, however, such that none of the 15 projects got underway. The variation of gas prices with fuel oil prices, the exchange rate, the quarterly price revisions, and the lack of synchronism between the revisions of electricity and gas prices generated investor anxiety. So Petrobras was required to offer an alternative solution with a blended gas price indexed to the U.S. Producer Price Index (All Commodities) (PPI), revised annually. In April 2000, the federal government issued a revised version of the PPT, with the new price option and, in response to political pressure from local politicians and state governors, increased the number of projects from 15 to 51, all over the country. Apart from the ambitious and unrealistic number of proposed plants, the rapid devaluation of the Brazilian currency, the real,

against the U.S. dollar created further difficulties, given that the gas price was set in dollars.

The electricity shortage of 2001 forced the government to launch its Emergency Thermal Power Plant Program, the last version of the PPT program, improving the conditions for all the project developers with gas already contracted or coming on-stream before June 2003 (this was later extended to December 2004), up to a maximum volume of 40 million m^3/day. For these plants, MME/MF Order No. 176, on June 1, 2001, set a new gas price formula, valid for 12 years. The timetable for tariff revisions was rescheduled to bring gas and electricity into line. Petrobras will assume the exchange rate risk for 1 year before passing it on to the power plants at the time of their tariff revision. The annual revision of gas prices considers the Brazilian inflation index IGPM, with a weighting of 20%, and the exchange rate plus the PPI, with a weighting of 80%. Prices will be renegotiated every 3 years and the gas supply contracts are transferable. A further benefit to the plants under the new program, established by Law No. 10,312 on November 27, 2001, was the elimination of PIS/PASEP and COFINS, two federal taxes on the gross revenue accruing from the gas sales to such plants. According to estimates made by the Ministry of Mines and Energy in October 2002, based on the regular follow-ups carried out by the Ministry and considering plants in operation, undergoing trial runs, and under construction, at several stages and contracting levels, 19 gas-fired thermal power plants are likely to come online by 2004, with a total installed capacity of 7157.6 MW, under the umbrella of the last version of the PPT.

When the gas supply contract for the Uruguaiana power plant was signed, during the early stages of the Brazilian electric power supply industry reform, new gas-fired thermal power plants were competitive with new hydropower stations, according to calculations made using the prevailing cheap gas price negotiated for the contract and the reference unit costs for both types of plants, in Brazilian reals. The sharp devaluation of the real since 1999 and high oil prices, however, changed this picture, against the gas-fired thermal power plants. The Brazilian government believed that, in the medium term, such plants would regain their competitiveness. This reasoning was based on (1) decreasing thermal power unit costs accruing from competition among gas suppliers and from the growth in industrial uses for the gas, creating the necessary conditions for the development of a secondary gas market, which, in turn, would allow more flexible "take or pay" and "ship or pay" contractual requirements, and (2) increasing hydropower unit costs arising from plants located farther from the main load centers. Thus the government of President Cardoso decided to subsidize the cost of transporting gas in the country. Law No. 10,604, enacted on December 17, 2002, allows such a subsidy up to R$500,000,000 per year, using the CIDE tax as a resource. With this subsidy, with the lower prices for the commodity expected to accrue from negotiations with the Bolivian government and producers, and with the substantially increased medium-term local production made possible by recent discoveries of large fields in the Santos and Campos basins, the government expects to reduce by $0.50 (U.S. dollars) per million British thermal units or more the price of the gas, which should make the gas-fired power stations competitive again in Brazil.

A fundamental issue is the fact that, in Brazil, in contrast to most other countries, the opportunity cost of natural gas for power generation in public supply plants is determined by hydro generation in new plants. Thus, indexing the price of such gas to the prices of a basket of fuel oils, as is traditional in the oil and gas industry, is meaningless, in economic terms, in Brazil. The new federal administration is less enthusiastic than the previous one about large expansion plans involving gas-fired thermal power stations. Regarding possible new energy policies to boost gas demand in the medium term, incentives may be given for other gas uses, particularly for cogeneration plants in the industrial and services sectors.

3.7 Generation of Electricity from Small Hydropower Plants, Biomass, and Wind Power

Power generation units employing renewable sources of energy (e.g., small hydropower plants, wind power, solar energy, and biomass) and cogeneration plants have received financial incentives in some countries. During the 1970s and part of the 1980s, the major reason was that they represented indigenous sources of energy, reducing the dependence on foreign sources. More recently, with globalization and the formation of economic blocks of countries, this argument has lost much of its early appeal. However, the potential of these generating units to create environmental benefits is being realized. The financial incentives can be orthodox, such as tax relief and attractive credit terms, or heterodox, such as (1) compulsory purchases by utilities of the power

generated by these plants at avoided costs; (2) purchase, for the public grid, of energy blocks through bidding restricted to some types of these plants; or (3) granting of purchase tariffs above the market rate for the energy generated in these plants (to be paid for by all consumers, or on a voluntary basis, depending on the willingness of consumers to pay more for "green" energy.

The sugar and alcohol, and paper and pulp sectors are the Brazilian industrial branches that rely most heavily on self-production to meet their electricity needs. They use mostly cogeneration plants burning industrial residues from biomass, e.g., sugarcane bagasse, firewood, and black liquor (a mixture of chemicals and dissolved wood materials). The new rules of the Brazilian electricity supply industry tend to encourage greater use of such industrial residues for process steam and power generation in cogeneration units, together with forestry residues and sugarcane waste (barbojo), since recent developments in harvesting machinery design and new collection practices are reducing the cost of the latter waste fuels for power generation, particularly if gasification is involved.

During the period 1996–1997, the Brazilian Minister of Mines and Energy discussed with interested parties a possible federal government decree that would oblige utilities to buy surplus power from cogenerators, up to a certain share of their market growth, more or less along the same lines of the American Public Utilities Regulatory Policies Act (PURPA) legislation, during its first phase. The project was badly designed and the proposed measures came up against the main directives dealing with the opening up of the Brazilian power sector. As a consequence, many utilities rallied against the project and succeeded in aborting it. Bearing in mind the American experience related to the application of the PURPA legislation, the board of directors of Brazil's regulatory agency for the electrical power industry, ANEEL, defined, through Resolution No. 021, on January 20, 2000, the minimum share of thermal energy production and the minimum total efficiency requirements that a cogeneration plant owner should meet to become a "qualified cogenerator." The creation of this qualification process aimed to set up procedures allowing the selection of eligible cogeneration units to receive incentives still to be defined. (Some of the requirements of ANEEL Resolution No. 021 should be revised, however, because they are either too slack regarding some combinations of technologies and fuels, or they are too strict regarding other combinations.) The first of the incentives was specified in December 2000 through MME Order No. 551, which included qualified cogeneration plants, using any kind of fuel available in the country, to be commissioned up to December 2003 (this was later extended to December 2004) in the PPT program, having rights to all program benefits.

For quite a while, Brazil's most important development bank, Banco Nacional de Desenvolvimento Econômico e Social (BNDES), has been offering some credit facilities for the building of cogeneration units and electrical power plants using nonconventional renewable energy sources. Although the conditions specified by BNDES are more favorable than what usually can be found on the Brazilian credit market, they are worse than those in the international market, particularly because of the long-enduring prevailing high interest rates in the country. Thus, this credit line was little used before 2001.

Before 2002, the owners of small hydropower stations (up to 30 MW) were the only renewable power producers to enjoy "heterodox" financial incentives in Brazil. In 1998, Law No. 9648 granted these producers access to any consumer with a contracted demand higher than 0.5 MW and relieved them from the payment of half the value of transmission grid use fees. The current minimum power demand limit, which defines "free" consumers, is 3 MW. Law No. 10,438, enacted on April 26, 2002, created the Incentive Program to Generate Electricity from Alternative Sources (Proinfa), comprising wind power, biomass, and small hydropower plants, to be implemented in two stages. Associated with this program, the law defined a new kind of agent in the Brazilian electrical power supply industry—the autonomous independent producer, whose business cannot be controlled or associated with any electricity generation, transmission, or distribution utility. Producers that do not meet this requirement can participate in the program, provided their share in the contracts does not exceed 25% (50% for wind power producers, in the first stage of the program), and no autonomous producer is precluded because of the requirements. Equipment manufacturers can be autonomous independent producers if at least 50% of the value of the equipment involved in the program is produced in Brazil.

Proinfa will hold public solicitations for each kind of power source. Priority will be given first to plants that have already obtained the Installation Environmental License (LI) and then to those holding a Preliminary Environmental License (LP). If more capacity is offered, satisfying the conditions above,

than the capacity scheduled to be contracted, the plants with the shortest remaining environmental license periods will be chosen. In the first stage of the program, 3300 MW, equally distributed among small hydropower plants, wind power stations, and biomass-fueled thermal power stations, will be installed up to the year 2006. Eletrobras will provide long-term contracts to purchase the energy produced by these plants, paying the so-called "economic value" associated with each technology, which should correspond at least to 80% of the average electricity tariff in the country. The cost of these acquisitions as well as the administrative cost of Eletrobras to manage this scheme will be shared among all categories of consumers in the National Interlinked System, proportional to measured individual consumption.

After completion of the first stage, a second stage will continue up to 2022, during which the generation from the plants should meet 15% of the annual load growth and, considering the results of the first stage, 10% of the electricity consumption in the country. Throughout 15-year-long contracts, Eletrobras will again buy the output of these plants, equally among the three technologies if there is enough supply. The purchase will, as before, be preceded by public calls and there will be the same selection criteria as used in Proinfa's first stage, but the price paid will be equal to the weighted average unit cost of new hydroelectric plants with an installed capacity above 30 MW and new gas-fired thermal power stations. The expenses associated with this purchase will again be shared among all consumers proportional to their measured consumption. The difference between the generation cost of each technology and the average unit cost will be paid straight to the producers, using the resources of a new fund (CDE) created by Law No. 10,438. ANEEL is responsible for overseeing the whole process, using, for this purpose, the Renewable Energy Certificates issued by the generators. The CDE fund consists of monies from the annual fees paid by the electrical power supply industry investors to the government for the right to use public goods, the revenues collected by ANEEL from the application of fines, and a new annual fee paid by all agents who sell electricity to consumers.

The creation of Proinfa by Law No. 10,438, inspired by successful legislation in Germany and Denmark, is a landmark approach to foster the generation of electricity from distributed renewable energy sources in Brazil. It has, however, some drawbacks, which should be addressed in future legislation. The first problem is the fact that the market share targets set for the generation of the renewable energy sources have no relationship to environmental policy targets, to the amount of these resources available in Brazil at reasonable costs, to the indigenous manufacturing capacity the government wishes to foster, or to supplementary power sources, e.g., new thermal power plants, required to complement the generation of random energy sources such as wind and hydropower. Also, there was no study of the impact of Proinfa targets on electricity tariffs, which is a major issue in a country with so many poor consumers. These targets should be reviewed in the future. Apart from eventually decreasing "economic values" for each technology, set by the Ministry of Mines and Energy, the program provides no further incentives to increase the cost-effectiveness of these sources; making the Renewable Energy Certificates tradable would be an important step forward in this direction.

In December 2003, the new federal administration put forward a proposal that would limit the annual addition of plants generating electricity from distributed renewable energy sources in the second stage of Proinfa, through specific auctions for such sources, to amounts which would not cause increases in the new pool prices (discussed in Section 1) above 0.5% in any single year and 5% on a cumulative basis. According to the same proposal, from January 2005 onward, the generators interested in participating in the auctions will have to prove that at least 60% of their equipment and services will be produced in Brazil; this share will increase to 90% in 2007.

4. ENERGY EFFICIENCY AND RESEARCH AND DEVELOPMENT PROGRAMS

Several energy efficiency programs have been sponsored by the federal government, as well as by the governments of some states (São Paulo, Bahia, Minas Gerais, and Rio Grande do Sul), since the 1970s. Of the national programs implemented in previous decades and still in operation, the most important ones are Procel, Conpet, and the mandatory energy efficiency programs run by the electricity distribution utilities and overseen by ANEEL.

The Ministry of Mines and Energy and the Ministry of Industry and Trade created, through the MME/MIC Order No. 1877, on December 30, 1985, the Program to Reduce the Waste of Electrical Energy (Procel), to be managed by Eletrobras. A

presidential decree of July 1991 gave the coordination of the program to the Ministry of Mines and Energy and increased its scope, which included electricity consumption labels for household appliances and electrical motors; electricity consumption audits in small and medium-size industrial and commercial premises; financing of research and development initiatives (particularly at the Eletrobras research center, Cepel), directed to the manufacturing of more efficient electrical appliances and motors; support for new legislation and regulation in the country concerning energy efficiency; support of projects directed to reduce losses in the generation, transmission, and distribution of electricity; setting up information systems and marketing activities on energy efficiency; and running educational and training programs aiming to bolster a culture of energy conservation. The Procel program has impacted households, the commercial and industrial sectors, public services such as illumination and water supply, and efficient management of electricity consumption in public buildings. Procel has gone through ups and downs. Since the mandatory energy efficiency programs run by the electricity distribution utilities were set up in the late 1990s, Procel's role has been downgraded; its activities have been redirected to support ANEEL in the evaluation of the utilities' programs.

A 1991 presidential decree created the National Program to Rationalize the Use of Oil Products and Natural Gas (Conpet), to be coordinated by the Ministry of Mines and Energy and to be operated by Petrobras. "Conpet in the School" is its main institutional project. In the transportation sector, Conpet has two successful projects, SIGA-BEM and ECONOMIZAR. SIGA-BEM is a partnership with BR, Petrobras' subsidiary company for the distribution and retail trade of oil products, directed to advise truck drivers in BR's filling stations about how to reduce the consumption of diesel oil in their vehicles. ECONOMIZAR is a partnership with the National Confederation of Transportation, which, through mobile units, provides assistance to garages and service shops of load/passenger transportation companies in the search of the optimal management of their diesel oil stocks, aiming to reduce specific fuel consumption and pollutant emissions of the serviced fleets. Most of Conpet's initiatives in the industrial sector have been directed to energy efficiency improvements in Petrobras' refineries, including a wider use of efficient cogeneration units. In the residential/commercial sectors, Conpet is responsible for pioneering the labeling of liquefied petroleum gas (LPG) consumption of stoves. So far, Conpet has been managing with less financial resources and a shorter scope of action compared to Procel, but has shown a much more stable performance in running its projects.

Since 1998, the concession contracts of the electricity distribution utilities have contained a clause that requires them to apply at least 1% of their annual income to energy efficiency and research and development programs, with at least 0.25% going to demand-side management programs and at least 0.1% going to research and development activities. ANEEL regulates these programs and oversees their results with the help of Procel's staff and experts from some state regulatory agencies that have contracts with ANEEL. ANEEL has set boundary conditions for the range of activities covered by these programs, which, in essence, has been similar to many of those developed earlier by Eletrobras in Procel. Law No. 9991, enacted in July 2000, rules that the electricity distribution utilities should apply annually at least 0.75% (0.5% up to December 2005) of their net operational income to research and development projects and at least 0.25% (0.5% up to December 2005) to energy efficiency programs on the demand side. Electricity generation utilities, independent power producers, and distribution utilities are also required by this law to spend at least 1% of their net operational income on research and development programs. Half of all these research and development resources will be managed by ANEEL, and the other half will be channeled to the Electricity R&D Fund, created by Law No. 9991, to be managed by the Ministry of Science and Technology. The new federal administration intends to redirect half of the resources managed by ANEEL to partially fund EPE's activities.

Petrobras has been sponsoring research and development activities related to the production chain of oil and natural gas since the early days of the company, particularly at its research center, Cenpes. The Petroleum National Agency has, since its installation in 1998, been regulating research and development programs in this field, with resources coming from the royalties paid for by oil and gas exploration and production concessions (Presidential Decree No. 2851, November 30, 1998, which created the National Fund for Scientific and Technological Development for the oil and gas industry) and by the concession contract of Petrobras (1% of the company's gross revenue accruing from production activities). The Ministry of Mines and Energy also funds several applied research projects in

various universities, involving alternative fuels and/or technologies, particularly in the Amazon region.

In terms of energy policy, the most important incentive in recent years to the search for a higher level of energy efficiency in Brazil was the enactment of Law No. 10.295, on October 17, 2001; this law allows the government to set up maximum levels of specific energy consumption, or minimum levels of energy efficiency, for energy-consuming equipment produced in Brazil or imported, after public hearings involving the interested parties. This law also mandates the government to promote energy efficiency measures in buildings. A permanent committee (CGIEE), with members from several ministries, was formed to set goals and to elaborate proposals for the public hearings (Decree No. 4059, December 19, 2001). The first type of equipment to fall under the mandate for minimum energy efficiency levels is the three-phase induction squirrel-cage rotor electrical motor (Decree No. 4508, December 11, 2002).

The mandatory energy efficiency programs run by the electricity distribution utilities, and the electricity supply shortage of 2001, boosted the market of the Energy Services Companies (ESCOs). The main barrier found for further development of this market is the financing of ESCOs, which has been addressed by the Ministry of Mines and Energy through proposals for the opening of new credit lines in state-owned banks and the setting up of a fund with resources provided by Eletrobras and/or BNDES. The certification of ESCOs and the technical qualification of energy efficiency projects are other measures being considered by the Ministry to push forward this market. The promotion of a greater use of high-efficiency electrical motors and household appliances, via credit facilities and tax reductions, and a gradual integration of the national programs directed to energy efficiency improvements are two other important policy measures that have been pursued recently by the MME.

5. ENERGY PRICES AND SOCIAL ISSUES

The price of oil products (gasoline, diesel oil, fuel oil, LPG, naphtha, aviation kerosene, and lubricating oil) in Brazil has been set by market conditions, without any regulation, since January 2002, as mandated by two laws (No. 9478/97 and No. 9990/00). The price of LPG was subsidized before January 2002 because a large number of poor people in the country use this fuel for cooking purposes. Resolution CNPE No. 4, on December 5, 2001, followed by Decree No. 4102 (January 24, 2002), and Law No. 10,453 (May 13, 2002), substituted the cross-subsidy then existing for all consumers of LPG with government grants just for the low-income consumers, registered in government aid-to-the-poor programs, using the resources of the CIDE tax. During the same meeting, on December 5, 2001, CNPE decided that the Ministry of Mines and Energy and the Ministry of Economy should keep regulating the prices of the natural gas produced in Brazil after December 2001, because, in practice, Petrobras had retained its monopolistic position. This control should remain in place until real competition in this market materializes. As defined at the end of the last government by the Ministry of Mines and Energy, this "real" competition will be obvious when there are at least three suppliers, none of which hold a market share larger than 75%. The state governments regulate the gas price for the consumers and there will be no competition in the downstream part of the gas chain in the short to medium term unless a general understanding is achieved among the federal and state governments or the Constitution is changed. There are currently far fewer subsidies available for the sugarcane producers and fuel alcohol manufacturers than in the past, but they still exist, using resources provided by the CIDE tax (Law No. 10,453, December 13, 2002), particularly for the poor northeastern region.

Frustrating the expectations of President Cardoso's government, so far few eligible "captive" electricity consumers have opted to become "free" consumers, i.e., to choose their supplier and negotiate the price to be paid for energy consumption. The main reason is that there are cross-subsidies for energy-intensive large-scale consumers, based on past regulations, discouraging the move from regulated to free arrangements. Recognizing this distortion, but concerned about likely losses in export revenues and job losses in the short term if large tariff increases are imposed on the energy-intensive industrial branches, the previous federal administration decided to spread these increases over 4 years, at 25% per year (Decree No. 4562, December 31, 2002). The current administration has thus decided to increase the transition period to 5 years, with just a 10% increase in 2003, provided the interested energy-intensive industrial consumer invests in generation expansion (Decree No. 4667, April 4, 2003). The government also aims to convince this type of industrial consumer to buy at favorable prices, through medium-term contracts (duration of 1 to 2 years), about 2000 MW, on average, out of a total

of 7500 MW, on average, available in the generation system in the first months of 2003, because of the decrease in demand caused by the current recession. The current recession was triggered by the electricity shortage of 2001, which also speeded up the construction and commissioning of several new power plants.

There have been cross-subsidies to low-income electricity consumers in Brazil for many years. Law No. 10,438 broadened the definition of the low-income consumer, particularly in the poor northern and northeastern regions of the country. In order to avoid sharp tariff increases for certain utilities, especially in those regions, the government also decided to create direct subsidies to low-income electricity consumers using resources provided by eventual extra income earned by the federally owned generation utilities. This extra income could come from trading in the public biddings, defined by Law No. 10,438; it was also decided, if necessary, during 2002 and 2003, to use resources from the RGR fund, managed by Eletrobras.

Expensive thermal energy, generated by engines fueled by diesel oil or, for the larger machines, fuel oil, supplies isolated networks, located mostly in the northern region of the country. This generation is subsidized by all consumers in the national integrated network through a fund known as CCC-Isol, which, according to Law No. 10,438, should last up to 2022.

Between 10 and 15% of the Brazilian population, comprising from 4 to 5 million households, mainly in remote, rural areas, has no access to electricity supply. To improve this situation, the Federal government set up two rural electrification programs in the 1990s, "Luz no Campo" and "Prodeem." Luz no Campo, managed by Eletrobras, has the goal of electrifying 1 million rural properties, basically through grid extensions, using resources from the RGR fund. Up to the beginning of 2003, 541,115 properties were electrified by the program. Prodeem, on the other hand, was conceived to meet the basic social demands, in terms of electricity supply, of isolated small rural communities through local generation, with preference to the use of renewable energy sources. The program, managed by the Ministry of Mines and Energy, has been employing photovoltaic panels as generating units in most cases. Law No. 10,438 determines that the payments for the use of public goods, and fines applied by ANEEL, which contribute to the CDE fund, should be applied with preference to rural electrification programs. The law also states that ANEEL should assign rural electrification targets to each distribution utility. The Agency board of directors hopes to have all Brazilian households electrified by 2016.

The new federal administration report on changes in the institutional model of the Brazilian electric power supply industry, issued in December 2003, proposes that the subsidies for power plants consuming distributed renewable energy sources should be borne by (small) tariff increases; thus the government hints that all of the CDE resources should be channeled with priority to rural electrification programs and for granting subsidies to poor electricity consumers.

6. ENERGY AND THE ENVIRONMENT

Brazil has an advanced body of legislation concerning the environment. Enforcement of this legislation, however, has had failures, mainly due to short budgets of the regulatory bodies, at both federal and state government levels; the situation has improved since the electricity shortage of 2001.

In terms of regulatory tools, the Brazilian environmental legislation uses "command and control" measures such as environmental licenses, pollutant emissions limits, and establishment of zones where certain activities are restricted due to potential environmental damages. The regulation leave little room for market-driven measures involving economic incentives and for negotiated agreements among the regulatory bodies and the agents they regulate, as is happening now in some countries. Environmental policies, planning, and regulation activities are decentralized in Brazil, involving not only federal and state government bodies, but also municipal ones. The same kind of decentralization was established by Law No. 9433, o August 1, 1997, for water resources. This law created a new agent, the Hydrographic Basin Committee, made up by representatives of municipalities, who are responsible for elaborating a Hydrographic Basin Plan and for defining the priorities of water usage in the basin; needless to say this committee is very important to the interests and activities of the energy supply industry.

There has been little connection so far between environmental and energy policies in Brazil. The energy supply shortage of 2001 brought together the work carried out by the Ministry of Mines and Energy and that of the Ministry of Environment, but essentially only on particular projects and mostly to speed up environmental licensing procedures. A joint

agenda for the electrical power sector set by the two ministries in 2002 is expected to enlarge the scope of joint activities, including formal exchanges between technical committees of CNPE and CONAMA, the National Council for the Environment, and a more proactive treatment of environment issues in the electricity supply industry's 10-year forward planning.

7. AN INTEGRATED APPROACH

Energy policies in Brazil have been formulated in the past mainly by the federal government. Separate policies have been developed for each energy supply industry branch (oil and gas, electricity, coal, nuclear, etc.), and these have had little or no relation to other public policies. This has been changing slowly in recent years. The installation of CNPE, which includes the seven most important ministers of state, was a big step forward toward the integration of energy policies with other public policies in Brazil. The development of long-term (20 years ahead) integrated prospective studies each year by the Ministry of Mines and Energy for CNPE, since 2001, for the energy sector as a whole, using alternative development scenarios that take into account the current and possible new economic, technological, and environmental policies, has provided a consistent technical background for such integration. There is, however, a big challenge still to be faced, which is to engage the state and municipal governments, similar to what has happened in the environmental and water resources areas, in order to decentralize to some extent the policymaking process, under the direction of CNPE and with the technical support and supervision of MME. Two important measures in this direction were taken in the second half of 2002 at MME, involving the integration of the National Energy Balance with the state balances, in terms of methodology and data basis employed, and the start of integrated resources planning studies in four Brazilian hydrographic basins.

2. Energy Policy under the Transition to a Market Economy, 1979–Present
3. Outlook for China's Energy Policy

Glossary

exajoule (**EJ**) A measure of energy; an exajoule is 10^{18} joules, equivalent to 0.9478 quads (10^{15} British thermal units).

Five-Year Plan (**FYP**) China's Five-Year Plans are developed by the State Development Planning Commission and are used to guide overall socioeconomic development policy.

State Development Reform Commission (**SDRC**) The comprehensive national agency in China that coordinates long-term planning of economic and social development; formerly the State Planning Commission, and then, until 2003, the State Development Planning Commission.

State Economic and Trade Commission (**SETC**) The agency in China that, until 2003, coordinated day-to-day government regulation and economic activities.

In China, the national government has a strong role in the energy sector. Under the central planning system, from the establishment of the People's Republic in 1949 to the initial economic reforms in 1979 championed by Deng Xiaoping, the government directly controlled extraction, generation, transport, and allocation of fossil fuels and electricity. During the transition to a market-oriented economy, the government has gradually, though not always consistently, withdrawn. It lifted controls on energy prices, created energy corporations, and assumed a regulatory role. Like China's other governmental structures, the institutional apparatus for energy policy has been frequently reorganized, with a single ministry responsible for energy in some periods and specialized agencies for each energy type in other periods. In the first three decades of the People's Republic, policy was concerned mainly with increasing supplies of coal, oil, natural gas, and electricity. In the early 1980s, after proposing ambitious economic development goals that would have outstripped conceivable growth in energy supply, China also adopted strong energy efficiency policies. There have been significant efforts to provide the two-thirds of the population that lives in rural areas with better energy services. In recent years, China has made greater efforts to integrate energy supply and efficiency policy with environmental protection and other social goals, in addition to bold economic development goals. The government faces energy security concerns as the dependence on imported oil and natural gas rises.

1. ENERGY POLICY UNDER CENTRAL PLANNING, 1949–1979

1.1 Energy for Industrialization

From 1949 until the 1970s, the Soviet system provided the model for industrial development in China. Investment in energy supply became the highest priority of national investment. As in the Soviet Union, there were large subsidies for extraction of natural resources. Subsidies for energy under the Chinese regime were intended to support expansion of heavy industry and to make energy available and affordable to all citizens. Energy and other natural resources were priced well below their cost of production. The result was very high growth in energy supply. China experienced rapid growth in commercial energy output, from a minuscule 0.7 EJ in 1949 to 18.9 EJ in 1979, an average annual growth rate of 11.8%. Large quantities of biomass fuels were used in rural areas, approximately 3 EJ in 1949 and currently about 6 EJ. The economy grew rapidly, also

 © 2004 Elsevier Inc. All rights reserved.

from a very small base. Energy supply grew even faster; energy elasticity (percent change in energy divided by percent change in GDP) from 1953 to 1979 was 1.26. Energy supply commanded a larger share of total capital investment than any other industrial sector. From 1970 to 1979, one-third of capital investment in industry was allocated to energy. From 1953 to 1979, 33% of energy investment went to coal, 24% went to oil and natural gas, and 43% went to electricity. No attention was paid to the environmental consequences of energy development. Large numbers of miners were killed in coal mines, and mines degraded surface water and groundwater and produced scars on the countryside. Emissions to the air from coal burning were uncontrolled, and solid waste was not treated before disposal.

Because of large subsidies provided to energy supply, lack of incentives to control its use, and absence of economic and environmental discipline, in 1978 Deng Xiaoping inherited a set of energy institutions that were deeply troubled. Most of them were state owned, and virtually all of them would have been bankrupt but for government subsidies. They were inefficient, overstaffed, lacking in modern technology, and without effective management structures and with few incentives to create them.

1.2 Energy Institutions

Under the Soviet-style bureaucratic structure, a web of constantly changing agencies managed planning, production, and distribution of energy. The State Planning Commission (SPC) included energy investment, production, and distribution in its Five-Year Plans (FYPs). The State Economic Commission coordinated and monitored implementation of annual and short-term plans. Day-to-day energy production was directed from a ministerial level. At the beginning of the 1950s, one body, the Ministry of Fuels and Power (MFP), managed production of all types of energy. In 1955, the State Council replaced the MFP with individual ministries for coal, petroleum, and electric power. During the 1960s, the Cultural Revolution reshaped China's institutional structures. Prevailing ideology favored institutional simplification, so in 1970 the Ministries of Coal, Petroleum, and Chemical Industry were merged into a Ministry of Fuels and Chemical Industries. Similarly, the Ministries of Electric Power and of Ministry of Water Resources Utilization were combined. Management of state-run enterprises in the energy sector was transferred to local governments. Poor performance of the energy sector eventually led the central government to resume control of larger enterprises and to reestablish separate ministries for coal and petroleum. Throughout the central planning period, ministries concentrated on short-term planning, and the SPC's FYPs provided only rough guides for long-term direction. Implementation relied on administrative decisions for production and allocation, and each year's targets were based on incremental changes from the previous year's targets.

2. ENERGY POLICY UNDER THE TRANSITION TO A MARKET ECONOMY, 1979–PRESENT

2.1 Energy Supply and Efficiency for Rapid Economic Growth

In 1979, Deng Xiaoping announced that China would quadruple its per capita gross domestic product between 1980 and 2000. This goal had significant implications for energy policy. If energy use continued to grow 26% faster than the economy, as it had over the previous 30 years, total energy use in 2000 would have reached 106 EJ. Actual consumption in 2000 was 38 EJ, while per capita GDP more than quadrupled (Fig. 1; Table I). For comparison, the United States in 2000 used about 117 EJ of energy. Had China continued its previous energy path after 1979, it would have suffered intolerable environmental insults. Hence, one of the

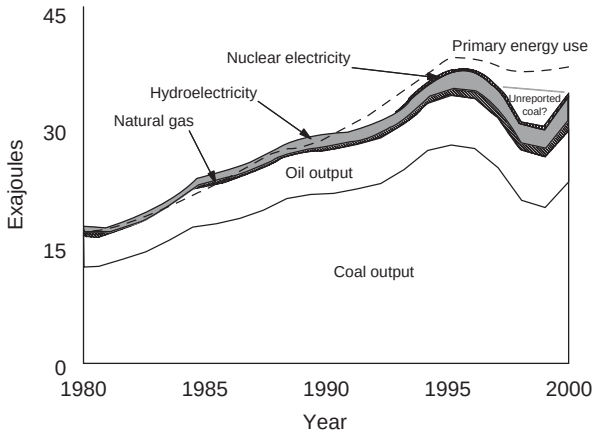

FIGURE 1 Primary energy output and use, 1980–2001. According to official statistics, China's energy output and consumption, mainly coal, rose from 1980 to the mid-1990s before falling temporarily. The difference between total energy output and use in most years represents net exports or imports of oil, except in the period from 1997 to 2000, when most of the difference is probably due to unreported output from small mines.

TABLE I

China's Energy Balances, 1949–2000[a]

	Exajoules used in year										
Energy balance	**1949**	**1955**	**1960**	**1965**	**1970**	**1975**	**1980**	**1985**	**1990**	**1995**	**2000**
Total primary energy supply	0.69	2.15	8.69	5.51	9.08	14.29	18.04	22.75	28.17	37.82	33.98
Coal	0.67	2.06	8.31	4.85	7.41	10.09	13.0	18.3	22.6	28.5	20.9
Oil	0.01	0.04	0.22	0.47	1.28	3.23	4.4	5.2	5.8	6.3	6.8

Losses							0.81	0.91	1.29	2.03	1.84
Balance							0.38	0.27	(0.76)	(0.62)	(4.21)

[a] Data from the National Bureau of Statistics for various years; *China Statistical Yearbook* (China Statistics Press, Beijing, China).
[b] In Chinese energy accounts, electricity is converted according to the average amount of primary energy consumed in power plants to generate electricity.

most important issues to explore in China's energy policy post-1979 is how the country was able to cut its energy elasticity from 1.26 to a figure less than 0.5.

A second major issue regards the choice of energy forms most suitable to the country's economic development. This has meant a continuation of the emphasis on electricity development, which fostered production of the most valuable and versatile energy form, but limited investment capital to the coal, oil, and gas sectors. A third major issue was protecting the environment, because the greatest environmental impacts on air, water, and land come from energy supply and use. Although energy elasticity fell, energy supply and demand still grew rapidly, because China sustained a 20-year period of extraordinary economic growth (roughly 10% per year by official figures and about 8% according to some independent economic analysts).

Finally, the structure of energy markets was a critical issue in development of the energy system after 1979. It became clear that energy prices needed to reflect costs, which they did not under the central planning system. Energy shortages in the 1980s and nonproductive investments led the Chinese to strive for reforms that encouraged a stronger role for markets for the energy system and for other sectors.

2.2 Transformation of Energy Institutions

Reforms of China's political economy have touched all sectors. Responsibility for overall planning has remained the domain of the State Council, the State Development and Reform Commission (SDRC), and, until its disbanding in 2003, the State Economic and Trade Commission (SETC), but ministries have been repeatedly reshuffled. Authority for energy sector activities has been spun off to large state-owned corporations, which retain many of the same personnel but have more freedom to allocate investments and manage production. The state no longer has the resources to direct the economy through its agencies and now seeks to influence development through institutions that use other means of control. Institutions currently in place may have more of the gloss than the substance of a market-oriented system, but they reflect the irreversible shift to a market

economy. Moreover, local agencies have become larger players.

Since the early 1980s, four major reorganizations occurred: in 1981–1983, 1985–1988, 1993–1994, and 1998–2001. The first reorganization focused on the oil sector and split the Ministry of Petroleum Industry into the China National Petroleum Corporation (CNPC), the China National Petrochemical Corporation (Sinopec), which were responsible, respectively, for upstream exploration and production and downstream refining and marketing. The China National Offshore Oil Corporation (CNOOC) was created in 1979 to manage offshore oil development.

The second wave of reorganizations, in 1985–1988, encompassed all energy subsectors. In place of central ministries with direct responsibility for investment and production, large state-owned companies were formed. A Ministry of Energy (MOE) was established as a coordinating body under the SPC, although it was active only in electricity. A State Energy Investment Corporation (SEIC) was formed and given responsibility for the central government's major investments in the energy sector. In the 1980s, China also incorporated energy conservation into the institutional structure. Energy conservation offices were established at central and provincial levels in planning and production agencies, and over 200 energy conservation technology service centers were set up nationally.

In 1993, MOE was disbanded and once again replaced with separate ministries for coal and electricity. SETC was established and given responsibility for coordinating short-term activities in energy supply. In 1994, control over state investment was unified, and SEIC, along with other state investment companies, was subsumed by the new State Development Bank. The China Energy Conservation Investment Corporation, formed in 1988, was the only exception and remained independent.

A major reorganization in 1998 transformed most remaining industrial line ministries, including those for coal and electricity, into departments of the SETC. Simultaneously, staffs were cut by half. The result was even greater independence for energy corporations and there was concentration of authority over energy supply policy, with SDPC responsible for long-term guidance and SETC responsible for short-term direction. To introduce competition in the oil industry, wells and refinery assets were split geographically between Sinopec and CNPC, which thus became vertically integrated oil companies. Further reorganization of SETC in 2001 absorbed separate departments responsible for energy into a single department with authority for all industrial activity. In 2003, SETC was broken up and its functions spun off to the renamed State Development and Reform Commission and to other agencies. Possible future institutional reforms under consideration include establishment of a utilities commission to set rules for the electric power sector, and reestablishment of a Ministry of Energy.

Nongovernmental organizations (NGOs) have been absent in most areas of Chinese policymaking, but the China Energy Research Society (CERS) has been influential in charting the course from central planning of the energy system to reliance on markets.

2.3 Coal

Coal is China's major fuel, providing an average of 73% of total energy consumption from 1980 to 2000. For many reasons, including its abundance in China, coal received limited policy attention and less capital investment than did any other energy form besides natural gas. Figure 2 makes clear that, after 1984, investment in oil and gas outstripped coal and that electric power investment "took off." By 1997, investment in electricity was 50% more than for oil and gas, and 3.5 times that for coal. This policy

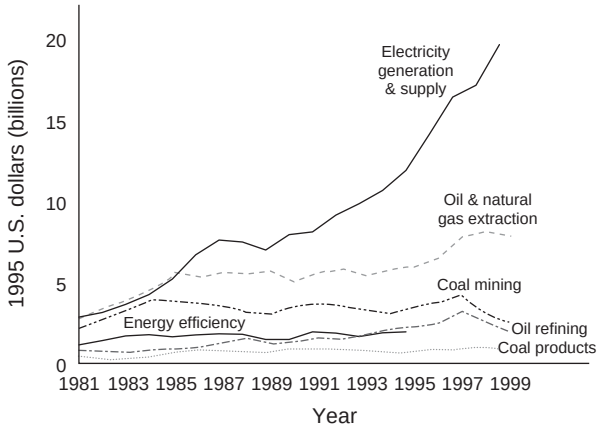

FIGURE 2 Energy supply and efficiency investment, 1981–1999. Investment in power generation and transmission has grown steadily since the early 1980s, and by the late 1990s made up three-fifths of all investment in the energy sector. Investment in other energy supply sectors remained flat until the late 1990s; during that period, investment in oil and natural gas extraction rose, while that in oil refining and coal mining fell, as capacities sufficed to meet demand. China has maintained a steady, even growing, level of investment in energy efficiency projects, in later years exceeding investment in coal mining. These data cover only state-owned and -invested enterprises, which account for the vast majority of energy investment in China.

essentially starved coal for capital, even more than previously. As a result, almost all expansion of coal output from 1980 through 1995 was from small collective and private mines, as shown in Fig. 3. This created a major new source of coal for China at virtually no investment from the central government. Unfortunately, it was an unsustainable policy. The government exerted little oversight over these small mines, which typically produce low-quality coal. Many of them are unsafe, contributing disproportionately to high accident and death rates. They cause serious environmental problems, polluting underground water sources, causing subsidence, and other harm. In most cases, the coal is used locally because it is not of high enough quality to be sold in regional markets, increasing local air pollution as well as pollution in homes (most rural and many urban households burn coal directly for cooking and heating).

Although the policy of encouraging the expansion of coal output from these small mines was clearly not desirable in the long term, there was a clear rationale in the 1980s. China faced a substantial shortage of coal; capital for energy was devoted to forms of energy that would best serve a modernizing economy,

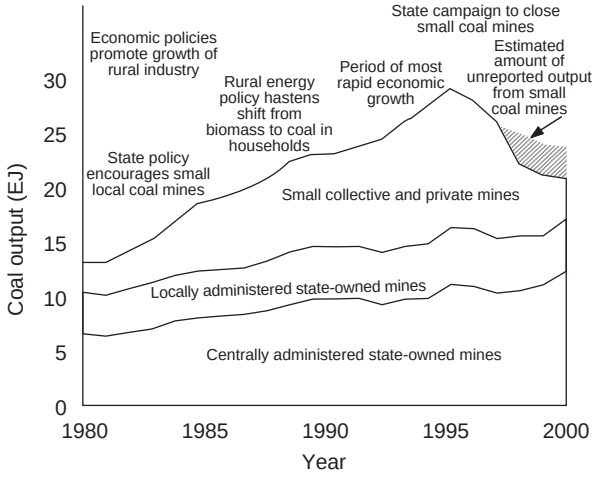

FIGURE 3 Coal production by type of mine, 1980–2001. National policy beginning in the early 1980s promoted small "township and village" mines. By 1995, these often tiny mines produced nearly half of China's coal, but at a tremendous cost in human life, wasted resources, and environmental pollution. Officially reported coal production peaked in 1996 at 1374 million metric tons. Small-mine output was already falling when, in 1998, the central government began a vigorous campaign to close small mines. Reported output from small mines fell by half within 2 years, but actual production from small mines may have been up to one-third higher than reported output, because many small mines continued to operate clandestinely.

and energy sectors were already consuming a large portion of total industrial investment, up from 37% in 1980 to 59% in 1997. Thus, China faced a serious dilemma in allocating investment. It followed a path that promoted economic development, but contributed to the increasingly serious environmental problems. By the late 1990s, China had not only overcome the energy shortages of the 1980s, but, because of declining economic growth, was in a position to reduce its coal consumption. This situation led to a campaign by the central government to close the small coal mines on a massive scale. As shown in Fig. 3, coal output from small collective and private mines declined from more than 600 Mt of coal (45% of all coal produced) to 200 Mt from 1996 to 2001, according to official figures. In fact, as shown by the upper right-hand shaded area in Fig. 3, it is unlikely that all of the private and collective coal mines were closed. These prohibited mines may have produced as much as 150 Mt of coal. Even so, the reduction of coal use from these mines was enormous.

China's coal industry is not appreciably stronger than it was some years ago. It is still undercapitalized, has poor environmental and safety records (about 6000 coal miners die annually in accidents), and has generally weak management, despite the country's heavy reliance on coal. Closing small mines has improved the environmental situation, but either alternatives to coal must be found or the coal industry must be modernized and pollution from both production and consumption reduced.

2.4 Oil and Natural Gas

In the late 1950s, the huge Daqing oil field was discovered in northeastern China, followed a few years later by the large Shengli field in Shandong. Development of these and other fields began in earnest in the early 1970s and oil production expanded rapidly. There was a widespread belief, in China and elsewhere, that the country would become the world's next major source of oil, with oil resources similar to those in the Middle East. The early promise of vast oil resources was not fulfilled. No large fields have been found in eastern China since the 1970s. Untapped oil resources in China are in harsh environments, i.e., in bitterly cold northwestern China and in offshore fields. Both sources are already being exploited. The need for advanced technology, experience, and capital to develop oil in such climates has meant that major projects are joint ventures with international oil companies, and are expensive.

The history of oil imports and exports tells an important story for China. As a result of the early oil discoveries and policy restrictions on nonindustrial oil use, China was an exporter for many years. The peak of its exports, at 1.6 EJ (36 Mt oil) occurred in 1985. Export earnings from energy that year were $7.1 billion (U.S. dollars), or 25% of export earnings for the entire economy. Net oil exports dropped to zero by 1993 and have since increased as dramatically as exports once did. By 2000, net imports were 3.3 EJ (76 Mt oil). With the automobile industry in its infancy in China, but growing very rapidly, dramatic increases in oil demand are expected. This oil will come from overseas, presenting China with a growing security issue.

China's interest in natural gas has grown, and a major exploration program has been initiated. Natural gas is still a very small part of total energy supply: 1.2 EJ (30 billion cubic meters) in 2001, or 3.4% of total energy production. However, production has been growing at an average of over 10% per year since the early 1990s. China is building a major pipeline from the northwest to Shanghai, to be completed in the middle of the first decade of the 2000s. It is not yet clear how the gas will be utilized, because the price of delivered gas will be very expensive. Natural gas has the clear advantage of over coal and oil of reducing pollutant emissions, but unless Shanghai decides to impose high externality costs on coal burning, or forbids the use of coal in various applications, development of the gas market may be constrained.

The major barrier to greater use of natural gas is its high cost in China. In the absence of large gas fields near the eastern population centers, gas will have to be brought in by pipeline from the far western region, imported from Russia or Central Asia, or imported as liquefied natural gas (LNG). These alternatives are costly and pose perceived geopolitical risks. Coal has been used in some industrial processes in highly inefficient ways (e.g., as a feedstock for fertilizer production) because of the lack of natural gas. Substitution of natural gas for coal would be a natural development. A second large potential market is as a substitute for electricity (e.g., in household water heaters), especially as direct coal burning is phased out. In small-scale applications, for which pollution control is prohibitively expensive, natural gas or oil is often the only viable alternative to coal. However, given China's ambitious plans for natural gas development, promoting gas for power generation is an obvious way to spur long-term growth of the fuel. Many markets will depend on China's policies to control emissions from coal combustion and the relative incremental costs of emissions controls and of natural gas.

Oil imports will continue to increase until an affordable substitute for liquid fuels from petroleum is found and widely disseminated. The drivers of future growth will be the rapidly expanding automotive and petrochemicals sectors. Without new large discoveries, China will become more dependent on imports, and has taken steps to mitigate dependency through investments in producing fields overseas. Predicting the future of natural gas is difficult. The key factors will be the rate of discovery of natural gas fields, their size and location relative to demand centers (thus determining the cost), and the development of suitable markets for the natural gas, which likely will remain expensive. After the current efforts to create a natural gas market, investment in continued exploration and development will depend on the assurance of markets for the gas, which will be closely related to environmental policy.

2.5 Electricity

From 1980 to 1998, electricity supply (and demand) grew at 8.3% per year, about the same rate as revised estimates of gross domestic product (GDP) growth. Over 80% of electricity is now generated by fossil-fired power plants, with the remainder coming mainly from hydropower, some from nuclear, and a tiny fraction from other sources. As already noted, the focus of China's energy policy has been electricity development. Investments in electrification have been highly beneficial to the nation in several ways. First, electric power is essential for a modernizing economy, because it provides the highest quality energy suitable for many uses that fuels cannot meet. Second, access to electricity in rural areas, including those suffering great poverty, provides a critical input into the economic and social development of the region. Moreover, it is easier to reduce pollutant emissions from large sources such as power plants, as compared to small ones such as household stoves, and a growing share of China's coal is used in power plants.

On the other hand, the policy of investing heavily in electricity has, as noted earlier, starved other supply sectors of funds. Two resulting problems are the poor quality of marketed coal and the lack of exploration for natural gas. Such problems could be overcome by making markets for international investments more open and transparent, a process that has proceeded slowly since the 1980s. Because China has long viewed energy as key to national

security, it has been cautious about relying on foreign energy supplies or encouraging "too much" foreign investment, although the definition of "too much" has never been made explicit and has apparently varied over time. Recently, the government has permitted companies outside of China to have a controlling interest in energy projects, subject to careful review.

China has the second largest hydropower resources after Russia, but the biggest dam sites are far inland, distant from coastal demand centers. The 1960s and 1970s saw preferential development of hydropower, but as electricity demand grew exponentially in the 1980s, China turned to coal. Large dams continued to be built, particularly with international development assistance, but more slowly than fossil plants, due to high costs of transmission, major problems encountered in earlier projects, and increasing environmental sensitivity. Since the late 1980s, most attention given to hydropower went to the giant Three Gorges project, but concerns about pollution from coal-fired generation and a desire to develop western provinces are helping to drive construction of other hydropower projects. As in most countries, large dams are planned as multipurpose projects, with water supply and flood-control objectives being particularly important. Pumped-storage facilities are also being built in coastal regions where power shortages during peak demand periods have sometimes been severe. Current policy aims to promote delivery of electricity from hydropower and coal from poorer western provinces to the wealthier coastal regions. This is intended to relieve projected shortfalls in generation capacity in the East, and to provide income to the West. Significant issues remain in funding investment in generation and transmission and in restructuring the regulatory system to allow large interregional transfers.

At least five factors affect the efficiency of China's fossil-fired power plants. Two factors—the high quality of large, new state-of-the-art power plants and the relatively high percentage of cogeneration (i.e., use of heat as well as power) in the power system—have contributed to improved efficiency. Two other factors—the small size and outmoded technology of many existing power plants and the relatively low quality of coal burned—have resulted in many inefficient plants. A final factor, the lack of natural gas as a supply source of electricity, has precluded the use of advanced combustion turbines that can produce electricity at high efficiency and with low levels of pollution (as well as favor cogeneration in many cases). In order to improve the technical and economic performance of power generation, the government has long had policies to close the least efficient power plants and to prohibit construction of new small power plants unless they are cogenerators. Over the past two decades, the average size of China's power plants has grown, and the average efficiency of fossil fuel power plants has improved.

The Chinese have long had the goal of developing nuclear power on a large scale, but growth has been slower than planned, largely because of high costs compared with coal. Nonetheless, as of 1993, China had installed eight nuclear generating units totaling 5980 MW, with another three units totaling 2510 MW under construction. China has sought to develop the capability to construct nuclear power on its own, but almost all construction so far has had active overseas involvement.

Hydropower has always been an important part of Chinese electricity supply. The 18,000-MW Three Gorges Dam will be the world's largest hydropower project, nine times the size of the Hoover Dam in the United States. It has been controversial from its inception because of environmental impacts, involving the relocation of 1.2 million people and the loss of historical sites. The reservoir is already being filled; the first turbine is expected to go online in 2004 and the project will be completed by 2009.

China has an active nonhydro renewable electricity program. There are large resources of geothermal energy, but because the high-temperature geothermal resources are in the West, far from end users, they contribute little to total electricity supply. Development of wind power is rapid, although from a low base. There are presently 28 wind farms totaling 403 MW. Two more, one near Shanghai and the other outside of Beijing, are committed for construction. There is discussion of policies to promote wind power, in the hopes that overcoming barriers will render wind a cost-competitive electricity source. Because China has many good-to-excellent wind regimes, wind could become competitive with coal-fired power, depending on environmental regulations.

The government is now restructuring the power system and planning to create regulatory commissions at the national and provincial levels, thus separating power generation from direct government oversight of performance and prices. Generation and transmission will also be separated. The government expects to introduce competition into the power generation market, although there may be only a

small number of companies owning large numbers of generators initially. The government will maintain authority over transmission lines and has ambitious plans for creating a national grid among its six regional and six provincial grids.

Some pressing issues regarding future electricity generation can be addressed by the following questions:

- Will China create meaningful environmental standards for new and existing power plants? When?
- Will China strive to replace coal in a significant portion of new power plants? What roles will natural gas, wind, and biomass play?
- Will the Three Gorges Dam work as planned, or will it run into significant operational and/or environmental problems?
- Will restructuring encourage improved performance of the electricity system?
- Will the bulk of domestic energy investment continue to be allocated to electricity? What will be the role of foreign investment?

2.6 Rural Energy

China's top priorities for rural energy development have been to meet basic fuel needs for cooking and heating, to provide electricity to as many households as possible, and to supply energy for rural industry. This last function has been accomplished mainly through allowing the development of local coal mines and grid extension. Most policy measures have been directed at fulfilling household energy needs. The vast majority of the rural population has at least minimal access to electricity. In remote areas in southwestern China, this has been accomplished through construction of small hydropower projects. Many of the "microhydro" projects of the 1960s and 1970s were poorly designed, but more recent projects have been more successful, and China has become a model for other developing countries. A growing number of remote communities are supplied by small wind generators. Still, as of 2000, about 16 million rural residents (i.e., slightly more people than the population of Florida) had no access to electricity. Most options for supplying those who remain without electricity are beyond local means, so the continued efforts to supply regions without electricity will depend on the central government's limited funds.

Throughout history, China's farmers have periodically faced serious fuel shortages. Various programs over the years have aimed to resolve those shortages. In the 1970s, for example, a campaign resulted in the construction of tens of thousands of small biogas digesters, intended to turn crop and livestock waste into fuel gas. Virtually all of these facilities failed, due to poor design, inadequate materials, and insufficient operating expertise. A new program, instituted in the late 1990s, emphasizes larger scales and better designs, and shows more promise. Direct combustion remains the major way biomass fuels are used. In the early 1980s, in response to rural fuel shortages, the government organized a large-scale National Improved Stove Program (NISP) to provide rural households with more efficient biomass stoves for cooking and heating, and later also improved coal stoves. By the early 1990s, the pressure on biomass supplies had eased in most areas, in part due to increased incomes and availability of coal and electricity. From the mid-1990s onward, support for the stove industry was replaced with extension services and certification systems to standardize stoves. The development and dissemination of improved stoves is now left to market actors. The government claims that by 1998, 185 million of China's 236 million rural households had improved stoves. Although many rural households now use fossil fuels, especially coal and some liquefied petroleum gas (LPG), and ownership of electrical appliances is increasing, nearly all rural households use at least some biomass. Solar water heaters and large plastic-covered greenhouses have become common features in rural areas. Passive solar design has been incorporated into some new housing, and solar cookers have been distributed in some western areas where fuel is short and sunlight is plentiful.

2.7 Energy Efficiency

The achievements of China's energy efficiency policy have been remarkable. As noted earlier, since 1980, energy has grown half as fast as GDP (Fig. 4). Virtually all other developing countries have seen energy demand grow at least as fast as GDP. In many ways, China serves as the "existence proof" that energy can grow at a substantially lower rate than that of the economy over a considerable period of time.

2.7.1 Energy Efficiency under the Planning System

China achieved results in the large-scale promotion of energy efficiency beginning with instruments of the planned economy. Energy efficiency became a national priority in 1980, after a confidential study by

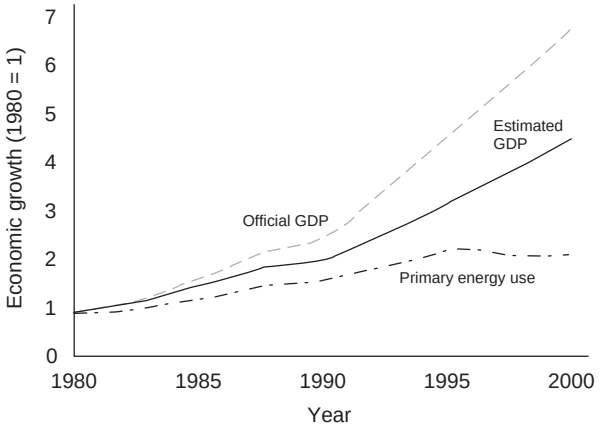

FIGURE 4 Official and estimated gross domestic product (GDP) and primary energy use, 1980–2001. Since 1980, according to official statistics, China's economy grew nearly sevenfold. Many economists believe official statistics exaggerate actual growth. Although experts differ on the correction to apply, a reduction of two percentage points in annual growth rates is a typical estimate. Even with revisions, China's economy in 2001 was 4.6 times larger than in 1980. Over the same period, primary energy use rose to 2.2 times its previous level. Unlike most developing countries, in which energy use rises faster than economic output, China has experienced growth in energy use only one-third to one-half as fast as economic growth.

a group of academics that proposed major changes in China's energy policy; among the proposals was establishment of a national efficiency initiative. In the Sixth FYP (1981–1985), China proposed and implemented a massive effort to promote energy efficiency. In 1981, investment in energy efficiency by the government was 9.5% of total energy investment (Fig. 2), or 1.5 billion yuan (about $830 million U.S. dollars in then-current exchange rates). Investment in energy efficiency, including cogeneration, grew to 3.2 billion yuan by 1985.

No other country in the world at that time, or since, has had a national program that allocated energy investment to energy efficiency, or one that was implemented so rapidly. China created a bureau of Comprehensive Energy Savings and Resource Utilization within the SPC, which was at that time China's top executive agency. This bureau undertook a wide range of reforms, some of which were carried out by a newly created (China) Energy Conservation Investment Corporation. Along with its regional offices, the bureau evaluated proposals from throughout the nation and chose the projects to be funded. The energy efficiency investments were only the most important of many measures put in place during the very innovative period of the early and middle 1980s. Other innovations that remained in place until the late 1990s concerned energy management, financial incentives, technical service centers, and research and development. Large factories were required to have energy managers to monitor energy use. Annual quotas for energy use were set and evolved into regulations relating to energy use of various types of equipment (e.g., motors and boilers) and manufacturing processes. Factories that performed better than the quota or exceeded the standards were given financial rewards. Many inefficient factories were shut down. Demonstration projects illustrated performance of efficient technologies.

Initially, energy conservation investments were financed by the national government. Later, the cost was shared with provincial governments. By the early 1990s, the investments had turned into low-interest loans. Other incentives included reduced taxes on energy-efficient products, subsidies to develop new energy-efficient technologies, and monetary rewards to energy-efficient enterprises. As mentioned previously, China created a network of over 200 energy conservation service centers that employed nearly 5000 staff at their peak; the staff performed energy efficiency feasibility studies, participated in investment projects, and trained energy managers and technicians. China instituted a national energy conservation week (in November), during which the national and local press spotlight energy efficiency and efficiency is included in school curricula.

China began an energy conservation research and development program in 1981 to complement its shorter term programs. The areas receiving the greatest attention were efficiency of coal combustion (e.g., improved briquettes and cookstoves), electricity end-use technologies (e.g., fans, pumps, and motor controls), boilers and furnaces for steel production, heat exchangers and waste heat recovery systems, transport technologies, fertilizer production processes, and industrial-process controls. Few of these programs have been formally evaluated. However, the reduction of the energy intensity of the Chinese economy from 1980 to the present is strongly suggestive of the overall success of the programs, which made more efficient equipment and practices widely known and available to the enterprises that were expanding production capacity in those years.

2.7.2 The Energy Conservation Law

In 1998, the national Energy Conservation Law came into force, codifying the country's approach to promoting energy efficiency under a more market-oriented economic system. Implementing provisions

are still being formulated to address some of the challenges:

- Creation of new fiscal and other incentives.
- Reassessment of existing energy price regulations.
- Establishment and enforcement of mandatory efficiency standards for common energy-using equipment and buildings.
- Integration of energy efficiency with environmental protection efforts.
- Improving efficiency of the rapidly growing rural industrial sector.
- Retaining and transforming the former system of efficiency centers.
- Institutional coordination in implementation, management, and supervision of energy conservation law.

2.8 Energy Pricing

Energy pricing remains heavily influenced by the central government, which has only slowly relinquished control. Under the planning system, state-dictated prices accompanied planned allocations to users. Controls on energy prices determined which energy enterprises and subsectors would make profits and suffer losses. Low coal prices, for example, consigned coal mines to a constant struggle to make ends meet, while price differentials between crude oil and oil products ensured that refineries became wealthy.

Energy-price reform began in the early 1980s and proceeded tentatively, because price policy was—and remains—politically sensitive. A portion of the energy products was allowed to be sold at prices higher than the in-plan prices, resulting in a multitrack pricing system. Today, most energy prices in China track international market levels. China's accession to the World Trade Organization in 2001 represents a step toward full integration of China's energy markets with international markets.

Price liberalization began with coal. In the early 1980s, the government allowed limited free markets for coal and permitted state-owned mines to sell small amounts at market prices, and then allowed a multitrack system. In 1993, the price of nearly all coal was liberalized and prices rose rapidly. State-owned enterprises, which had previously been required to purchase from state-owned mines, were able to buy lower cost (and lower quality) coal from small local mines. In the mid-1990s, coal prices leveled off and then fell as coal demand fell. Price controls remain in place for some users, particularly fertilizer plants that use coal feedstock.

Two distinct markets for coal have emerged, with two different pricing systems. Large mines and consumers, like power plants and steel mills, negotiate supply contracts at national semiannual coal-marketing conferences. The product is of relatively high quality, is shipped long distances, and is expensive. Local markets match small non-state-owned mines with consumers, often in the same area, and provide generally cheaper, lower quality coal. Prices vary significantly by region; in coastal areas, far from the major coal mines, domestic coal can be expensive by world standards, and small amounts of coal are imported.

Oil prices have followed a similar path of deregulation. Central control of wellhead prices contributed to slow growth in oil production during the 1980s, even though a two-tiered pricing system was introduced in 1982. In 1988 the government increased plan prices, but by a very small amount compared to market levels, and by 1990 the cost of production had surpassed the average in-plan wellhead price. Distortions in pricing of upstream and downstream products allowed refineries to profit at the expense of oil fields. Local governments built many small, inefficient refining facilities to capture rents created by this system. At the same time, oil exploration and extraction became much less attractive, resulting in a slowdown in oil field development.

In 1994, the two-tiered pricing system was replaced by a single set of central price controls on crude oil and oil products that were adjusted periodically with reference to international prices. Faced with fixed ex-refinery and retail prices up to twice the level of import prices, oil consumers sought alternatives to the high-priced oil. By 1998, smuggling had become rampant, and a new import and pricing regime—linking Chinese domestic prices for the first time to the Singapore market—was announced along with a crackdown on smuggling. Consequently, oil imports dropped in 1998 (before rising again; Fig. 5) and smuggling activity has declined. In 2001, the basis for the pricing regime was broadened to refer to Rotterdam and New York prices as well as Singapore prices. As yet, China has few domestic price-discovery mechanisms and continues to rely on references from international markets.

Natural gas prices, particularly the large portion of gas provided to fertilizer plants, remain tightly controlled by the government, which has tried to make investment in natural gas more attractive by adjusting domestic prices closer to international levels.

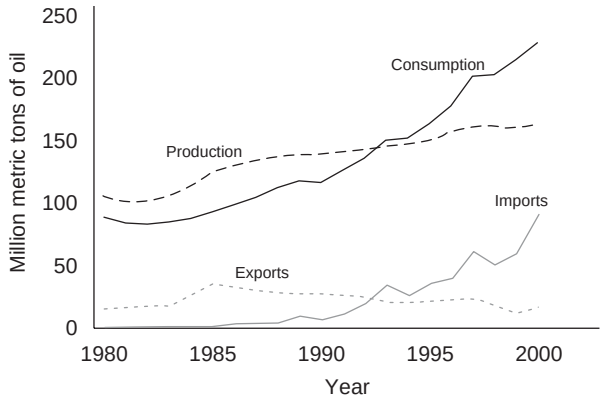

FIGURE 5 Oil production, consumption, and international trade, 1980–2000. In 1993, China went from being a net exporter to a net importer of oil.

However, gas pricing varies widely from city to city, and in the absence of a national pipeline network, a true market for natural gas does not yet exist.

Pricing policy in the electricity sector has been motivated by attempts to ease the serious electricity supply shortages that plagued much of China until the late 1980s. To encourage electricity production, the central government established a multitiered and diversified price system for the sector in 1985. Prices for enterprise-owned power plants (China's version of independent power producers) and small hydropower stations were set higher than plan prices for state-run utilities, and state-owned utilities were allowed to sell above-quota generation at higher prices. As shortages persisted in the late 1980s, the government allowed tariffs to be set on the basis of total costs plus a profit margin to encourage capacity expansion. In 1987, peak-load and seasonal pricing were introduced in some areas. In 1988, state-owned enterprises were levied an added electricity consumption tax for national electric power development, in addition to other national and local taxes on electricity, e.g., the national tax for financing the Three Gorges Dam project. Electricity price classifications, as well as rules and regulations for price settings, remain confusing, defeating any incentives for users to conserve. Prices vary greatly depending on region and class of user, as well as between urban and rural areas. The impact on prices of the current wave of power-sector reforms remains unclear.

2.9 Energy and the Environment

All across China, and particularly in the wealthy coastal provinces, cities and towns are becoming stricter in enforcing limits to pollutant emissions. When local administrations are supportive, environmental protection bureaus can levy significant emissions fees and fines, mandate process changes, and apply more drastic measures. Forceful application of environmental regulations could change industrial energy demand significantly. The regulation of sulfur dioxide emissions in China's legislatively defined "acid rain control zones" may, for instance, result in greater use of washed coal and installation of flue-gas desulfurization (FGD) equipment at power plants. Coal washing would provide a higher heat-content product that would burn more efficiently, reducing demand for coal, all else being equal. FGD, on the other hand, requires a great deal of a power plant's output, raising demand for coal inputs to power generation. Requiring urban factories to move or to replace equipment often results in the use of newer, generally larger, cleaner, and more efficient equipment. Sustained support for environmental policies is a factor in the continuing decline of coal use by households. In households, coal is being replaced by LPG, natural gas, town gas, and electricity.

3. OUTLOOK FOR CHINA'S ENERGY POLICY

China's demand for energy services will grow to meet the demands of its expanding economy and urbanizing population. Widely circulated baseline scenarios of primary energy demand in China to 2020 forecast total energy use to be between 70 and 90 EJ in 2020, compared to actual consumption in 2001 of 39 EJ (Fig. 6). The country faces numerous challenges in meeting this demand in a way that is economically, socially, and environmentally sound. It will be crucial for China to continue its progress in structuring markets, establishing institutions of corporate governance, revamping the finance sector, and finding other means to fulfill the social-welfare functions that formerly were provided by enterprises. These are broad tasks with multiple goals, but they will affect energy supply and use at least as much as policies aimed directly at energy.

Challenges for energy-supply policy abound. In the long term, commitment to developing renewable energy will have a tremendous impact on fuel structure, but for now conventional energy will be central. For coal, ensuring that large mines become financially viable remains a key task. How China finds ways to improve coal supply to meet environmental goals, such as reducing acid precipitation, will affect how coal is used. The debate, driven by

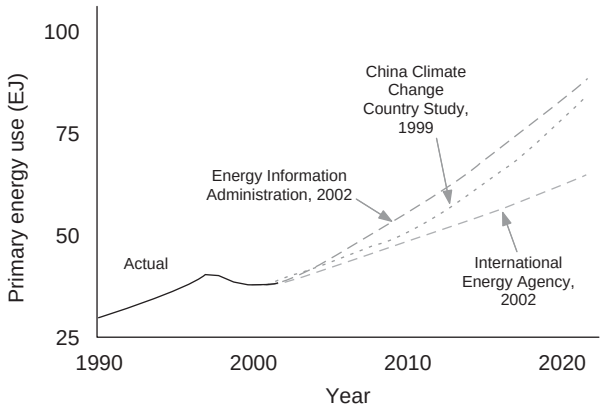

FIGURE 6 Major baseline scenarios of future fossil energy consumption in China to 2020. Widely circulated baseline scenarios of primary energy demand in China to 2020 forecast total energy use to be between 70 and 90 EJ in 2020, compared to actual consumption in 2001 of 39 EJ. The scenarios were adjusted to account for the discrepancies between forecast and actual energy use 2000; trends are the same as in original forecasts.

financial and security concerns, over whether China should rely more heavily on domestic coal resources instead of imported oil, also bears watching, though the potential for greater coal use will hinge again on coal quality, which, in turn, will depend on water availability in the arid coal-mining regions. Greater reliance on coal will signal higher growth in energy use and carbon emissions, because coal emits more carbon dioxide per unit of useful energy. In the long term, China's reliance on coal will be determined not by resources, but by climate change. If, as seems likely, significant reductions of carbon dioxide emissions from fossil fuel use in all countries are required, then coal use will be limited, unless an inexpensive way can be found to permanently sequester large amounts of carbon dioxide.

Because accession to the World Trade Organization has left China with fewer tools to restrict oil imports, policies that affect demand will be crucial. Transport policies that affect mode choices (e.g., road vs. rail; private vehicle vs. public transportation) and fuel-efficiency standards for vehicles, and policies affecting demand for petrochemicals, will influence China's oil imports. Natural gas is such a desirable fuel for so many reasons that consumption will likely be limited by supply. Policies affecting international trade in natural gas, support for construction of pipelines and distribution networks, pricing policies, and regulatory development all become relevant.

For electricity, the main question is how regulatory reform of utilities will proceed. Issues include how government will reduce its role in the management and operation of utilities, how generation will be separated from transmission and distribution, and how markets for electricity will be transformed and regulated. How China treats the activities of foreign participants in the sector will also be important, as well as national policy regarding development of nuclear power and nonhydro renewables. Changes in these areas will affect what types and scale of new generating units are built, system efficiency, environmental performance, and what kinds of demand-side electricity efficiency programs can be feasibly deployed in China. Energy efficiency policies are unlikely to bring about great change on their own, but they will help to create attractive opportunities for energy suppliers and users to raise efficiency—and slow growth in energy use—when the economic and institutional environments permit.

Within all these areas, there are substantial opportunities for international assistance and cooperation. On the supply side, efforts to help ease China's participation in international energy markets will be important to ensuring that China has access to adequate supplies of oil and natural gas. International experience is a valuable guide to establishment of China's national gas network. For the other oil-importing countries, a key challenge will be to find ways to accommodate China's needs for access to energy from the Middle East and Central Asia. Although China still has some claim to status as a developing nation, it is increasingly a heterogeneous country, with aspects that are highly developed and others that are much less developed. Consequently, the kind of multi- and bilateral assistance that would be most valuable is different from that usually provided to developing countries. As the country's financial system evolves, direct grants and loans will become less important than efforts to develop strong domestic financial institutions and commercial links to international capital markets. Promoting development and transfer of efficient technologies could be particularly valuable, including joint precommercial research and development. Even though most exchanges affecting how particular actors obtain and use energy will occur in the commercial realm, cooperation at the policy level remains important. If the guiding philosophy behind assistance is one of helping a partner build capabilities that will serve mutual interests, rather than one of providing a handout to a poor neighbor, then the chances will be much greater that strong, peaceful, trusting, collaborative relationships will develop, relationships that

will allow countries to work together to solve global challenges.

Glossary

biogas A gas composed of methane and carbon dioxide; produced from the anaerobic decomposition of organic material in landfills, biogas fuel provides a medium level of energy (British thermal units); also called biomass gas.

chulhas Traditional cooking devices that use biomass as a fuel.

coal bed methane (CBM) An environmentally friendly, clean fuel with properties similar to those of natural gas. Most of CBM is in an adsorbed state on the micropores on the surface of coal.

energy intensity The amount of energy required by an economy to produce one unit of national product.

fuel cell A type of cell capable of generating an electrical current by converting the chemical energy of a fuel directly into electrical energy. Fuel cells differ from conventional electrical cells in that the active materials, such as fuel and oxygen, are not contained within the cell, but are supplied from outside.

gas hydrates Solid, crystalline, waxlike substances composed of water, methane, and usually a small amount of other gases, with the gases being trapped in the interstices of a water and ice lattice. Gas hydrates form beneath the permafrost and on the ocean floor under conditions of moderately high pressure and at temperatures near the freezing point of water.

reserve replacement ratio The amount of natural resource added in a unit of time. It is calculated as the gross addition of reserves minus the production during the time frame, taken as a ratio of existing reserves.

solar thermal collector A device designed to receive solar radiation and convert it to thermal energy. Normally, a solar thermal collector includes a frame, glazing, and an absorber, together with appropriate insulation. The heat collected by the solar thermal collector may be used immediately or stored for later use. Solar thermal collectors are used for space heating, for domestic hot water heating, and for heating swimming pools, hot tubs, or spas.

In India, several committees appointed by the government to review energy policy from time to time have emphasized the need for a nationally coordinated approach to energy policy formulation. As a result, sporadic efforts have been made to bring together various departments or ministries dealing with energy for the purpose of arriving at a unified and integrated approach. However, this has not met with much success and initial efforts have been abandoned in every case. Currently, the National Development Council (NDC) functions as an umbrella organization to approve of each Five-Year Plan as prepared by the Planning Commission. The development of each successive Five-Year Plan involves a significant effort in consultation between the Planning Commission and several ministries; the plan receives the final stamp of approval from the NDC. The aggregation of component plans, however, is not an effective substitute for a properly integrated comprehensive national energy policy. For instance, several countries worldwide have a single energy ministry that serves the requirement of integration; with the tradition established in India, such an arrangement has neither been attempted explicitly nor has it presented great appeal to political decision makers. With rapid growth of the economy and increase in demand for energy, issues of energy security, efficiency of the entire energy system, and the effects of energy production, conversion, and consumption on the environment require policies that optimize some of these variables on an integrated basis, rather than by fuel or by specific source of energy. There is, therefore, a growing

 © 2004 Elsevier Inc. All rights reserved.

imperative for India to articulate a forward-looking integrated energy policy.

1. EVOLUTION OF THE NATIONAL ENERGY POLICY IN INDIA

The energy sector in India is administered at the apex level by four ministries and one department, representing the five supply sectors, namely, coal, oil and gas, power, renewable energy, and atomic energy. Coordination and integration are achieved within the Government of India (GoI) through the Cabinet and the Planning Commission. The respective ministries do coordination and integration with state governments, with the National Development Council providing a forum at the highest level.

This structure has evolved over time and has also led to a vacuum for coordinated vision and action on a sustained basis. However, this has not always been the position. A Fuel Policy Committee that had been set up in 1974 took an integrated view of the energy requirement of the country and made recommendations for the entire energy sector. With a rapidly changing international oil scenario, a Working Group on Energy Policy was set up in 1977. Its report, submitted in 1979 (after the beginning of the second oil shock), expressed that there could be no guarantee of steady oil supply to any importing country. It emphasized that although efforts were required to conserve resources of commercial fossil fuels through efficient production and utilization, it was essential to switch to renewable resources such as agricultural and animal wastes and to new and renewable sources such as energy from the sun and wind. An important recommendation of the Working Group was that energy planning and policy formulation should be done on a full-time basis and an energy ministry, or, alternatively, an energy commission, should be in place to deal with all these matters.

In 1982, the Ministry of Energy, comprising the Departments of Coal and Power, was expanded to include the Departments of Petroleum and Nonconventional Energy Sources. Thus, except for atomic energy, all other energy departments in the GoI had been brought under one ministry. In addition, in 1983, the GoI established an Advisory Board on Energy. The functions of the board included formulating an integrated energy policy covering commercial and noncommercial sources of energy. Its functions were advisory in nature and it was to submit its reports directly to the Prime Minister (Table I). Since then, this structure has become more decentralized, with all the energy subsectors falling under separate ministries or departments. It is only at the time of the formulation of Five-Year Plans (FYPs) that the sector is looked at as a whole. A brief review of the various pronouncements related to the energy sector in the FYPs is summarized in Table II.

TABLE I

Evolution of National Energy Policy

Major milestone	Impact/function
Fuel Policy Committee (1974)	Looked at energy sector as a whole
Working Group on Energy Policy (1977)	Report submitted in the aftermath of the second oil shock expressed apprehensions regarding security of oil supplies and thus recommended conservation of energy and encouragement of renewable energy
Expansion of Ministry of Energy to include Departments of Petroleum and Nonconventional Energy Sources (1982)	Except for atomic energy, all other forms of energy were brought under one ministry
Advisory Board on Energy (1983)	Set up to formulate an integrated energy policy covering commercial and noncommercial energy resources
Exploration rounds	The exploration rounds to attract the private sector were introduced in 1979, but not much headway was made till 1995
Committee on Integrated Coal Policy (1996)	Recommended adoption of coal conservation measures, inviting private capital in the sector, deregulating the coal and coal product prices, and setting up a regulatory body, among other things
Common Minimum National Action Plan for Power (1996)	Initiated the reforms in the power sector with trifurcation of state electricity boards, setting up of state and union level regulatory commissions, and rationalization of tariffs
New Exploration and Licensing Policy (NELP) (1997)	NELP was introduced in 1997 with modified terms and conditions; three rounds have been held with moderate success
Administered Pricing Mechanism (APM) dismantling (1997)	Phase-wise dismantling of APM started in 1997; APM was completely abolished early in 2003

Broadly speaking, the overall objective of a National Energy Policy (NEP) should be to meet the energy needs of all segments of population in the most efficient and cost-effective manner while ensuring long-term sustainability. This objective entails the following major tasks:

- Providing clean and affordable energy to all.
- Ensuring security of the energy supply.
- Improving the efficiency of the energy system.
- Reducing the adverse environmental impacts of energy use.

The following discussions review the Indian experience in light of these objectives.

TABLE II

Five-Year Plans[a]

Plan	Goal
First FYP (1951–1956)	Set out the objectives of national planning with immediate focus on agricultural and industrial development and attendant development of irrigation and power
Second FYP (1956–1961)	Emphasized the long-term perspective while planning for short-term horizons
Third FYP (1961–1966)	Elaborated the need for a comprehensive review of the extent of available information and data on India's natural resources
Sixth FYP (1980–1985)	Aimed at a decentralized approach to increasing availability of renewables to meet rural energy requirements; thrust was on management of oil demand, conservation, and renewable resources; contained the first oblique reference to the environmental impact of energy use
Seventh FYP (1985–1990)	Recognized that energy planning involves not only potential increase: in indigenous availability of energy, but also better utilization, because the trends in India's commercial energy consumption show high rates of growth and because of the growing share of oil dependency
Eighth FYP (1992/1993–1996/1997)	The environmental dimension was given due significance only in this plan, which emphasized the long-term need for promotion of technologies of production and consumption of energy that are environmentally benign and cost-efficient
Ninth (1997–2002) and Tenth FYP (2002–2007)	These plans placed special emphasis on the need to introduce reforms in the energy sector in order to improve efficiency in the sector and to enhance infrastructure development in view of the impending growth in the sector in the long term. Due importance has also been given to the pricing issues in the sector and the need to make prices indicative of the market. Concern was also raised regarding the direct and indirect subsidies present in the sector and the need to streamline them and make the process more focused. Energy conservation is to be promoted in the plan periods mainly through improvements in the industrial sector

[a]Data are from each plan, as specified by the Indian government.

2. *ENERGY FOR ALL*

2.1 Present Scenario in Energy Consumption

Total primary energy consumption in India has increased nearly fivefold in the three decades from 1970 to 2001. The total primary energy consumption stood at 437.7 million tonnes of oil equivalent (MTOE) in 2001/2002 (GoI 2002). The share of commercial energy in total primary energy consumed rose to more than 68% in 2001, up from 28% in 1950 and, as the economy develops, this share is expected to rise even further. However, the per capita energy consumption in India is still 479 kilograms of oil equivalent (kgOE), which indicates a tremendous scope for even higher energy consumption in the coming years. Additionally, the 5.4% annual growth rate of energy consumption achieved by India, over the period 1970–2001, is the 14th highest in the world.

Figure 1 shows the comparative position of India with respect to per capita income and per capita energy consumption. Countries with high per capita income are also characterized by high per

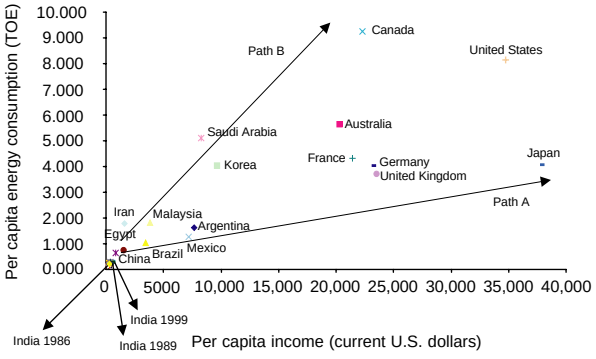

FIGURE 1 Comparison of per capita energy consumption and income in India and other countries. The gross domestic product and population data are from the World Bank; energy consumption data are from *BP Statistical Review of World Energy (2002)*.

capita energy consumption. This is not to suggest that India should be looking toward energy consumption levels of the West, as it marches on its path of development, because that would simply be unsustainable. In fact, it does indicate that there is tremendous scope for increase in energy consumption, admitting, though, that the link between energy and economy will gradually become weak as the economy matures and moves more toward the services sector. This is shown in Table III, which gives the trend in elasticity of consumption of various fuels with reference to the gross domestic product (GDP) over time. From Fig. 1, it is evident that Japan is more efficient than the United States because its energy consumption is much lower than that of the United States for the same level of per capita income. Accordingly, developing countries could aim to follow path A for development in order to build a sustainable economy. Development along path B will result in a high, potentially fatal dependence on energy for countries like India, which are dependent on imports for meeting their energy needs. Figure 2 shows the path that India has taken for the past two decades. As shown, since 1990, the per capita energy consumption in India has not risen commensurately with its per capita income, which indicates that it is possible to reduce energy intensity and/or improve energy efficiency in the economy while still enabling economic development.

The elasticity of consumption of various fuels with respect to the GDP has declined over the years, with current commercial energy elasticity lower than unity; this means that a 1% increase in the GDP will increase the commercial energy consumption by less than one. However, underprivileged sections of Indian society do not have access to efficient sources of energy. The World Bank estimates indicate that, of the 2 billion people who have no access to modern energy sources such as electricity and liquefied petroleum gas (LPG), about 700 million live in India. Within India, there is a big rural–urban divide in terms of access to modern energy sources (Figs. 3 and 4). Access to modern fuels can be improved by short-term government measures such as subsidies as was done by the introduction of Public Distribution Systems to make available kerosene to the underprivileged section. However, these measures have not proved to be sustainable in the long term. State interventions in the form of programs for poverty alleviation are important to enable continued use of modern resources even after subsidies are phased out.

TABLE III

Elasticity of Consumption of Commercial Energy with Respect to GDP[a]

Period	Coal	Oil	Electricity	Total commercial energy
1953/1954–1960/1961	1.10	2.14	3.02	1.37
1960/1961–1970/1971	0.53	2.31	3.04	1.16
1970/1971–1980/1981	0.98	1.83	2.06	1.37
1980/1981–1990/1991	0.31	1.12	1.57	0.82

[a]Data from Sengupta (1993).

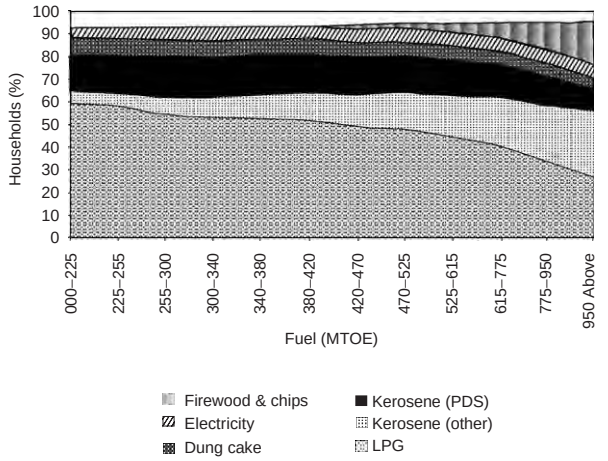

FIGURE 3 Fuels used by rural households (percentage). PDS kerosene is kerosene sold through the "fair price" shops under the Public Distribution System. Data are for 2001, from the National Sample Survey Organization.

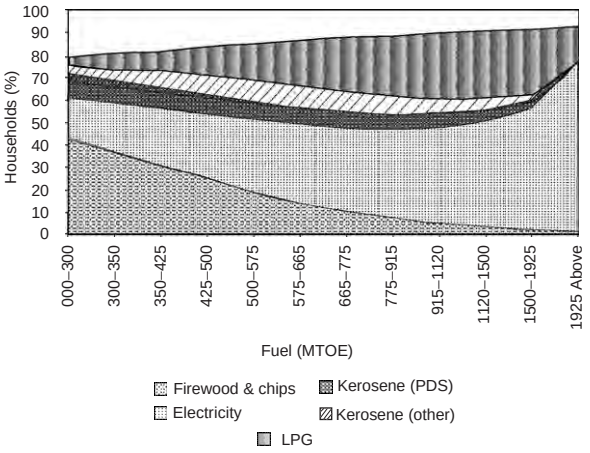

FIGURE 4 Fuels used by urban households (percentage). PDS kerosene is subsidized kerosene sold through the "fair price" shops under the Public Distribution System. Data are for 2001, from the National Sample Survey Organization.

Figs. 3 and 4 show that the percentage of electricity usage among all classes of urban households is quite high, as is the consumption of LPG. However, the dominant fuel among the rural households is firewood, which is both inefficient and leads to indoor air pollution. Thus, promoting fuels such as electricity and LPG would not only promote efficiency but would also help curb respiratory problems among rural women.

2.2 Energy–Economy Linkage

Energy is the key driver of many sectors of the economy, namely, agriculture, industry, commerce, services, and domestic. With advances in technology and the growing need for higher productivity, most of these sectors are also becoming more energy intensive. This is especially true in developing countries, which show a strong energy–economy linkage in the form of high-energy intensity/elasticity of the economy. The developed countries have been able to weaken this linkage due to development of more efficient processes that can do the same amount of work with less energy, or more work with the same amount of energy. However, developing countries—most of them highly industrialized—are still highly dependent on energy.

The picture is not different for India. Though India now boasts of a big services sector, accounting for 49% of its GDP, the energy intensity of Indian economy is still high. Figure 5, which shows the trends in the GDP and the primary energy consumption in India since 1970, indicates a strong linkage

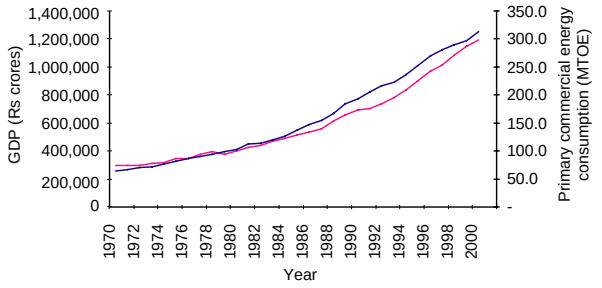

FIGURE 5 Comparative trends in gross domestic product (GDP) and total commercial energy consumption. The GDP is expressed in crores (=10 million) of rupees (Rs). The gross domestic product data are from *Economic Survey 2002/2003;* energy consumption data are from *BP Statistical Review of World Energy (2003).*

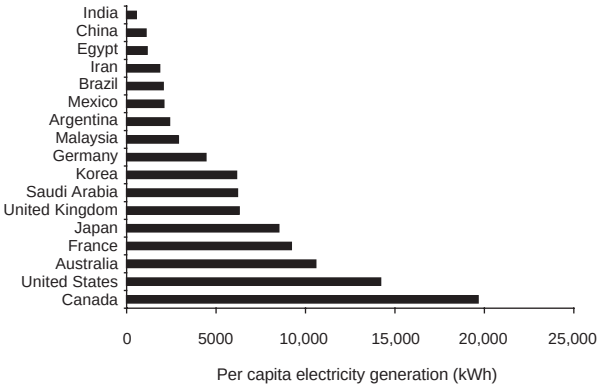

FIGURE 6 Comparison among countries with respect to per capita electricity generation (in kWh, kilowatt-hours). Electricity data are from the International Energy Agency; population figures are from the World Bank.

between energy and economy. However, the years since 1985 have witnessed a gradual distancing between the two curves that is indicative of a growing share of the services sector, which is less energy intensive as compared to the industrial sector. Per capita electricity generation and oil consumption levels in India are among the lowest in the world, lower even than those of its neighbors, as shown in Figs. 6 and 7.

3. ENSURING SECURITY OF ENERGY SUPPLIES

The issue of ensuring affordable supplies of energy in various required forms is central to India's socio-economic development. As already mentioned, the link between energy and economy in India is still strong and any disruption in energy supplies is bound

to have negative impact on the economy. The important issue is to assess both the vulnerability of the economy to an external supply shock and the measures that can be taken to cushion the economy against such a shock.

With the entry of the private sector, market forces in the energy sector have added a new dimension to the whole issue of energy security. Market forces will ensure that, during crises, demand and supply will always balance. Prices will indicate the relative shortage and surplus in the sector. Thus, the impact of external shock will be felt in prices rather than in demand and supply.

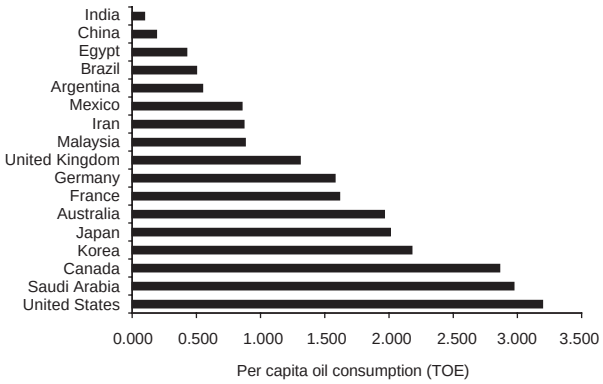

FIGURE 7 Comparison among countries with respect to per capita oil consumption (in TOE, tonnes of oil equivalent). Oil consumption data are from *BP Statistical Review of World Energy (2003)*; population figures are from the World Bank.

3.1 India's Fuel Mix

India's energy mix has not undergone much change in the past 30 years. Coal still remains the dominant fuel; 55% of the total primary energy is accounted for by coal, down from 58% in 1970, though the consumption of coal has grown by 5.21% annually. The share of oil has increased marginally from 30% in 1970 to 31% in 2001, though consumption has grown at 5.5% annually since 1970. Gas has witnessed major gain, increasing by a share of 8%, which is up from virtually nothing in 1970, with gas consumption growing at 13.73% annually. However, because of domestic discoveries, it is only since the 1980s that gas has really seen major improvement. The share of hydropower has declined, although it displayed an annual growth rate of 2.38% over the past 30 years. This is primarily due to high growth rates achieved by oil and gas (Table IV).

The high percentage of oil consumption in the economy, along with high oil elasticity, points toward increasing dependence of Indian economy on oil as a fuel. This dependence becomes more

TABLE IV

India's Fuel Mix[a]

	Mix per year (in MTOE)					
Fuel	**1953/1954**	**1960/1961**	**1970/1971**	**1980/1981**	**1990/1991**	**2001/2002**

threatening if it is seen in conjunction with the meager quantity of domestic crude oil production and, consequently, the high level of dependence on imported oil. However, the economy's dependence on oil is much more than is suggested by the share of 31%. This is because of the heavy dependence of the transport sector on oil. The avenues for fuel substitution in the transport sector are limited, notwithstanding recent endeavors to use compressed natural gas (CNG) in lieu of gas oil and gasoline. Initiatives to increase use of solar-powered vehicles and fuel cell vehicles are still many years from impacting the share of oil use by transport sector. Certain reform strategies to improve energy efficiency, however, can be implemented with immediate effect in the transport sector:

- Measures to improve the efficiency of oil use in vehicles (this would also improve the already degraded urban environment).
- Taxes on fuel consumption to signal importance of fuel conservation.
- Strict adherence to vehicular fuel-efficiency parameters.
- Policy interventions to encourage faster turnover of old vehicles.
- Incentives to attract foreign players into the market to create competition, promoting the latest and most efficient technologies.
- Improvements in highways and internal city and town roads and promotion of foreign direct investment (FDI).
- Strengthening of public transport systems to reduce the use of personal vehicles.
- Policy options and improvements in railways to promote cargo movement and to reduce the pressure on roadways.
- Policy options and rapid work on the megaproject to link rivers across the country, to reduce the load on road transportation.

The issue of energy security assumes even greater importance when future energy demand and supply scenarios are examined.

3.2 Future Energy Demand

The preceding discussion highlighted the low per capita income and high per capita energy consumption that characterize the Indian economy. These trends indicate the possibility of even larger energy consumption in the coming years. The *International Energy Outlook 2003*, published by the U.S. Department of Energy, projects India's energy consumption

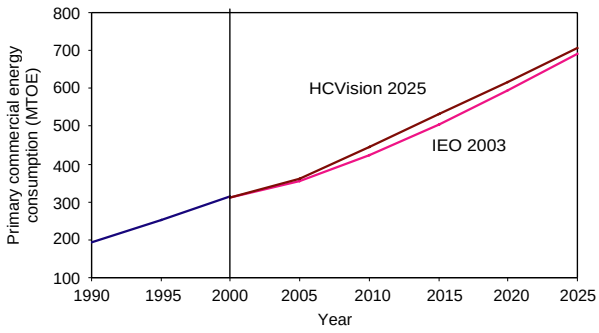

FIGURE 8 Past and projected energy consumption trend. MTOE, Million tonnes of oil equivalent. Data are from *Hydrocarbon Vision 2025* (HCVision) and *International Energy Outlook 2003* (IEO); additional data are from *TERI Energy Data Directory and Yearbook* for years 1999–2000.

at 690 MTOE by 2025, up from 322 MTOE in 2001, and an average annual percentage change of 3.2% during the period 2001–2025. Based on the population estimates given by the World Bank, the per capita energy consumption works out to be 529 kgOE, which is 10% higher than the current level. The energy intensity at this level of energy consumption, assuming a GDP growth rate of 6%, works out to be 13.67 kgOE per 1000 rupees, which indicates a decline of 43% over the 22-year period (2003–2025). This level of consumption will increase India's share in total world primary energy consumption to 4.27%, up from the current level of 3.1%.

Hydrocarbon Vision 2025, the long-term energy policy document published by the GoI, also projects energy demand and fuel mix for the period 2002–2025. It pegs India's total primary energy consumption at 616 MTOE in 2020, of which 238 MTOE will be derived from oil, representing 38% of the total; gas will contribute 16%; coal, 38%; hydro, 6%; and the rest will be met by nuclear power. These projections are not very different from the *International Energy Outlook 2003* projections, as shown in Fig. 8. The resultant change in fuel mix is shown in Fig. 9. The share of coal is projected to decrease, from 55% in 2001 to 38% in 2020 (Fig. 9), whereas that of natural gas is projected to double to 16%. The share of oil is projected to rise to 38%. This fuel mix indicates a gradual shift toward cleaner fuels (natural gas and oil) in the wake of rising environmental concerns. On the other hand, the projection also indicates a rise in dependence of the economy on imports, because domestic reserves of oil and gas cannot support such high consumption levels under the most optimistic scenario.

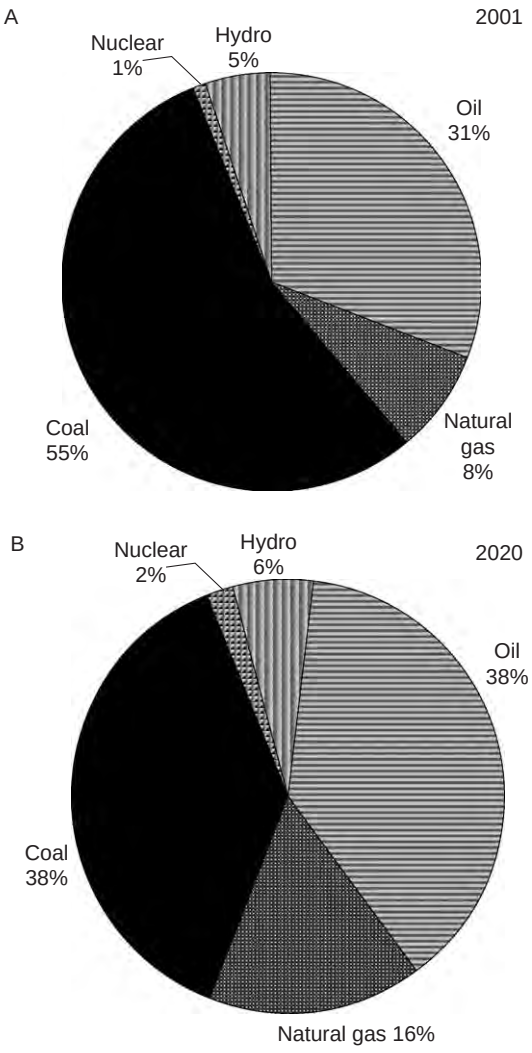

FIGURE 9 Current (A) and projected (B) commercial energy mix. Data are from *Hydrocarbon Vision 2025*.

3.3 Present Resource Availability and Future Outlook

Given that India is a huge consumer of energy, supply options are very limited. Already, India imports around 74% of its crude oil requirement and, though India has vast reserves of coal, coal imports are on the rise due to the low quality of native coal and the faulty taxation structure that makes coal imports cheaper for some consumers located near the coast. Development in the nuclear energy sector has increased in recent years, but it is unlikely that this sector will play a role in the development of Indian economy comparable to the role it played in France. India has a huge potential for hydropower, especially small/micro hydro/electric (hydel) power projects, but these opportunities are concentrated in a few states. This makes it imperative to improve the efficiency of the transmission system so that surplus power in one state can be reliably transferred to a deficit state. To achieve this, reforms in the power sector are essential. Table V shows the level of reserves in coal, oil, and natural gas in the country along with the reserve replacement ratio. The reserve replacement ratio for crude oil, though positive, is still low and the same goes for gas. India's position in coal seems to be comfortable but, as is discussed later, there are some environmental concerns.

TABLE V

Coal, Oil, and Natural Gas Reserves[a]

Fuel	Reserves	Current production	Reserve replacement ratio
Crude oil (million tonnes)	644.8	32.45	0.59
Natural gas (billion cubic meters)	647.5	26.57	0.33
Coal (million tonnes)	213,905.5	322.2	8.46

[a]Data from TEDDY 2002/03, see TERI (2003).

Efforts such as the New Exploration Licensing Policy (NELP) are being made to increase the indigenous production of crude oil, but the prospects for discovery of another oil field equivalent to the Bombay High field (discovered in the late 1970s) remain remote. Availability of gas in the form of liquefied natural gas (LNG) is slated to improve in the coming years, but there are many policy issues that remain to be sorted out before gas can be delivered cheaply in the country. Several pipeline projects are also planned, but political risks seem insurmountable. These issues are discussed in detail in the following sections. The locations of various coal, lignite, oil, and gas fields are shown in Fig. 10.

3.3.1 Crude Oil Supply Outlook

It has been almost two decades since Bombay High was discovered. Given the fact that consumption is around 100 million tonnes (MT) of petroleum products every year and production is only 33 MT, four more Bombay Highs would be required for India to become self-reliant in oil at present. As oil consumption rises in the future, discovering even more domestic reserves becomes imperative with

FIGURE 10 Crude oil, natural gas, and coal/lignite reserves in India. Data are from The Energy and Resources Institute.

respect to security in both oil supplies and prices. This appears far-fetched, given the lackluster response to the NELP by international oil companies, which were expected to bring in both technology and capital. Though the Oil and Natural Gas Corporation Ltd. (ONGCL) is planning to double its reserves in 20 years, the oil demand by then would also have more than doubled, leaving the import dependency unchanged. The Planning Commission has projected domestic production of only 45 MT by 2011/2012 against the projected demand for petroleum products ranging from 187 to 160 MT. This indicates high import dependency with all its repercussions on energy security and the foreign exchange reserves. The low prospect of discoveries in Indian sedimentary basins, due to poor exploration methodology, is an indication of the need for diversification of energy sources and application of effective and efficient exploration techniques to discover new oil and gas basins in India.

3.3.2 Electricity Supply Outlook

Given the high positive elasticity of electric power with respect to the GDP, reliable electricity supply is a necessary ingredient for economic development. The current installed capacity in India is 105,083 megawatts (MW). However, there is a 10.5% energy shortage and a 15.9% peak shortage. The high transmission and distribution (T/D) losses mean that even the peak demand of 78,841 MW, which is 26,242 MW less than the installed capacity, is not being met. To meet the electricity requirement, the National Thermal Power Corporation (NTPC) is planning to add 20,000 MW of additional capacity by 2020; but these plans are largely dependent on the availability of LNG at reasonable prices. The Central

Electricity Authority (CEA) projects an addition of 47,000 MW during the period 2002–2007, which seems highly unlikely, given that India has been able to add only about 20,000 MW per plan period previously. The private sector was expected to play an important role in improving the power situation in the country, but the slow pace of reforms has discouraged investors, and many independent power producers (IPPs) have thus abandoned their plans for new plants. As indicated previously, to realize the full potential of hydropower, substantial investments in T/D are required.

The government has targeted a nuclear-based capacity of 20,335 MW by 2020. Considering the fact that current nuclear-based capacity is only 2720 MW, this also seems a bit ambitious. This is not only because of high initial investment costs, but also due to many other issues concerning nuclear power, such as long development period, reactor safety, waste disposal, and the continuance of government support. Thus, in the present scenario, nuclear energy is not expected to play the same important role that it played in France. The important aspect that emerges is that interventions are required to expedite the pace of reforms, attract IPPs back into the energy market in India, and create investment opportunities in T/D of power grids to tap the high prospect of hydropower.

3.3.3 Gas Supply Outlook

Gas is slated to play an important role in India's energy mix. As per *Hydrocarbon Vision 2025*, the share of gas in total energy consumption is projected to be 16%, up from 5% at present. However, projections for indigenous gas production imply that much of this gas is likely to be imported, primarily in the form of LNG. The Planning Commission has projected domestic production of 105 million standard cubic meters per day (MSCMD) by 2011/2012; the demand projected by *Hydrocarbon Vision 2025* ranges from 216 to 313 MSCMD in the year 2011/2012.

The recent discovery of 10.5 trillion cubic feet (TCF) of natural gas by Reliance in the Krishna–Godavari Basin is expected to boost the current gas production by 50% in 2–3 years. This discovery, in the NELP 1 block, has led to an improved outlook on indigenous gas production, and many plans for importing natural gas are being reviewed. However, this gas is concentrated in southeastern India and the major demand centers are in northern and western India. Whether this gas will flow to these demand centers remains to be seen, but in the present scenario, the dependence on imported gas will continue. Several proposed LNG projects will serve to fill this gap, but progress is slow due to various issues concerning the reforms in the oil and gas sector in the country.

Several pipeline projects are also planned to reduce the demand–supply mismatch in the country, including the Indo–Iran pipeline, the Indo–Oman pipeline, and the Indo–Bangladesh pipeline. The security concerns surrounding the Indo–Iran pipeline are given great weight by the policymakers, rendering this project, too, a nonstarter. The Indo–Oman pipeline was officially declared dead when the feasibility report admitted the lack of technology for deepwater pipelines. Bangladesh has recently hinted at limited gas exports to India, but the issue is still under debate.

The GoI has also framed policies for the development of nonconventional gas resources such as coal-bed methane (CBM) and gas hydrates. India has 850 billion cubic meters (BCM) of assessed CBM resources and 6150 trillion cubic meters (TCM) of assessed gas hydrate reserves. Private sector players such as Reliance and Essar have evinced interest in CBM, and the National Gas Hydrates Program is underway to develop gas hydrates. All these initiatives to strengthen the nonconventional gas resources are steps in the right direction and will boost India's energy security.

4. IMPROVING THE EFFICIENCY OF THE ENERGY SYSTEM

Figure 11 shows energy intensity (kilograms of oil equivalent per 1000 rupees) and energy consumption

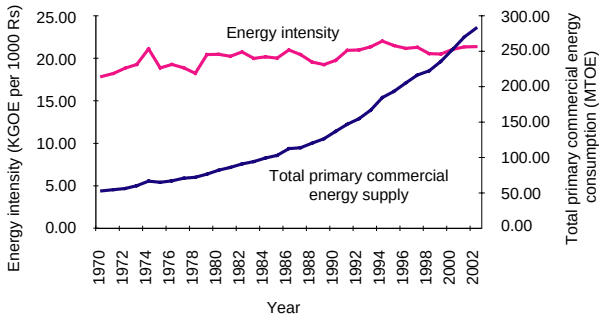

FIGURE 11 Trend in commercial energy intensity and total commercial energy consumption (in kgOE, kilograms of oil equivalent); Rs, rupees; MTOE, million tonnes of oil equivalent. Total commercial energy consumption data are from *BP Statistical Review of World Energy (2003)*; gross domestic product data are from *Economic Survey 2002/2003*.

over several decades. The rate of growth of commercial energy intensity of the economy has been slower than that of the total commercial energy consumption. This decline is due to the high growth in the services sector and/or improvements in the energy efficiency of the economy.

Sectoral trends in energy intensity also yield important insights into the country's energy efficiency. The energy intensity of the industrial sector has declined since the 1980s, primarily due to a decline in the oil intensity of the industry, although intensity of gas usage has increased. Presently, gas demand in the country is constrained due to deficiency in supply, even though gas is more efficient than oil in industrial applications. Energy intensity of the agriculture sector has risen, primarily due to a huge rise in electrical energy intensity of the sector. This trend is also expected to continue as Indian agriculture tries to rely more on man-made irrigation options than on monsoons. Also, new-age farming processes require measured irrigation at the right time to yield desirable results. This will further necessitate the use of pump sets in irrigation.

Energy intensity of transport (excluding railways) rose till 1989/1990, when it reached its peak, and declined thereafter. This is probably due to the introduction of more fuel-efficient vehicles following the liberalization of the economy in 1990/1991. Improving efficiency in the sector would entail introducing market-based reforms. Some progress has been made along these lines (a detailed analysis of the status of reforms to date is discussed later). According to estimates of the United Nations Development Program (Table VI), there is still room for improvement in energy efficiency in various sectors of the economy.

TABLE VI

Potential for Improvement in Energy Efficiency[a]

Sector	Energy efficiency (%)
Industry	
Iron and steel	15
Cement	17
Pulp and paper	20–25
Textile	23
Aluminium	15–20
Household	
Lighting	10–70
Refrigeration	25
Air-conditioning	10
Agriculture	
Pump sets	25–55
Transportation	
Cars	7.5–10.0
Trains (diesel)	5–10
Trains (electric)	5–10

[a] Data from United Nations Development Program (2000).

5. REDUCING THE NEGATIVE ENVIRONMENTAL IMPACTS

5.1 Effects of Conventional Energy on the Environment

Being a developing country, India does not have any commitments for reduction of CO_2 (carbon dioxide) emissions, though India has ratified the United Nations Framework Convention on Climate Change (UNFCCC) and is party to several international environmental treaties (e.g., the Montreal Protocol). However, the noncommitment on emissions should not lead India to a pursue development that is unsustainable and has adverse impacts on the environment. Through the concept of sustainable development, a long-term vision that can bind various policy objectives of each subsector of the economy should be developed. Reducing environmental distress should undoubtedly be among the main policy objectives of an integrated energy policy.

India's energy-related carbon emissions have grown ninefold over the past four decades. With 162 MT of carbon released from consumption and burning of fossil fuels in 2001, India ranked fourth in the world. Coal burned in electricity generation accounts for 64% of all carbon emissions from coal. Technology improvements and diversification of fuels for the power sector are an utmost priority. In a business-as-usual scenario, according to *International Energy Outlook 2003* projections, CO_2 emissions from the power sector will rise to 261 MT of carbon equivalent by 2020. The average annual percentage change in CO_2 emissions from 1990 to 2020 will be 2.2%. India should gear up now, because it may be called on to cut emissions in the second commitment period (2012–2018). Given the long lives of power plants, these issues have to be kept in mind while planning national electricity capacity. Due emphasis should be given to research and development to implement effective and efficient technology for future emissions reductions.

India's carbon intensity is also high, primarily due to low efficiency of coal-based generating plants. Taxation policies that make domestic coal competi-

tive with cleaner imported coal are also responsible for the high carbon intensity of the economy. An integrated energy plan would consider the effects of such energy policies on the already degraded environment of the country. In sum, analysis easily identifies the key areas—decentralized grass-roots initiatives and production and usage of renewable energy—for policy interventions for sustainable development and for reducing adverse environmental impacts.

5.2 Potential for Renewable Energy

The share of hydrocarbons in India's commercial energy mix is slated to rise to 54% in 2020 from the current level of 38% (see Fig. 9). Given the paucity of hydrocarbons in India, it is important to develop a renewable energy base that would reduce import dependence. Table VII shows the estimated potential for renewable energy in the country. Comparison of the potential with achievement paints a bleak picture. Although India ranks first in the world in utilization levels of solar cookers and biomass gasifiers, and can claim decent utilization levels in biogas plants and cookstoves, in solar photovoltaic energy, and in wind power, the potential to exploit these resources still remains unfulfilled. One major deterrent to the utilization of renewable energy is the high utilization cost of these technologies. However, these costs are slated to decline in the future, which will make the technologies economically competitive. Solar photovoltaic (PV) energy is an important alternative for power generation, and specific intervention is required to promote its use. The annual global market for PV energy is estimated to be around 200 MW and has grown at a rate of 15% over the past 15 years. In India, the annual PV production volumes are of the order of 10 MW, making India one of the largest markets and manufacturers of PV modules in the world after the United States, Japan, and the European Union.

Very few power-generating renewable energy sources are currently connected to the grid in India. As energy from renewables becomes more and more competitive, this aspect will automatically cease. Renewable energy can be used not only to generate power, but also for cooking, space heating, water desalination, etc. All these uses suggest that rural India represents a vast market for renewable energy; with provision of energy becoming more and more decentralized, such options will be explored more thoroughly. In fact, the Ministry of Nonconventional Energy Sources has targeted 5750 remote villages for electrification through the use of renewable energy by 2012.

TABLE VII

Potential and Achievement in Renewable Energy[a]

Energy source	Potential	Achievement[b]
Biogas plants	120 lakh[c]	32.75 lakh
Improved chulhas[d]	1200 lakh	338 lakh
Wind	45 000 MW	1507 MW
Small hydro	15 000 MW	1423 MW
Biomass power/ cogeneration	19 500 MW	358 MW
Biomass gasification		42.8 MW
Solar photovoltaic	20 MW per km^2	82 MW per km^2
Waste-to-energy fuels	1700 MW	17.1 MW
Solar water heating	1400-lakh m^2 collector area	6-lakh km^2 collector area

[a] Data from Ministry of Nonconventional Energy Sources (2002).

[b] As of 31 December 2001.

[c] Lakh is a term denoting 100,000; it is used here to indicate efficiency.

[d] A chulha is a fuel-burning stove; chulhas are made of many materials and have shapes and components that make them more or less efficient.

6. IMPERATIVES FOR THE NATIONAL ENERGY POLICY

Energy demand in India is projected to increase in the coming decades, as discussed earlier. Though efforts are being made to ensure reliable supply of energy at reasonable prices, entry of market forces due to the globalization and privatization process will play an important role in the process. Ensuring the reliable supply of energy, in required forms and at reasonable rates, has become one of the priorities of governments the world over, and this holds true especially for energy-deficient countries such as India. However, market forces are increasingly encroaching on this traditional domain of state influence. This essentially means that though demand and supply will always match, prices will reflect the shortage or surplus in the economy. Hence, energy shortages are likely to translate into higher prices. Because there is a strong energy–economy linkage, this will slow down the pace of development and depress the economy. Thus, the

National Energy Policy should aim first to weaken the energy–economy linkage, by improving the efficiency of energy use, and then to ensure that dependence on any one source is reduced effectively, thereby reducing the vulnerability of the economy to external shocks. The various policy issues that are critical to ensuring these aims are discussed in the following sections.

6.1 Role of Market Forces

Traditionally, energy has been one of the main domains of state influence in which the private sector had been excluded from effective participation. This is evident in developing countries, in which scarce resources are utilized in optimal ways in the interest of the entire nation. At the same time, the developed world has moved toward market forces. In the recent past, market forces have also begun to make their presence felt in increasing numbers of developing countries (India, Brazil, Mexico, and several East Asian countries). It is being gradually realized that the market is the best allocator of resources and that the government should at best be a facilitator and regulator that sends signals in the form of incentives to the market, to orient market objectives toward national aims. In India, entry of market forces in each sector of the economy was planned and allowed when reforms were launched in 1990/1991.

The entry of private players in the energy sector means that prices will become important tools for signaling shortage or surplus in the market. In the controlled era, quantitative restrictions played a major role in balancing demand and supply. This, however, created a lopsided consumption pattern and efficiency was put on the back burner. Industries, assured of fixed returns, paid no attention to the efficiency of the process, which increased the energy intensity of the economy. Wasteful spending by consumers who could afford it led to shortages in the market, which then forced the government to resort to quantitative restrictions in order to supply energy to those who could not afford it. Meanwhile, the import bill for the country continued rising, given the importance of oil in the energy mix.

With prices now becoming important tools, such tendencies are likely to be curbed. This is already showing in the improving energy intensity of the economy, which is becoming more and more competitive. For example, the prices of petroleum products have been decontrolled and are now set by oil companies fortnightly, based on international price of crude. This gives the consumer strong signals about the real value of these products and, hence, is likely to have an impact on the consumption pattern and fuel economy of vehicles. Such a rise of market forces, however, raises the question of regulation of the market by the government. Markets are nowhere near perfect; to prevent market abuse, regulation has to play an important role. Thus, regulating the energy market is one of the major tasks for the NEP.

Pricing policies adopted by the government so far have resulted in the largest state-run power-generating company in the country, the National Thermal Power Corporation, which holds the decision to use gas for power plants (Anta, Auraiya, Kawas, and Kayamkulam) in abeyance due to uncertainty over final delivered gas price. In the absence of an integrated LNG policy, the tax status of LNG remains uncertain and, hence, the cost of delivered LNG differs from state to state. On the other hand, an increasing number of studies are proving that gas will be competitive with coal, at least in the western region of the country. This uncertainty, in turn, affects the investment in the infrastructure sector of the country, which is crucial for development.

6.2 Status of Reforms

Reforms were launched in India almost a decade ago. So far, the scorecard has been mixed. In some sectors, reforms have seen greater consumer choice, availability of latest technologies, and reduction in prices due to increased competition. However, reforms in the energy sector have not been adequately effective, because this sector requires an integrated approach involving all the sectors that are directly or indirectly linked with it.

6.2.1 The Energy Conservation Act (2001)

The Energy Conservation Act (2001) was enacted in September 2001 to deal with all matters related to the efficient use of energy and energy conservation. Under the act, the Bureau of Energy Efficiency was set up to discharge the following functions:

- To look into the energy consumption norms for each energy-intensive industry and encourage proper labeling of energy consumption indicators on every electrical appliance.
- To provide guidelines for energy conservation building codes.

- To take measures to create awareness and disseminate information for efficient use and conservation of energy.
- To strengthen consultancy services in the field of energy conservation, develop testing and certification procedures, and promote testing facilities for certification and energy consumption labeling of equipment and appliances.
- To provide financing for certain measures taken by consumers to enhance efficiency in energy consumption.
- To maintain a list of accredited energy auditors to carry out energy audits of industries and recommend measures for improving efficiency.

The responsibility of the central and the state governments under the Energy Conservation Act is to ensure effective and efficient implementation of the suggestions given by the Bureau of Energy Efficiency, for which a system of penalties and incentives has been devised. On the whole, the enactment signifies the importance that the government has accorded to efficiency improvements in all sectors.

6.2.2 Oil and Gas Sector Reforms

In 1997, the government had established a timetable for abolishing the Administered Pricing Mechanism (APM) by 2002 and for deregulating the entire oil and gas sector. Though the APM has been abolished, it is not certain that the oil and gas sector has been freed of government diktats. Though the pricing of sensitive fuels (motor fuels, high-speed diesel fuel, LPG, and superior kerosene oil) is supposed to be market determined, prices are still set after consulting the government.

In order to prevent exploitation of consumers in the deregulated scenario, the Petroleum Regulatory Board Bill was introduced to ensure that each marketing company displays the maximum retail prices for the notified petroleum products and take steps in accordance with regulations to prevent profiteering by the entities. However, the bill has not been passed and has been referred back to the Parliamentary Standing Committee. Therefore, the regulator is still not in place and gas prices are not yet completely linked to international parity. The ONGCL still negotiates with the refineries for an internationally competitive crude price.

LNG importers have been demanding granting of infrastructure status for LNG that would make it eligible for a central sales tax of only 4%. Because the sales tax rates vary widely from state to state, LNG is likely to be costlier than coal, which jeopardizes investments being made by companies in building LNG terminals. To deal with this, the government has introduced the draft Integrated LNG Policy, which focuses on the various tax sops given to the project developers to make LNG viable in the country. It is expected that the delivered LNG will be 22% cheaper under the new policy and will bring it on par with 100% fuel oil parity price of the domestic gas. The government has also announced a new Petroleum Product Pipeline Policy on a common carrier principle. The new guidelines for grant of right of use (ROU) on land do not contemplate any restrictions or conditions for grant of ROU for crude oil pipelines. As per the guidelines, the investors will have complete freedom with respect to the pipelines originating from refineries or meant for captive use by companies for which ROU will be unconditional.

The delay in the sell off of the Hindustan Petroleum Corporation Ltd. and Bharat Petroleum Corporation Ltd. has not gone in the government's favor and has discouraged foreign investors. So far, NELP rounds have been only moderately successful in attracting small international oil companies, but have failed to generate interest among the very large-size oil companies. Whether this is due to low prospects of Indian sedimentary basins or due to faulty policy has to be examined. However, the recent discovery in the Krishna–Godavari basin should improve the prospect of Indian sedimentary basins in the international market. Subsequent to this discovery, the government decided to include more deepwater areas in the fourth round of NELP.

6.2.3 Power Sector Reforms

Mounting power shortages and critical financial condition of state electricity boards (SEBs) have rendered the boards unable to add significantly to the power generation capacity, prompting the national government, in 1991, to encourage private-sector participation, with an objective of mobilizing additional resources for the sector. The milestones in power sector reforms are briefly summarized in the Table VIII. However, power sector reforms are also plagued with multiple problems. Even though the government has provided incentives to the reforming state in the form of higher allocations for the sector, this has not yielded the expected result, i.e., restructuring of the SEBs. Trifurcation of the SEBs into generation, transmission, and distribution companies has been initiated in only a few states, with no visible benefits yet evident. In view of high electricity

TABLE VIII

Milestones in Power Sector Reforms[a]

The Ministry of Power formulated a Common Minimum National Action Plan (MNAP) in 1996. The MNAP introduced wide-ranging reforms in the power sector, touching every aspect from generation to transmission and distribution and the state of finances of state electricity boards. The agenda for reforms included the following decisions:

1. Each state/Union Territory shall set up an independent State Electricity Regulatory Commission (SERC), which shall have the tariff fixation, licensing, and planning powers. The Indian Electricity Act of 1920 and The Electricity [supply] Act of 1948 were amended to enable these changes
2. A Central Electricity Regulatory Commission (CERC) was set up to regulate the bulk tariffs for central generating power plant and transmission utilities. Licensing and planning will come under CERC when the Union government gives notice.
3. The action plan also aimed to rationalize retail tariffs, which were to be set by SERC. Norms for minimum tariffs and cross-subsidization were also to serve to guide SERC in the tariff fixation process
4. Private-sector participation was allowed in the distribution of electricity, with initial coverage limited to few areas
5. The action plan also envisaged greater autonomy for state electricity boards, which were to be restructured and corporatized and run on a commercial basis

[a] The progress on all these fronts has been slow. SERC has not been established in all states, and tariffs for many sectors are still not reasonable. Major issues, such as allowing Independent Power Producers (IPPs) to sell power directly to bulk consumers, are still unresolved and so is the sorry state of finances of the state electricity boards. With the status of LNG being uncertain, many many gas-based power plants have either been postponed or are being run on naphtha. The National Thermal Power Corporation is still uncertain about the status of its gas-based power plants at Anta, Auraiya, Kawas, Gandhar, and Kayamkulam. The transmission and distribution losses are still very high in a majority of states, which is inhibiting improvements of the financial positions of state electricity boards. The procedure for getting permission for setting up a generating station is still lengthy and opaque. All these factors have caused many foreign IPPs to either abondon or postpone their plans for setting up power stations in India.

generating requirements projected for the future, and to promote private-sector investments, the government recently passed the Electricity Bill (2003), which seeks to create a liberal framework of development for the power sector by distancing the government from regulation. It replaces three existing laws, the Indian Electricity Act of 1910, the Electricity (Supply) Act of 1948; and the Electricity Regulatory Commissions Act of 1998. The Electricity Bill seeks to promote competition in the electricity sector in India by decoupling generation, transmission, distribution, and supply of electricity. The bill also envisages preparation of a national electricity policy (including tariff) for the development of the power system based on optimal utilization of natural resources. In consonance with this policy, the Central Electricity Authority will prepare the National Electricity Plan once every 5 years. Perhaps the most important feature of the bill is the provision of open access to the transmission and distribution infrastructure in the country. Under the new bill, the generator and the consumer can individually negotiate the power purchase and use the common-access T/D system to meet the goals. The commissions aim to reduce cross-subsidization in the system and reward efficiency in performance. Thus, the Electricity Bill (2003) maintains the trend in electricity reforms witnessed the world over by exposing generation and the supply side of the market to competition, but placing T/D sections under an incentive regulation.

6.2.4 Coal Sector Reforms

A Committee on Integrated Coal Policy was initiated by the Planning Commission in 1996 to address problems in the coal sector. The proposals of this committee included the following major recommendations:

- Adoption of coal conservation measures.
- Augmentation of domestic coal production by inviting private capital.
- Integration of the exploratory efforts of coal and lignite.
- Deregulation of coal prices.
- Creation of a regulatory body.
- Establishment of more pithead thermal power plants.
- Augmentation of the railways and port infrastructure facilities.
- Acceleration of project clearance procedures.

The recent move by the government toward reforming the coal sector is exemplified in the constitution of Expenditure Reforms Commission (ERC). However, to date, deregulation of prices and the distribution of coal of all grades are the only recommendations that have been implemented by the government.

6.3 Subsidies

Subsidies form an issue of major concern, not only for the energy sector, but also for the entire economy. Problems due to subsidies arise when long-term gains are sacrificed for short-term gains, which are guided

by political will and have major influence on policymakers. It has been common experience that subsidies are not withdrawn until long after they have stopped serving the purpose for which they were instituted. Subsidies doled out by the government to one sector often have a lasting impact on some other sector.

The International Energy Agency (IEA) estimated in 1999 that energy savings from removal of subsidies amount to 7.2% of total primary energy supply, and that CO_2 emissions would be cut by 14%. The fiscal savings would amount to $8.6 billion. Eliminating all subsidies may not be feasible for the Indian political system, but rationalization of the plethora of subsidy schemes is definitely of prime importance and the government has taken important steps toward removing price controls on oil and coal and lowering of subsidies generally. Coal prices were decontrolled in 2000, and there are no longer any direct subsidies to coal production or consumption. Delivered coal prices, nonetheless, remain below market levels due to continuing subsidies on rail transportation. In April 2002, the government completed the dismantling of the APM for oil products and natural gas, and the removal of all subsidies, except for those for kerosene and LPG used by households. The Indian electricity sector is heavily subsidized. In 2000/2001, the average rate of subsidy expressed as a proportion of the estimated full cost of electricity supply was 93% for farmers and 58% for households. Industrial and commercial customers and the railways pay above-cost prices.

6.3.1 Effects of Subsidies on Sector Development

One prominent example of cross-subsidization impact, i.e., hurting one sector of the economy at the expense of another, is the imposition of a high electricity tariff on the Indian Railways. The Working Group on Energy Policy in 1980 had recommended electrification of 1000 km of route of railway track every year because of low costs and high efficiency of electrified engines. It is estimated that the cost of energy per 1000 gross tonne km for a diesel engine is 78 rupees, compared to 55 rupees for an electric engine. The cost of operation and maintenance per 1000 gross tonne km for a diesel-based engine is 26.5 rupees, whereas that for an electrified engine is 17.5 rupees. However, because the railways subsidize the residential and agricultural sectors and pay a high electricity tariff, only 550 km of track has been converted per year since 1980. This type of cross-subsidy, apart from exerting a toll on railway finances, undermines system efficiency and clogs up the railway network. More important, it makes the railways dependent on crude oil for operation, a situation not desirable from either the economic or the security point of view.

6.3.2 Timely Review of Subsidies Essential for Effectiveness

LPG subsidies were instituted in order to encourage consumers to use LPG as cooking fuel. The penetration of LPG in urban centers is now near saturation, yet subsidies are still in place. Efforts by the government to eliminate them have not been successful, even though the subsidy monies could be better used elsewhere. This serves as another example to highlight the impact that a policy framed in one sector may have on other sectors. The National Energy Policy should recognize linkages between sectors and account for them in the policy framework.

7. IMPLICATIONS FOR NATIONAL ENERGY POLICY

Energy consumption in India is bound to grow manifoldly as India aims for sustained economic growth; growth will primarily be driven by increasing commercial energy consumption, given the positive and greater-than-unity energy elasticity of the economy. Usage of commercial energy sources, particularly oil and gas and power, will remain crucial for development. Therefore, policy initiatives to ensure flow of investments in these sectors become imperative. Domestic energy supply is likely to fall short of indigenous demand and, hence, reliance on imports will be unavoidable. To meet the growing demand for energy in a sustainable manner, India needs to look at all possible ways of bridging the energy gap. To achieve this, India has to take a long-term view of economic imperatives and move away from crisis management to providing strategic direction for energy development.

Before embarking on an integrated energy policy, policymakers should study the effect of existing energy policies on the already degraded environment and initiate effective research and development for alternatives to the conventional form of energy use. A long-term integrated NEP should keep in view both macro- and microlevel implications. Various recent technological innovations are giving rise to a competitive fuel market. For example, in the new-age power plants, gas is more efficient than coal. There-

fore, with improved LNG supplies, prospects of using gas for power generation are also improving, which will lead to gas providing tough competition to coal. Hence, for balanced energy consumption, linkages between different ministries need to be strengthened; in view of the fuel choice facing the power sector today, pricing policies adopted by the government will play an important role in influencing the decisions made by power generators.

Environmental concerns can no longer be ignored and policies should take into account the likely impact on the environment, and every attempt should be made to reduce negative impacts. Reforms in the energy sector are also important, both to attract private sector investment and to improve the energy efficiency of the economy.

To sum up, achieving energy efficiency and sustainable development requires the following essential approaches:

- A cabinet committee under the chairmanship of the Prime Minister (for effective coordination and monitoring between ministries).
- Immediate and effective reforms in various energy sectors and subsectors, representing both the supply side and the demand side, with an integrated approach.
- Policy coordination across energy ministries and other ministries for an integrated energy policy.
- Effective linkages with foreign policy.
- Revival of the National Environmental Council and its promotion as the forum for discussion and debate on energy–environment policies for the country and the changes that need to be brought about from time to time.

Overall, it can be said that energy has to be seen as part of overall development strategy. Interventions in the energy sector provide only short-term benefits unless they are combined with matching interventions in other sectors that lead to the spread of economic opportunities among the poor.

2. Energy Deregulation
3. Social and Environmental Impacts
4. Conclusion

Glossary

deregulation The time period over which countries/states open up to full retail competition of a preferred energy supplier, down to the household level.

distribution network The low-voltage electricity network that runs from electricity substations to the end user. Distribution is effectively a monopoly activity.

economies of scale A cost function exhibiting "natural monopoly" properties; economies of scale are present if the marginal costs of production of a single-product firm are less than the average costs of production over the relevant range of output. Put differently, economies of scale are said to exist over the relevant range of output should unit costs decline with the volume of production (on a kilowatt-hour basis.)

independent power producer (IPP) A producer of electricity whose plant is not affiliated with a local utility company; independent plants operate in a competitive, unregulated environment.

kilowatt-hour (kWh) A standard unit of electric consumption corresponding to usage of 1000 W for 1 hour. A 100-W light bulb burning for 10 hours consumes 1 kWh.

tariff A public schedule detailing utility rates, rules, service territory, and terms of service; tariffs are filed for official approval with a regulatory agency.

total primary energy supply (TPES) This is made up of production + net exports − international marine bunkers ± stock changes.

The objectives of Japan's national energy policy today are defined by the Ministry of Economy, Trade, and Industry (METI) as the "four Es": energy security, environmental protection, economic efficiency, and economic growth. Although each goal is separately crucial to the long-term national good, implementation and compatibility of these four objectives have been in conflict for much of the time since World War II. The second largest economy in the world, Japan in the year 2000 represented 0.28% of the world's landmass, 2.1% of the world's population, and 15.3% of the world's gross domestic product. Such statistics form the backdrop to a densely populated industrial society that heavily depends on stable supplies of energy to survive. Yet, the country suffers from a lack of indigenous natural resources, especially fossil fuels such as oil, coal, and natural gas—resources that are crucial in the maintenance of infrastructure and rising aggregate consumption. As such, Japan imported nearly 84% of the total amount of its primary energy supply in fiscal year 2000. This rate is the highest of any major industrial country (save Italy.) The problems and prospects of Japan's changing economy and how this relates to its energy policy are discussed in this article.

1. ENERGY RESOURCES

Historically, geographical and commodity vulnerabilities have led Japan to a "dependence-based" energy strategy in which Middle Eastern oil-producing countries have been afforded special considerations. This strategy became critical during the oil shock in 1973, when the price of Brent crude oil rose substantially, thereby forcing Japan to take special measures not always compatible with the broader goals of its U.S. ally. Thus, reevaluation of Japan's domestic energy policy resulted in further energy diversification and, in particular, a major nuclear construction program.

With the end of the Cold War and advent of the economically stagnant 1990s, Japan's energy policy has moved away from one of pure "dependency" and

 © 2004 Elsevier Inc. All rights reserved.

"economic aid in exchange for oil" within highly regulated energy markets to a policy of gradual deregulation, market efficiency, and alignment with the United States to obtain regional security in the maintenance of its oil supply flow. Judging by the country's position in energy consumption among the Group of Seven (G7) countries (Table I), Japan ranks second in terms of total primary energy consumption as well as in oil and coal, third in nuclear and hydroelectric energy, and fifth in natural gas. Moreover, the country relies heavily on overseas sources for its total amount of primary energy supplied (84%) in fiscal year 2000. This percentage is the highest of any major industrial country. Consequently, Japan accounts for a very large proportion of the world's energy imports, ranking second after the United States in total imports of primary energy, first in coal and natural gas, and second in crude oil and oil products. This situation suggests that Japan is both a driver and a vulnerable target of material fluctuations in the price of fossil fuels on the world market.

1.1 Domestic Energy Supply and Demand: A History

The process of energy development in Japan's postwar economy can be divided into five stages: postwar reconstruction (1945–1955), the high-growth period (1955–1973) lasting until the 1973 oil crisis, the stable growth period (1973–1985) and its subsequent adjustments, followed by the incipient "bubble" growth period (1985–1991) that ultimately led to the country's current stage, the so-called restructuring period (1991–present). These five periods of development are different in their respective patterns and correspond to changes in Japan's energy supply and demand.

1.1.1 Postwar Reconstruction (1945–1955)

The postwar reconstruction period was characterized by its industrial reorganization, development, and modernization in the aftermath of Japan's defeat in World War II. In an attempt to meet the challenge of securing a stable supply of energy and saving foreign exchange, the Japanese government adopted "a priority production system" in 1946 that targeted the domestic extraction of coal and increased development of hydroelectric power. As shown in Fig. 1, coal continued to play a central role in Japan's primary energy supply until it was overtaken by oil in 1963. Concurrently, the shift toward greater use of electricity as an alternative to coal coincided with the establishment of nine regional, but privately owned, electric power companies in 1951.

1.1.2 Rapid Growth (1955–1973)

Throughout a stage of rapid growth from the mid-1950s to the early 1970s, Japan's real gross domestic product (GDP) growth averaged 9.2% per annum. One important factor in the development of this performance was the increasing supply of imported fossil fuels, such as inexpensive crude oil. In conjunction with this "oil revolution," the country structurally shifted its emphasis away from agricultural services to heavy and chemical industries; the

TABLE I

Energy Consumption, 2000: Japan's Rank among G7 Countries[a]

Rank	TPES (%)[b]	Oil (%)	Nuclear (%)	Hydro (%)	Coal (%)	Natural gas (%)
1st	United States (56.4)	United States (56)	United States (42.9)	Canada (43.1)	United States (66.9)	United States (58.2)
2nd	Japan (12.9)	Japan (13.9)	France (22.3)	United States (29.9)	Japan (11.6)	United Kingdom (9.3)

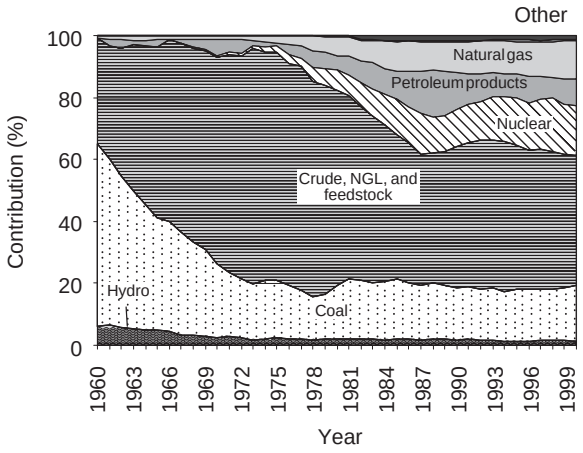

FIGURE 1 Long-term trends in primary energy supply by fuel. NGL, Natural gas liquids. Data from International Energy Agency (2002); calculations by the author.

government's primary objective was to support an "export-led" strategy of economic development in which oil consumption for domestic use increased materially. The share of oil as a percentage of the total primary energy supply increased from 17.6% in 1955 to 55.2% in 1965, while coal declined from 47.2% to 36.5% during the same period (Fig. 1). This trend continued as oil's share peaked at 76.4% in 1973, the year of the first world oil crisis. Oil replaced coal as the country's leading source of energy in 1963, and in that year thermal power replaced hydroelectric power as a percentage of total electric energy supplied.

1.1.3 The First Oil Shock and Stable Growth (1973–1986)

By 1973, Japan's energy self-sufficiency rate reached its nadir (10.6%). The country's dependence on imported oil (99.8%) suggested that any sudden fluctuation in world prices would cause serious discontinuities within the Japanese economy. The outbreak of the first oil crisis in 1973 dispelled the notion that cheap, readily available supplies of imported oil would always prevail. Crude oil prices increased fourfold, and Japan was compelled to rethink its national energy strategy. The second oil crisis in 1978/1979 reinforced this need. Industries began to adopt energy efficiency measures, and Japan's industrial framework shifted again from energy-intensive industries (e.g., basic materials) to less energy-demanding industries (e.g., assembly and processing). Consequently, energy consumption only grew 1.5% per annum from fiscal 1973 to 1979, and decelerated to 0.5% per annum from fiscal 1979 to 1985.

With the onset of the two oil crises, the energy policy of the government prioritized national energy security, and this was implemented in a few ways. First, the government sought to minimize its risk by increasing oil stockpiles and diversifying its imported oil sources. The second policy aim was to reduce dependence on oil by adopting a "diversified fuel-mix strategy." Alternative energy sources such as coal, liquefied natural gas (LNG), and nuclear energy were emphasized (Fig. 1).

1.1.4 Japan's "Bubble" Growth Era (1985–1991)

The Japanese economy witnessed a material turnaround in both performance and consumer activity during the so-called bubble years; this was a period characterized by rapidly rising real estate and stock market prices in highly speculative markets. In 1986, the material decline in crude oil prices, brought about by a reduction in the crude target prices of the Organization of Petroleum Exporting Countries (OPEC) for the first time since the 1973 oil crisis, led to a surplus on the world market. In turn, Japan's economy became a major beneficiary of the development as the compound annual growth of the primary energy supply from 1986 to 1991 increased by 3.9%, or 4.5% in industry, 4.3% in the household/service sector, and 5.3% in transportation. Japan, once again, was seeing an increase in energy consumption.

Concurrently, export-led companies attempted to compensate for the economic shocks imposed on the Japanese market of the previous decade, by rationalization efforts, cost-cutting, and increased exports. As the trade surplus with the United States increased, international pressure to shift Japan away from an "export-led growth strategy" to a "consumer-led growth strategy" intensified. In April 1986, the Advisory Group on Economic Structural Adjustment for International Harmony, a panel appointed by the prime minister and headed by former Bank of Japan Governor Maekawa Haruo, issued a set of recommendations otherwise known as the *Maekawa Report*. [The Japanese practice of putting family names of Japanese people first is followed in this article (for example, Ono Yoko, rather than Yoko Ono). Western names retain the standard form of first and last names (for example, Dwight Eisenhower).] This report set the stage for a series of proposals to restructure the Japanese economy with long-term ramifications for many domestic sectors, including energy. The concrete steps proposed

centered first on the expansion of domestic demand, focusing on areas such as industry restructuring, technology development, and changes to the quality of housing.

1.1.5 Structural Adjustment (1991–Present)

Since 1991, after the bursting of its bubble economy, Japan has faced unprecedented and difficult questions. Electricity demand growth, crippled by stagnant GDP elasticities, has fallen to barely flat levels, and incumbent energy industries have been forced to accept new regulatory enhancements to ensure greater market efficiencies under the banners of internationalization, globalization, and liberalization.

Throughout the decade, the government fundamentally shifted its policy from energy security to an overall reconsideration of its national agenda. Economic efficiency as an economic policy driver became another pillar to the METI's growing list of goals. Although deregulation incrementally lowered prices in energy industries, including oil, electricity, and gas, it also undermined profitability, forcing industrial consolidation and corporate efficiency measures.

1.2 Energy Consumption by Sector

Changes in demand can also offer valuable insights into the nature of energy growth. Since the 1973 oil shock, industrialized nations have made concerted efforts to conserve energy (Fig. 2). On an index with 1973 set at 100, Japan led the industrialized nations in energy conservation; between 1973 and 1987, the total consumption level as a percentage of GDP fell

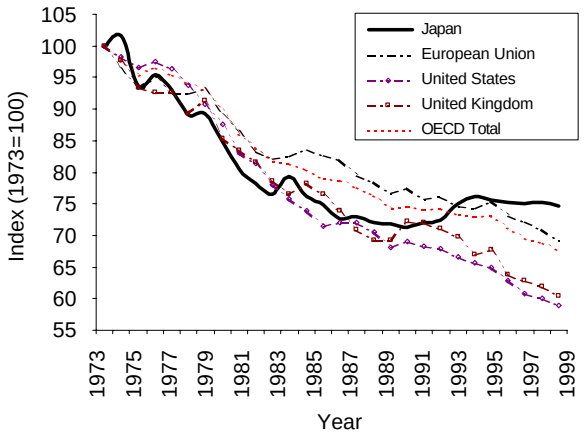

FIGURE 2 Index of total primary energy supply per unit of gross domestic product. OECD, Organization for Economic Cooperation and Development. Data from International Energy Agency (2002); calculations by the author.

(energy efficiency improved) at a compound annual rate of 2.3%, which was higher than that of any other Organization for Economic Cooperation and Development (OECD) country. As mentioned, such efficiency gains were due, in part, to a shift in orientation from heavy, energy-intensive industries, such as iron and steel, cement, nonferrous metals, and petrochemicals, to machine-based and high-technology industries, such as automobiles, appliances, consumer electronics, and industrial ceramics, and a further shift from secondary to tertiary industries with increasing emphasis on service trades. This shift can be expected to continue, but at a slower pace than in the past. Japan is under pressure to increase its domestic consumption to a level more in line with its trade competitors. This international pressure, in conjunction with growth in road transport, can be expected to increase energy intensity.

It is important to note, however, that the industrial sector has been the only contributor to major energy efficiency improvements. As Fig. 2 indicates, by the 1990s, the total primary energy supply per unit of GDP materially shifted; energy consumption levels within the household/service, commercial, freight transportation, and passenger transportation sectors markedly increased, thus outweighing previous efficiency gains in the industrial sector. An international comparison of per-household energy consumption reveals that, adjusting for heating figures related to atmospheric temperature differences among countries, Japanese data values are still quite low, suggesting that the current growth in energy consumption is the direct result of income elasticity among affluent economies. In 1973, for example, there was only one car for every two families in Japan. In 2000, the number of cars on the road reached over 52 million versus only 45 million households. Moreover, in 1970, fewer than 10 out of every 100 Japanese homes had such things as videocassette recorders, microwave ovens, and air conditioners, and only 43 out of every 100 homes had color televisions. By 2000, the number per 100 households had risen to 84 for videocassette recorders, 95 for microwave ovens, and 217 for air conditioners, and color televisions topped the list at 231.

2. ENERGY DEREGULATION

Deregulation of the Japanese economy began in the mid-1980s with the introduction of the so-called *Maekawa Report*. In the 1990s, deregulation ex-

tended into the energy industry; first materially affecting the petroleum industry and later extending into the electricity and gas industries. For many years, Japan's energy industry was a textbook example of a regulated industry, but the picture has changed. A string of events has taken place, altering the operational landscape, including partial liberalization of the electricity and gas retail markets and the lapse of the Refined Petroleum Import Law.

2.1 Electricity

The Japanese electricity market is not only one of the largest in the world, but also one of the most lucrative. In 2001, total market revenues (*ex* self-generation) were worth more than ¥15 trillion (=$115.3 billion U.S. dollars; $1=¥130). Tokyo Electric Power Corporation (TEPCO), the world's largest privately owned utility, boasted total assets of more than ¥141.3 trillion ($1087 billion), volumes of 275.5 TWh, and revenues of ¥5.2 trillion ($40.1 billion). The sheer mass of TEPCO translated into one of the highest net profit streams in Japan despite high interest payments on debt. The key feature to this arrangement has been the existence of vertically integrated regional monopolies that have been heavily regulated by the state. After a brief period of government wartime control, nine private power companies were reorganized in 1951 to come into control of most of the generation, transmission, and distribution businesses of electric power throughout the country. Their reclaimed monopoly status was the result of successful lobbying by utilities to return to a system of centralized private power, reminiscent of the early 1930s, not of the highly competitive era of the 1920s.

The greatest strength of the new "1951 system" was that it exploited economies of scale, maintained stable electricity prices for over 20 years, and kept dangerous dioxide emissions in check. Its greatest weakness was that it eventually disproved the theory; the 1951 regulatory structure failed to reconcile rising demand with mounting variable (fuel) and fixed (capital) costs. Over time, the weaknesses became more pronounced. As Fig. 3 indicates, from 1975 to 1985, average monopoly tariffs increased by almost 100% from 11 yen/kWh to 21 yen/kWh. Utility companies argued that the phenomenon was the result of exogenous variable shocks stemming from an overdependence on imported fossil fuels. Although true to an extent (99.8% of Japan's consumed oil is imported, 87% of which is imported

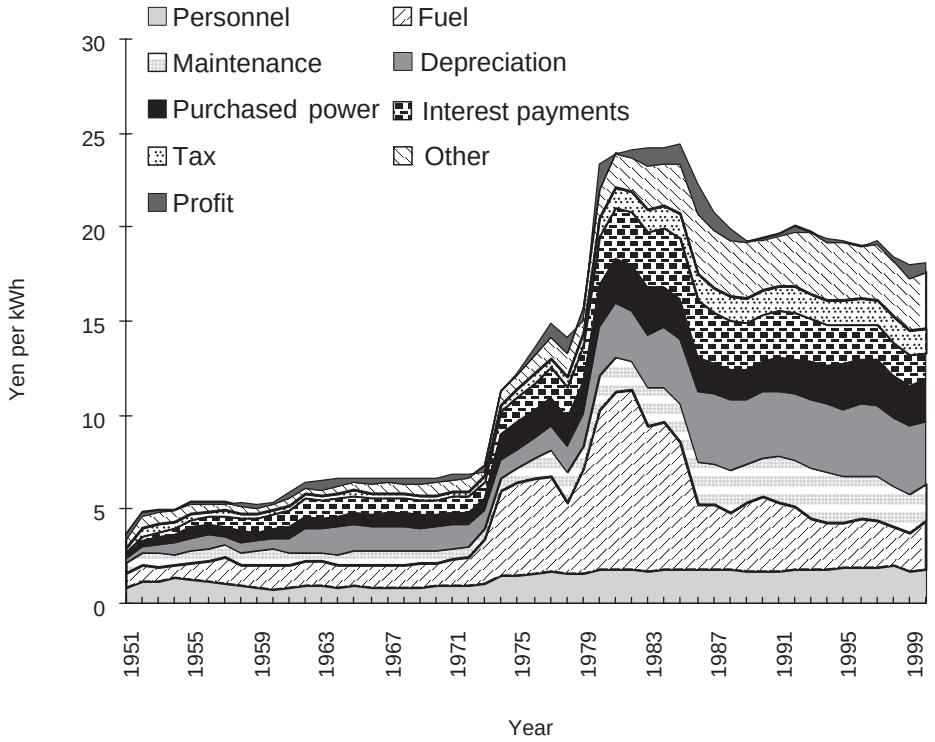

FIGURE 3 Average electricity tariff, fiscal years 1951–1999. Based on data from the 2002 annual report of the Tokyo Electric Power Company; calculations by the author.

TABLE II

Compound Annual Growth in Electricity by Industry Type[a]

Industry	Compound growth, fiscal years 1965–2000 (%)		Compound growth, fiscal years 1990–2000 (%)	
	Total volumes	Self-generation	Total volumes	Self-generation
Mining	−3.2	−1.5	−1.5	−5.3
Food	8.2	9.5	3.0	7.5

[b] Grand total equals total manufacturing demand plus railroad demand and other.

from the Middle East), average tariff rates and the unit cost of fuel per kilowatt-hour continued to decouple after 1985. The lack of continuity became more pronounced as market rigidities and rising capital costs prevented a nominal readjustment to pre-1973 tariff levels. Nevertheless, the original presence of "natural monopoly" technologies continued to provide justification for a regulated power industry and accordingly to impose entry barriers, price controls, and obligations to serve. Unlike other industrialized nations, the postwar regulatory regime did not breakdown with the "energy crisis" of the 1970s. Rather, the then-Ministry of International Trade and Industry (MITI) overcame the crises through close cooperation with incumbent utilities, preserving the vertically integrated monopoly structure. The exploitation of economies of scale while controlling market power was not only considered the progressive "public interest" view of the country's utility regulation until the early-1990s, it was also a means of preserving the political status quo.

Industry restructuring began in earnest with the advent of the Hosokawa Morihiro coalition government in 1993. By that time, electricity prices from 1983 to 1993 were not only perceived to be high domestically, but also internationally. Pretax Japanese electricity tariffs were three times the average U.S. price in 1993. Broadly speaking, pressure to enact reforms was initiated by several actors, including the incumbent utilities concerned with the threat of self-generators (*jika hatsudensha*) capturing further market share (Table II) the export-led industries burdened with an appreciating currency and mounting operational costs; the potential new entrants seeking to duplicate their success in foreign deregulated markets; and the central government, which was looking not only to maintain its legal powers over the market, but also to placate foreign government pressures (*gaiatsu*).

In response to such growing pressure to lower electricity tariffs, the government decided to undergo regulatory reform. Revisions to the Electric Utility Industry Law were intended to produce a more competitive market, albeit incrementally. Phase one (1995) permitted the nine major power companies (*ex* Okinawa) to act as "single buyers" through a revision of the 31-year-old Electric Utility Industry Law. A bidding structure organized independently of government control was established whereby independent power producers (IPPs) and other self-generators could bid for new contracts for their supplementary power needs. Major players in phase one were predominantly steel makers such as Nippon Steel Ltd. and Kobe Steel Ltd. Phase two (2000)

expanded the scope of liberalization measures to include the following steps:

1. Retail choice for large-lot customers: Competition was opened to utilities servicing customers with contracts for 2 MW or greater and connected to a supply system of 2000 V or higher. Such customers included owners of large-scale office buildings, industrial factories, hotels, hospitals, and department stores. Unlike phase one, customers could now choose their preferred wholesale supplier, whether foreign or domestic.
2. Competitive bidding process for thermal capacity acquisition: The nine incumbent power companies (*ex* Okinawa) were required to place competitive bids when they purchased thermal capacity. Hydroelectric and nuclear power competition were (and are) beyond the scope of the regulatory changes.
3. Profit sharing: Incumbent utilities were no longer required to submit rate case applications for tariff reductions. This served as an incentive to reduce costs voluntarily because the incumbent utility could reserve part of the increased profit margin through reduced service costs.
4. Abolition of Article 21 of the Antimonopoly Law: Without this provision, discriminatory rights to railroad and utility companies (natural monopolies) were no longer upheld. Both the Japan Fair Trade Commission (JFTC) and the Ministry of Economy, Trade, and Industry enacted guidelines that legally prohibited any exclusionary activities inhibiting new entrants.

As of the date of writing of this article, a quantifiable results-oriented assessment of Japan's electricity deregulation suggests only tepid competition, average incumbent tariff declines, and minimal corporate efficiencies. New electricity market entrants account for only 0.85% of total installed capacity nationwide. Structural barriers to market entry, such as extensive backup, wheeling, and maintenance charges, preclude cost-competitive access to many incumbent networks (transmission and distribution). Furthermore, lack of available land for further capacity build and stringent environmental regulations in generation also present strong obstacles to market entry.

Incumbent electric power companies have begun to lower tariff rates in anticipation of future market competition, but, as Fig. 3 indicates, readjustments have been preemptive and voluntary, not forced through direct competition. On an index with 1990 set at 100, average electricity tariffs for Japan's three largest electric power companies (TEPCO, Kansai Electric Power Co., and Chubu Electric Power Co.) in 2002 fell to 93, suggesting only tepid market pressures to date.

2.2 Gas

In contrast to the electric power industry, the Japanese gas distribution industry is best characterized as vertically truncated, but within a framework of several regional monopolies. Non-Japanese firms have traditionally conducted the "upstream" activities of exploration and supply. The "downstream" activities of refinement and distribution have fallen within the purview of companies such as Tokyo Gas, Osaka Gas, Toho Gas, and Saibu Gas, to name only the four largest companies in terms of volumes, revenues, and assets. Historically, the Japanese gas industry was privately owned but publicly regulated in the postwar era under the Gas Utilities Industry Law. Policymaking and regulatory functions were the responsibility of the MITI (now METI). This situation, however, is beginning to show signs of change, due to the strategic importance of liquefied natural gas (LNG) to Japan's long-term energy needs.

The majority of LNG is used within the electric power sector. In 2000, power plants accounted for nearly 70% of total gas consumption. With the gradual liberalization of the electric power industry in the 1990s, liberalization and restructuring are currently underway in the gas industry as well. The first measures aimed at liberalizing Japan's gas market were adopted in June 1994 and went into effect in March 1995. Revisions were made to the Gas Utilities Industry Law that allowed gas utilities to sell gas on a retail basis to large-lot volume users, thereby circumventing incumbent gas distribution companies. These contestable customers were defined as those consuming more than 2 million cubic meters (MMcm) per year, representing approximately 720 gas users. The changes permitted non-gas companies (power, steel, oil, and other companies with access to gas) to supply large-lot industrial customers for the first time. The revisions also lifted tariff regulations so that parties in the liberalized segment of the market were free to determine price and other contract terms on a negotiated case-by-case basis.

Phase two of the Japan's gas liberalization was adopted in May 1999 and went into effect the following November. These revisions expanded the contestable market to eligible consumers of 1 MMcm per year, or approximately 993 large-lot users. Designated general gas companies were also ordered

to grant third-party access to gas pipelines on a nondiscriminatory basis. The designated companies are Tokyo Gas, Osaka Gas, Toho Gas, and Saibu Gas. The smaller gas distribution companies, such as Shizuoka Gas, Hiroshima Gas, Chubu Gas, and Hokkaido Gas, to name a few, have no obligation to provide access to their infrastructure.

In 2000, a subcommittee established by the METI recommended a pricing formula for third-party access to both the incumbent electric power transmission system and the incumbent gas distribution pipeline system. Known as the "wheeling charge," this forward-looking cost method allowed for historical comprehensive costs, including depreciation, taxes, and other operational costs, to be added to a stipulated rate in return for third-party access to the transmission network or pipeline. Based on these rules, the four gas companies issued rate schedules for transportation, backup, and storage in March 2000. Further transparency was also imposed regarding the accounting methods and public disclosure requirements to be used by the gas companies in allocating costs among various business segments.

At the time of writing this article, new entrants to the newly liberalized gas industry have been predominantly incumbent electric power companies. TEPCO, for example, as of January 2001, has supplied local city gas companies via its own low-pressure pipeline in Chiba Prefecture; since 2001, Chubu Electric Power Co. has had a joint venture with Iwatani International Corporation and Cosmo Oil to supply LNG via a lorry operation in Mie Prefecture, and Tohoku Electric Power operates a mass natural gas supply business through its subsidiary Tohoku Natural Gas using the Niigata–Sendai pipeline. METI is currently monitoring the outcome of these liberalization measures and subsequent moves by new entrants. The agency is also examining what measures could be taken next and recently impaneled a new committee to develop recommendations for further liberalization.

2.3 Petroleum

Unlike the vertically integrated electric power industry, but similar to the gas industry, Japan's privately owned petroleum industry has a long history of rigid regulations and failed government direction, resulting in a vertically truncated and horizontally fragmented industry. Incremental deregulation of the Japanese petroleum industry eventually illustrated that regulatory change could lead to greater consumer benefits and corporate consolidation, but not necessarily increased industrial structures or reduced fiscal burdens of the government. The reason for such a regulatory framework stems from the fact that crude oil, natural gas liquids (NGLs), and feedstock consumption meet 42% of Japan's annual energy needs. Japan accounts for 7% of total world oil consumption. Although the country's dependence on oil has decreased from 77% in 1973 thanks to a concerted effort to diversify the national energy supply, oil remains a key energy source (Fig. 1). At 99.8%, Japan's import dependence on oil is extreme and oil is therefore considered a strategic national resource, especially because 80% is sourced from the politically unstable Middle East.

Historically, the petroleum industry was bifurcated into the "upstream" activities, related to the exploration for and production of oil, and the "downstream" activities, related to oil refinement and distribution (wholesale and retail). These two activities coincided in the prewar era, but slowly gave way to strictly "downstream" activities owing to insufficient domestic supply, horizontal market fragmentation, and high fixed costs. Japanese oil firms became heavily dependent on the "majors" (large international oil companies) for upstream operations. It is within this framework that the 1962 Petroleum Industry Law was enacted. Essentially, the law was written to achieve a stable supply of oil by controlling downstream oil refining, effectively authorizing the separation of upstream and downstream activities through permits to establish refineries or to purchase equipment for them. Several laws were subsequently enacted to reinforce the 1962 framework; these include the Petroleum Supply and Demand Balance Law, the Emergency Temporary Law for Stabilizing the Nation's Livelihood, the Petroleum Stockpiling Law, and the Quality Assurance Law. As a by-product, these laws indirectly managed to protect the fragmented structure of the industry, thereby propping up many of the smaller firms that were dependent on existing regulations to stay in business.

For a brief period during the 1980s, foreign pressure (*gaiatsu*) from Western nations in conjunction with foreign companies caused a media stir in Japan. It was suggested that the majors and independent oil companies could circumvent these laws in order to achieve greater market share in Japan's abundant downstream activities. Although unsuccessful, what followed was a gradual easing of regulations and laws in order to bend to public pressures to reduce high gasoline, kerosene, and naphtha prices in a domestic market that was

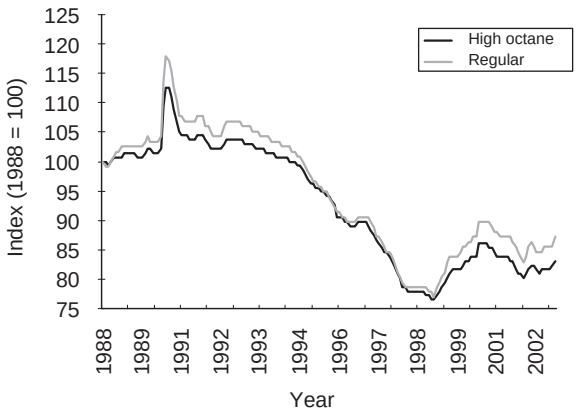

FIGURE 4 Gasoline per liter, fiscal years 1988–2002 (indexed). Based on data from the Oil Information Center; calculations by the author.

experiencing a clear slowdown in economic growth compared to the previous two decades. Technically, such liberalization of the petroleum industry began with the 1986 Refined Petroleum Import Law. The MITI eased its requirement for obtaining a license to import such refined products, answering calls from domestic and international actors to open markets. However, incumbent oil refiners successfully lobbied to limit the impact of the new legislation by requiring only those refineries in Japan with existing domestic production, stockpiling, and quality control to import oil products. The requirement effectively blocked all imports from nonincumbent players, making "petroleum liberalization" a paper tiger.

On March 31, 1996, the Refined Petroleum Import Law expired and the Gasoline Sales Law and Stockpiling Law were also revised. Emphasis shifted away from "energy stability" of imported petroleum to "energy efficiency," partly aided by advocates of reform in the newly established Hosokawa Morihiro coalition government. As shown in Fig. 4, extreme inefficiencies and ineffective legislation kept gasoline prices high in the 1980s, but real liberalization of the market led to greater market competition and increased consumer welfare gains despite yen depreciation and stable crude oil prices. Indexing average gasoline prices per liter at 100 in 1988, the price of regular and high-octane gasoline, respectively, fell steadily from their Gulf War high of 112 and 118 in 1990, to a historic low of 76.5 in 1999.

The key to such consumer welfare gains emanated from laws enacted to stir competition in the mid-1990s. With the Refined Petroleum Import Law removed, stringent restrictions on petroleum imports were also removed; import licensing was readjusted to require new capacity to decrease from 120 days' worth of product storage (a clear structural barrier to market entry) to only 60 days' worth of product. In turn, the abolition of the Specified District System, which prohibited new entrants from targeting fragmented districts in which there were already a number of gasoline stations, allowed for greater competition among retail players. Consequently, incumbent gasoline stations began to lower prices in an effort to build customer loyalty. Corporate profit margins, historically low by world standards, continued to decrease in the newly competitive operating environment. Consequently, consolidation, asset streamlining, and cost cutting were initiated in the industry. In 1999, Nippon Oil and Mitsubishi Oil, for example, merged to form the largest Japanese oil distributor by market capitalization (667 billion yen as of November 22, 2002), sales (estimated at 4 trillion yen in fiscal year 2002), and market share (23%).

3. SOCIAL AND ENVIRONMENTAL IMPACTS

Energy policy does not exist in a vacuum: like all governments, Japan's national energy policy must coexist with social and environmental issues. How these factors shaped Japan's changing energy policy landscape is discussed in the following sections. On the one hand, Japan's fossil fuel dependency did not add to national security. Alternative sources of energy, such as nuclear energy, were encouraged and developed to serve this end. On the other hand, Japan, as a leading nation, had environmental obligations such as those defined in the Kyoto Protocol in 1997. Environmental concerns were not always in conflict with Japan's wish to free itself from its fossil fuel dependency. However, the goals were not always in tandem.

3.1 Kyoto Protocol

In December 1997, delegates from 159 countries gathered in Kyoto, Japan, for the Third Conference of the Parties (COP3) to the United Nations Framework Convention on Climate Change (UNFCCC). The results of that conference, known as the Kyoto Protocol, addressed important commitments from developed countries to reduce emissions of carbon dioxide and other greenhouse gases between the years 2008 and 2012. Industrial economies were required to cut aggregate man-made emissions of six climate-affecting gases by an average 5.2% below

1990 levels by some point in the 2008–2012 time frame. The six gases, carbon dioxide (CO_2), nitrous oxide (NO_x), methane (CH_4), hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), and sulfur hexafluoride (SF_6), were considered to be ozone-depleting chlorofluorocarbons. As such, developed countries agreed to incorporate into their efforts to implement the Kyoto Protocol measures that would promote, assist, and finance technology transfers in fighting occurrence of such emissions in developing countries.

Japan's emissions reduction target was agreed to be 6% and that for the European Union was 8%; the goal of the United States was to be 7%. As host nation, Japan stressed the importance of the Kyoto Protocol. Conservation and efficiency improvements yielded a double benefit. Conservation policies not only limited the country's overall dependency on imported fossil fuels, they also made export-led companies, such as the Japanese automakers, more competitive through fuel-efficient products.

One strategy to meet the stipulated goals of the Kyoto Protocol was to redouble efforts in the development of alternative sources of energy that reduce or eliminate pollution. If alternatives were palatable enough, significant reductions in the consumption of fossil fuels could be made. Solar, geothermal, fuel cell, and wind power sources were (and are) four such contenders in the implementation of such a strategy. These renewable energy sources currently hold only a small market share of the total primary energy supply. Wind power, for example, had an estimated 0.03% market share in 2000, but is projected to capture a 20% market share by 2020. The METI has been researching and developing practical development of these sources.

3.2 Nuclear Power

In complying with the goals of both the Kyoto Protocol and the METI's long-term energy strategy (energy security, environmental protection, economic efficiency, and economic growth), nuclear power continues to play an important, albeit controversial, role. Despite being the only country to suffer directly the fallout of nuclear weapons, Japan has adopted the peaceful use of nuclear technology to provide a material portion of its electricity generation. Today, nuclear energy accounts for some 30% of the country's total electricity production. However, nuclear accidents, policy contradictions, "not-in-my-backyard" protests, and regional funding issues present recurring obstacles to the government's plans to perfect a completely indigenous fuel source for the 21st century.

3.2.1 Nuclear Development and Policy: A Brief History

Following U.S. President Dwight Eisenhower's historic speech, "Atoms for Peace," at the United Nations in 1953, Japan began its nuclear research program. The Atomic Energy Basic Law was enacted in 1955 with the aim of ensuring the peaceful use of nuclear technology in Japan. Democratic methods, independent management, and transparency were (and are) the foundation of nuclear research activities, as well as the promotion of international cooperation. Several nuclear energy-related organizations were established in 1956 under this law to further promote development and utilization, including the Atomic Energy Commission; the Science and Technology Agency; the Japan Atomic Energy Research Institute (JAERI), and the Atomic Fuel Corporation (renamed the Power Reactor and Nuclear Fuel Development Corporation in 1967).

As Fig. 5 indicates, Japan has 52 reactors with a combined installed capacity of 45.7 GW, or approximately 30% of the nation's total installed capacity. The country imported its first commercial nuclear power reactor from the United Kingdom (Tokai-1) in 1966. This gas-cooled (Magnox) reactor built by General Electric Company (GEC) had a relatively small installed capacity of 160 MW; the reactor was finally decommissioned in March 1998. After this unit was completed, only light-water reactors (LWRs) using enriched uranium, either through pressurized water reactors (PWRs) or boiling water reactors (BWRs), have been constructed. Since 1970, 23 PWRs and 28 BWRs (including two advanced BWRs) have been brought online. Initially, Japanese electric power utilities purchased designs from U.S. vendors and built them with the cooperation of Japanese companies, who received licenses to then build similar plants in Japan. Companies such as Hitachi Co Ltd., Toshiba Co Ltd., and Mitsubishi Heavy Industry Co Ltd. developed the capacity to design and construct LWRs. An additional 11 reactors are in the planning stages or are currently under construction.

3.2.2 Reprocessing and Waste Disposal: National Policy

As already mentioned, one of the obvious goals of Japan's national energy policy is energy security. With the increase in nuclear power as a percentage of its total primary energy source, Japan hopes to

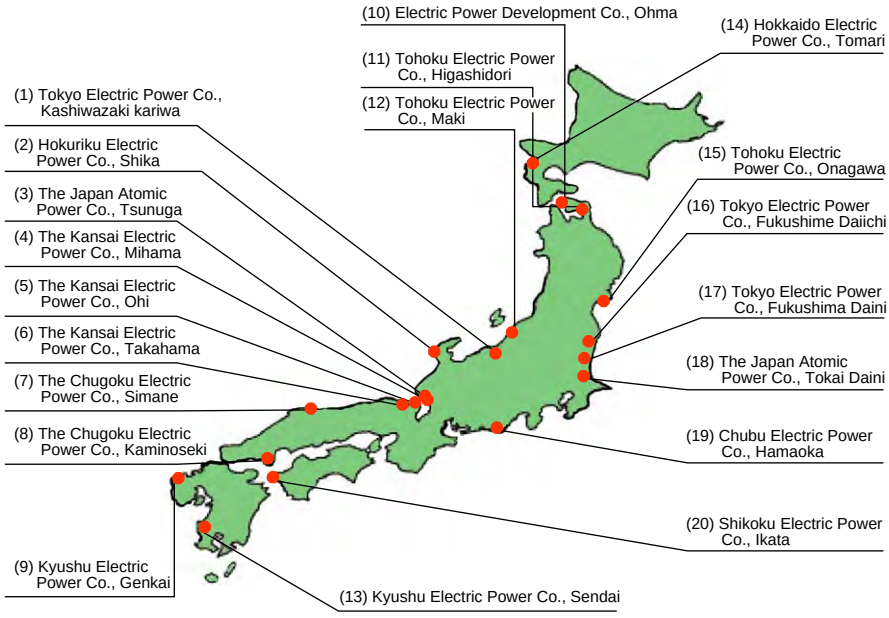

FIGURE 5 Nuclear power plants in Japan. As of 2003, 20 locations are power plant sites (or will be) for 63 units (52 operational, 3 under construction, and 8 in the planning stage), with an expected total output of 59,895 MW (45,742, 3838, and 10,315 MW, respectively). The locations on the map are numbered; the following key details the operational (OP), under-construction (UC), or planning-stage (PS) unit output at each location: (1) seven OP units, each >1000 MW; (2) one OP unit <1000 MW and one UC unit >1000 MW; (3) two OP units, one <500 and one >1000 MW, and two PS units, each >1000 MW; (4) three OP units, one <500 and two <1000 MW; (5) four OP units, each >1000 MW; (6) four OP units, each <1000 MW; (7) two OP units, one <500 and one <1000 MW, and one PS unit >1000 MW; (8) two PS units, each >1000 MW; (9) four OP units, two <1000 and two >1000 MW; (10) one PS unit >1000 MW; (11) one UC unit >1000 MW; (12) one PS unit <1000 MW; (13) two OP units, each <1000 MW; (14) two OP units, each <1000 MW, and one PS unit <1000 MW; (15) three OP units, each <1000 MW; (16) six OP units, one <500, four <1000, and one >1000 MW; (17) four OP units, each >1000 MW; (18) one OP unit >1000 MW; (19) four OP units, two <1000 and two >1000 MW, and one UC unit >1000 MW; (20) three OP units, each <1000 MW. The Japan Atomic Power Company Tokai plant closed in March of 1998. Map, plant locations, and output derived from the 2003 data of the Federation of Electric Power Companies.

reduce its import dependency on fossil fuels. However, the challenges facing the Japanese government are much more daunting with the introduction of nuclear power. Plutonium is essential as a major fuel for nuclear power generation. The more plutonium used by a country, the more likely the nation becomes influenced by international politics, especially because plutonium produced within the nuclear reactor can be used for nuclear weapons.

Recovering plutonium through a process known as the "fuel cycle" essentially reprocesses spent fuel. The theory is that once the nuclear fuel cycle is established domestically, nuclear power virtually becomes an indigenous energy. Until now, Japan relied on the reprocessing of spent fuel by European contracts through British Nuclear Fuels (BNFL) and Cogema, with vitrified high-level wastes being returned to Japan for disposal. However, this reprocessing has proved to be expensive and time consuming. In 2005, Japan Nuclear Fuel Ltd. (JNFL) will begin its first commercial enrichment plant at Rokkasho in northern Japan. Its planned capacity is to be 1.5 million separative work units (SWUs)/year (in the nuclear power industry, the separative work unit is a measurement of mass: 1 kg of separative work = 1 SWU). Spent fuel has been accumulating in Rokkasho since 1999 in anticipation of the full operation of the plant (shipments to Europe stopped in 1998).

The plutonium recovered by foreign reprocessing in the United Kingdom (BNFL) and France (Cogema) will be used in LWRs as mixed-oxide (MOX) fuel. MOX fuel was first intended to be used in the Takahama nuclear plant of Kansai Electric Power Company. However, local concerns surrounding the safety of MOX fuel in 2002–2003 created scheduling problems for the implementation of that program.

3.2.3 The Economics of Nuclear Power

The economics of nuclear power generation is largely controversial. Although the fuel cost of generation

is relatively inexpensive ($\geq$20% of total nuclear generation costs), its capital costs are increasingly expensive. In a deregulating market where the marginal cost of new entry is increasingly competitive vis-à-vis incumbent prices, the incumbent competitiveness of Japan's nuclear power remains unclear. Current nuclear projects depend not only on material cost-cutting within tight schedules, but also on operating such generators at reasonably high utilization rates over many years. By way of contrast, fossil fuel-fired power plants are relatively cheap and quick to build, but expensive to operate due to their cost of fuel (currently $\geq$70% of total thermal generation). Thus, the economics of nuclear power further inform the already contentious debate.

3.2.4 "Not-in-My-Backyard" Issues

The "not-in-my-backyard" (NIMBY) attitude is far from being a Japan-specific obstacle to national energy policy, but is one with significant long-term ramifications for the implementation of a successful nuclear power development program in Japan. Simply put, NIMBY refers to a grassroots movement to prevent the further construction and maintenance of nuclear power plants in local communities, where it is believed to represent critical environmental and safety hazards for the general public. A series of nuclear power accidents, mishaps, and scandals have further exacerbated the already volatile and emotional debate on the peaceful use of nuclear energy sources, thus eroding public support in Japan and reinforcing NIMBY sentiments. The accidents involved a sodium leak at the Monju fast breeder reactor (FBR), a fire at the Japan Nuclear Cycle Development Institute (JNC) waste facility connected with the Tokai reprocessing plant, and a 1999 criticality accident at Tokaimura. The latter accident, which claimed two lives and seriously injured three others, was the direct result of workers following an unauthorized procedures manual.

In 2002, an additional scandal—non-accident-related—erupted over an alleged cover-up of safety inspection procedures. Inspection of the shrouds and pumps around the nuclear reactor core, the responsibility of the electric power company, had been contracted out by the power company. In May 2002, questions emerged about data falsification and the significance of reactor shrouds and whether faults in the shrouds were reported to senior management. This incident further sullied the reputation of the incumbent electric power companies and the METI's designs for nuclear power development, in general.

4. CONCLUSION

Japan is a naturally resource-deficient island nation that relies heavily on imported fossil fuels for its energy needs. Stability in the international community continues to be a prerequisite for acquisition and maintenance of Japan's energy supplies. Especially in the case of oil, the fuel on which Japan is most dependent, securing access to stable supplies has been the mainstay of Tokyo's energy policy for over 30 years.

The two oil crises of the 1970s were set in motion by developments on the supply side, but if a third oil crisis should occur, the problem may be a strictly demand-side affair. World oil consumption, especially in Asian countries, continues to rise year after year, calling into question viable energy sources for future consumption. Japan has recognized the need to adopt a strategy that embraces both its imported energy dependency and its ability to offset such problems with indigenous natural forms of energy, such as nuclear, wind, solar, and geothermal power. In advancing the four Es—energy security, environmental protection, economic efficiency, and economic growth—the Japanese government endeavors to convince the Japanese public of the benefits of nuclear power, but with limited success. Nuclear accidents and scandals, both domestically and internationally, have tarnished nuclear power's image as a safe, viable alternative to imported fossil fuels. Moreover, NIMBY protests and the introduction of liberalization have added extra political and economic dimensions to this already contentious subject matter.

Deregulation of the energy industries (electricity, gas, and oil) will likely continue. Already, revisions to the basic laws have shown signs of material change. Prices in all three sectors have gradually fallen. Competition has led to partial consolidation in at least the petroleum industry, with prospects for the other sectors in the years to come. In conclusion, Japan's national energy policy is in a state of constant fluctuation and development. The foremost priority is stability of supply. Especially vital to this goal is maintaining an ample supply of oil and other imported fossil fuels needed to feed the world's second largest economy.

Glossary

Btu tax A tax on the heat or energy content of fuels. A British thermal unit (Btu) is defined as the amount of heat necessary to change the temperature of 1 lb of water at sea level by 1°F. The Broad-Based Energy Tax proposed in 1993 by the Clinton Administration would have placed a tax on energy based on its energy or Btu content. A gallon of diesel fuel, has more Btus than a gallon of liquefied natural gas. Thus, under the Clinton Administration proposal, fuels with a high energy content, which tend to be the dirty fossil fuels, would have been taxed at a higher rate than many alternative energies, which have lower average energy contents.

Corporate Average Fuel Economy (CAFE) Standard A miles per gallon standard established by law that manufacturers of cars and light trucks must obtain. In 2003, CAFE standards are set at a minimum of 27.5 miles per gallon averaged across a manufacturer's entire fleet. If a manufacturer does not meet the standard, it must pay a civil penalty of $5.00 for each 0.1 mile per gallon that the fleet does not obtain multiplied by the number of vehicles the manufacturer produces.

Energy Policy and Conservation Act (1975) This was one of the earliest laws enacted in the United States with the explicit purpose of regulating and reducing energy consumption. The Act also established a Strategic Petroleum Reserve in the Gulf of Mexico. During reauthorization, a national inventory of onshore energy sources was created and a home-heating oil reserve was established in New England.

Public Utilities Regulatory Policies Act (1978) This law was passed in the face of high energy prices in an effort to reduce dependence on foreign oil, to encourage energy efficiency, and to promote alternative energy sources. It required electric utilities to purchase power from independent companies that were able to produce power at a lower cost than what it would have cost the utility to generate the power. The Act is credited with the development of nonhydro renewable energies and has been especially favorable to the development of natural-gas-fired "cogeneration" plants that produce both electricity and steam.

Efforts to establish a national energy policy in the United States began under Jimmy Carter's presidency during the late 1970s, but then languished for over a decade. Since the early 1990s, there have been renewed attempts to establish a national energy policy. In 1992 a National Energy Strategy was formulated but U.S. dependence on imported energy continued to grow. Under the George W. Bush administration, there have been renewed efforts to establish a national energy policy, but sharp differences of opinion have prevented the passage of new energy legislation, at least for the time being.

1. ENERGY POLITICS

Understanding energy politics in the United States and efforts to develop a national energy policy requires an understanding of the different actors involved and their economic and political interests. There are widely divergent views regarding how to deal with America's large and growing appetite for energy and the pollution this produces.

The fossil fuel industries—the oil, coal, and natural gas producers—tend to support policies that favor the expansion of drilling and mining activities, including in protected lands and offshore. The automobile industry is typically opposed to legislation that mandates fuel efficiency improvements or raises gasoline taxes. The nuclear industry is eager to see a renewal in government support for nuclear

 © 2004 Elsevier Inc. All rights reserved.

energy. Environmental groups and the renewable energy industries tend to call for greater governmental support for energy conservation and renewable energy and legislation to control pollution from fossil fuel burning. Labor unions tend to be most concerned with the implications of governmental policies on jobs and consumer groups with the prices consumers will have to pay for energy. Each of these groups tends to frame energy issues in a different light, with some groups concerned more with economic security and quality of life concerns, others with national security interests, yet others with environmental protection, and some primarily with jobs.

Energy politics is also closely tied to the nature of the energy source, risk perceptions related to the use of the energy source, and the distribution of energy resources in the country.

Coal mining has been central to U.S. energy politics for well over a century and coal production is on the rise. However, although coal mining was a major employer in the past, the number of coal miners has steadily declined with time. Whereas in 1980 there were an estimated 220,000 coal miners in the country, in 2003 that number is down to approximately 100,000. Coal is a heavily regulated energy source because of the high safety risks for miners and the pollution emitted from coal burning as well as the damage that can be caused to lands from coal extraction.

Coal mining is heavily concentrated in Wyoming, West Virginia, and Kentucky, which together account for more than one-half of U.S. production of coal. Other major coal-producing states include Pennsylvania, Texas, Montana, and Illinois. Efforts to regulate coal production and coal burning in power plants for environmental reasons has resulted in considerable interstate politics, pitting producing states against downwind states suffering from acid rain.

Crude oil production is also heavily concentrated in a few states. Texas, Alaska, and California are the three largest producers, with Louisiana, Oklahoma, New Mexico, and Wyoming also being substantial producers.

Federal and Indian lands are of great interest to energy developers. Approximately 38% of total U.S. coal production was from Federal and Indian lands in 1999. The federal government owns the outer continental shelf, which is the territory that lies approximately 3 nautical miles from the shoreline and extends out 200 nautical miles. In 1998, the outer continental shelf (primarily in the Gulf of Mexico) was the source of close to 25% of domestic natural gas and 20% of crude oil production.

The politics surrounding nuclear energy are distinct from those regarding other energy sources. The future of nuclear energy remains highly uncertain and heavily debated. There are 103 licensed nuclear reactors operating in 65 plants in 31 states. In the 1960s and 1970s, the government provided the nuclear energy industry with substantial subsidies to offset the heavy initial investment required for new plant construction. The government also guaranteed the nuclear industry that it would develop a national nuclear waste depository. There are, however, many obstacles facing the nuclear energy industry. The accident at the Three Mile Island nuclear station in March 1979 that led to the permanent shutdown of reactor number 2 sent chills through the nation and intensified an already strong tendency for local communities and environmental groups to object to the building of new nuclear power plants. According to the report, "Nuclear Energy Policy," high construction costs are another serious problem for the industry; construction costs for reactors completed since the mid-1980s have been between $2 and $6 billion, or more than $3000 per kilowatt of electric-generating capacity (in 1997 dollars). Although no new nuclear power plants have been ordered since the Three Mile Island disaster and over 100 reactors have been canceled, 16 commercial reactors have received 20-year license extensions, with another 14 plants undergoing reviews for such extensions.

Over time, there has been some consensus established among stakeholders on the importance of energy efficiency improvements and energy conservation, but there is no real agreement on how the nation should deal with its large and growing appetite for energy. How much of a role should the government play in ensuring a stable energy supply? To what extent should government policy favor particular energy industries? Is deregulation of the electricity sector a good idea? What mix of energy sources should be achieved? To what extent should environmental considerations play a role in the nation's energy plans?

1.1 Energy Supply and Demand

The United States is the world's largest consumer of energy, accounting for 24% of total world energy consumption; it is a major importer of energy and is the world's largest source of greenhouse gas emissions. Approximately 86% of total fuel consumption is of fossil fuels. The United States is the world's second largest producer of coal after China and the second largest producer of natural gas after Russia. It also is a major producer of oil, representing 9% of

global production and nuclear energy, accounting for 31% of global nuclear electricity production.

Almost three decades after the 1973 oil embargo by the Organization of Petroleum Exporting Countries (OPEC), the United States remains highly dependent on energy imports. In 2001, the United States consumed 97 quadrillion British thermal units (Btu) of energy. Approximately 39% of this was oil, 24% natural gas, 23% coal, 8% nuclear, and 6% renewable energies (primarily hydro and biomass). In contrast, the United States produced approximately 72 quadrillion Btu of energy [33% coal, 28% natural gas, 21% oil, 11% nuclear, and 8% renewables (largely hydro and biomass)]. This means that approximately 30% of all energy consumed in the country is imported.

U.S. dependence on oil imports is especially large, at 53% of all oil consumed. Given that approximately 20% of oil imports are from the Persian Gulf and another 40% from OPEC, U.S. energy markets are very dependent on the politics of the Middle East, a highly volatile region. The United States has also become a net importer of natural gas.

Although there have been substantial improvements in energy efficiency over the past three decades, total energy consumption continues to rise as a result of a growing population and more energy-intensive lifestyles. Thus, although the U.S. economy has become approximately 60% more efficient in the past 30 years, per capita energy consumption levels in the United States are among the highest in the world. On average, an American uses 342 million Btu of energy per year, or almost twice as much as a Japanese (174 million Btu) or a German (172 million Btu). Moreover, as the U.S. population is expected to grow substantially in the next decades due to a combination of immigration and a relatively high birth rate compared with many other advanced industrialized states, energy demand is expected to continue to rise.

1.2 Energy Planning in U.S. History

Unlike many other advanced industrialized democracies, the United States does not produce regular multiyear national energy plans. Historically, the lack of interest in long-term energy planning in the United States stems both from a relative abundance of energy and from a fairly strong tendency toward neoliberal economics. Prior to the 1970s, energy policy change tended to be incremental and largely reactive.

Through the late 1950s, the United States produced at least as much energy as it consumed. In contrast with many countries in Europe, which nationalized energy industries in the first half of the 20th century, in the U.S. energy production remained in private hands and little consideration was given to long-term energy supply.

In the 1960s, energy consumption began to surpass energy production and by the 1970s, the United States had become a major importer of energy, and especially petroleum. Over the course of the 1970s, in response to the nation's severe environmental problems and sharp increases in energy prices, the government became increasingly involved in regulating the energy industry, promoting energy conservation, and providing incentive schemes for the targeted development of specific energy sources.

1.2.1 The Impact of the OPEC Oil Embargoes

The 1973 oil embargo by OPEC sent world oil prices soaring. In reaction to the embargo, in 1975 at Gerald Ford's urging, Congress passed the Energy Policy and Conservation Act, which established Corporate Average Fuel Economy (CAFE) standards for automobiles, extended domestic oil price controls, and created the Strategic Petroleum Reserve, an oil stockpile for emergency situations. Two years later, Congress created the Department of Energy (DOE).

Jimmy Carter was convinced that the nation's energy security demanded a comprehensive energy plan. Carter's 1978 National Energy Plan was the first attempt by a president to establish a national energy policy, one that called for both expanded production of coal and enhanced energy conservation. The plan included numerous measures for the promotion of renewable energies, provisions for energy conservation, and energy taxes. It also led to the establishment of the Public Utilities Regulatory Act, which required utilities to purchase energy from "qualifying facilities," effectively ending the electric utility monopoly on electricity production and helping to foster a market for renewable energy sources.

1.2.2 The Ronald Reagan Years

Many of the policy goals laid down in Carter's National Energy Plan, however, came under attack during the years of the Reagan administration. Reagan was eager to down-size government and remove many of the regulations he felt were burdening the energy industry. Although he failed in his effort to close the Department of Energy, he succeeded in winning Congressional support to rescind tax breaks for energy-saving devices and decreased government funding for research and development of renewable energy sources and energy conservation initiatives.

1.2.3 George H. W. Bush's National Energy Strategy and Energy Policy Act

Although George H. W. Bush had a political outlook similar to that of Ronald Reagan, like Carter he did see the need for the creation of a national energy plan. Thus, in 1989 he ordered the DOE to prepare a National Energy Strategy (NES). The NES was a response to growing concerns with global warming and rising energy prices in the late 1980s and early 1990s. The plan was criticized by environmentalists, however, because it included plans for oil drilling in the Arctic National Wildlife Refuge (ANWR) and did little to reduce U.S. carbon dioxide emissions. Indeed, a decade later these same issues remain two of the major points of contention between Republicans and Democrats in the formulation of a national energy plan.

The NES led to the adoption by Congress in 1992 of the Energy Policy Act, which began the opening of the electric utility industry to competition, established energy efficiency standards for federal facilities, mandated that the federal government replace some of its fleet with alternative fuel vehicles, established the (unmet) goal of having 10% of the nation's gasoline use be replaced by alternative fuels (as of the year 2000, only 3.6% of the nation's highway gasoline use had been replaced), called for voluntary reporting of greenhouse gas emissions and the establishment of a national inventory of greenhouse gases, and initiated measures to aid the nuclear energy industry (including a revision of the regulatory framework and environmental standards governing nuclear waste disposal at Yucca Mountain in Nevada).

Although the 1992 National Energy Policy Act was the most important energy legislation to be passed in over a decade, it failed to do much to move the nation toward greater energy independence or to do much to promote a more sustainable energy future.

1.2.4 William J. Clinton's Failed Btu Tax

Little progress in these directions was made under the Clinton administration, either. Clinton and Vice President Al Gore proposed a tax on the heat content of fuels (a Btu tax) in an effort to cut energy consumption (and thereby reduce dependence on imported oil) and to reduce greenhouse gas emissions. The Btu tax, however, was rejected by Congress in favor of a 4.3 cent per gallon increase in the federal gas tax, which, because of the historically low price of gasoline at the time, was politically palatable. The Senate also made known its lack of intention to ratify the Kyoto Protocol that the Clinton administration formally signed in 1998. Had the Kyoto Protocol been ratified by the Senate, major efforts at energy conservation and the establishment of a carbon emissions trading system would have been necessary.

2. GEORGE W. BUSH'S NATIONAL ENERGY POLICY

Soon after George W. Bush entered office, California was hit by rolling electricity blackouts and sharp increases in electricity prices. In reaction to the California "energy crisis" and fulfilling a campaign pledge, shortly after taking office Bush announced his intention to establish a national energy plan. Vice President Richard Cheney was given the task of leading an energy task force that was charged with drafting a plan. After 3 months of closed-door meetings and with considerable fanfare, in May 2001 the energy task force released its National Energy Policy (NEP) report, "Reliable, Affordable, and Environmentally Sound Energy for America's Future." The report and pursuant energy bills have been the subject of heated Congressional debate and a number of lawsuits.

The NEP report suggests that the nation is facing the most serious energy crisis since the oil embargoes of the 1970s. Moreover, in the coming decades, unless action is taken, "projected energy needs will far outstrip expected levels of production. This imbalance…if allowed to continue, will inevitably undermine our economy, our standard of living, and our national security." To deal with the crisis and future energy needs, the report calls for promoting energy conservation, repairing and modernizing the energy infrastructure, and increasing energy supplies.

Perhaps the strongest theme to come out of the NEP report is the need to increase the nation's energy supply. The NEP calls for oil drilling in ANWR, the promotion of clean-coal technology, nuclear energy development, and natural gas exploration. It also makes mention of the need to encourage renewable energy development, but suggests that renewable energies are unlikely to make a large dent in U.S. foreign energy dependence. A second theme of the report is the potential to make major gains in energy efficiency and new energy sources through technological developments. The report also urges a modernization and expansion of the nation's aging energy infrastructure (oil and natural gas pipelines, refinery capacity, and electricity transmission grids).

In total, the report included 105 recommendations, including many that called for cooperation

with foreign governments to improve the environment for energy investment and to improve the stability and security of supply.

The release of the NEP has had a mixed reception. Conservatives like it. The Heritage Foundation's Senior Policy Analyst for Energy and Environment calls the plan "a step in the right direction" because it calls for meeting the nation's energy needs through developing as yet untapped domestic energy sources, removing interstate transmission restrictions, modernizing energy delivery systems, promoting nuclear energy (which does not produce greenhouse gas emissions) and clean coal technology, and removing regulatory burdens that create market inefficiencies.

In contrast, environmentalists have been highly critical of the NEP. Greenpeace, for example, argues that the NEP is leading the nation "down the wrong road" because the plan fails to take steps to reduce greenhouse gas emissions, calls for 1300 new fossil fuel and nuclear power plants, favors oil extraction in ecologically sensitive areas (including ANWR and the Rocky Mountains), and will use taxpayer subsidies for the nuclear energy and fossil fuel industries.

Several lawsuits have been brought against the Vice President's office as well in relation to the closed-door process by which the NEP was drafted. The National Resources Defense Council (NRDC) sued the Department of Energy, a key member of the task force, under the Freedom of Information Act, for the release of thousands of pages of documents used by the task force in formulating the plan. Although the DOE provided some 13,000 pages that the NRDC has since made available on the Internet for public scrutiny, thousands of additional pages of documents were not released. In February 2002, the NRDC won a District of Columbia court motion requiring the DOE to expedite the release of the remaining documents.

Judicial Watch and the Sierra Club are suing the Vice President's office for the release of additional documents, task force minutes, and computer records that would shed light on who advised the task force and how this may have influenced the document's development. Their lawsuits are motivated by the concern that private industry representatives essentially functioned as members of the advisory group, and under the law, this would mean that the group's deliberations should be made open for public scrutiny. The collapse of Enron in early 2002 and the revelations that Enron had tried to manipulate California's electricity markets for profit have also played into these lawsuits since Cheney met with Enron's Chief Executive Officer, Kenneth L. Lay, several times while he was heading up the task force. Cheney's office has sought unsuccessfully to have the cases dismissed.

The terrorist attacks on the World Trade Center and the Pentagon on September 11, 2001, and the subsequent U.S. decision to go to war in Iraq, for a time shifted government and public attention to national security concerns.

Events in the Middle East did, however, feed into energy debates and renewed concern about U.S. oil dependence on the Middle East. They strengthened national sentiment on the need to reduce U.S. dependence on imported oil. But clear partisan differences remained on how greater energy independence should be achieved. The Republicans have tended to favor greater domestic production, including production of nuclear energy, whereas moderate Republicans have at times joined Democrats in calling for more energy conservation and support for nonnuclear renewable energies.

Thus, although recognizing the need for some kind of national energy policy plan, the 107th Congress failed to pass comprehensive national energy legislation even though both houses had passed energy bills. Major differences in the Democratic-controlled House and Republican-controlled Senate versions of energy legislation could not be bridged and, thus, Congress ended its session without passing energy legislation. The November 2002 elections returned control of the Senate to the Republicans and strengthened the position of Republicans in the House.

Despite the Republicans' strong showing in the 2002 election and high voter-approval ratings, the Bush administration has a poor environmental image. The administration has done little to win the confidence of environmentalists with its rejection of the Kyoto Protocol, its failure to regulate carbon dioxide emissions or to set more stringent fuel efficiency standards, and its efforts to open protected federal lands to mining, oil and natural gas drilling, logging, and recreational purposes. An August 23, 2003 public opinion poll found that of the 1011 adults surveyed by telephone 53% preferred the Democrats' approach to the environment and 29% preferred Bush's (the respective figures in January 2002 were 43% and 38%). Similarly, 42% of Americans said they preferred the Democrat's approach to energy compared with 33% who said Bush was doing a better job (the respective figures in January 2002 were reversed, with 33% favoring the Democrats and 46% favoring Bush's approach).

In a bid to improve its image on environmental and energy issues, the Bush administration has begun to focus the domestic energy debate on hydrogen fuel development. Hydrogen is being billed as a pollution-free fuel since the energy-generating chemical reaction between hydrogen and oxygen produces only water as a waste product. Hydrogen production, however, requires energy from other energy sources. Natural gas is the most affordable means of producing hydrogen although its cost is still four times as high as the cost of producing gasoline. The administration's hope is that, through technology development, it will be possible to produce hydrogen more affordably, including with the use of coal and nuclear power.

In his January 2003 State of the Union address, President Bush announced his intentions to fund hydrogen fuel technology research and development. The administration targeted $1.7 billion to be distributed over the subsequent 5 years for the Freedom CAR and Fuel Initiatives, public–private cooperative endeavors for the development of hydrogen fuel cells, hydrogen fuel cell-powered cars, and hydrogen infrastructure. The administration's stated goal is to have hydrogen-powered vehicles and a fuel distribution network in place by 2020.

The initiative has won praise, especially from Republicans and Democrats in states with automobile manufacturers, but has earned more mixed reviews from Democrats and environmentalists who have criticized the administration for placing so much emphasis on a still unproven energy source and providing relatively little investment for available renewable energy technologies. Concern has also been raised that in order to develop hydrogen it will be necessary to build more coal-burning fossil fuel plants and nuclear power facilities.

The 108th Congress took up the energy legislative debate that the 107th Congress failed to complete. The House of Representatives was the first to act. In April 2003, the House of Representatives passed H.R. 6 on a vote of 247 to 175. The bill includes approximately $19 billion in energy-related industry tax incentives over a 10-year period for alternative fuels, energy efficiency, electricity restructuring, and oil and gas production. The bill provides tax breaks to oil and gas companies to encourage production from marginal wells and offshore drilling, provides millions of dollars for clean coal technology, and permits utilities to more easily write off the cost of new transmission systems. The bill also grants tax credits for solar and wind power and encourages energy-efficiency improvements in homes.

On a vote of 228 to 197, the House killed a proposed amendment that would have removed the provision for oil drilling on 2000 acres of the Arctic National Wildlife Refuge. Moderate Republicans joined Democrats in calling the move ill-conceived, arguing that the Arctic National Wildlife Refuge should be protected as one of the nation's most important pristine areas and that a more effective approach would be to save oil through the introduction of higher automobile fuel efficiency standards. In an earlier vote, however, the House defeated a provision that would have required a 5% reduction in automotive fuel use by 2010 (or an average fuel efficiency standard of approximately 30 miles per gallon). The justification given by opponents of higher auto mileage standards was that it would be bad for the economy as it would make it harder for manufacturers to produce popular sports utility vehicles, would result in layoffs, and would pose safety hazards because the standards would require the production of smaller cars.

Democrats in the House also failed in their efforts to rewrite electricity rules to protect consumers from market manipulation that could lead to huge price swings and ban methyl tertiary butyl ether as a fuel additive despite its role as a potential source of groundwater pollution. The Natural Resources Defense Council has criticized the House bill for providing huge subsidies to the coal, natural gas, and nuclear industries but providing relatively few incentives for less polluting industries.

Attention then shifted to the Senate, which began voting on measures related to its national energy bill. Repeating events in the House of Representatives 3 months earlier, Senate Democrats failed in their effort to win support for a proposal for a 40-mile-per-gallon fuel-economy standard for passenger cars by 2015. Instead, the Republican majority voted to direct the Department of Transportation to work on a new standard, taking into consideration the impact it would have on jobs and consumer safety. The current CAFE standard of 27.5 miles per gallon has not been changed since the 1986 model year.

Deadlock in the Senate on a number of other energy issues was finally broken on July 31, 2003, when the Senate Republicans in a surprise move agreed to a suggestion by Senate Minority Leader Thomas A. Daschle that last year's energy bill (that was negotiated by a Democratic-controlled Senate) should be resurrected. The Republican majority agreed to this proposal, knowing that they would be able to write new provisions into it in the coming months. The Democrats extracted a promise that

separate votes would be taken in 2003 on climate change control and measures to give federal regulators greater authority to oversee utility mergers. In accepting the 2002 Senate Bill, the Republicans gave up on provisions for loan guarantees for new nuclear power plants.

The sense of urgency behind the need for a national energy policy was rekindled by the August 2003 electricity blackout that left New York City and large sections of the Northeast sitting in the dark. The primary cause of the blackout was determined to be an antiquated electricity distribution infrastructure.

In the following months in largely closed-door conferences, Republican leaders of the House and Senate met to try to iron out differences between the House and Senate versions of energy legislation. The controversial House decision to drill in ANWR was dropped from the bill by the Republican leadership after it became clear that the bill stood no chance of being passed in the Senate if it were included, but other controversial elements remained.

The bill proposed by the conferees included $23 billion in tax incentives primarily for coal mining, oil and exploration, the construction of new transmission lines and power plants, and the building of a natural gas pipeline from Alaska to the Midwest. It also included tax incentives for wind power and biodiesel fuel made from soybeans and a doubling of ethanol fuel mandates. While the House of Representatives passed the bill, it was blocked by a coalition of 32 Democrats, 7 Republicans (mostly from Northeastern states), and one Independent in the Senate. The bill was supported oddly enough by labour unions, energy companies, and renewable energy producers. It was opposed, however, by those concerned with its large price tag (estimated to be over $30 billion over 10 years). Senators from Northeastern states also objected to the incentives provided for Midwestern coal-fired utility plants because the pollution from these plants affects them. There was also bipartisan opposition to the provision that would have exempted manufacturers of methyl tertiary-butyl ether from product liability lawsuits.

Thus, although there was great demand for new energy legislation, strong differences between Democrats and Republicans, between Midwestern agricultural and mining states and Northeastern states, and between energy producers and environmentalists prevented passage of new energy legislation prior to the adjourning of the 108th Congress for the holiday break.

Glossary

economic rent What remains of revenue after deducting the production costs of a mineral deposit, including normal return (mean industrial return) on the required capital.

expropriation Obligatory transfer of the property of a particular party to state administration for the public interest, normally in exchange for an indemnity payment.

nationalization Authoritative transfer of private sector means of production to national collective ownership represented by the state for reasons of national security or public interest.

public monopoly Exclusive right of the state to undertake an economic activity such as oil or natural gas extraction.

sovereignty Abstract principle that designates the instance that detains legitimate authority, the only authority with the capacity to enact norms; the international community recognizes that sovereignty over natural resources in inherent to the nation and is exercised by its representative, the state.

state interventionism A growing and direct process of intervention by the state in the economy or a sector of the economy, acquiring property rights and undertaking business activities and productive activity.

Nationalism is a doctrine of a people under foreign domination who try to free themselves and form a sovereign nation. The oil industry evokes such doctrine—a historical phenomenon, a process, a value, a feeling, and a vision of a country. As a doctrine, nationalism claims the nation's ownership of its natural resources, the state's valuation of such resources, and the subordination of the management of reserves and production by development policies. It is a dogma fed on socialist, communist, anti-imperialist, and anti-capitalist ideas that have been expanded here and there, imitating the achievements made by other countries.

1. INTRODUCTION

The term "nationalism" is commonly used to describe state interventionism that permeated the oil industry since the beginning of the 20th century. It was born in Latin America with the first concessions and was generalized in all continents during the postwar period and culminated by "overturning" the Organization of Petroleum Exporting Countries (OPEC) during the 1970s. The nationalist intervention took on various forms. Taken to its ultimate consequences, it led to the nationalization of oil property and activities and finally to a state-owned monopoly.

In its character of patriotic value, nationalism means defense of sovereignty. Territorial sovereignty, one of the essential bases of nation-state, becomes extendible to the subsoil and, therefore, to the resources contained within. In certain countries, ownership and the state-owned monopolies over oil and natural gas have even been indispensable elements in the consolidation of the nation-states themselves.

Equally, nationalism translates a sentiment against an external action. It evokes the struggle for the liberalization of oil, of which greedy foreign companies have taken control. Just as the imperialist practices of the superpowers awoke the nationalism of oppressed populations, the predatory practices of the multinationals aroused oil nationalism. It was a reply to the plundering, the arrogance, and the arbitrariness of the concession system. And this sentiment has tended to prevail.

However, nationalism also gave birth to independent development following a colonial past. To put oil at the service of development through ownership of the resources, a greater share of income and gradual control of related activities was the fundamental objective proposed by oil-producing countries. That nationalist vision contained a mix of values, interests, and aspirations that converted it into a vital challenge, an image that strongly took root in society.

Contrary to popular belief, nationalism does not exist per se. It emerges when the conditions are favorable, when the state cannot exercise sovereignty over its natural resources, and/or when foreign interests threaten that original, inalienable, and imprescriptible right. However, its achievements will be few if the context does not favor the state's intervention in the economy.

Because of these objectives, nationalism has been one of the political factors that have contributed the most to the structural transformations of the international oil industry. It called a halt to the concession system and performed a crucial role in recovering the ownership of natural resources and the administration of complete sectors of the oil industry by oil-producing countries. Following its peak during the 1970s, the nationalist fervor abated but did not disappear altogether. In a worldwide context characterized by the stagnation of oil prices, economic liberalism, and the end of the cold war, the international oil companies have returned to the oil-producing countries, but not on the same terms as before. Nationalism is currently lethargic but will reemerge if the circumstances change and become favorable once again.

2. THE RISE AND PEAK OF NATIONALISM: 1920–1980

History repeats itself from one country to another. A few years after oil exploitation began by multinational companies, a social discontentment arose and grew to become a national movement of rejection. And although the nationalist struggles took on different forms and accomplished diverse goals, they shared the same driving force: the reclaiming of the permanent sovereignty of the nation's natural resources. In 1917, Russia was nationalized without any indemnity whatsoever, but this related to a different logic: the assumption of control by the state of all means of production, not just the oil industry.

2.1 The Nationalist Movements

Nationalism was born in Latin America at the beginning of the 20th century. From there, it radiated all over the world. Historical reasons explain that course. On the one hand, it was the natural expansion zone for the North American oil industry; on the other hand, it was the zone that had achieved greater political consciousness and institutional maturity because it consisted of countries that had ceased to be colonies decades earlier. The savage capitalism of the concession system (Table I) and a heightened political consciousness conjugated to breathe life into the nationalist phenomenon.

Argentina created the first nationalized company in 1923, and Uruguay created the first state-owned refinery in 1931. The Bolivian government nationalized the assets of Standard Oil of New Jersey in 1937 after it was discovered that the company had played a dual role in the Chaco War of 1932–1935, a bloody conflict between Bolivia and Paraguay that was instigated and backed by Standard Oil and its rival, Royal Dutch Shell.

Lázaro Cárdenas expropriated in 1938 following failed attempts to control and put the oil industry at the service of internal development through laws and regulations. The 1917 constitution had established the state-owned ownership of oilfields but maintained the concession system. Standard Oil and Shell took advantage of this situation to divide up the territory, plunder the subsoil, and make Mexico the second-largest oil exporter in 1920 without a single tangible benefit for the country. The companies, although paid off, organized a blockade against Mexican crude and the national oil company (PEMEX).

At the end of the fierce dictatorship that turned the country into a vast petroleum field dominated by Shell, Esso, and Gulf, Venezuela changed the law in 1943 to recover a part of the oilfields and established a less unfair distribution of the oil benefits. But it was not until 1948 that Juan Pablo Pérez Alfonso managed to impose the "50/50" principle on the oil companies. A year later, such a principle was being applied in the Middle East oil-producing countries.

In Iran, the Anglo–Iranian Company rejected that distribution. In response, the Mossadegh government nationalized oil in 1951 and created the National Iranian Oil Company (NIOC). The International Court of Justice at The Hague, Netherlands, ruled in the Mossadegh government's favor, but the process was not completed due to a military coup d'êtat that ousted the government in 1952. The new authorities ratified state ownership of the oilfields and the

TABLE I

Inheritance from the Old Colonial Regime

The Concession System

Using skill, influence, and the support of its country of origin, an oil company obtained from the government of an underdeveloped country the concession for a vast territory to carry out oil exploration operations for 50 years or more. Frequently, it was the men close to power who obtained the concessions, but sooner or later, they were transferred to the oil companies. In the end, the majority of national territory was under concession.

The concession implied the exclusive right to explore, extract, and export the product so that no other investor could do the same in the zone indicated in the mining deed. The concessionaires organized and controlled the operations to suit their own criteria and interests. They decided the volume and nature of the investments, working areas, exploration plans, oilfields to be exploited, production capacity, extraction rates, and exportation volumes. The criteria used were linked to agreements between the oil companies and, in the last instance, to the evolution of a world demand broadly managed by the large multinationals. The role of the state was reduced to that of simple tax collector.

From there arose the dual economic structure. The oil industry was isolated from the rest of the economy. Its evolution depended on the behavior of world demand. From there, some oil areas suffered from overexploitation, and others suffered from stagnation. Also, the oil companies could monopolize very cheap oil to resell it at high prices. The main beneficiary was not the owner but rather the entity that extracted, exported, transformed, and sold the oil as products. The concessionaire ensured the highest benefits without the slightest obligation to satisfy the demands of economic and social development, neither of the country nor of the oil sector itself. In summary, the companies managed a geological heritage that was not theirs to their own convenience. They exercised sovereignty over oil resources of the country that had opened its doors to them. They usurped a right that was not theirs.

Another equally important problem was the manner in which the companies operated the concessions. With the complicity of weak or corrupt governments, they turned the oil areas into regions with their own laws, authorities, and police forces. They created a state within a state. Communities and farmers stripped of their land, workers in misery, accidents of gigantic proportions, destruction of oil fields, the accelerated wastage and exhaustion of reserves, enormous fortunes in the hands of a few, and interference in the internal affairs of the country were some of the concession system. It was not for nothing that this is historically considered as one of the most savage forms of capitalism. The unjust nature of such a system awoke nationalism, which caused its collapse.

Agreements between Large Companies

In 1928, Anglo–Iranian (BP), Royal Dutch Shell, Compagnie Française des Pétroles (Total), Standard Oil of New Jersey (Exxon), and Mobil Oil agreed, through the Red Line Agreement, to jointly penetrate the old frontiers of the Ottoman Empire (Turkey, Iraq, Syria, and the Arab peninsula) with the exception of Kuwait. Each company would make its own investments, independently of the others, in refining, distribution, and marketing. That same year, the three largest companies (Standard Anglo–Iranian, and Shell) signed the Achnacarry Agreement to conserve the market portions, regularize production, and determine world oil price, Mobil Gulf, Texaco, and Chevron joined the pact. These and other subsequent agreements allowed the "Seven Sisters Cartel" and Total to exercise total control over the extraction and exportation of Middle East oil. However, because the collusion among companies limited the aspirations of putting oil at the service of national development, the producing countries rebelled.

existence of the NIOC but maintained the concession system. That nationalization, aborted by the intervention of the International Oil Cartel and the large capitalist powers, had a double effect of dissuading other countries from following its example but confirming the legitimacy of the struggle. It propagated the idea that the state should ensure absolute control of oil operations through nationalization or negotiated agreements. The Iranian experience represented a real basis for the subsequent political changes in the region.

Nationalism gained strength during the 1960s. Certain Latin American countries created upstream monopolies but respected existing rights (e.g., Brazil, Argentina, Chile), whereas others nationalized (e.g., Cuba, Peru, Bolivia). The infection traveled as far as India and Syria. In parallel, numerous national companies were created in Venezuela, Kuwait, Saudi Arabia, Argelia, Iraq, and Libya, some of which were strengthened by technical assistance from the former Soviet Union and from companies on the margin of the cartel.

A decisive factor in the progress of nationalism was the creation of OPEC in 1960 by Iran, Iraq, Kuwait, Saudi Arabia, and Venezuela at a meeting in Baghdad, Iraq. These were later joined by Qatar in 1969, Indonesia and Libya in 1962, Abu Dhabi in 1967, Argelia in 1969, Nigeria in 1971, Ecuador in 1973, and Gabon in 1974. Born to combat the reduction in posted prices, unilaterally fixed by the oil companies, the cartel was not only dedicated to that. It encouraged the adoption of a single tax treatment in member countries, the recovery of ownership rights, and state control of production. In 1966, OPEC pronounced the principle of the countries' sovereignty over hydrocarbons. In 1968, it

pronounced the principle of national participation in the concessions. The organization's support turned out to be crucial when one of its members took action against the consortia. The example prospered. In 1965, the Latin American State Oil Reciprocal Assistance Organization was created. In 1968, the Organization of Arab Petroleum Exporting Countries (OAPEC) was formed.

Another fundamental factor in the rise of nationalism was the peak in the liberation and decolonization process. A total of 45 countries in Asia, Africa, and Oceania gained independence during the 1960s decade.

The movement of the nonaligned countries contributed to maintaining nationalist feelings on a high—on being constantly present against the political blockades and foreign domination, on the one hand, and for each country's right to liberty, independence, and autonomous development, on the other. However, the persistence of poverty was a reminder that access to independence was not enough to ensure progress. Economic independence must be conquered until a standard of living in accordance with the most elementary rules of human dignity is achieved. Developing countries wanted to make use of their wealth, organize their development, and cooperate on a basis of equality and reciprocal interest. From there arose, in particular, a movement ever more important in the rejection of the control of their natural resources by foreign companies and of reclaiming their national sovereignty. This discussion gained strength at international forums.

Two additional factors encouraged developing countries' aspirations of freeing themselves from the control of the large multinational companies. The first was the appearance and strengthening of new investors—the national companies of the industrialized nations such as France, Italy, Belgium, and Japan and the "independent" U.S. companies such as Occidental, Amoco, Conoco, Getty, and Arco—that were prepared to accept a share of the benefits more in favor of the producing countries with more restricted access to the oilfields as well as offering technical and commercial assistance to the national companies so as to gain certain permits and guarantee cheaper sources of supply. The second factor was the appearance of new production zones with high oil potential such as Libya and Nigeria. This led to fierce competition among companies, and the developing countries used this competition to their advantage to impose their conditions.

Nationalism reached its peak during the 1970s, not only as a consequence of a historical process but also due to a series of favorable circumstances. On the economic plane were tensions regarding the availability of oil as a result of transportation problems, increased global production costs associated with the development of high-cost oilfields (e.g., the North Sea, Alaska) necessary to respond to the rapid growth in demand, and the need for higher international process to correct imbalances in the U.S. supply system. On the political front were the rise to power or consolidation of nationalist governments and a new Arab–Israeli war. Taking advantage of the political climate, the OPEC countries rebelled against the companies. Advances in one country were reproduced in the others, dealing simultaneously with ownership rights, the distribution of benefits, and administration of oil operations.

In 1970, Libya managed to increase taxes and posted prices. Iran and Kuwait copied the measure. Argelia went further by unilaterally fixing such prices. These events set the criteria to begin negotiations between OPEC and the companies, resulting in the Tehran (1971), Tripoli (1971), and Geneva (1972–1973) agreements. The most important achievement was that the determination of prices ceased to be a decision made only by the oil companies. From that point onward, the OPEC countries intervened in such decisions.

Argelia nationalized the interests of six companies and 51% of the French concessions in 1970. The following year, Libya nationalized BP's assets. In 1972, Iraq nationalized the Iraq Petroleum Company, Ecuador nationalized its oil, and Libya acquired 50% of ENI's assets. In 1973, Saudi Arabia's share in the ARAMCO concessions took effect; from an initial value of 25%, it would reach 51% by 1982. The shah of Iran and the companies agreed to immediate nationalization of all the assets of the Anglo–Iranian Company in exchange for a supply contract guaranteed for a 20-year period. Libya nationalized 51% of the remaining concessions. Nigeria acquired a 35% share of BP–Shell assets.

On October 6, 1973, the Yon Kippur War broke out. Ten days later, OAPEC members reduced their exports and declared an embargo against the United States and the low countries for having assisted Israel against Egypt and Syria. Weeks later, the exporting countries started to fix sovereignty and posted prices without consulting the oil companies. By the end of the year, Iraq had nationalized Exxon's and Mobil's equity in the Basrah Petroleum Company. The following year saw the full nationalization of Iraqi oil.

In 1974, the General Assembly of the United Nations recognized the right to nationalize or

transfer to state the control and execution of mining projects. The Declaration and Action Program for the Establishment of a New International Economic Order stipulated the following:

> *In order to safeguard its resources, each state is entitled to exercise effective control over them and their exploitation with means suitable to its own situation, including the right to nationalize or transfer ownership of such resources to its nationals, this right being an expression of the full permanent sovereignty of the state. No state may be subjected to economic, political, or any type of coercion to prevent the free full exercise of this inalienable right.*

In 1974, Nigeria took a 55% share of all concessions. Kuwait, Qatar, the United Arab Emirates, and Saudi Arabia fixed their shares at 60%. The Saudis also increased the tax rate to 85% and fixed royalties at 20%. In 1975, Venezuela nationalized and Kuwait acquired all concessions, with the oil companies receiving compensation on the value of the assets and a long-term trading agreement with certain advantages in exchange for technological and transportation services. This formula served as an example to other countries.

2.2 From Nationalism to the Application of the Principle of Sovereignty

The "overturn of OPEC" encouraged nationalism in the Third World. The world's perception of ever more scarce and more expensive oil played in its favor. The rhythm and intensity with which each country imitated the organization depended on political will; the technical, human, and financial capacity of the public sector to develop oil industry activities; the geological potential; the level of production and importance of demand; the weight of the oil bill; external indebtedness; and the shortage of currency. These factors determined the goals and margin for maneuver of the state when faced by the multinationals.

Nationalist efforts were focused in several directions: the recovery of ownership rights, state administration of activities considered as strategic, the creation or strengthening of national companies, the substitution of concessions for the system of contracts, and tightening up on taxes imposed on companies with regard to access, operation, and distribution of benefits.

2.2.1 Recovery of Ownership Rights

Many countries substituted the royal prerogative system for the ownership system. In the first place, the mineral resources, before being discovered, belonged to nobody. The state used its royal prerogative power, formerly attributable to the king, to concede the right of use, determine the general conditions of the search and exploitation of the oilfields, and designate the right to mine or extract to the company of its choice. In the second place, under the ownership system, the oilfields are the property of the state, which may entrust their exploitation to a state-owned monopoly or grant a contract to a third party, establishing the most convenient terms and conditions on a case-by-case basis. If the resource is already being exploited, the state has the right to nationalize it. The third possibility, the occupation system, postulates that the owner of the soil or the surface is also the owner of the subsoil. This did not echo among the developing countries as being incompatible with history, politics, and the ideology dominant at that time.

2.2.2 Direct Control of Strategic Activities

Certain nations imposed state exclusivity on exploration, development, production, transportation, refining, processing, distribution, marketing, exportation, and importation of crude oil, natural gas, gasoline, and petrochemical products. Others assigned exclusive rights to exploration and production but left the other segments open. Still others limited exclusivity to crude oil imports. The remainder of the countries decided to promote competition in all of the links in the chain.

2.2.3 Incorporation or Strengthening of National Companies

One of the nationalist goals most appreciated by the producing countries was the state's direct intervention in oil production activities in two ways: (1) as an investor (through a share in the consortia or concessions) and (2) as the direct executioner of the projects. In this manner, the state became not only owner but also entrepreneur. That role led to the creation or strengthening of state-owned companies. These should be capable of taking control of nationalized assets, executing the projects, maintaining the rate of production, and (if necessary) negotiating agreements with the multinational companies to obtain capital, technology, and know-how. During the 1970s, 38 state-owned companies were incorporated and 19 already existing companies were strengthened.

2.2.4 Substitution of the Concession System for the Contract System

Abandoning the concept of concessions had become a question of principle. As a result, production sharing contracts and risk service contracts flourished

in their many forms. However, the title of "concession" did not disappear. It survived, adapting itself to the new circumstances, normally incorporating the state ownership of the oil and an obligatory share of the national company under association agreements. The concession system continued to be used by countries lacking known oil potential that had small, little explored territories and pragmatic governments. Countries that had interesting geological potential or that were already producers were inclined toward production sharing or association contracts. Nationalist countries, with experienced state-owned oil companies and great geological potential, were inclined toward risk service contracts. The companies quickly adapted to the new system because it did not exclude the possibility of limiting risks and making significant profits. Together with the World Bank, they promoted rate of return-based profit-sharing contracts.

2.2.5 Toughening the Conditions of Access, Operation, and Benefit Distribution

Nationalism meant searching for the maximum economic or industrial benefit that a country could obtain from the relationship with the companies. To achieve rapid, efficient, and complete prospecting of the sedimentary basins, as well as optimum extraction of hydrocarbons, the terms of the contracts were reduced, the investment obligations were increased, programmed periods were contracted, delivery of the contracted zones was accelerated, surface rents were increased, and the control and follow-up processes were improved.

To increase the share in the benefits, the tax burden was increased through greater premiums per contract signed and for commercial discovery (bonus), increases in royalties and taxes on benefits, reductions in cost oil (the part of production destined to recovering costs) and profit oil (the part that produces income for the companies), increases in amortization periods, greater state participation in the projects, and the disappearance in the depletion allowance for the reconstitution of oilfields. The tax collection mechanisms multiplied and were perfected with an emphasis on efficient collection of taxes such as the rent-skimming tax, cost stop, price cap, and windfall profit tax.

Rights, taxes, customs tariffs, obligations for national content, limitations for repatriating benefits abroad, commitments to create infrastructure, the use of local goods and services, the hiring of local labor, and the carrying out of social projects were established to prevent the flight of oil profits from national territory. With the intention of dominating the local oil industry, clauses were imposed relating to the transfer of technology as well as to training the national companies' employees. Finally, measures were demanded to protect the natural environment and the productive and social activities that may be affected by oil projects.

The most notable toughening up was seen in the large and medium oil-exporting countries that remained unnationalized, such as Egypt, Oman, and Qatar, and in the smaller producers that strongly embraced nationalism, such as Ivory Coast, Zaire, and Sri Lanka. Some countries, such as Argentina, India, and Turkey, were more pragmatic, following the trend but without frightening away the oil companies. Following the 1979 oil glut, a second wave of reclamations was observed, driven by the non-OPEC countries of Malaysia, Colombia, and Egypt as well as by other member countries, such as Ecuador, Indonesia, and Gabon, that previously had shown a degree of moderation.

3. PRAGMATISM SUBSTITUTES NATIONALISM: 1981–2003

The toughening of the conditions of access, operation, and distribution of benefits would not have been possible without favorable circumstances. The factors of the oil industry itself were particularly important. The dramatic growth in demand, the substantial increase in oil prices, and the general perception of scarcity caused savage competition among the oil companies to obtain mining rights. The Rome Club's catastrophic projections reflected the climate of that period. The perspective of ever more expensive and scarce oil forced companies to accept less advantageous conditions on the "invest now or go away" principle. Such circumstances did not last long. The prevailing conditions following the second oil glut were very different from those that had existed during the 1970s. The producing countries ceased to enjoy the correlation of forces in their favor due to changes both in the oil industry and in the economic and global political contexts that serve as a backdrop. Under those circumstances, thriving competitions developed among producing countries to attract foreign investment.

3.1 Nationalism Weakened by Lower Capital Availability

The industry structure changed as a result of the nationalist movements in the large exporting

countries. Vertical integration was broken, new markets were created, and new producers that did not join OPEC emerged. When the companies lost control of world reserves, the quantities produced, and the fixing of prices, relationships with the producing countries became highly dependent on the peaks and troughs of the market. From that point onward, the availability of risk capital for exploration and extraction projects depended directly on oil price levels, which were difficult to predict. In a tense market with perspectives of scarcity, the owners of the reserves had more leeway to impose their conditions. In a surplus market, the foreign operators could impose theirs.

Oil price quotations declined during the 1980s. The reduced budgets of the multinationals were not directed at developing countries as a priority but instead were directed at politically safe areas or at stock exchanges to absorb firms with proven reserves. Therefore, the companies began to pressure the producing countries for more favorable conditions. The World Bank and other credit institutions turned the thumbscrews by ceasing to finance public investment in oil. This situation changed little during the 1990s. Price increases during 1995–1996 and 1999–2002 were translated into greater availability of funds, but these were directed toward regions that were politically safe but had potential (e.g., the North Sea), at large producers that opened up their territories (e.g., Russia, Venezuela), at large producers that lowered their pretensions (e.g., Nigeria, Angola, Oman, Egypt), and at the frontier zones in industrialized countries (e.g., the Gulf of Mexico).

3.2 Economic Crisis, Neoliberal Paradigm, and a Unipolar World Close in on Nationalism

Changes in the general frame of reference also contributed to weakening the position of the producing countries. The solution to the delicate economic situation of the 1980s known as the "debt crisis," characterized by inflation, currency depreciation, and high levels of debt, was sought through structural adjustment programs agreed to with international financial organizations that invariably included measures to enable foreign investment. Credit restrictions of debt service obligations reduced the availability of public funds. This reduction directly affected the national oil companies, especially when such limitations combined with inadequate prices, poor efficiency, and the diversion of funds for purposes other than productive reinvestment to reduce their response capacity to face an ever growing demand due to industrialization processes, the gradual elimination of social backwardness, and population growth. And although the economic urgency was slowly disappearing, neoliberal politics continued to be applied under the pressure of the so-called "Washington consensus."

The frame of reference changed completely during the 1990s and the first few years of the new millennium. The North–South confrontation, which until then had formed the backdrop of the relationships between the producers and the companies, changed with the end of the cold war. With the collapse of the Soviet Union and the socialist regimes of Eastern Europe, the political, technical, economic, and human support that had been offered to several developing countries disappeared, leaving them with no other option but to turn to the multinationals.

On confirming U.S. dominance, pressure increased on those countries that had nationalized their oil industries. As a result of the Gulf War in 1990, Iraqi oil exports were administered under the UN "oil-for-food" program. Since 1996, Iran and Libya have been subject to U.S. economic sanctions that particularly affect the oil sector. Hugo Chavez's government, trying to regain governmental control over Petroleos de Venezuela (PDVSA) and restrain the opening up of foreign investment in Venezuela, has been subject to destabilizing pressures since 2001. Also, following the military intervention in Iraq in March 2003, Iraqi oil is under U.S. guardianship.

In parallel, the generalization of the neoliberal paradigm accelerated the opening of economies and the liberalization of activities as well as the flow of investment. The outline of the state decreased notably. The energy sector, one of final defenses of the state-entrepreneur, did not escape the change. The restructure included the opening of reserved areas, the segmentation of activities, the introduction of competition, and the sale of state-owned companies. The effervescence centered in the natural gas and electricity industries but also reached the oil industry. In a kind of historical revenge, the multinational companies and their governments took advantage of the new circumstances to reclaim positions and privileges that they had enjoyed in the past.

All countries ceded, although with varying scope and speed. The need to attract foreign capital was less urgent for those that possessed important oil potential and national companies with balanced trade and economies. For most, the adverse conditions limited their negotiating power. That notable

asymmetry had repercussions in OPEC. Ecuador left the organization in 1992, and Gabon left in 1995. The defense of sovereignty over hydrocarbons had united OPEC, but once ownership rights had been recovered, it was divided by pricing strategies.

3.3 Adjustments to Attract Risk Capital

The politics of openness are best understood by classifying countries based on their oil industry experience, geological potential, and economic health. In that sense, three main groups may be identified:

- *Countries that were completely dependent on external contributions of capital, experience, and technology.* Their negotiating power with the multinationals was very weak. They were highly sensitive in the economic context and to the international oil market situation. They had a modest or unknown oil potential, the production levels of some were low, and their economies generally were poorly developed. Countries in this category included New Guinea, Congo, Guatemala, The Philippines, and Paraguay.
- *Countries that partially or fully controlled exploration and production activities but did not achieve full control of their industry due to, among other factors, budget restrictions that weighed heavily on the national oil companies.* To maintain productions rates, they entered into association agreements and shared production agreements or risk service contracts. This category included medium-sized exporters such as Indonesia, Oman, Nigeria, Qatar, Ecuador, and Egypt as well as importers with solid state-owned companies such as Argentina, Brazil, and India.
- *Nationalized countries that enjoyed a generous geology and that had taken control of all sectors of the oil business.* They were able to undertake vast exploration campaigns, managing to obtain capital, know-how, and technology to carry out such projects. Their experience in commercial circles allowed them to optimize production in advantageous conditions and allowed them to undertake an internationalization process. In the beginning, their relationship with the companies was limited to service contracts, but later they agreed to negotiate agreements regarding access to production. This was the case with Iran, Iraq, Venezuela, Argelia, Kuwait, Saudi Arabia, and Mexico.

With regard to sovereign management of resources, the dynamics in which the countries in the first two groups evolved were similar; with some exceptions, they had always turned to the companies. Conversely, the countries in the third group, having nationalized and started an internationalization process, evolved in a different dynamic.

3.4 A Step Back for the Small and Medium Producers

The countries in the first group, small or medium producers or those with no production, introduced faster and more vigorous adaptations to attract the oil companies. For these, the principle of sovereignty was limited to ideological debate. They quickly concluded that encouraging exploration to prove the potential existence of hydrocarbons was the main objective in controlling the industry or maximizing the taxation of the eventual production of oil or natural gas.

On the other hand and with some exceptions, the countries in the second group reacted relatively slowly and moderately. The problems arising from the change of context did not seem to make a mark in their nationalist conviction. However, to the extent that the exploration budgets were reduced and the economic reforms deepened, the adjustments in oil contracting became ever more important.

Despite their differences, the small and medium producers were faced with a policy of adjustment whose content and essential components were comparable. They adopted the following measures (among others): assignment of a better cost oil and profit oil for the companies, reduction or elimination of the state's participation in projects, reductions in taxes, suppression of oil price controls and currency exchange, reduction or elimination of royalties, signing of seismic option contracts, elimination of local personnel training, and relaxation of the restrictions related to burning natural gas.

There were some countries that did not want to relax their nationalism and others that did just the opposite. They did not take just one step backward; they took many. For example, they accepted waiving the renegotiation of contracts in case of oil price increases, applying the same advantageous conditions that other companies obtained in negotiations with states, guaranteeing a substantial benefit to foreign companies, and exonerating the operators from the payment of taxes, the elimination of royalties, and so on.

In summary, the small and medium producers consented to sacrificing economic profit and desisted

from the objective of dominating the oil industry. However, they did not waive ownership rights, an eminently political claim.

3.5 Adjustments in the Large Producers

Because the countries in the third group had to wait, the large producers were the last to call the oil companies again. But they did so not to occupy the place they had before nationalization; instead, they did so to participate in the specific activities that the national companies had developed with difficultly due to lack of capital, technology, and experience. The important role that these factors play is seen with greater clarity during times of crisis—when oil prices collapse, debts increase, fiscal resources become stunted, and state company exploration and production budgets collapse. The insufficiency of these key factors explains the advance of pragmatism to the detriment of nationalism.

The first to call the oil companies again, in 1986, was Argelia, a country overwhelmed by huge foreign debt. Its government even proposed the sale of some of the largest oilfields. It was followed by Iran and Iraq. Faced with enormous needs to rebuild their economies after the war, they opened negotiations in 1989 to rebuild and expand production capacity with the help of the multinationals. In the case of Iraq, the granting of sharing production contracts to non-U.S. firms was not far removed from the strategy of obtaining powerful allies such as France and China, a strategy that pressured for the end of sanctions that the UN Security Council had imposed on Iraq following the Gulf War. Under the tutelage of the United States, the Iraqi oil industry would be privatized and the oilfields would be granted in concession.

In 1990, Venezuela began an opening up process through operating service agreements to reactivate inactive or abandoned fields as well as association agreements in liquid natural gas (LGN), heavy-duty oils, and orimulsion. In 1995, profit-sharing agreements were introduced. In 1999, the natural gas industry was opened. And in 2001, a 51% share was established for PDVSA in all exploration and production agreements.

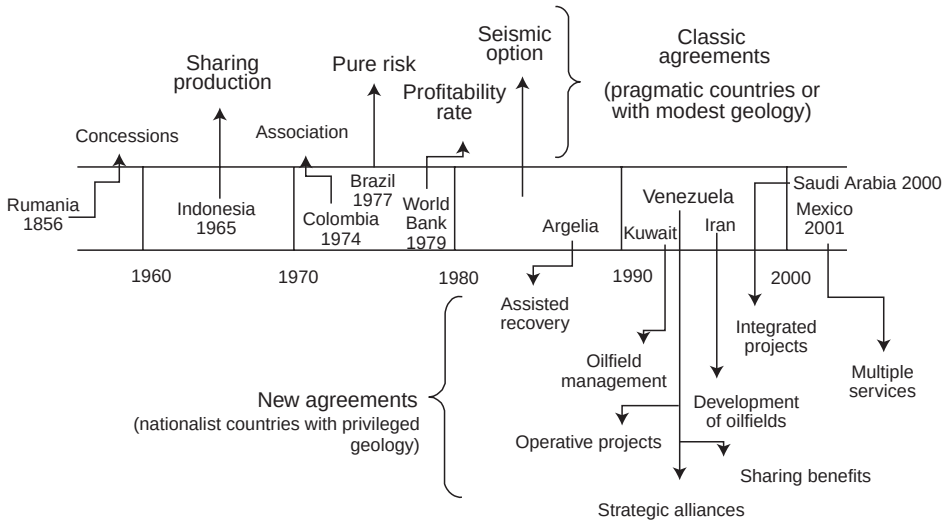
After the Gulf War, Kuwait called on the oil companies temporarily to rebuild its extraction installations. Government and Congress are face to face regarding the possibility of newly granting mining rights to the private sector. Saudi Arabia opened negotiations in 2000 to allow the multinationals to exploit nonassociated natural gas through agreements, including its use in the generation of electricity and the desalting of water. Finally, the Mexican government in 2001 announced its intention to enter into service agreements to share the risks and benefits of nonassociated gas and (later) oil, despite Congress's opposition.

What has been the nature of the changes in terms of the principle of sovereignty over natural resources? In the first place, no country has resigned ownership of oil and natural gas. In the second place, and leaving to one side Argelia and Venezuela, countries have not changed their oil legislation to grant mining deeds to the oil companies. What they have done is reinterpret the legal framework in such a way that the state companies may enter into contracts so that the international oil companies contribute capital, technology, and management capability, at the same time assuming part of the risk. As a consequence, new oil agreements have emerged that are unlike the concessions or contracts of the 1960s and 1970s (Fig. 1). Governments have tried to find politically acceptable ways of permitting the local oil industry to participate again, making a few visible institutional adjustments so as not to awake nationalist opposition, although not always successfully (as in the cases of Kuwait and Mexico).

3.6 The Opening of Economically Planned Countries

In the framework of Perestroika, a set of reforms aimed at modernizing a country internally and bringing it closer to the West as foreign policy, the Soviet Union began in 1985 by signing a series of technical assistance and technology transfer agreements, culminating in 1990 with the signing of exploration agreements with the Elf, Chevron, and Total companies. Since the fall of the Soviet Union in 1991, the 11 republics have been conceding various types of mining rights.

In the Eastern European countries, the return to a market economy and the changes in the Soviet oil industry, above all concerning the oil supply and the technical cooperation they received, arose mainly from the opening up of their territories to foreign capital. The first country to invite bids for the granting of exploration and production permits was Bulgaria in 1989. In mid-1991, all of the other countries (Lithuania, Estonia, Poland, Czechoslovakia, Hungary, Rumania, and Albania) had already signed agreements with the oil companies or were in negotiations to do so.



Other agreements: Technical assistence, transfer of technology, service contracts, joint ventures, etc.

FIGURE 1 Diversification of exploration and production agreements.

In the developing countries with planned economies, the opening up began before the fall of the Berlin Wall, such as in the cases of China (1979) and Vietnam (1986). Although the call to the Western companies is recorded in the framework of a broader economic opening, in both cases the need for capital and technology to develop offshore oilfields was observed. In the case of Cuba, the opening up was a logical consequence of the cooling off of relations with Moscow. In 1990, the Cuban authorities decided to turn to the European companies in the search for marine oilfields. Moreover, as a test of autonomy, in 1989, Mongolia created a state-owned company to negotiate association agreements with Western companies. Finally, Laos and Cambodia, which were practically unexplored, signed their first contracts in 1991.

3.7 Nationalism Weak but Not Extinct

The nationalist movements allowed the correction of a very unfavorable situation for underdeveloped countries. However, the international context changed rapidly, and the majority of countries did not have time to provide themselves with the means necessary to take economic control of their economic resources.

The following important conclusions may be drawn from the exercise of sovereignty over natural resources over the past three decades or so by developing countries:

- The management of the local oil industry, in terms of sovereignty, is a valid objective. Past experience has not demonstrated that such a thesis is erroneous.
- Although the state is the owner of the subsoil's resources, this does not guarantee economic control over hydrocarbons. The state must be able to directly execute such projects.
- The state directly manages the oil industry, but this does not automatically guarantee said economic control. Certainly, it is indispensable to have an operational sovereign instrument over hydrocarbons (i.e., to have a state-owned oil company), but that is not enough.
- The design of contracts and efficient fiscal mechanisms is a necessary but not sufficient condition to guarantee the correct exploitation of oilfields, the recovery of the greater parts of the profits, and the transfer of technology and know-how.

To achieve the economic control of natural resources required by developing countries, besides the aforementioned ownership rights, a state-owned company and an efficient taxation system are required to reach a high level of economic, social, political, and institutional development.

Also, such economic control is reached only when the product is delivered to the end user. Therefore, some countries, such as Kuwait and Iran, have allowed the state companies to invest and operate in the consuming countries in both the oil and energy sectors. This is an impossible task if the state

companies do not have sufficient room for maneuvering on the operative, administrative, financial, and strategic fronts. Paradoxically, state control over the oil business is refined with autonomy and internationalization such as in the case of Venezuela.

Nowadays, the balance of power is different from what it was during the 1970s. Total sovereignty over hydrocarbons, as it was conceived in the past, seems difficult to reach. Approximately two decades ago, steps were made in the opposite direction: transfer of assets to the private sector and downsizing or disappearance of state companies. This does not mean that nationalism is dead.

The persistence of a market dominated worldwide by purchasers, neoliberal economic policies, the conditions imposed by international financial organizations, and government pressure that supports and promotes the large oil companies are some of the factors that limit sovereignty over hydrocarbons. Military aggression only annihilates it, such as in the case of Iraq. In those cases, the existence of nationalism is ensured. It will exist insofar as the state's right to exercise permanent sovereignty over the nation's natural resources is not guaranteed or is threatened.

Glossary

Achnacarry agreement Second oligoplistic accord reached by major international oil companies at Achnacarry castle in Scotland to control downstream marketing of oil and divide it according to market shares existing in 1928.

futures market An organized market, such as the New York Mercantile Exchange, in which contracts are bought and sold to deliver a specified quantity of oil (or other commodities) at a specified future date at a price to be paid at the time of delivery. Futures contracts allow the holder to hedge risk.

Hubbert curve U.S. petroleum geologist King Hubbert predicted (correctly) in 1956 that U.S. oil production followed a bell-shaped curve and would peak in approximately 1970.

International Energy Agency Established in 1974 within the Organization for Economic Cooperation and Development to promote energy cooperation among consumer countries including oil crisis management; currently has 26 member countries.

Kyoto Protocol International agreement signed in 1997 that sets binding emissions reductions of greenhouse gases with an average 5.2% reduction below 1990 levels for industrial countries. As of 2002, the protocol had not yet entered into force. The European Union and Japan have ratified it, but the United States has declined to participate.

Organization of Petroleum Exporting Countries (OPEC) - Founded in 1960 in Baghdad; members are Algeria, Indonesia, Iran, Iraq, Kuwait, Libya, Nigeria, Qatar, Saudi Arabia, United Arab Emirates, and Venezuela.

Red Line Agreement Agreement in 1928 on oil production in most of the former Ottoman Empire by American and European major international oil companies; established structure of the Iraq Petroleum Company and was an important foundation of the international oil company cartel.

Seven Sisters A cartel of seven international oil companies that dominated the world oil market after 1928 until the rise of OPEC; five of the companies were American—Standard Oil of New Jersey (Exxon), Socony Vacuum (Mobil), Standard of California (Chevron), Texaco, and Gulf—two were European—Anglo-Iranian Oil, which became British Petroleum, and Royal Dutch/Shell.

Strategic Petroleum Reserve U.S. government oil reserve established under the Energy Policy and Conservation Act of 1975 to be used to mitigate effects of oil market disruptions; contained approximately 650 million barrels as of 2003 located in four underground salt caverns along the Texas and Louisiana Gulf Coast.

Texas Railroad Commission A state agency that in 1932 acquired authority to regulate oil production via a system of market demand prorationing within the state.

Traditionally, energy policy has sought security of supply, affordability, and limited impact on the environment. Until recently, energy security has been dominated by oil security, since oil has been the leading fuel and is subject to the influence of the OPEC cartel and the geopolitics of the world oil market. This article reviews the history of oil, how it became a strategic commodity, and the importance of oil today. It analyzes the multiple dimensions of oil security: the long-term outlook for oil supply, OPEC market power, oil and the economy and the costs of oil market disruptions, the role of oil imports and the balance of payments, oil crisis management, oil and environmental security, and the link between oil, foreign policy, and geopolitics. The article concludes by considering other energy security concerns: shortages and price volatility in electricity and natural gas, and potential threats to energy facilities by terroist attacks.

1. INTRODUCTION

Energy policy is a subset of economic policy, foreign policy, and national and international security policy. Traditionally, energy policy has sought security of supply, affordability, and limited impact on the environment. According to the Bush administration's "National Energy Policy," energy should be "reliable, affordable, and environmentally sound." Until recently, energy policy was dominated by oil policy since oil has been the leading fuel in the United States and most industrial economies, and it has been subject to price volatility and the vagaries of the world oil market that is greatly influenced by the Organization of Petroleum Exporting Countries (OPEC) cartel. Most of this article therefore reviews the elements of oil security. It begins with a brief historical review of the oil market and how oil developed as a strategic commodity with an eye to its military uses. After World War II the focus shifted to its rapidly expanding role in the civilian economy and how to deal with oil supply interruptions and their macroeconomic effects as well as possible resource constraints.

Other types of energy security concerns have surfaced, including shortages and the effects on consumers of high electricity and natural gas prices as a result of problems with deregulation. In the future, there could be potential threats to energy facilities by terrorists in the wake of the September 11, 2001, attacks. These aspects are discussed toward the end of the article.

2. OIL: BACKGROUND

2.1 History

Early concerns about oil and security date back to World War I. In 1913, Winston Churchill, then First Lord of the Admiralty, decided to convert the British Navy from using coal to bunker oil, which was a cleaner and more efficient fuel. To ensure adequate oil supply, the British government took a majority share in the Anglo-Persian Oil Company (later renamed British Petroleum). This was one of the first major government interventions in the oil industry. Other navies soon followed the British example. The appearance of tanks and other motorized military vehicles highlighted oil's important new role as a strategic commodity. During World War I, allied nations established government controls over oil supply. Just after the war, the U.S. government established three Naval Petroleum Reserves.

Following World War I, as oil became more important in the civilian economy in transportation and industry, the U.S. Geological Survey predicted that the United States was about to run out of oil because of insufficient domestic reserves. The U.S. government in turn supported the efforts of American oil companies to gain access to concessions in the Middle East. In 1928, the Red Line and Achnacarry agreements provided mechanisms for coordination of supply and markets by a secret cartel of seven American and European international oil companies (the seven sisters), which dominated the international oil market until well after World War II. Following the discovery in 1930 of large oil fields in east Texas, which produced an oil surplus, state regulation of production began in 1933 under the mantra of conservation by the Texas Railroad Commission to help stabilize oil prices and the health of the domestic industry. (The Texas Commission later provided a model for OPEC.)

World War II demonstrated the growing importance of oil in modern warfare to fuel fighting ships, freighters, submarines, tanks, troop transports, and airplanes. Access to oil was a major reason behind Germany's invasion of the Soviet Union and Eastern Europe and Japan's advances on the Dutch East Indies and Southeast Asia, including the Japanese attack at Pearl Harbor. (The United States had placed a de facto oil embargo on Japan. U.S. naval forces could have interfered with Japanese efforts to secure oil supplies in Southeast Asia.) Meanwhile, the future importance of the Middle East, where major new oil fields had been discovered in the 1930s, was clearly recognized. In 1943, President Roosevelt announced that the defense of Saudi Arabia was vital to the United States and extended Lend-Lease aid. After the war, the U.S. government supported the efforts of four American oil companies (Exxon, Mobil, Texaco, and Chevron) to form a consortium to develop Saudi oil, the Arabian–American Oil Company (Aramco).

The first postwar oil crisis occurred in 1951 in Iran when a nationalist leader, Mohammed Mossadegh, seized power and decided to nationalize the Anglo-Iranian Oil Company (BP). Because of the strategic importance of Iran, the CIA helped to stage a countercoup that ousted Mossadegh 2 years later and restored the Shah. At the same time, the U.S. government took the lead in organizing a new Iranian oil consortium, which for the first time included participation by American oil companies.

During the Suez crisis in 1956 (the second postwar oil crisis), when Egypt's President Nasser nationalized the Suez Canal and Israel invaded the Sinai and began moving toward the Canal, Britain and France intervened and sent troops. Concerned about escalation of the crisis and Soviet involvement, the United States offered to provide oil to its European allies if they would agree to a cease-fire and withdraw, which they did. Excess U.S. oil production capacity enabled this diplomatic action. By the early 1970s, this excess capacity had disappeared.

After the postwar recovery, a boom period of U.S. and global economic growth stimulated increasing demand for crude oil and petroleum products. In the United States, this was driven by a rapid expansion of highway transportation and growing environmental concerns over coal-fired power plants. However, new oil supplies were also becoming available, especially from the Middle East. OPEC was founded in 1960 to put pressure on the international major oil companies not to reduce prices further in a period of increased competition in the oil market from independents and more than adequate supply. However, by the early 1970s, demand increases and rising U.S., European, and Japanese imports led to a much tighter market. This set the stage for stronger OPEC actions in the oil crises of the 1970s.

In October 1973, when the United States supported Israel in the Yom Kippur war, Arab nations responded with an oil embargo and production cutbacks. OPEC quadrupled oil prices, raising concerns about the security of oil supply to the Organization for Economic Cooperation and Development (OECD) nations and the long-term adequacy of oil resources. In response, the United States created a Strategic Petroleum Reserve (SPR) and took the lead in establishing the International Energy Agency (IEA) associated with the OECD. The principal purpose of the IEA was to establish an emergency oil-sharing system among member countries to assist in managing future supply interruptions.

The Iranian revolution caused an oil supply shortfall in 1979 and produced another oil crisis as oil prices doubled, led by the spot market and adopted by OPEC. The outbreak of the Iran–Iraq war in 1980 exerted further upward pressure on oil prices, which reached a high of $34/barrel for the Saudi benchmark crude in 1981. This action turned out to have negative consequences for OPEC because the high oil prices in the first half of the 1980s encouraged fuel switching, the development of more efficient technologies, and a strong increase in non-OPEC oil production, which, along with decreasing demand due to recession, reduced OPEC's market share from more than 30 million barrels/day (mbd) in the 1970s to as low as 16 mbd by the mid-1980s. Following Saudi Arabia's decision in 1985 to abandon its role as "swing producer," oil prices collapsed in 1986 to less than $10/barrel, although prices returned to the $15–20 range the next year after OPEC regrouped and reinstated production quotas.

By the time of the outbreak of the Persian Gulf War in 1990, the world oil market had become more competitive. Players included national oil companies, international majors, and larger numbers of independent oil companies. Oil was now traded like other commodities in forward and futures markets, providing a mechanism to hedge price risk. Market transparency was also stronger because of the expanding application of information technologies, which enabled faster adjustment to market trends. Also, several governments, led by the United States, had built up strategic oil stocks for use in emergencies.

The Persian Gulf crisis (1990–1991) demonstrated the traditional aspects of oil diplomacy and military force along with market-based mechanisms. After Iraq invaded Kuwait in October 1990, the United Nations (UN; urged by the United States) placed an embargo on oil shipments from Iraq, removing more than 4 mbd of crude from the world market. A U.S.-led UN expeditionary force was deployed to Saudi Arabia during the fall to protect Saudi Arabia and to prepare for military action to push Iraq out of Kuwait. Although some of the oil shortfall was made up by increased production from Saudi Arabia and other producers, oil prices escalated to nearly $40/barrel in part because of uncertainty regarding what would happen next. Although other motives may have played a role in the U.S. action, clearly the threat posed by Saddam Hussein to the security of the world oil market, and to the world economy, was a paramount concern. When air strikes against Iraq commenced in January 1991, the United States, Germany, and Japan initiated a drawdown of strategic oil stocks that was coordinated by the IEA. As a consequence of both actions, oil prices declined to normal levels closer to $20/barrel. During this oil crisis many buyers and sellers hedged oil transactions on the futures market.

At the end of the 1990s, another oil price collapse and then a price shock took place, which were much more the result of market forces. After a misjudgment of the oil market by OPEC at the end of 1997 when it expanded production as Asia was going into recession, oil prices plunged in 1998 and early 1999 to approximately $10 barrel, causing serious damage

to the economies of oil-producing countries. OPEC rallied, and acting with greater cohesion beginning in March 1999, it lowered production, causing prices to rebound and then increase to more than $30/barrel in 2000. In 2001, OPEC struggled to manage falling prices set off by a global recession made worse by the attacks of September 11, 2001, and the war on terrorism.

2.2 Importance of Oil Today

Although the importance of oil in the world economy has diminished somewhat since the 1970s, oil remains the largest source of primary energy in industrial countries at 40% (compared to 55% in 1980). The oil intensity [i.e., the amount of oil required to produce a unit of gross domestic product (GDP)] of industrial economies has fallen considerably due to fuel switching, structural change, and advances in energy efficiency. In 2000, oil imports represented only 4% of the total value of OECD imports, compared to 13% in 1981. However, oil is still very important, accounting for two-thirds of international energy trade. Oil reserves are less abundant than those of coal and natural gas and less evenly distributed. Most oil reserves are located in developing countries, which makes the oil market more amenable to cartel control than other commodity markets, hence the influence of OPEC.

For the United States, oil accounts for 39% of primary energy consumption, which in 2000 amounted to 19.5 mbd of petroleum products (Fig. 1). Of this amount, approximately 10 mbd was derived from crude oil and product net imports. Most oil (approximately 13 mbd) is consumed in the transportation sector. The United States accounts for approximately 25% of the world's oil consumption. The U.S. oil demand is expected to grow approximately 1.5% annually until 2020, led by growth in the transport sector. Net imports, which amounted to 53% of crude and product needs in 2000, are projected to increase to 62% in 2020. Imports come from a variety of countries, both OPEC and non-OPEC (Fig. 2). The U.S. domestic oil production was approximately 9.5 mbd in 2000. The U.S. onshore production is scheduled to decline, but production in the Gulf of Mexico is expected to increase, which will probably lead to stable or slightly expanded production in the next few years.

In peacetime, the U.S. military uses less than 5% of national consumption of crude oil and petroleum products. In case of military conflict, this requirement would increase. However, the military requirement represents a relatively small percentage of domestic oil consumption, and it is dwarfed by the needs of the civilian economy. Most of the incremental military demand in wartime would likely come from overseas in one or more war zones, and most of the needed supplies would be purchased abroad. In case of a large-scale conflict involving the domestic homeland, the military has mechanisms in place to procure oil and other fuels for defense needs. This would involve invoking the Defense Production Act and the Energy and Security Act. The Department of Defense maintains petroleum stocks in the United States and abroad.

3. DIMENSIONS OF OIL SECURITY

3.1 Long-Term Outlook for Oil Supply

The oil shocks of the 1970s and their associated uncertainties led to major questioning about future oil resource scarcity, as highlighted by the publication

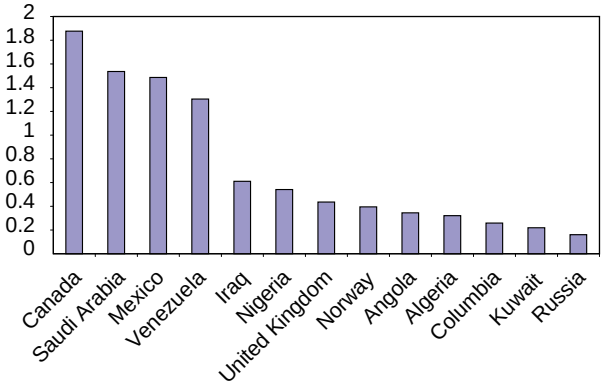

FIGURE 2 U.S. oil imports, source countries (million barrels/day, first 6 months of 2002). From *Monthly Energy Review*, Department of Energy, Washington, DC.

of the Club of Rome study, "The Limits to Growth." After the oil price collapse of 1986, this view was less prevalent. However, at the end of the 1990s debate had begun on the future of oil supplies, spurred by articles in prominent journals by geologists Colin Campbell and Jean Laherrere, who argued on the basis of applying the Hubbert curve to the world that conventional oil production would peak in the first decade after 2000 and set the stage for a coming oil crisis. (King Hubbert was a famous U.S. geologist who correctly predicted that U.S. oil production would peak in approximately 1970.) Their argument was based on the proposition that all large oil fields have already been found and that world reserve data are inaccurate, especially in the Middle East, where several OPEC member countries suddenly and mysteriously increased their reserve figures in the late 1980s. According to these pessimists, world recoverable oil reserves at the end of 1998 were estimated at 1800 billion barrels, and world production could peak by 2010 if not sooner. A similar perspective is presented by geologist Kenneth S. Deffeyes in his book, "Hubbert's Peak: The Impending World Oil Shortage."

Among the leading opponents of this view are economists M. A. Adelman and his associate Michael Lynch, who pointed out serious limitations of the Hubbert curve and emphasized the role of investment and new technology in expanding reserves. Oil reserves are better viewed as inventory, which is replenished by investment. Depletion is constantly delayed by new knowledge and advances in production technology. Oil supply forecasts have tended to be dominated by a pessimistic bias.

In 2000, the authoritative U.S. Geological Survey (USGS) published its latest estimates of world oil and gas reserves outside the United States that have the potential to be added during the period 1995–2025. The estimated volumes of undiscovered conventional oil are 20% greater than the 1994 estimate. The potential addition to reserves from reserve growth (e.g., due to applications of new technology) is also very large. When the new mean global estimates are combined with previous estimates for the United States, the USGS contends that worldwide ultimately recoverable reserves (URRs) of conventional oil total 3.021 trillion barrels, and natural gas liquids (frequently added to oil estimates) total an additional 324 billion barrels. URRs include cumulative production to date, identified remaining reserves, undiscovered recoverable resources, and estimates of "reserve growth" in existing fields. The 1994 USGS estimate listed URRs of conventional oil at approximately 2.3 trillion barrels.

The new USGS estimates have been adopted by two organizations that regularly publish widely respected energy market forecasts. Both the IEA in its 2001 "World Energy Outlook" and the U.S. Energy Information Administration (EIA) in its "International Energy Outlook 2002" take an optimistic view of future world oil supply and conclude that proven oil reserves are adequate to meet demand until 2020, with a world production peak to occur sometime thereafter. In addition, the world has very large reserves of unconventional oil, including Venezuelan heavy oil and Canadian tar sands, which will become economic to produce at higher oil prices. In short, the world appears to have sufficient oil reserves for the foreseeable future.

An important factor in the increased estimates for oil reserves, especially for oil reserve growth, is the recent advances in oil production technology, which have improved success rates and lowered costs of finding oil and production. These advances include three- and four-dimesional seismic for locating and evaluating underground deposits; directional drilling; floating production systems; deep-water platforms; and the general widespread application of computers and information systems by oil companies and service contractors to improve analysis, management, and communications. Direct production costs for the international oil companies are estimated to average $3–6/barrel worldwide.

3.2 OPEC Market Power

The world's conventional oil reserves are concentrated in a relatively few countries. Most of these countries are members of OPEC, established in 1960, which controls approximately two-thirds of global oil reserves and in 2002 slightly less than 40% of world oil production. OPEC has a formal organization, meets approximately four times per year, and attempts to act as a cartel to manage world oil supply and prices. Since 1982, it has set production quotas for its members. As an organization of 11 countries, not firms, OPEC has not always been successful at maintaining cohesion. Members have political as well as economic objectives and are known to cheat on their quotas. However, since the 1970s OPEC has been successful most of the time in using its market power generally to maintain the price of oil well above the costs of production (which are less than $2/barrel in the Persian Gulf or approximately $4/barrel including finding and development costs.)

It has also been successful at either causing or capitalizing on oil market disruptions to obtain very high prices. Basic to its success in this regard is the fact that oil demand and, to some extent, supply are inelastic and do not respond quickly to changes in price. There are few readily available substitutes for oil, especially in the transportation sector.

OPEC, however, has made mistakes. As previously noted, after locking in very high prices in 1981, which caused a recession and a precipitous decline in oil demand, along with an increase in non-OPEC production, OPEC lost market share and prices collapsed in 1986. However, OPEC regrouped and benefited from an oil price spike at the time of the Persian Gulf War in 1990, and Saudi Arabia increased its production following the UN embargo against Iraq. During the early and mid-1990s in a more competitive oil market, prices were more volatile and ranged from approximately $18 to $20/barrel. Following a bad decision by OPEC to increase production at the end of 1997, oil prices collapsed in 1998 and early 1999. However, OPEC—led by Saudi Arabia, the largest producer—reasserted cohesion in its March 1999 decision and succeeded in obtaining support from non-OPEC states Norway and Mexico, which resulted in lower production and a price recovery in 1999 and 2000—initially to more than $30/barrel before settling back into the mid-$20 range. Thus, OPEC has shown that it still has market power and is able to use it, even if it is not a perfect cartel. It has never been able to agree on an enforcement mechanism for its decisions. In economic parlance, OPEC is an imperfect monopolistic cartel of the von Stackelberg type. OPEC has a large enough market share to influence prices, but its influence is limited by the existence of other competitive suppliers.

Looking to the future, OPEC's market share is expected to grow, which will give it even more leverage on the world oil market. Both the EIA and the IEA predict that OPEC production will increase from 30 mbd in 2000 to approximately 60 mbd in 2020 to meet growing oil demand, which would represent a market share of more than 50%. Non-OPEC production is also projected to grow but less rapidly.

3.3 Oil and the Economy and the Cost of Oil Market Disruptions

Research has shown that sudden increases in oil prices are linked to inflation, increased unemployment, and higher interest rates. Eight of 10 post-World War II recessions in the United States (including several recent ones) were preceded by oil price shocks (Fig. 3). A study by the Stanford Modeling Forum concluded that the first oil shock of 1973–1974 reduced U.S. GNP in 1975 by 3–5.5%, and the second shock in 1979–1980 reduced U.S. GNP in 1981 by 2–4%. An OECD study reported the real income losses to all OECD countries due to the second oil shock at approximately 5% in 1980 and 8% in 1981. However, there is asymmetry in the oil–economy relationship. Whereas rising oil prices tend to retard economic growth, declining oil prices or an oil price collapse (such as occurred in 1986 and again in 1998) do not necessarily stimulate growth, apparently because there are more economic adjustment costs and coordination problems associated with rising prices.

David Greene, Donald Jones, and Paul Leiby of the Oak Ridge National Laboratory analyzed the macroeconomic impact of oil price increases on the U.S. economy. They contend that there are three types of economic losses:

Loss of potential GDP: When the price of oil is increased by monopoly power, oil becomes more scarce. The economy is able to produce less output with the same resources of capital, labor, materials, and land.

Macroeconomic adjustment costs: When prices increase rapidly, there are additional transitional costs because wages and prices are not able to adjust rapidly enough to the higher oil prices to permit the economy to operate at full employment. There is also the possibility of adjustment required by changes in monetary policy.

Wealth transfers from U.S. oil consumers to foreign oil exporters: These transfers are equal to the quantity of U.S. oil imports multiplied by the difference between the monopoly price and the competitive price of oil. These transfers go to OPEC and non-OPEC producers and are a cost to the U.S. economy.

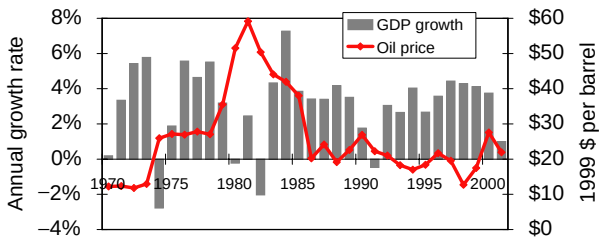

FIGURE 3 Oil price and economic growth, 1970–2001. From Greene and Tishchishyna (2000) and data updates, 2001.

In the most recent update of this analysis, David Greene and Nataliya Tishchishyna estimate the costs to the U.S. economy of oil dependence and oil monopoly power over 30 years at approximately $7 trillion 1998 dollars, which as they point out is approximately equal to the payments on the national debt during the same period. (This estimate is controversial since it assumes a competitive oil price of approximately $10/barrel. There are a range of views regarding what oil prices would be absent the OPEC cartel.) Whether or not this figure is correct, the costs of oil price shocks to the economy have clearly been substantial.

Greene and Tishchishyna define oil dependence as the product of a noncompetitive world oil market dominated by OPEC; high levels of U.S. oil imports; the importance of oil to the U.S. economy, where it is critical in the transportation sector; and the absence of readily available or affordable substitutes. The transportation sector is key because on-road vehicles account for two-thirds of U.S. oil consumption and there are no substitutes immediately available. In their view, the cost of oil dependence to the United States is a market failure because of the cartelization of the world oil market.

The United States can take some actions to reduce the costs of this dependence, including developing advanced technologies to increase efficiency in the transport sector, pursuing alternative energy technologies, and improving the technology of oil exploration and recovery to increase oil supply. Furthermore, the United States can diversify its sources of oil to more non-OPEC countries, a trend that is already under way.

It should be noted that the economic significance of oil consumption in the U.S. economy is much less today that it was in the past. In 1999–2000, the oil cost share of GDP was 1.4–2.0% of GDP. This compares with a 4–6% share in the early 1980s. Changing economic structure and improvements in efficiency of oil use have both contributed to this development. As discussed by Brown and Yûcel, the relationship between oil prices and economic activity also weakened by the end of the 1990s.

3.4 Role of Oil Imports and the Balance of Payments

In the media and political debates, oil security is frequently equated with the level of U.S. oil imports, which has been rising. (Net U.S. oil imports were 55% of oil consumption in 2001.) The transfer of wealth to pay for oil imports is a factor, as noted previously. However, equally if not more important is the level of overall oil consumption, which is related to the oil intensity of the U.S. economy.

In recent oil market disruptions, the increase in oil prices has been the most important factor. Any supply shortfalls have not lasted more than a few months. Since crude oil is traded on a world market, the amount of oil a country imports has little effect on the price of oil in the short term since that price is set on a world market. The vulnerability of the United States and other countries to oil shocks depends more on the level of oil consumption and the price of oil.

Arguments are often made that rising U.S. oil imports are harming the U.S. economy, and therefore national security, because of their contribution to the trade deficit. Although U.S. oil imports are increasing, they have amounted in recent years to 8–10% of the value of total U.S. merchandise imports. This is certainly acceptable for a complex economy the size of that of the United States. By comparison, several European countries and Japan import more oil (more than 90% of their oil needs) than does the United States, and this has not harmed their economies. (The situation can be different for a developing country with a simpler economy and reduced ability to pay for a large amount of oil imports.) The changing role of oil imports in the trade deficit is more a function of changes in the imports and exports of other commodities than it is in the role of oil imports. In short, the United States will need to get used to increasing levels of oil imports. Reducing import dependence would be very costly in the short to medium term. However, as noted previously and later, there are reasons to consider ways to reduce oil consumption overall in the future.

3.5 Oil Crisis Management

An international framework for oil crisis management is provided by the IEA, established in 1974 and located in Paris, where it is associated with the OECD. The 26 member countries are obligated to hold oil stocks equivalent to 90 days of imports. The heart of the agency is the formal oil-sharing mechanism, which is intended to mitigate future supply disruptions. The system is triggered by either a 7% or a 12% or greater supply shortfall in the daily rate of oil supplies to one or more member countries, whereupon a request can be directed to the secretariat that the oil-sharing mechanism be triggered. The 7% case would normally be dealt with by demand restraint/conservation measures, but the 12% plus case is more serious and might require

sharing of oil supplies. In any case, the governing board would need to be convened to decide on the appropriate response by a weighted majority vote. The system has never been triggered, although a request was considered in 1979.

With growing awareness that small market disruptions can yield sharp oil price spikes, IEA countries agreed in 1984 to a less formal system of international consultations aimed at release of government-controlled emergency stocks known as Coordinated Emergency Response Measures by member countries that possess such stocks (mainly the United States, Germany, and Japan, although other countries are considering the idea). This framework was first used in January 1991 for a coordinated stock release at the beginning of military action in the Persian Gulf War. In 1995, the governing board reached agreement that coordinated stock draw should be given priority in response to market disruptions regardless of size and before activation of the formal allocation mechanism.

The other purposes of the IEA are to promote the development of alternative energy sources and energy efficiency, to gather data and conduct studies on the world oil market and other energy markets, to encourage cooperation with nonmembers, and to assist in the integration of energy and environmental policies.

The European Union (EU) also has a requirement that member countries hold stocks of petroleum products covering at least 90 days of average daily consumption for the previous calendar year. Unlike the IEA, the EU lacks the necessary power to manage the stocks in a crisis. Member states own and control their own stocks. They are obliged to consult each other before releasing stocks from the strategic reserve. The EU is considering adding to its strategic oil reserves and managing them on a more centralized basis.

Stocks in IEA net importing countries have been declining during the past 15 years or so at the same time that OECD oil import dependence has been increasing. Meanwhile, the world oil market is growing, and much of the new oil demand will come from developing countries in Asia, which do not possess strategic oil stocks. Global oil security would be increased if Asian countries established minimum emergency stock requirements, as has been recommended by the Asia Pacific Energy Research Center.

The U.S. SPR was established in 1975 to help protect the nation against future oil market disruptions. Managed by the Department of Energy (DOE), the SPR oil was mainly acquired during the 1980s and is stored in underground salt domes along the coast of the Gulf of Mexico. At the end of 2003, the SPR contained 650 million barrels of oil. President George W. Bush has instructed the secretary of energy to proceed with further filling of the reserve up to its 700 million barrel capacity using principally royalty oil from federal offshore leases.

The president determines whether there is a severe supply interruption that warrants use of the SPR. If so, the secretary of energy announces an auction sale of a certain amount of oil at a price determined by the market. Bidders (oil companies) send their offers to the DOE and, after selection, submit a letter of credit or a cash deposit. The oil is then delivered through a pipeline or a marine terminal. The whole process can take 3 or 4 weeks to complete. The amount of import coverage afforded by the SPR depends on the level and rate of increase in imports. With U.S. net imports of approximately 11 mbd at the end of 2003, the current SPR offers approximately 53 days of import coverage if all imports were cut off, which is a very unlikely case given that U.S. oil imports come from a diversified group of nations.

There has been controversy about how and when to use the SPR. In the first Bush administration, the president refused to order an SPR drawdown despite a sharp escalation in oil prices in the fall of 1990 after Iraq invaded Kuwait (although the DOE did proceed with a SPR test run.) However, in January 1991, a drawdown of 33.75 million barrels of oil was authorized at the beginning of Desert Storm in coordination with stock draw by other allies under the IEA (later reduced to 17.3 million barrels of oil actually sold). That release, coupled with the success of the air war, helped to reduce oil prices and restore stability to the market. In September 2000, President Clinton authorized release of oil to bolster supplies at a time of high oil prices and low inventories of heating oil in New England before the start of winter. This was actually an oil swap, not a sale, because companies accepted obligations to take oil and return slightly more 1 year later. During the 2000 election campaign, candidate G. W. Bush criticized this action and argued for retaining the SPR for truly emergency uses.

In Germany, the government works closely with industry to administer a government-owned reserve, the Erdölbevorratungsverband, which stocks both crude oil and products to meet the 90-day IEA import requirement. Most other European countries rely on mandates to industry to hold private emergency stocks. In Japan, the Ministry of International Trade and Industry supervises government and private stocks.

3.6 Oil, Transportation, and Environmental Security

In the United States, transportation accounts for 27% of overall energy consumption and 68% of petroleum use. The petroleum share of transport energy in 1999 was 96%. Most transportation energy use (76%) comes from highway vehicles—light vehicles and trucks—with the rest coming from aircraft, boats and ships, pipelines, rail, and off-highway construction and farm vehicles. For European countries, transportation is also the most important and fastest growing sector for oil use, whereas the situation in Asia is more diversified, with more oil being used in industry and power generation. Oil use in transportation contributes importantly to air pollution and to greenhouse gases that are responsible for global climate change.

Transportation in the United States is a source of every major pollutant except sulfur dioxide. Of the criteria pollutants listed in the U.S. Environmental Protection Agency's (EPA) National Ambient Air Quality Standards, the oil/transport contribution (1999) is as follows: carbon monoxide, 77%; nitrogen oxides (NO_x), 55.4%; volatile organic compounds (VOCs), 47%; and very small amounts of particulate matter (PM-10) and sulfur dioxide. (Carbon dioxide is not yet regulated.) Although much progress has been made in reducing emissions from vehicles, and lead has been essentially phased out of gasoline, challenges remain. The most important air pollution challenge is low-level ozone, which is formed in the atmosphere by complex photochemical reactions involving VOCs and nitrogen oxides in the presence of sunlight. Exposure to high levels of ozone can cause coughing, eye irritation, sore throat, headache, and chest pain, especially for children and old people who have asthma conditions. Efforts to limit criteria pollutants by the EPA have been made under the Clean Air Act, originally passed in 1970 and amended several times.

There are still many U.S. cities that do not meet minimal standards for ozone, of which the precursors come from vehicle tailpipe emissions and evaporative emissions. The major problem seems to be NO_x emissions, which are increasing. (NO_x emissions also come from electric power plants.) Another problem is that although engines are much cleaner today, vehicle miles traveled continually increases as more cars are purchased. More efficient engines also tend to produce more NO_x. A third problem is that sport utility vehicles are being purchased in increasing numbers, and they have not been regulated as stringently as light-duty vehicles. They are less efficient and produce more emissions.

The Clean Air Act Amendments of 1990 provided for tier 1 standards on emissions from mobile sources covering nitrogen oxides in addition to carbon monoxide, hydrocarbons, and particulate matter for light-duty vehicles beginning with model year 1994. More stringent tier 2 standards will apply to all passenger vehicles starting in 2004, including a reduction in the sulfur content of gasoline in order to ensure the effectiveness of emission control technologies. Standards will also be tightened for heavy-duty vehicles (trucks) beginning in 2004, including a tighter combined NO_x and VOC standard. This will be followed in 2007 by new "ultra-low" sulfur content requirements for diesel trucks and specific NO_x emissions control technologies. Europe is not far behind the United States in strengthening its emissions requirements for mobile sources.

Oil use is also a major contributor to greenhouse gas emissions. According to the EIA, CO_2 emissions (the leading greenhouse gas) from industrialized countries accounted for 51% of the global total in 1999, followed by developing countries at 35% and transition economies in Eastern Europe/FSU at 13%. In the industrialized world, oil use contributed almost half (49%) of carbon dioxide emissions. The transportation sector is an important contributor. In the United States, transport contributed 33% of carbon dioxide emissions in 1999.

The Bush administration rejected participation in the Kyoto Protocol in March of 2001 and put forward an alternative voluntary plan to reduce the carbon intensity of the U.S. economy in spring 2002. However, it has not offered to regulate carbon dioxide emissions, which were absent from the administration's "Clear Skies Proposal" to strengthen limits on three other pollutants. In what may be a harbinger of the future, the state of California legislature passed a bill in July 2002, subsequently signed by the governor, calling for a plan by 2005 to reduce greenhouse gas emissions from cars and light trucks. Methods of achieving reductions are not specified but presumably might include fuel efficiency, hybrid engines, fuel cells, or other technologies. Cars and light trucks emit approximately 40% of greenhouse gas emissions in California. As has happened in the past, once again the state of California may be blazing a new trail in environmental regulations.

Currently, the future of the Kyoto Protocol is uncertain; it has been ratified by the EU and Japan but needs to be approved by the Russian parliament

before it can come into force. Several European countries have already been experimenting with carbon taxes.

3.7 Oil and Geopolitics, Foreign Policy, and International Security

Oil has implications for foreign policy, international security, and geopolitics. However, the implications are more international than national, except for the United States, for which the two are intertwined. The fact that two-thirds of the world's oil reserves are located in the Persian Gulf states makes them targets for aggression. The end of the Cold War and the disintegration of the Soviet Union removed the Soviet threat to the region. However, the Gulf remains an unstable place, subject to revolutions and regional wars, as the Gulf War of 1990–1991 demonstrated when Iraq attacked and annexed Kuwait and threatened Saudi Arabia. In that war, a UN military force was assembled, led by the United States, to protect Saudi Arabia and force Iraq to relinquish Kuwait. Although there were probably several reasons for the U.S. action, surely the protection of access to Gulf oil supplies was a major reason. It appears that the United States, as the world's remaining superpower, is the only country that can play this role.

A U.S. security role will continue to be needed in the Gulf, where there is no regional balance of power. That role is strengthened but has also become more complicated following the U.S. invasion and occupation of Iraq in 2003. Any threat to Gulf oil supplies would pose a threat to the world economy if supplies were cut off and oil prices escalated. The United States will oppose any serious threat to the world economy because it is increasingly interconnected with that economy, whatever the level of Persian Gulf imports into the United States (which is much lower today). Europe and Japan are much more dependent on imports of Gulf oil than is the United States.

As noted in "Energy Security," the DOE's 1987 report to the president, "Increased dependence on insecure oil supplies reduces flexibility in the conduct of U.S. foreign policy." A key example of this is U.S. relations with Saudi Arabia, for a long time considered a key ally in the Middle East presumably because of its leading role as an oil producer. However, Saudi Arabia is an autocratic regime, not a democracy, with weaknesses in the area of human rights and treatment of women, and it is the country that produced many of the terrorists who participated in the September 2001 attacks on the World Trade Center and the Pentagon. However, the "oil factor" reduces U.S. leverage and freedom of action vis-à-vis that country.

The globalization of the world oil market is widening the context of international oil security in the future. For example, the rapidly growing economies of Asia will import increasing amounts of oil from the Middle East in the years ahead. Oil tankers en route to Asia must pass through the narrow Strait of Malacca near Singapore. If the strait were closed by terrorists or military action, tankers would be required to add considerable distance and expense to deliver their oil, which would immediately raise freight rates worldwide. Will the United States sometime be asked to police this vital Strait?

Central Asia, as another example, is a region of increased interest for future oil production, assuming pipeline routes can be constructed to ship the oil to Western markets. However, the new republics around the Caspian Sea are not democracies and could become unstable during future transfers of power or revolutions or ethnic strife. A security framework for the region has yet to be devised.

Oil interacts with foreign policy in other ways. The United States maintains trade sanctions on many countries throughout the world, including Iraq (subject to UN sanctions after the Gulf War), Iran, and Libya. These three countries are major oil producers but they are off limits to U.S. companies for major oil development projects. Leaving Iraq aside as a special case, there is some question whether these sanctions are working effectively if they are not multilateral and accepted by other countries.

3.8 Strategies to Reduce Oil Dependence

The best long-term strategy to reduce the costs and risks of oil dependence lies in research and development of affordable alternatives to petroleum, especially in the transportation sector, in which there is a need for new technologies and fuels. Early efforts focused on developing vehicles that use compressed natural gas or liquefied petroleum gas or on alcohol fuel additives, such as ethanol or methanol, that can be blended with conventional gasoline. Electric vehicles have been tried, but they have been limited by the distances they can operate before batteries need to be recharged—and a breakthrough in battery technology has so far been illusive. Hybrid vehicles, which combine a small conventional internal combustion engine with an electric motor and offer increased efficiency and lower emissions, appear to be the best candidates for a transition period. Ultimately, fuel cell vehicles, which produce no

emissions except water and can run at high efficiency, are the best hope, although they would require a new infrastructure to provide hydrogen or a way to create it on board the vehicle. Fuel cells are still very expensive, but the second Bush administration has invested in a new government–industry partnership to promote their development.

It is unclear how much time this will take, but by 2010–2015 fuel cell vehicles could be available on the market, and by 2020 they could be expanding their market share. Such a development could have a major impact on reducing future world oil demand, although the transition to a new transportation technology will take a considerable amount of time.

4. RELIABLE ELECTRICITY SUPPLY AND PRICE VOLATILITY

Because electricity cannot be stored, security of supply is critical. Previously, this was ensured by monopoly utilities under government regulation. With the beginning of liberalized markets, there are new questions. Liberalization shortens contracts and threatens adequate investment. The California electricity crisis of 2000–2001 brought the problem sharply into focus.

The California crisis occurred 2 years after the state reformed its power market. In June 2000, in a period of exceptionally hot weather and in which there were some problems with grid operation, there were rolling blackouts in the San Francisco Bay area. Later in the summer, electricity prices tripled in the southern part of the state, and San Diego Gas and Electric asked the Federal Energy Regulatory Commission for price controls in wholesale markets. High wholesale prices led to questions about market power. The governor signed legislation placing rate caps on residential and small commercial users in southern California. In December, the price of electricity spiked to 30 ¢/Kwh. Pacific Gas and Electric (PG&E) and Southern California Edison, facing high pool prices and unable to raise retail prices, later defaulted on $12 billion of debt. PG&E eventually declared bankruptcy.

In early 2001, California experienced a series of short-duration rolling blackouts. Meanwhile, Governor Davis signed an emergency order authorizing California's Department of Water Resources to become a temporary buyer of power, allowing it to float revenue bonds to finance power purchases under long-term contracts. The state's experiment with deregulation and a power pool had apparently failed.

The details of what happened in California are still being investigated. There was a combination of bad planning and bad luck. A 3-year drought in the Northwest had reduced hydroelectric capacity normally available for import into California. Natural gas prices spiked during the same period because of insufficient pipeline capacity at the border and within the state. There was physical congestion in north–south transmission. When pool prices escalated, market power among wholesale producers (many of them out of state) became a problem. However, one of the most significant facts was long-term underinvestment in electric power plants in a state in which population, and therefore electric demand, was increasing. This was not an optimal condition on which to proceed with full-scale liberalization of the electric market.

As highlighted by a recent IEA study, "Security of Supply in Electricity Markets," during the past 20 or 30 years the electric systems of most OECD countries have generally maintained adequate reserve margins, even to the point of overinvestment, which ensured security of supply but at additional costs to consumers. In a liberalized market in which market players bear the costs and risks, the incentives to overinvest are removed. At the same time, there may be market imperfections that hinder the ability to achieve reliable supply, including limited demand-side response to market conditions, price distortions, policy barriers for certain technologies or the use of certain fuels, or cumbersome licensing procedures for new power plants.

The United States is midway in the complex process of restructuring the electric industry, previously regulated at both federal and state levels. Some states are further along in the process and have done better than California at making competition work (e.g., Pennsylvania and New York). Other states are holding back. The Federal Energy Regulatory Commission, which has played an important role in the process, is pressing utilities and states to form regional transmission organizations and has issued an important new proposed rule on standard market design. Meanwhile, Congress is considering new energy legislation, which may provide more guidance at the federal level.

In Europe, the United Kingdom and the Nordic countries have led the movement toward liberalized markets. Also, the EU has begun a process with its 1997 electricity directive to move the EU countries collectively toward more competition in the electric industry.

The issue of security of the U.S. electric supply was highlighted more broadly by a major power blackout on August 14, 2003, whcih lasted up to 2 days and affected some 50 million people in the Midwest and Northeast as well as in Ontario, Canada. The blackout reportedly began with downed power lines at a utility in Ohio. A U.S.–Canada Task Force is investigating the causes. The incident may lead to a stronger government role in enforcing reliability standards in the electric industry and in modernizing an aging power grid.

5. NATURAL GAS AND PRICE VOLATILITY

Natural gas is the fastest growing energy source worldwide, and its share of total energy consumption, according to the EIA, is projected to increase from 23% in 1999 to 28% in 2020. For the United States, the gas share is predicted to increase from 23.6% in 2000 to 26.5% in 2020. Gas is the cleanest of the fossil fuels, and it is the preferred choice for new electric power plants driven by gas turbines. Coal is likely to remain the lead fuel for power generation, but natural gas will expand its share considerably.

Gas is more difficult to transport than oil and requires pipelines or special liquefied natural gas (LNG) tankers. For this reason, natural gas tends to be traded in regional markets (e.g., North America, Europe, and Asia). However, although the amount of gas traded internationally (20%) is much less than the amount of oil (50%), international gas trade is also growing via international pipelines and expanded LNG trade.

There is no shortage of natural gas in the world. The USGS reports in its 2000 "World Petroleum Assessment" that only 10% of worldwide gas resources have been produced (compared to 25% for oil). Considerable volumes of gas remain to be discovered and developed. A major problem has been that much of the world's gas is located far from demand centers. More than half of the world's remaining reserves are in the former Soviet Union, Middle East, and North Africa. Two countries, Russia and Iran, hold approximately 45% of the world's reserves. Thus, there is some concentration of reserves.

Western Europe, which holds only approximately 2% of world gas reserves (mostly in the North Sea), imports approximately 40% of its requirements, mainly from Russia and Algeria. European gas demand is likely to expand rapidly during the next 20 years, which will require increased imports. The European gas industry is also in the process of deregulation following an EU directive in 1998 that set forth a staged plan of achieving more competitive gas markets.

In 1995, the IEA study on gas security concluded that most European countries could withstand gas supply interruptions, but it also noted that gas infrastructure is less flexible than that of oil. Could gas supply security become an issue in the future? If so, it might be desirable to establish a framework for gas security with obligations to hold strategic stocks and develop demand restraint programs. Since the power industry will be using increasingly more gas, reliable gas supply is crucial to the functioning of the electricity industry.

The United States has considerable gas supplies, but it imports approximately 15% of its gas needs from Canada. It also receives other gas imports via LNG. Although LNG shipments are currently small, they are projected to increase.

The U.S. gas industry has been deregulated and functions mostly on short-term contracts and spot sales. On the whole, the liberalized U.S. gas market has worked well. However, there have been some problems. In 2000, natural gas prices increased dramatically and were pushed even higher by very cold weather in November and December. Prices remained high through the first half of 2001. The mean price range during the period was $2.53–7.85 per million Btu, up from $1.98 per million Btu during 1995–1999. The spot price reached more than $10 per million Btu at the Henry Hub at the end of December 2000. What was troubling was the length of time that prices stayed at high levels. High-demand growth and cold weather, plus inadequate gas reserves in storage, explain part of the problem. So does the inelastic short-term supply response to price. Later in 2001, gas prices declined because of the slowdown in the economy and milder temperatures.

Although gas pipelines were used to capacity during the crisis period, there were apparently few infrastructure constraints except in and near California, where transmission capacity was not adequate to transport all the gas needed and natural gas prices spiked higher than elsewhere in the U.S. market (and contributed to the California electricity crisis).

In 2003, at the request of the Secretary of Energy, the National Petroleum Council published an

industry study, "Balancing Natural Gas Policy: Fueling the Demands of a Growing Economy." The study notes that traditional North American gas producing areas can only meet 75% of projected U.S. gas demand in 2025. This includes Canadian production which is reaching a plateau. The gap could be filled by encouraging increased production in the Rocky Mountains, by Arctic gas (which requires a new pipeline), and by expanded LNG imports. At the same time there will be a need to expand gas infrastructure and to deploy new technologies to increase the efficiency of gas use. The study notes that gas price volatility will likely continue, reflecting the variable nature of supply and demand in a free market.

6. TERRORISM AND ENERGY SECURITY

The September 11, 2001, attacks against the United States by the Al-Quaeda group have raised the specter that future terrorist assaults could be made against U.S. energy infrastructure. The subject is not new. Oil companies operating in Columbia have suffered attacks against pipelines and other facilities by guerillas operating in that strife-torn country. However, it is new for the United States. Although electrical/nuclear power plants might be considered especially vulnerable targets, certainly oil refineries and, to a lesser extent, oil and gas pipelines are potential targets as well. New efforts are being made to increase physical security around these facilities, but it is a daunting task. Cyber attacks against energy systems are also a possibility.

The analysis of energy infrastructure vulnerabilities has begun and will require extensive government–industry cooperation. A new Office of Energy Assurance was created soon after September 11, 2001, in the DOE, but it may be folded into the new Department of Homeland Security if endorsed by Congress.

Although physical security can be strengthened at large power plants and petroleum refineries, it will undoubtedly be impossible to protect power lines and pipeline systems from attack. Instead, strategies need to be developed to promote redundancies and reserves in our energy systems to be able to respond to interruptions and reinstate normal service as quickly as possible.

A study of this subject by the U.S. Energy Association, "National Energy Security Post 9/11," recommends some initial actions, which require the application of advanced energy technologies. First, detailed risk assessments need to be made of North American energy system vulnerabilities to terrorism, which might be called probabilistic vulnerability assessments, and corresponding countermeasures. Second, because many existing control systems are linked to the Internet and are therefore vulnerable to cyber attacks, steps should be taken to develop secure, private communications networks for energy systems, with adequately protected back-up systems. Third, with regard to the widely dispersed electricity grid, which is particularly vulnerable, a more flexible strategy of intelligent "islanding" is needed to minimize the impacts of an attack, along with self-healing mechanisms. For major energy facilities, there is a need to develop and install sensors to detect dangerous biological and chemical agents, which might be released in cooling towers, and to identify and deploy countermeasures. Contingency planning is needed for all kinds of attack scenarios against centralized and local facilities.

Glossary

Appalachia The mountainous region stretching from northern Mississippi to southern New York and commonly characterized by rural communities and poverty.
British thermal unit (Btu) The amount of heat required to change the temperature of 1 lb of water 1°F at sea level.
Federal Energy Regulatory Commission (FERC) The successor to the Federal Power Commission; created in 1977.
Federal Power Commission (FPC) The federal regulatory agency responsible for regulating the interstate natural gas industry; created in 1920 and abolished in 1977.
hydrocarbons Organic compounds that are composed entirely of carbon and hydrogen. Petroleum products are composed of hydrocarbons, and methane, or natural gas (CH_4).
Insull, Samuel (1859–1938) A leader in the American public utility industry during the early 20th century. He was born in London and served as Thomas Edison's secretary as a youth.
manufactured coal gas A fuel gas for illuminating and heating purposes produced by heating coal in a retort and capturing the resulting vapors for distribution.
waste gas Natural gas, considered to be a nuisance in the production of oil.

Natural gas is a vital fuel for modern society. During the last 50 years of the 20th century, natural gas satisfied approximately 25% of U.S. energy demand. It has been used for electric power generation, industrial heat processes, domestic heating and cooking, and transportation fuel. Natural gas is composed primarily of methane, a hydrocarbon consisting of one carbon atom and four hydrogen atoms (CH_4). As a "fossil fuel," natural gas is rarely pure. It is commonly associated with petroleum and often contains other hydrocarbons, including butane, ethane, and propane. In the United States, substantial natural gas utilization did not begin until after the discovery of large quantities of both crude oil and natural gas in western Pennsylvania during 1859.

1. ORIGINS

Natural gas was observed and utilized in limited quantities during ancient times. References in literature to burning springs, burning bushes, or perpetual lights suggest that natural gas was used, albeit rarely, for heating. In ancient China, burning gas springs heated brine water in order to extract salt, and there were flaming gas springs in Greece and Rome. Recorded observations of burning springs in France, Italy, and Russia also exist. The philosopher Plutarch and theologian St. Augustine described lights that may have been produced by burning natural gas.

In colonial America, both George Washington and Thomas Jefferson observed natural gas springs. During the autumn of 1770, Washington participated in an expedition along the Ohio and Kanawha rivers in West Virginia and Ohio. Near the present-day town of Pomeroy, Ohio, Washington described a location "wch. the Indians say is always a fire." About perhaps the same site, Thomas Jefferson recorded his observations of "a hole in the earth…from which issues constantly a gaseous stream." Other visitors to these springs reported that hunters used them to cook food.

 © 2004 Elsevier Inc. All rights reserved.

Through the early 19th century, these "burning springs" had little practical or widespread use. Most importantly, there was no practical method of either capturing the gas emanating from the springs or storing and redirecting its flow through piping.

2. NATURAL GAS IN FREDONIA, NEW YORK

Residents of Fredonia, New York, were perhaps the first Americans to use natural gas for lighting on a regular basis. Gas springs in the vicinity of Fredonia had been observed in the early 1800s, but it was not until the mid-1820s that a local gunsmith named William Aaron Hart organized an apparently successful effort to utilize gas from the local gas spring to provide light for local homes and establishments.

Some accounts written much later state that citizens of Fredonia used natural gas to illuminate their town when the French military leader Marquis de Lafayette visited. Lafayette toured America during the years 1824–1825, and he traveled to New York in the summer of 1825. Of his visit to Fredonia, Lafayette's private secretary, A. Levasseur, recorded that they had observed a great many lights in the town. The local newspaper featured a story on the same events and noted lamps and chandeliers that provided illumination in the town during Lafayette's visit. Contemporary reports of Lafayette's visit do not mention gaslights at Fredonia; only the accounts of this event written much later mention gas lighting. Lafayette's secretary did note gas lighting at other locations. While in a Boston theater, Levasseur recorded observations of "gas blazing abundantly from numerous pipes, and throwing floods of dazzling light over the hall." These lights were fueled by manufactured coal gas, however, and not natural gas.

After Lafayette's visit, William Hart continued to develop his interest in natural gas in Fredonia. During 1827, he began work on a plan to supply natural gas to a lighthouse at nearby Barcelona Harbor. After the U.S. government granted him a contract for this service, he installed a primitive gas works. It consisted of a fish barrel placed over the gas spring located at Westfield along Lake Erie. The barrel served as a "gasometer," or gasholder. Hart sealed the gasometer and transported the gas for one-half mile through hollowed out pine logs to the lighthouse. Gas from the spring provided enough fuel to illuminate 144 burners and create a bright light.

3. EARLY COMMERCIAL UTILIZATION

It was not until Colonel Edwin Drake discovered oil in Titusville, Pennsylvania in 1859 that natural gas became a significant source of energy in the United States. Although Drake had been searching for oil, he found natural gas as well; oil and natural gas are often found in the same geologic structures. Natural gas discovered in eastern Pennsylvania was marketed to regional customers. Therefore, the Drake discovery heralded the beginning of both the modern U.S. oil and natural gas industries.

Prior to Drake's discoveries, there were few successful long-term attempts to utilize natural gas for either industrial or commercial purposes. By the mid-19th century, only those factories or towns located very near a natural gas well could utilize the fuel. The difficulty of containing a natural gas spring, storing the gas, and transporting it over long distances limited its utility. For example, significant natural gas discoveries such as the high-volume well discovered by William Tomkins in 1841, near Washington's burning spring on the Canadaway Creek, attracted some attention but little commercial interest. Alternatively, manufactured coal gas plants could be built and operated anywhere as long as coal, or the feedstock, was readily available. Thus, the manufactured coal gas industry developed much

TABLE I

Introduction of Manufactured Gas to Major Cities[a]

Year	City
1816	Baltimore
1825	New York City
1829	Boston
1832	Louisville
1835	New Orleans
1836	Philadelphia
1843	Cincinnati
1846	St. Louis
1849	Chicago
1854	San Francisco
1867	Kansas City
1867	Los Angeles
1871	Minneapolis
1873	Seattle

[a] The dates primarily reflect the year manufactured gas was first produced in the city for commercial use. In some cases, however, the date reflects when a city charter was granted, and charters were sometimes granted before and even just after gas service began.

more quickly than that of natural gas in the 19th century. By the mid-19th century, many towns and cities had a manufactured gas plant and a local distribution system that provided some coal gas for residential and business lighting. (see Table I).

The earliest recorded use of gas for industrial purposes in the United States occurred in 1840, near Centerville, Pennsylvania. The gas was used to distill salt from brine water. Gradually, in the 1860s and 1870s, local deposits of natural gas were utilized for a variety of industrial heating applications. Even in Fredonia, New York, where some residents and shop owners utilized natural gas for lighting beginning in the mid-1820s, a formal natural gas company was not organized for many years. In 1858, businessmen established the Fredonia Gas Light and Water Works Company to operate the local gas wells and discover new ones.

Natural gas was not used on a large scale until the 1880s, and gas wells were most likely to be abandoned when oil was not concurrently discovered. An example of early abandonment occurred in 1865 when a 480-foot drilling effort struck a natural gas reservoir near West Bloomfield, New York. The operators estimated the gas flow to be about 2000 cubic feet (mcf) per day; they directed the gas into a large balloon and attempted to measure the flow by calculating the time required to fill it. Because the investors were disappointed that oil was not discovered, they abandoned the project. Not everyone was disappointed that this well contained only natural gas. Several businessmen formed the Rochester Natural Gas Light Company and purchased the same gas well in 1870. The nearest town desiring natural gas was Rochester, about 25 miles away. The company constructed a pipeline system to connect the well with the town. They built a pipeline out of Canadian white pine. The 2- to 8-foot log segments were planed to a uniform 12.5-inch exterior diameter, and they were bored for an 8-inch interior diameter. Construction and maintenance of the wood pipeline system was particularly problematic, but the company began transporting natural gas during the winter of 1872. Consumers in Rochester discovered quickly that hotter burning natural gas was not easily interchangeable in their burners with manufactured coal gas. This situation resulted in lower than expected natural gas demand. Continuing problems with gas transportation facilities caused significant problems for the company; rotting and leaking wood pipelines simply prevented the adequate transportation of natural gas from well to consumer. Soon, the company stopped operations.

A more successful attempt to transport natural gas took place in 1872. New natural gas discoveries created a demand for specialized gas pipelines. In this case, a 2-inch wrought-iron line was constructed and used to connect a gas well 51 miles away. The line transported "waste gas" from nearby oil fields to Titusville. This pipe transported 4 million cubic feet (mmcf) per day to 250 customers, both residential and industrial.

The primary obstacle to the expansion of the natural gas industry in the mid-19th century was inadequate pipeline facilities and technology, not lack of supply. Hollow log pipelines leaked and disintegrated, but cast and wrought iron lines also suffered from significant intrinsic defects. Wrought iron lines in the period 1872–1890 were typically less than 8-inches in diameter, and the pipe segments were attached with couplings tightened with screws. Gas leaks were common problems. Most of the gas transported in pipelines during this period flowed under the natural pressure of the well without the aid of additional compression.

4. NATURAL GAS IN PITTSBURGH

Pittsburgh became the first major U.S. city in which industry utilized large volumes of natural gas for industrial heat processes. Abundant Pittsburgh area coal deposits and the importation of iron ore from the Juanita region in central Pennsylvania (and later from the Mesabi range) facilitated development of a substantial iron industry originally fueled by coal. Extensive coal burning for industrial heat created significant air pollution, and Pittsburgh became known as the "Smoky City." Contemporary newspaper articles noted the black smoke produced by burning coal. In 1884, *The New York Times* reported that natural gas would be used in Pittsburgh's industries to reduce coal smoke pollution.

The earliest recorded use of natural gas in a Pittsburgh iron works occurred in 1870–1871, but widespread natural gas utilization did not commence until the early 1880s, after the development of nearby gas wells. Entrepreneurs then organized new regionally based gas firms. One group of Pittsburgh area manufacturers established the Chartiers Valley Gas Company in 1883 to transport natural gas from local gas fields to their glass and steel plants. This company's first line extended from the Hickory gas field to Pittsburgh. The wrought-iron line was the first "telescoping" pipeline, meaning that a smaller diameter pipe installed at the well's origin led to a larger diameter pipe in the city. The telescoping line system

was useful for lowering the gas line pressure as gas flowed into the city. For pipe less than 12 inches in diameter, the typical connection was a screw coupling. Pipe segments were threaded on the outer edge of each length end that turned into a screw coupling.

As of 1886, the Chartiers firm also laid claim to operating the largest continuous pipe in the world. The company installed a 16-inch pipe extending from the Murrysville gas field to Pittsburgh. After 8 miles, the 16-inch line was fed into a 6-mile-long 20-inch pipe, and it in turn fed into a 5-mile section of 24-inch cast-iron tubing, tested at 300 pounds per square inch (psi). The National Tube Works constructed this line; J. P. Morgan controlled National Tube.

By the late 1880s, Pittsburgh had become the locus of the American steel and coal industry, and it was also the center of the natural gas industry. In 1886, there were 10 iron and steel mills using natural gas in their puddling furnaces, with many more planning to convert to gas. Six glass-making factories and reportedly every brewery in Pittsburgh used natural gas instead of coal. The Sampson Natural Gas Crematory also used the invisible fuel. Pittsburgh received its natural gas from the lines of six companies tied into 107 regional gas wells. Five hundred miles of pipeline transported natural gas from wells to the city, including 232 miles of line within the Pittsburgh city limits.

As natural gas utilization increased, local engineers addressed technological problems associated with its transportation. Solomon R. Dresser focused attention on drilling and oil-field-related technology. In 1880, he formed S. R. Dresser & Company and conducted pioneering work in pipe coupling. In 1887, Dresser received a patent for using a rubber ring in pipe joints to create a leakproof coupling. Although this method proved not entirely satisfactory, less than a year later Dresser designed a second coupling that was more effective. He developed a two-part mechanical device that pulled the pipe segments together. Between the tightened sections, an internal rubber ring created a seal. Dresser proved the leakproof qualities of this coupling method when he developed his own gas field near Malta, Ohio and used the couplings in a gas line that extended into town. The Malta Natural Gas Line established Dresser as a leader in the natural gas business, and his couplings attracted widespread favor; gas companies located throughout the country ordered them. As much as 90% of the gas pipeline industry used these couplings into the 1920s.

Improved couplings not only reduced leakage, they also lessened the possibility of explosions. In Pittsburgh, city ordinances prohibited gas lines from operating at pressures higher than 13 psi. This pressure limitation was intended to reduce the leaks prevalent in more highly pressurized lines. Leaks often resulted in accumulations of gas in cellars, leading to explosions and fires. Within the city, regulating valves further reduced the gas pressure. To prevent leaking gas from ending up in residential cellars, the Chartiers Valley Company used its patented "broken stone escape system." This system involved laying a pipe in a trench filled with dirt to the center of the pipeline. Workers then placed about 9 inches of broken stone on top of the line. A layer of tarpaper was then placed over the stone; dirt covered the tarpaper. The stone barrier was placed adjacent to every city lamppost so that escaping gas could vent through the stone. In addition, gas firms used "escape pipes," very small diameter lines leading from each pipe joint to a lamppost. Inspectors checked each escape pipe for possible leaks and identified the joint to which each escape line was connected. A system of 4-inch pipes distributed gas to individual residences. In these pipes, gas pressure was limited to about 5 psi. As the gas entered homes, an additional regulator/shutoff valve lowered gas pressure again to about 5 ounces per square inch, so that gas could be burned satisfactorily in gaslight fixtures.

George Westinghouse, inventor of the railroad air brake and a resident of Pittsburgh, also became involved in the expanding natural gas industry. He explored for natural gas close to home. He drilled for gas in his own backyard located in a fashionable Pittsburgh neighborhood. In late February 1884, a small volume of gas began flowing from the well. The workers continued drilling to a depth of about 1560 feet. At 3 a.m. one morning, Westinghouse awoke to the sound of a tremendous explosion and the loud sound of hissing gas from the well.

Westinghouse needed a company organization to proceed with his new plan of selling his natural gas to Pittsburgh-area customers. He purchased a moribund company, the Philadelphia Company, to produce the fuel. As President and Director of the company, Westinghouse watched the firm become one of the largest gas businesses in the Pittsburgh area. For additional supply, the company leased substantial gas production acreage in western Pennsylvania. By 1887, the Philadelphia Company supplied approximately 5000 residential and 470 industrial customers with gas from about 100 natural gas wells located on 54,000 acres.

Westinghouse's financial participation in the natural gas business brought his inventive mind in touch with

some of the major problems of this new industry. Between the years 1884 and 1885, he applied for 28 gas-related patents, and during his lifetime he applied for a total of 38 gas equipment patents. Some of Westinghouse's most important inventions for natural gas included a system for enclosing a main gas line in residential areas with a conducting pipe to contain gas leaks. Westinghouse also developed a method for "stepping down" the highly pressurized gas in main trunk lines to lower pressure in residential areas. To prevent accumulations of gas in homes and shops after gas service was shut down and then restarted, Westinghouse patented a pressure regulator and cutoff valve that automatically restricted gas flow when the pressure dropped below a particular point. Tragedies nonetheless occurred. On the morning of January 31, 1885, two major explosions at Thirty-fifth and Butler streets in Pittsburgh nearly leveled an entire city block, killing two and injuring 25 others, some severely. The first explosion occurred at George Hermansdorfer's butcher shop after an accumulation of gas in his cellar; two or three people were badly burned. People rushed to investigate the explosion when a second, larger explosion occurred nearby. Subsequent explosions caused substantial injury to life and property, damaging as many as 15 buildings. Local residents threatened a riot against the gas company, and a representative of the Fuel Gas Company made a stunning admission: the pipes had not been tested before the gas was turned on. Efforts to develop gas regulators and emergency shutoff valves were absolutely required to ensure that this fuel could be utilized safely.

Andrew Carnegie, Pittsburgh's foremost entrepreneur, understood that natural gas had superior heating characteristics. He wrote: "In the manufacture of iron, and especially in that of steel, the quality is also improved by the pure new fuel. In our steel rail mills we have not used a pound of coal for more than a year, nor in our iron mills for nearly the same period." The iron and steel maker also noted that natural gas burned much more cleanly compared to coal.

By 1885, 150 companies had charters to sell gas in Pennsylvania, but the future of natural gas was not certain. Gas fields tended to exhaust themselves within several years after discovery. Selwynn Taylor, a Pennsylvania mining engineer, believed that most regional natural gas fields would soon be exhausted, and the price of coal would rise to the levels existing prior to the discovery of regional gas fields. His beliefs were typical of the time: existing natural gas fields and current production, transportation, and distribution systems simply could not supply enough gas to satisfy the demand and natural gas was ultimately unreliable. Fears of short-lived wells aside, gas discoveries in other Appalachian states, first in Ohio and then West Virginia, made this fuel economically significant to the entire region. Industries located in cities such as Buffalo, Cleveland, Toledo, and Cincinnati all began using natural gas from nearby wells. Waste and poor planning, however, led to many failed ventures. In one episode, the Indiana Natural Gas & Oil Company had built the longest pipeline to date in 1891. The transmission system consisted of two parallel 8-inch lines extending from northern Indiana gas fields to Chicago, a distance of approximately 120 miles. These lines transported natural gas at 525 psi. The supply quickly declined and the lines were soon removed from service. Episodes such as this but on a smaller scale were repeated throughout the region.

Similar supply problems in Indiana continued. During the late 19th century, an area covering 7000 square miles included a large number of producing natural gas fields. Despite attempts to regulate the production and flow of natural gas, unrestrained gas demand soared in the state. By 1907, many of Indiana's once productive natural gas fields had expended their valuable fuel, and many natural gas customers had to return to manufactured gas utilization. Gas discoveries in Oklahoma and in the eastern and southern Kansas gas fields suffered similar stories of rapid development followed by depletion. Episodes such as these characterized the natural gas industry, as opposed to manufactured gas, as fairly undependable.

By the turn of the century, the natural gas industry was most developed in the Appalachian region. Productive gas wells in West Virginia, Pennsylvania, New York, Kentucky, Tennessee, and Ohio led to the establishment of regional gas firms that built pipelines to serve local markets in the entire region. Natural gas was used primarily for industrial purposes, but, where available, its higher heating content meant that it was a superior cooking and heating fuel, although appliances for these purposes were still not widely available until later in the 19th and early 20th centuries. Natural gas was a promising fuel, but its limited availability and dependability forced entrepreneurs to proceed cautiously with plans to develop fields and build pipelines.

5. NATURAL GAS IN THE SOUTHWEST

The discovery of massive southwestern natural gas fields and technological advancements in

long-distance pipeline construction dramatically altered the early 20th-century gas industry market structure. In 1918, drillers discovered a huge natural gas field that became known as the Panhandle Field, situated primarily in North Texas. In 1922, drillers discovered the Hugoton Field, located in the common Kansas, Oklahoma, and Texas border area (generally referred to as the midcontinent area). The combined Panhandle/Hugoton fields became the nation's largest gas-producing area, comprising more than 1.6 million acres. It contained as much as 117 trillion cubic feet (tcf) of natural gas and accounted for approximately 16% of total U.S. reserves in the 20th century.

As oil drillers had done earlier in Appalachia, they initially exploited the Panhandle Field for petroleum only while allowing an estimated 1 billion cubic feet/day (bcf/d) of natural gas to escape into the atmosphere. As new gas markets appeared, the commercial value of southwestern natural gas attracted entrepreneurial interest and bolstered the fortunes of existing firms. These discoveries led to the establishment of many new southern firms, including the Lone Star Gas Company, Arkansas Louisiana Gas Company, Kansas Natural Gas Company, United Gas Company, and others, some of which evolved into large natural gas companies.

The sheer volume of these southwestern gas fields and their distance from distant urban markets emphasized the need for advancements in pipeline transport technology. In particular, new welding technologies allowed pipeline builders in the 1920s to construct longer lines. In the early years of the decade, oxyacetylene torches were used for welding, and in 1923, electric arc welding was successfully used on thin-walled, high-tensile-strength, large-diameter pipelines necessary for long-distance compressed gas transmission. Improved welding techniques made pipe joints stronger than the pipe, and seamless pipe became available for gas pipelines beginning in 1925. Along with enhancements in pipeline construction materials and techniques, gas compressor and ditching machine technology improved as well. Long-distance pipelines became a significant segment of the gas industry beginning in the 1920s.

These new technologies made possible for the first time the transportation of southwestern natural gas to midwestern markets. Soon, the southwest supplanted Appalachia's position as the primary region for marketable gas production. Until the late 1920s, virtually all interstate natural gas transportation took place in the northeast, and it was based on Appalachian natural gas production. In 1921, natural gas produced in West Virginia accounted for approximately 65% of interstate gas transportation whereas only 2% of interstate gas originated in Texas. Most interstate gas flowed into western Pennsylvania and Ohio. Appalachian fields experienced serious depletion in the 1920s, however, and various state legislators attempted to prohibit out-of-state gas exportation. These attempts to corral natural gas for intrastate utilization were largely unsuccessful.

Between the mid-1920s and the mid-1930s, the combination of abundant and inexpensive southwestern natural gas production, improved pipeline technology, and increasing nationwide natural gas demand led to the creation of the new interstate gas pipeline industry. Metropolitan manufactured gas distribution companies, typically part of large holding companies, financed most of the pipelines built during this era. Despite the high cost of the long-distance lines, access to natural gas even for mixing with existing manufactured gas could be a profitable venture. Natural gas was so abundant it was often substantially less costly than coal gas.

In 1927, Cities Service built the first long-distance line originating in the Panhandle field. This 250-mile, 20-inch pipeline connected the Panhandle field with a Cities Service gas distributor in Wichita, Kansas. Standard Oil (New Jersey) also participated in several significant pipeline ventures during these years. The first of these was Colorado Interstate Gas Company. Organized in 1927 by Standard, Cities Service, and Prairie Oil & Gas, this firm built a 350-mile, 22-inch line originating at the Texas–New Mexico border and extending to Denver. In California, natural gas from the Buena Vista field in the San Joaquin Valley fueled industry and commercial establishments in Los Angeles, and in 1929, Pacific Gas & Electric (PG&E) constructed a 300-mile pipeline from the Kettleman field north of Los Angeles to bring natural gas to San Francisco. San Francisco was one of the first major urban areas to switch from manufactured gas to natural gas. Because the same volume of natural gas had nearly twice the heating content as coal gas, burners and airflow valves in stoves and water heaters had to be adjusted to accept the natural fuel. With near military precision, PG&E divided San Francisco into 11 districts that were successively converted to natural gas. Six hundred trained men divided into 35-member crews converted PG&E's service area within 5 months. The conversion of 1.75 million appliances cost $2 million, but natural gas was less costly for the utility to market compared to coal gas.

New long-distance gas lines and expensive conversion programs were necessary if gas utilities were

TABLE II

Estimated Waste of Natural Gas in the United States in Billions of Cubic Feet[a]

	Natural gas waste[b]		
Year	Total U.S.	Texas panhandle	Total U.S. natural gas consumption
1919	213	n/a	256
1920	238	n/a	286
1921	193	n/a	248
1922	233	n/a	254
1923	416	n/a	277
1924	343	n/a	285
1925	324	n/a	272

[b] Waste means gas production that was flared or vented and otherwise not utilized. n/a, data not available.

going to meet consumer demand. The new holding companies marshaled tremendous amounts of capital to build pipelines, extend service, and promote gas utilization. They also became adept at advertising and marketing. Trained salesmen, company servicemen, and even co-opted plumbers touted gas. During the 1920s, utility companies offered for sale a wide variety of gas-powered appliances, including space heating units, water heaters, stoves, and even gas-powered refrigerators. By 1926, about 50,000 automatic water heaters had been installed in homes, but gas appliances were not inexpensive.

Another use for natural gas beginning in the late 19th century was carbon black production. Produced by burning natural gas, carbon black was used for coloring in paint and inks. It was also used as a reinforcing agent in rubber and automobile tires. Natural gas produced in fields not connected by pipelines to urban markets was a prime candidate for carbon black production. Even by the late 1930s, about two-thirds of the amount of marketable gas produced was either flared, vented, or used to make carbon black. (see Table II). But greater profits awaited entrepreneurs willing to finance pipelines connecting gas fields to urban and industrial gas markets. Urban natural gas utilization also brought forth efforts to develop a standardized odorant. Unlike coal gas, which typically has a distinct smell, natural gas is odorless. Thus, a leak or inadvertently opened valve might allow odorless gas to accumulate in an enclosed space and asphyxiate people, or explode. Experiments with odorants date to at least 1885, and in 1930, the Bureau of Mines conducted experiments with mercaptan, which later became the standardized gas odorizer.

6. LONG-DISTANCE PIPELINES

By the late 1920s, four public utility holding companies dominated the U.S. gas industry and sought to control interstate gas transportation as well. Two of the largest holding companies, Columbia Gas and Standard Oil (New Jersey), distributed more than half of the gas sold in the entire Appalachian region. Henry Doherty's Cities Service dominated the lower midwest. The largest public utility conglomerates included Middle West Utilities, Inc. and Insull Utility Investments, Inc., both controlled by Samuel Insull and headquartered in Chicago. By the late 1920s, Insull's empire included 248 gas, coal, and electric power firms serving 4741 communities in 30 states.

Planning for the first 1000-mile pipeline began in 1926 when Samuel Insull and associates discussed the possibility of building a natural gas pipeline connecting southern gas fields with Chicago area gas utilities. They sponsored engineering studies, considered a pipeline route, and examined potential gas acreage. In April, 1930 they first incorporated as the Continental Construction Corporation; a year later the company changed its name to the Natural Gas Pipeline Company of America (NGPL). NGPL's proposed 24-inch line would extend 980 miles from north Texas to Chicago. Commonly referred to as the "Chicago pipeline," this line would allow Insull to convert Peoples Gas Light & Coke Company's service area from dependence on manufactured coal gas to cleaner, hotter burning, and less expensive natural gas.

The NGPL venture was jointly planned, financed, and controlled by three utility holding companies and three other oil firms. The three holding companies were Samuel Insull's Insull & Sons, Henry Doherty's Cities Service, and Standard Oil of New Jersey. NGPL purchased its gas supply from gas fields controlled by the pipeline's owners. Standard Oil (NJ) agreed to furnish 25% of NGPL's requirements indirectly through the Canadian River Gas Company. Canadian River was a partnership of Cities Service and Prairie Oil & Gas, Standard's partners in

the Colorado Interstate line. The Texoma Natural Gas Company supplied the remaining 75% of NGPL's gas requirements.

Henry L. Doherty & Company contracted to build the NGPL line. Construction began in August, 1930, and the main line was completed 12 months later. A total of 418 million pounds of steel pipe buried 6 feet transported gas at 600 psi. Construction costs for the main line, nine compressor stations, and telephone lines totaled $35 million. Although NGPL's major market was Insull's Chicago area utilities, some gas was also sold to gas distributors in Kansas and other states. The first gas deliveries in Chicago commenced on October 16, 1931, and by January 1, 1932, the line was delivering 55 mmcf/d with an originally designed total capacity of 175 mmcf/d. With access to abundant volumes of natural gas, Chicago became the largest U.S. city to convert its utility distribution system to "mixed gas," and later to straight natural gas. Peoples Gas Light and Coke Company first began producing a mixed gas with a 800-Btu content. Mixed gas, a mixture of lower Btu coal gas and higher Btu natural gas provided a hotter burning flame than did coal gas alone, for both cooking and heating. Peoples Gas Light and Coke Company began charging for gas based on a price per "therm" (1 therm = 100,000 Btu) basis, rather than by volume; natural gas had nearly twice the Btu rating compared to an equal volume of manufactured gas.

Peoples Gas Light and Coke Company organized a massive campaign to merchandise gas house-heating equipment. The company placed full-page and three-quarter-page advertisements in newspapers serving Chicago and in 50 outlying communities; advertisements appeared on billboards, streetcars, and shop windows. In addition, the utility hired 270 company-trained salesmen, 60 heating engineers, and 14 sales directors to promote gas consumption. Within the first 10 weeks of the promotion, Peoples Gas Light and Coke Company installed about 10,000 conversion burners, and the company made 30,000 gas installations during the gas sales promotion. Servicemen adjusted existing residential furnaces to accept the higher Btu mixed gas. In order to convert appliances, gas mains required cleaning to remove oil residue and other impurities from the manufactured gas.

Also during this time, a consortium led by North American Light & Power Company, which owned gas and electric properties throughout the midwest, purchased from Odie R. Seagraves and William L. Moody III (Moody–Seagraves Interests) the beginnings of the pipeline these two men had planned to build from Seagraves's Hugoton gas field properties to Omaha, Nebraska. The North American Light & Power Company joined the Lone Star Gas Company and United Light & Power Company in a partnership to purchase the Moody–Seagraves project and rename it the Northern Natural Gas Company. North American financed the construction of Northern Natural, which was completed 1931. The 1110-mile, 24- and 26-inch line transported gas to various cities along its path to Minneapolis via Omaha.

During the 1930s, a third group of entrepreneurs formed a third pipeline to connect southwestern gas fields with midwestern customers. They incorporated the Panhandle Eastern Pipe Line Company. By 1936, it was transporting gas from the Texas Panhandle through an affiliated firm to Detroit, Michigan.

7. NATURAL GAS IN THE GREAT DEPRESSION

In the late 1920s and early 1930s, the most well-known public utility figure was Samuel Insull, a former personal secretary of Thomas Edison. Insull's public utility empire headquartered in Chicago did not fair well in the economic climate that followed the 1929 Wall Street stock market crash. His gas and electric power empire crumbled, and he fled the country. The collapse of the Insull empire symbolized the end of a long period of unrestrained and rapid growth in the U.S. public utility industry. In the meantime, the Federal Trade Commission (FTC) had launched a massive investigation of the nation's public utilities, and its work culminated in New Deal legislation that imposed federal regulation on the gas and electric industries. The Public Utility Holding Company Act (1935) broke apart the multitiered gas and electric power companies and the Federal Power Act (1935) and the Natural Gas Act (1938), respectively, authorized the Federal Power Commission (FPC) to regulate the interstate transmission and sale of electric power and natural gas.

During the Depression, the gas industry also suffered its worst tragedy in the 20th century. In 1937, at New London, Texas, an undetected natural gas leak at the Consolidated High School resulted in a tremendous explosion that virtually destroyed the Consolidated High School, 15 minutes before the end of the school day. Initial estimates of 500 dead were later revised to 294. Texas Governor Allred appointed a military court of inquiry that determined an

accumulation of odorless gas in the school's basement, possibly ignited by the spark of an electric light switch, created the explosion. This terrible tragedy was marked in irony. On top of the wreckage, a broken blackboard contained these words, apparently written before the explosion: "Oil and natural gas are East Texas' greatest mineral blessings. Without them this school would not be here, and none of us would be here learning our lessons." Although many gas firms already used odorants, the New London explosion resulted in the implementation of new natural gas odorization regulations in Texas.

8. APPALACHIAN GAS AND FEDERAL WAR PLANNING

During World War II, the Pittsburgh, Youngstown, and Wheeling areas contained hundreds of steel mills and metallurgical factories, as well as rubber and chemical plants that required large volumes of natural gas. Natural gas was vital to these factories because it burned at a constant specific temperature, providing high-quality product manufacture. Approximately 660 Appalachian area factories used a substantial amount of natural gas, and wartime energy demands put further pressure on Appalachian gas reserves. Appalachian natural gas production had peaked in 1917 at 552 bcf of natural gas, or about 63% of total U.S. gas production; this percentage declined to approximately 15% by the late 1930s. The decline resulted from diminishing Appalachian gas reserves as well as a proportionate increase in southwestern-produced gas. By 1943, Appalachian production alone was insufficient for meeting regional industrial, commercial, and residential demand. (see Table III).

TABLE III

Natural Gas Production by Region, 1912–1970[a]

Year	Region (%)[b]			Total marketed production (tcf)[c]
	Appalachia	Southwest	Other	
1912	74	22	2	0.56
1920	55	34	11	0.80
1922	46	37	17	0.76
1924	31	45	24	1.14
1926	26	50	24	1.31
1928	21	57	22	1.57

[b] Appalachia includes Pennsylvania, Ohio, West Virginia, and Kentucky (and New York for 1920 only). Southwest includes Texas, Louisiana, Oklahoma, and Kansas.

[c] tcf, trillion cubic feet.

The intense drain on Appalachian reserves stimulated private entrepreneurial efforts to increase production and build new pipelines. At the same time, some industry executives were already looking forward to a burgeoning gas industry after the war. During one meeting held during 1942, J. French Robinson, a prominent gas utility executive, stated that "in the postwar sunshine of abundant materials for our use, we will be able to realize the potential values of natural gas to all this nation as never before." Patriotic fervor aside, the business of war stimulated both industrial production and entrepreneurial ambition.

To direct the federal government's wartime energy policy, Roosevelt chose Harold I. Ickes, who was then Secretary of the Interior. On May 28, 1941, Ickes assumed his new position as the first Petroleum Coordinator for National Defense; this agency was later renamed the Petroleum Administration for War (PAW). In this role, the new "oil czar" exercised special emergency powers over much of both the oil and gas industries. Despite initial industry fears, Ickes implemented a cooperative relationship with the energy industry during wartime. The PAW created a Natural Gas and Natural Gasoline Division to be responsible for the gas industry. E. Holley Poe, a former executive of the American Gas Association, headed the division. His charge was maintaining natural gas production and deliverability, particularly in the Appalachian region. Poe also attempted to marshal support for joint-industry cooperation while administering the wartime industry. The PAW's authority over natural gas was relatively modest compared to that of the Supply Priorities and Allocation Board (SPAB). The SPAB, which later merged into the War Production Board (WPB), had much broader powers over industry. Regarding

natural gas, the agency dictated specific gas sales allocation orders to gas pipelines.

During late 1941, representatives of the natural gas industry, military, PAW, WPB, and the American Gas Association met several times in different cities to discuss recommendations for restricting some classes of natural gas consumption and maintaining production levels during the war. J. A. Krug, Chief of the WPB Power Branch, was particularly concerned about potential shortages in Appalachia, southern California, and the midcontinent areas. He proposed a special "Limitation Order" for conserving natural gas. The order had two major goals: (1) to increase production and (2) to curtail nonessential consumption. Major General H. K. Rutherford wrote a letter of support and noted the critical situation faced by war industries dependent on natural gas.

In early February, 1942, the WPB issued Order L-31. This action called for voluntary compliance with pooling arrangements "to achieve practicable maximum output in the area or areas in which a shortage exists or is imminent." The order authorized the WPB to integrate natural gas systems, curtail gas sales when necessary, and reallocate existing gas sales. The WPB actively encouraged pipelines to transport gas at 100% load factor, to use gas storage fields whenever possible to free up pipeline capacity for gas transmission, and to develop curtailment schedules. Six months later, the WPB issued Order L-174, which imposed the same restrictions on the manufactured coal gas industry.

The PAW and WPB also addressed the Appalachian gas production problem. First, the PAW set guidelines for a new drilling program, M-68, for developing a nationwide oil and gas drilling program "consistent with the availability of material and equipment." This program limited drilling of gas wells to not more than 1 every 640 acres. Industry leaders objected to M-68, believing that it would stymie efforts to maintain current production levels. In response, the PAW issued new spacing provisions that permitted drilling one well on each 160 acres for specified deep horizons and one to each 40 acres for shallow wells.

The importance of Appalachian natural gas supply to the war effort was reflected in the disproportionate number of wells drilled there. Between 1942 and 1945, approximately 70% of all gas wells drilled in the country were drilled in Appalachia, even though overall production levels did not rise significantly. Wartime demand simply sped up the depletion of Appalachian gas fields. Government drilling and consumption regulations could not reverse this situation.

TABLE IV

Natural Gas Prices and Demand, 1945–1970[a]

Year	Marketed production	
	Trillions of cubic feet	Average wellhead price (cents/million cubic feet)
1945	4	4.9
1950	6	6.5
1955	9	10.4
1960	13	14.0
1965	16	15.6
1970	22	17.1

9. GAS IN THE POSTWAR ERA

In the period following World War II, the natural gas industry expanded rapidly. A new round of long-distance pipeline construction made natural gas available throughout the nation. Natural gas fueled factories, electric power-generating facilities, and provided heat for homes and cooking. Demand for gas fuel rose dramatically as it became available. (see Table IV). In this postwar era, entrepreneurs organized several long-distance gas pipeline firms to connect southwestern gas supply with northeastern markets. New pipeline firms organized to sell natural gas to northeastern markets. One group of entrepreneurs purchased the so-called Big Inch and Little Big Inch pipelines from the United States government and converted them for natural gas transportation. The government had financed these lines during World War II to transport oil from the Texas Gulf Coast to the New York refinery area. Under new private ownership, the newly named Texas Eastern Transmission Corporation and affiliated lines delivered natural gas for the first time to Philadelphia, New York, and Boston. Two other new pipelines built either during or immediately after the war, the Tennessee Gas and Transmission Company and Transcontinental Gas Pipe Line Company, also began delivering southwestern-produced natural gas to northeastern customers in major urban areas.

Other pipelines extended from southwestern gas fields to growing urban markets on the West Coast and in the Southeast. California is a large producer of natural gas, but rapid population and infrastructure growth fueled the demand for more of it. El Paso Natural Gas became the first interstate pipeline to deliver natural gas to California, followed by

Transwestern Pipeline Company in the early 1960s. The Northwest Pipeline Company began transporting natural gas produced in the San Juan Basin in Colorado and New Mexico to customers in Seattle after 1956. In 1959, Florida Gas Transmission Company delivered the fuel to Floridians. By the mid-1950s, therefore, the beginnings of a national market for natural gas emerged. During the last half of the 20th century, natural gas consumption in the U.S. ranged from about 20 to 30% of total national energy utilization. However, the era of unrestricted natural gas abundance ended in the late 1960s.

The first overt sign of serious industry trouble emerged when natural gas shortages appeared in 1968–1969. Economists almost uniformly blamed the shortages on gas pricing regulations instituted by the so-called Phillips Decision of 1954. This law had extended the FPC's price-setting authority under the Natural Gas Act to the natural gas producers that sold gas to interstate pipelines for resale. The FPC's consumerist orientation meant, according to many economists, that it kept gas prices artificially low through federal regulation. Gas producers consequently lost their financial incentive to develop new gas supply for the interstate market, and shortage conditions developed.

10. DEREGULATION

The 1973 OPEC oil embargo exacerbated the growing shortage problem as factories switched boiler fuels from petroleum to natural gas. Cold winters further strained the nation's gas industry. The resulting energy crisis compelled consumer groups and politicians to call for changes in the regulatory system that had constricted gas production. In 1978, a new comprehensive federal gas policy dictated by the Natural Gas Policy Act (NGPA) created a new federal agency, the Federal Energy Regulatory Commission, to assume regulatory authority for the interstate gas industry.

The NGPA also included a complex system of natural gas price decontrols that sought to stimulate domestic natural gas production. These measures appeared to work almost too well and contributed to the creation of a nationwide gas supply "bubble" and lower prices. The lower prices wreaked additional havoc on the gas pipeline industry because most interstate lines were then purchasing gas from producers at high prices under long-term contracts. Some pipeline companies had also invested tremendous amounts of money in expensive supplemental gas projects such as coal gasification and liquid natural gas (LNG) importation. The long-term gas purchase contracts and heavy investments in supplemental projects contributed to the poor financial condition of many gas pipeline firms. Large gas purchasers, particularly utilities, also sought to circumvent their high-priced gas contracts with pipelines and purchase natural gas on the emerging spot market.

Once again, government was forced to act in order to bring market balance to the gas industry. Beginning in the mid-1980s, a number of FERC orders, culminating in Order 636 (and amendments), transformed interstate pipelines into virtual common carriers. This industry structural change allowed gas utilities and end-users to contract directly with producers for gas purchases. FERC continued to regulate the gas pipelines' transportation function, but pipelines ceased operating as gas merchants as they had for the previous 100 years. Restructuring of the natural gas industry continued into the early 21st century as once-independent gas pipeline firms merged into larger energy corporations.

Natural gas is a limited resource. Although it is the most clean burning of all fossil fuels, it exists in limited supply. Estimates of natural gas availability vary widely, from hundreds to thousands of years.

TABLE V

Natural Gas Production and Consumption in the United States[a]

Year	Total dry production	Total consumption
1970	21,014,292	21,139,386
1972	21,623,705	22,101,452
1974	20,713,032	21,223,133
1976	19,098,352	19,946,496
1978	19,121,903	19,627,478
1980	19,557,709	19,877,293
1982	17,964,874	18,001,055
1984	17,576,449	17,950,524
1986	16,172,219	16,221,296
1988	17,203,755	18,029,588
1990	17,932,480	18,715,090
1992	17,957,822	19,544,364
1994	18,931,851	20,707,717
1996	18,963,518	21,966,616
1998	19,125,739	21,277,205
2000	19,072,518	22,546,944

In millions of cubic feet.

Such estimates are dependent on technology that must be developed in order to drill for gas in more difficult geographical conditions, and actually finding the gas where it is expected to be located. Methane can also be extracted from coal, peat, and oil shale, and if these sources can be successfully utilized for methane production, the world's methane supply will be extended another 500 or more years.

Since 1970, natural gas production and consumption levels in the United States have remained reasonably stable. During the 1980s, both consumption and production levels dropped about 10% from the 1970 levels, but by the later 1990s, production and consumption were both on the rise. (see Table V). In the absence of aggressive conservation programs, unexpected shortages, or superior alternative energy sources, natural gas consumption will continue to increase.

For the foreseeable future, natural gas will continue to be used primarily for residential and commercial heating, electric power generation, and industrial heat processes. The market for methane as a transportation fuel will undoubtedly grow, but improvements in electric vehicles may well dampen any dramatic increase in demand for engines powered by natural gas. The environmental characteristics of natural gas, however, should retain this fuel's position at the forefront of desirability of all fossil fuels, while supplies last.

1. Introduction
2. Examples of Natural Gas Policy

Glossary

associated/dissolved natural gas A type of natural gas that occurs in crude oil reservoirs either as free gas (associated) or as gas in solution with crude oil (dissolved gas).

dry natural gas The natural gas that remains (1) after the liquefiable hydrocarbon portion has been removed from the gas stream (i.e., gas after lease, field, and/or plant separation) or (2) after any volumes of nonhydrocarbon gases have been removed, when they occur in sufficient quantity to render the gas unmarketable. Dry natural gas is also known as consumer-grade natural gas. The parameters for measurement are cubic feet at 60°F and 14.73 pounds per square inch absolute.

methane A colorless, flammable, odorless hydrocarbon gas (CH_4); the major component of natural gas. It is also an important source of hydrogen in various industrial processes. Methane is a greenhouse gas.

natural gas A gaseous mixture of hydrocarbon compounds, the primary one being methane. The U.S. Energy Information Administration measures wet natural gas and its two sources of production (associated/dissolved natural gas and nonassociated natural gas) and dry natural gas (which is produced from wet natural gas).

nonassociated natural gas A form of natural gas that is not in contact with significant quantities of crude oil in the reservoir.

wet natural gas A mixture of hydrocarbon compounds and small quantities of various nonhydrocarbons existing in the gaseous phase or in solution with crude oil in porous rock formations at reservoir conditions. The principal hydrocarbons normally contained in the mixture are methane, ethane, propane, butane, and pentane. Typical nonhydrocarbon gases that may be present in reservoir natural gas are water vapor, carbon dioxide, hydrogen sulfide, nitrogen, and trace amounts of helium. Under reservoir conditions, natural gas and its associated liquefiable portions occur either in a single gaseous phase in the reservoir or in solution with crude oil and are not distinguishable at the time as separate substances. The Securities and Exchange Commission and the Financial Accounting Standards Board refer to this product as natural gas.

Natural gas has come a long way as a good with intrinsic value. This resource was once considered a mere by-product of oil and thus not worth the significant capital investment required to find, gather, treat, transport, and distribute it. The relative abundance, wide dispersion, and cleanliness of natural gas have propelled it to the forefront of the fossil fuels, so that natural gas today is poised to become a global commodity, a bridge fuel to the next energy future, and a source of molecular building blocks to new materials. The key policy challenges lie in differentiating the various markets associated with natural gas molecules and fashioning competitive supply, demand, and pricing mechanisms; designing appropriate policy approaches for components of the natural gas value chain that bear public service attributes and thus affect the public interest; and mobilizing capital investment while balancing efficiency and equity concerns.

1. INTRODUCTION

The term "natural" is used to distinguish gaseous and associated liquid hydrocarbons that are produced in the earth from those that are "manufactured," typically from coals (and often referred to as "town gas"). Methane (one carbon and four hydrogen atoms) is the most abundant molecular component of a natural gas stream, typically comprising as much

 © 2004 Elsevier Inc. All rights reserved.

as 85%, depending on whether the natural gas occurs with crude oil or separately. Other molecules in the natural gas stream, in varying proportions, include ethane, propane, butane, carbon dioxide, oxygen, and nitrogen, and impurities such as hydrogen sulfide and rare gases that must be removed before the natural gas can be used. Liquefied petroleum gas (LPG), a propane/butane mixture, is stripped out of the natural gas stream during field production; LPG can be shipped by pipelines or separately by truck or tanker for uses such as petrochemical manufacturing, charcoal starter fuel in backyard grills, or vehicle transport fuel. In many countries, particularly those with short heating seasons, LPG comprises the principal domestic fuel source for water and space heating and cooking. Natural gas liquids (NGLs)—ethane and larger molecules—also are stripped out as feedstocks for petrochemicals (methane can also be used instead of the heavier molecules for petrochemical applications, but much larger volumes of methane are required). The NGL molecules can also be transported by pipeline, truck, or tanker. Other than pipeline delivery, methane can be liquefied and thus transported economically over large distances in liquefied natural gas (LNG) ships or by truck; LNG cargoes may contain molecules other than methane if there is no processing at the point of liquefaction. Methane can also be compressed and transported shorter distances by truck as compressed natural gas (CNG); eventually, depending on emergence of viable technologies and cost structures, it may be possible to transport CNG on tankers. Compression and liquefaction are required for methane to be used as a vehicle fuel, whereas LPG can be used directly.

Worldwide, the natural gas industry has grown rapidly in recent years. Nations with rich natural gas resources have aggressively added new petrochemical capacity. These huge investments tend to be quite lumpy and the products are subject to intense global competition (with commensurate impacts on the feedstock molecules), leading to the well-known cyclicality in these businesses. Likewise, LNG investments are also sizable, lumpy, and subject to global forces, and are also fast growing. For nations that do not have large enough domestic demand relative to the size of their resource base, or that have not developed petrochemicals capacity for conversion of natural gas to other products, LNG is an important means of deriving value for their natural resource endowments through international trade. LPG as a domestic energy source has also grown, proving to be a relatively cheap (in terms of local infrastructure) and clean replacement for biomass. In particular, LPG has replaced wood (and is therefore preferable in places where deforestation has been rampant) and animal dung. LPG also represents an improvement in both cleanliness and safety over kerosene, also used as domestic fuel. Where LPG is in wide use, typical policy challenges include pricing and transparency in market organization. Because LPG is most often found as a domestic fuel in poorer countries, the tendency has been toward government control of final prices charged to customers and heavy subsidization of these prices. These policy approaches are usually neither fair nor effective; they are also costly to governments. In many countries, lack of transparent market organization for LPG contributes to widespread theft, increasing distortions and injuring the consumers least able to make alternative choices.

Above all, it is the growth in demand for piped methane as a clean convenient option for consumer energy markets that has garnered the greatest interest. Thus, from hereon "natural gas" refers to pipeline delivery of methane and the myriad operational and commercial aspects involved. Generally, worldwide, natural gas/methane infrastructure systems consist of upstream, midstream, and downstream operational elements. Upstream operations involve two components:

1. Exploration. This consists of activities that lead to discovery of new natural gas resources. Exploration risk is one of the strongest forms of risk.
2. Production. Extraction of discovered supplies from hydrocarbon fields either with crude oil (as associated natural gas) or separately (nonassociated natural gas). If natural gas is associated with crude oil, it must be separated.

Midstream operations are more extensive:

1. Gathering. Collection of natural gas production from multiple wells connected by small-diameter, low-pressure pipeline systems and delivery to a processing plant or long-distance pipeline.
2. Processing and treatment (if necessary). Processing is the separation of heavier molecules and unwanted substances such as water from a methane gas stream. If the gas stream contains impurities such as hydrogen sulfide, then treatment is required.
3. Storage. Containment of supplies, usually in depleted underground reservoirs or caverns such as those associated with salt domes. Storage can be located either near production or near demand.
4. Transportation. Delivery of gas from producing basins to local distribution networks and

high-volume users via large-diameter, high-volume pipelines. In countries that are federal republics, pipeline systems may be distinguished by whether they cross state or provincial boundaries (for example, in the United States, interstate pipelines as opposed to intrastate systems that operate within the state jurisdiction). Countries vary greatly with respect to allowable pipeline specifications for heat content, as measured by the British thermal unit (Btu) in the United States, Canada, and elsewhere, and as related to the presence of molecules other than methane in the piped stream. For example, pipelines transport and distribute methane or "dry" gas in Canada and the United States, which means that heavier molecules are removed before the natural gas stream enters the pipeline system. Exceptions do exist, such as the Alliance Pipeline, which transports "wet" gas from British Columbia to Chicago, where molecules other than methane are stripped out in processing for use in other markets. Pipeline standards generally are set for safety reasons.

5. Liquefaction, shipping, and regasification. Known collectively as the LNG value chain, this entails conversion of gas to a liquid form via refrigeration, resulting in a cryogenic fluid (temperature −256°F) for transportation from a producing country or region to a consuming country or region via ship. LNG is stored until it is returned to the gas phase (regasification, using vaporization) for pipeline transportation within the consuming region. In the United States, LNG is also used as a storage form of natural gas produced from domestic fields, until the gas is needed, primarily for peak use. Both storage and transport of LNG are done at nearly atmospheric pressure.

Finally, the infrastructure system consists of downstream operations:

1. Distribution. Retail sales and final delivery of gas via small-diameter, low-pressure local gas networks operated by local distribution companies (often termed gas utilities).
2. End use and conversion. Direct use or conversion for use in other forms (petrochemicals, electric power, or vehicle fuels).

The following commercial elements serve to bind the operating segments of the natural gas infrastructure system, linking suppliers, transporters, and distributors with their customers:

- Aggregation. Consolidation of supply obligations, purchase obligations, or both as a means of contractually (as opposed to physically) balancing supply and demand.
- Marketing. Purchase of gas supplies from multiple fields and resale to wholesale and retail markets. Retail marketing constitutes sales to final end users (typically residential, commercial, industrial, electric power, and public sectors).
- Capacity brokering. Trading of unused space on pipelines and in storage facilities.
- Information services. Creation, collection, processing, management, and distribution of data related to all the other industry functions listed here.
- Financing. Provision of capital funding for facility construction, market development, and operation start-up.
- Risk management, Balancing of supply, demand, and price risks.

Altogether, the upstream, midstream, downstream, and commercial elements constitute the natural gas value chain. The various segments are highly interdependent but, in an open, competitive market, they also can be highly competitive. The policy challenges associated with increased worldwide use are numerous. Frameworks for efficient discovery and optimal production are the first hurdle. Efficient and equitable mechanisms, often at odds, for pipeline transportation and local distribution are the second major hurdle. Methane is of little use in consumer energy markets without pipeline infrastructure. These large systems tend to be characterized by strong technical economies of scale and high barriers to entry. Particular problems also emerge with respect to the public interest/public service component of these facilities, mainly with respect to reliability and pricing of systems that are usually operated in monopoly, duopoly, or limited competitor regimes. In all cases, a specific policy quandary is how best to achieve prices for natural gas transportation and distribution through tariff designs that yield something close to what competitive markets might be able to achieve, with contestability (potential competition) usually providing a basis for market-based pricing in larger markets.

A third challenge is development of transparent markets for natural gas supply and consumption. If pipelines are an essential feature, a central question is whether molecules have intrinsic value or whether the combination of pipeline and molecule together must constitute the service. Increasingly, the trend has been to separate infrastructure and product (often termed "unbundling") and to search for ways

of providing competitive access to pipeline systems for multiple suppliers and users of natural gas (often termed "third-party access" or "open access"). In these cases, pipelines become like toll roads, priced through tariff design, whereas molecules become priced in discrete, competitive markets. When pipelines become subject to third-party access regimes, the commercial activities described earlier and associated with pipeline operations, i.e., the linking of suppliers to buyers, can be separated into competitive business activities. Once subjected to competitive markets, methane molecules become commoditized. With all market participants as price takers, new sources of risk and new policy challenges arise. In recent years, the rapid commoditization of methane in the United States and Canada triggered growth in marketing and trading (both of the physical product as well as financial derivatives) as separate businesses. With methane a commodity, and pipeline capacity close to being commoditized, balancing supply and demand across a market becomes both more efficient and more fragmented, as new combinations of activities and relationships across the value chain become established. The fuel's growing importance in the international economy, as natural gas becomes globalized via LNG shipments and disparate national and regional markets become linked, has meant new incentives for technical improvements in supply and demand management and balancing. The principal segments of a natural gas infrastructure system—exploration, production, transportation and distribution—share substantial capital requirements and comparable, albeit different, risks. The long lead times required for development of each sector's assets present both industry leaders and policymakers with the problem of adequately anticipating changes in supply and demand. These projections must be accurate and timely to attract the necessary long-term investment consistently and to minimize market disruptions and distortions. Inadequate projections create conflicts to the extent that they result in supply–demand imbalances, which neither industry nor government has the flexibility to correct in a timely manner.

Both the international trade linkages and the evolution of market-based policies for natural gas mean timely and accurate data and information on supply, demand, and prices, a fourth requirement. A fifth and increasingly complicated challenge is dealing with integration, with respect to industry organization and international trade. Industry organization can encompass both vertical (meaning up and down the value chain) and horizontal (meaning over some geographic or market extent) integration. Paradoxically, the forces for integration within a natural gas industry often occur in spite of policy objectives that seek to instill deintegration and competition as part of transitions to competitive markets. Integration of physical infrastructure across international boundaries has grown rapidly with increased demand for piped methane. As transportation and information technologies have improved, so have the opportunities for system linkages—first within a country, then among geographically contiguous nation states, and increasingly across the globe. With improved physical and commercial linkages comes an ever greater need for more complex, sophisticated, and coordinated policy solutions, posing new dilemmas in international trade.

Natural gas policy across nations is most easily differentiated by how the value chain is organized and operates with respect to the balance between markets and government—that is, sovereign ownership of or control over the critical segments of the value chain. The high degree of interdependency across the value chain segments, the propensity toward integration, the fact that, in most cases, large deposits of natural gas are associated with oil (a strategic commodity for many producing nations), the energy security aspects of natural gas supply and delivery, and the public interest/public service concepts embedded in pipeline infrastructure have all resulted in a strong pattern of government ownership, control, or, in the least, intervention in natural gas enterprises and markets. In most countries, the natural gas value chain has been developed through integrated, sovereign owned, or heavily controlled enterprises. The rare exceptions are the United States, Canada, and Australia, all of which have allowed the natural gas system infrastructure to emerge through the activities of private, investor-owned companies. For the United States and Canada, this experience extends roughly 100 years; for Australia, this has been the practice since the 1960s. The United States is even more unique in that private ownership of much of the resource base is allowed; indeed, it is a powerful tradition. Federal and/or state ownership of the natural resource is limited to certain onshore lands and offshore, and even in these cases, development of sovereign-owned and controlled resources has always been through competitive acquisition of leases in organized auctions and private investment in exploration and production (a tradition also maintained in Australia,

where states and territories play a comparable role, and in Canada, which has limited private ownership of natural gas resources in southern Alberta province; the vast majority of the resource base, both onshore and offshore Canada, is controlled by the provincial crown governments). Of great interest is the transition in many countries away from sovereign ownership and/or control of integrated natural gas enterprises, as well as the push for ever more competitive markets in many locations, including Canada and the United States.

To a large extent, these transitions have been driven by specific needs for increased efficiency and to introduce innovations, to solve fundamental problems in pricing and service, and to attract investment into the natural gas value chain. As with any industry, natural gas market development requires sufficient supply availability and enough demand to justify the infrastructure systems to connect buyers and sellers. To attract this investment, governments have experimented with policies designed to stabilize the investment environment by optimizing participant choice at predictable prices that reflect, or at least attempt to mimic, actual supply and demand conditions. During the past 15 years or so, the progression toward competitive markets has meant movement toward market determination of investment, and operation of assets subject to real-time supply-and-demand interactions. Under these conditions, actionable information must be timely, accurate, and transparent. For such information to be truly actionable, the decision maker also must have timely access to whatever system capacity the information prompts that decision maker (supplier, customer, or intermediary) to demand. Finally, competitive markets must comprise systems wherein this information and capacity cannot be dominated or manipulated by a few anticompetitive participants. These conditions are difficult to create, implement, and maintain, and imply new and changing roles for market participants and government overseers.

2. EXAMPLES OF NATURAL GAS POLICY

2.1 United States

2.1.1 Overview

Natural gas exploration and production on private lands, including environmental and safety controls, are regulated at the individual state level by conservation commissions. Exploration and production on state lands are controlled by separated state agencies charged with management of those lands. Exploration and production on federal lands, onshore or offshore, are managed by federal agencies. Natural gas exploration and production, gathering, and processing are all viewed to be "workably competitive" industries and are not regulated for prices. Tariffs for transportation within state boundaries on intrastate pipelines are regulated by state public utility commissions (PUCs). The PUCs also license new intrastate pipelines. Tariffs for transportation across state boundaries in interstate pipelines are regulated by the Federal Energy Regulatory Commission (FERC). The FERC also issues licenses (certificates of public need) for new interstate pipelines. Tariffs for natural gas distribution to final customers are regulated by PUCs. The most competitive gas service in the United States is for industrial customers. The least competitive service is to residential customers.

The FERC is governed by five appointed commissioners and operates as an independent authority. Enabling legislation for the FERC dates back to the 1930s (it was created as the Federal Power Commission and charged principally with development of water and hydroelectric facilities). The FERC's authority to regulate interstate natural gas commerce is embodied in the 1938 Natural Gas Act. The individual state PUCs were established at various times, generally between the late 1800s through the 1970s. Each state has a separate enabling legislation for the formation of its PUC. Notable exceptions are the state of Nebraska, which does not regulate natural gas, and Texas, where natural gas is regulated by the Texas Railroad Commission rather than the PUC. The PUCs also vary with regard to numbers of commissioners, whether commissioners are elected or appointed, and sizes of staffs and budgets. The FERC and state PUCs are funded through fees charged to regulated industries.

The style of regulation in the United States traditionally has been "cost of service" or "rate of return," which involves a determination of revenue requirements and rate structures based on costs provided by the regulated firms. A regulated company may be a local distribution company (gas utility), an intrastate pipeline, or an interstate pipeline. The regulated company's revenue requirements are the total funds that the company may collect from ratepayers (customers). Revenue requirements are calculated by multiplying the company's rate base by an allowed rate of return (ROR) and adding this

product to the company's operating costs (OCs), as shown in the following formula:

$$\text{Revenue requirement} = (\text{rate base} \times \text{ROR}) + \text{OC} - (\text{taxes} + \text{depreciation})$$

The rate base is the total value of the company's capital investments, which may include construction work in progress. The allowed rate of return constitutes a profit sufficient to pay interest on accumulated debt and to provide a "fair" return to investors. A fair return is determined through a comparable earnings test (whereby a company's earnings are measured against those of a firm facing comparable risks), a discounted cash flow approach (whereby a company's capital costs are estimated by analyzing conditions in the financial market), or some other method. Operating costs include expenses for purchased gas, labor, management, maintenance, and advertising. The costs of taxes and depreciation are also part of a company's revenue requirements. The regulatory process can be generally described as follows:

- A regulatory commission (a PUC or the FERC) first seeks to determine how much of an applicant's capital stock should be included in the rate base, then attempts to determine which elements of test-year costs and revenues should be allowed for regulatory purposes and whether to allow specific changes since the test year. The final step is to determine what the fair rate of return is for the company.
- States and the FERC have legal rules for deciding what should be included in the rate base, although the same is not necessarily true for the method of calculating allowed rate of return.
- States may vary from each other and from the FERC according to the particular sets of rules that are used (for example, to calculate rate base) and the impact of these rules on rate case decisions. However, over the course of the long history of natural gas regulation in the United States, the states and the FERC have generally shared practices fairly quickly.
- All regulators are constrained in their abilities to calculate cost of capital. This is due in part to general disagreement within the industry of how market cost of capital should be computed, and in part because commissions are not well equipped to deal with the complexities surrounding these issues. As a result, a critical component of a rate case proceeding is a commission's reliance on historical information, or precedent, as well as the testimony of interveners, parties with specific interests in the outcome of rate cases (principally large customers and consumer advocates representing small business and residential users; competing regulated firms may also intervene).
- All U.S. regulatory commissions hear rate cases, issue blanket rulings that set broad policy parameters, and act as judges and adjudicators on disputes.

With the implementation of unbundling (separation of pipeline transportation from natural gas sales, with nondiscriminatory open access or third-party access) in 1992, the FERC and many of the states now encourage market-based rates for transportation service. With respect to distribution, many states are experimenting with "incentive-based" regulation designed to encourage more efficient operation and capital cost decisions than has historically been achieved with cost-of-service regulation.

2.1.2 History

When comparing the United States to other countries, an important difference is that the U.S. natural gas system has always been characterized by the participation of private companies, with regulation as a substitute for competition to moderate private monopoly market power. For the most part, regulation has been directed toward pipeline transportation and local distribution. However, during periods of U.S. history, cost-of-service-style regulation was also applied to natural gas production at the wellhead with disastrous results. Table I illustrates the complex progression of regulatory policy eras in the United States.

In the early days of the U.S. natural gas industry, the construction and operation of natural gas distribution systems tended to be concentrated around local deposits of natural gas. Cities and towns that were near the early discoveries of natural gas in the late 1800s were often the centers of intense competitive activity as companies struggled to build competing systems. Because all of the early natural gas companies were private and because the intense competition reduced the returns to shareholders, state-level regulation of local distribution companies (LDCs) through public utility commissions evolved. The strategy was to stabilize investment returns to shareholders while attempting to mimic most of the benefits of competition to customers through regulation (competition by substitution, as it is often called). The form of regulation typically used was "cost of service," in which regulators granted a rate of return that was deemed to be reasonable to the LDCs. In exchange for a limited return, the LDCs enjoyed a monopoly franchise for service in a city or

TABLE I

Natural Gas Industry Regulation/Deregulation in the United States

Policy history	Impact
Competitive local distribution company industry	Emergence of natural gas industry as local distribution companies were established to provide town gas and later natural gas service
State public utility commissions, 1885–1927	Formation of Massachusetts Gas Commission in 1885 through regulation of intrastate pipelines (in all 48 states by 1927); followed the Supreme Court ruling (*Munn v. Illinois,* 1877) that established the basis for regulating monopolies (grain elevators and warehouses) as public utilities
Development of interstate transportation, 1930s	Technological advances (mechanized trenching and arc welding) allowed construction of long-distance pipelines to transport natural gas from large producing fields in the southwestern United States to key market in the Northeast and upper Midwest
Federal regulation of interstate transportation (Public Utility Holding Company Act and Federal Power Act of 1935; Natural Gas Act of 1938)	Interstate Commerce Act of 1887 provided the basis for federal intervention. A U.S. Supreme Court decision in 1934 (*Nebbia v. New York*, dealing with milk prices) expanded the basis for public utility regulation. Disputes centered on pricing natural gas in cross-state sales activities and market power of interstate public utility holding companies. The Federal Power Act established and authorized the Federal Power Commission; the natural gas industry was thus comprehensively regulated, from the burner tip, to intrastate transmission, to interstate transmission, by state and federal jurisdictions
Federal regulation of wellhead prices (U.S. Supreme Court *Phillips* Decision, 1954)	Dispute regarding pricing of natural gas produced in Oklahoma for delivery in Michigan led to cost-of-service regulation at the wellhead, with the FPC as agency with authority
Beginning of wellhead price decontrol (Natural Gas Policy Act, 1978; Public Utility Regulatory Policy Act of 1978; Powerplant and Industrial Fuel Use Act of 1978)	The FPC's inability to deal with the scope of wellhead regulation and provide sufficient adjustment to increase price ceilings and encourage production, as well as disparity in pricing natural gas sold in interstate markets, with gas sold in unregulated intrastate markets, and resulting curtailments, all led to decontrol. The Natural Gas Policy Act of 1978 extended wellhead price ceilings to the intrastate market, introducing the process of deregulation by loosening certification requirements to facilitate gas flows
First stage of open access for interstate pipelines (FERC Orders 436 and 500, 1985)	"Phased decontrol," with surplus conditions created by the Natural Gas Policy Act; the need for flexible pricing and transportation led to "special marketing programs" that released gas from long-term contracts into price-discounted supply pools. FERC Order 436 in 1985 created the open-access era and Order 500 provided some resolution for take-or-pay liabilities
Final restructuring rule for interstate pipelines (FERC Order 636, 1992)	FERC Order 636 continues separation of merchant and transportation functions of interstate pipelines
Regulation of interstate transportation and related services (FERC Order 627, 1999)	In Order 637, the FERC moved to improve competitive markets, mainly targeting capacity and operations for captive customers and to deal with pipeline affiliate issues

town but also had the obligation to serve all customers within that franchise.

The discovery of huge natural gas deposits in Texas and Oklahoma fundamentally changed the U.S. natural gas industries. Companies began to build long-distance pipelines to carry natural gas from the southwestern United States to the Northeast and Midwest, where gas was needed for winter heating. Almost immediately, disputes arose among individual states with regard regulatory jurisdiction over interstate sales of natural gas. By 1938, the U.S. government was prepared to step into the conflict. Passage of the Natural Gas Act (NGA) that year gave the Federal Power Commission (FPC) regulatory

authority over interstate natural gas commerce. This action was consistent with the philosophy of the times. Following the Great Depression, there was considerable mistrust of large businesses and greater faith in the ability of government to intervene and solve problems.

The NGA treated the interstate pipelines as natural monopolies. (It should be noted, however, that in debating the NGA, the U.S. Congress deliberated on contract carriage as an alternative approach.) The economics of early pipeline construction and operation and conditions in the early natural gas markets were considered to be such that it was unlikely for many companies to build competing facilities. As a result, the pipelines acted as "merchants," contracting with natural gas producers for supply and also with local distribution companies for deliveries. Disputes related to the price of natural gas in the interstate market did not end, however, and the federal government intervened again, this time through the Supreme Court. In the landmark *Phillips* decision in 1954, the Court concluded that the FPC should also have regulatory authority over the price of natural gas at the wellhead. By this time, thousands of natural gas wells had been drilled in Texas, Oklahoma, Louisiana, and other states, including the beginnings of the U.S. offshore industry. The task faced by the FPC was daunting, and the ability of federal regulators to perform efficiently was limited. Distortions began to show up immediately, most importantly in the difference between prices for natural gas in the regulated interstate market and prices in the unregulated intrastate market (meaning gas produced and sold within the boundaries of individual states). Demand for natural gas had grown and prices were rising in the intrastate market. As a consequence, producers shifted their strategies so as to sell more gas in that market. By the time of the oil embargoes and supply shocks in the early 1970s, insufficient amounts of natural gas were committed to the interstate market. During the severe winter in 1976, shortages and curtailments of natural gas supplies occurred all over the eastern United States. To make matters worse, because the interstate pipelines controlled all transactions, there was no way for natural gas producers to engage in sales directly with customers.

Broad dissatisfaction with how the natural gas sector was managed led to an unwinding of federal regulatory control. By the 1970s, public opinion regarding government management of economic activity, including energy, had begun to erode. The preference for market-based solutions was increasing. Already the United States was engaged in major transformations to reduce government intervention in other sectors, such as airline transportation, telecommunications, and banking. The first step was to remove regulatory control of natural gas at the wellhead, with the Natural Gas Policy Act (NGPA) of 1978, which also transformed the FPC into the Federal Energy Regulatory Commission. The strategy chosen by the U.S. government was flawed, with a tremendously complicated schedule for decontrol of natural gas from different formations, by year of discovery (vintage), and so on. The U.S. Congress created more than 200 different categories of natural gas. Overall, natural gas prices rose rapidly in response to demand. After a period of time, higher natural gas prices caused demand to fall as customers, especially large industrial users, shifted to cheaper fuels. Demand adjustments were further complicated by two additional laws that had been passed to deal with 1970s energy crises, the Public Utility Regulatory Policy Act (PURPA) and the Powerplant and Industrial Fuel Use Act (PIFUA), which, together with the NGPA, encompassed the National Energy Act. PURPA encouraged experimentation with "cogeneration" of electricity using natural gas at industrial facilities, which sold their electric power to electric utilities at a price that (presumably) reflected the costs utilities would avoid by not building new electricity generation capacity themselves. PIFUA, however, prohibited natural gas use in most industrial applications and by the electric utilities. The resulting confusion and fluctuations in prices created havoc on both sides of the interstate pipeline merchant contracts. Both pipelines and producers were left holding contracts with take-or-pay obligations that led to severe financial strain for many companies. Because interstate pipelines still acted as merchants, bottlenecks existed all over the natural gas system, preventing efficient transactions from taking place.

In 1983, the FERC began to put into place the policies that have led to the restructured natural gas market that we see in the United States today. Through a series of actions, the FERC began to dismantle the interstate pipeline merchant function. Pipelines came to be treated as common carriers, conduits through which any seller or buyer could ship gas. Natural gas came to be treated as a commodity, whereas previously oil companies had treated natural gas as a by-product with no intrinsic value. Pipeline construction technology had changed dramatically over the years, and many parts of the

United States were served by more than one interstate pipeline, reducing the natural monopoly advantage. The advent of sophisticated computer information systems allowed real-time trading of natural gas, and financial instruments (futures contracts and other mechanisms) enabled suppliers and customers to manage commodity price risk. Although conditions today are vastly different—natural gas in recent years has enjoyed a growing share of the U.S. energy mix, albeit with great price elasticity for certain kinds of demand—there is no doubt that policies in the past constrained market growth of the industry. Indeed, the position that Canada enjoys as a major exporter of natural gas to the United States (approximately 15% of U.S. consumption) is a direct outcome of the 1976 shortages.

2.1.3 Issues

Several issues remain following restructuring to restore and enhance competition in the U.S. gas system.

2.1.3.1 Market Disruptions The FERC's actions to implement open access on U.S. interstate pipelines created a "wholesale market" for natural gas, with competitive pricing, trading, and marketing activities; price risk management (the New York Mercantile Exchange established a natural gas futures contract in 1993); market mechanisms to facilitate trading of unused pipeline capacity; and a national standards board (the Gas Industry Standards Board) to facilitate commercial activity. Beginning in 2000, surging prices for natural gas and electric generation constraints as a result of extended drought in the Pacific Northwest resulted in collapse of the electric power market in California. Disparities in natural gas prices between the California internal market and other U.S. locations and related improprieties in natural gas trading, along with the bankruptcy of Enron Corporation, led to a general collapse in the "energy merchant" segment, including credit downgrades, additional bankruptcies, and severe losses in market capitalization. Energy merchant businesses deal in unregulated wholesale market activities, including construction and operation of competitive, unregulated infrastructure assets. Many energy merchants were affiliated with regulated natural gas interstate pipelines and utilities. Continued conflict around issues that emerged during these events heavily impacted natural gas markets in the United States and Canada. A subsequent natural gas spike in 2003, with ancillary concerns regarding natural gas field production trends and disputes regarding how natural gas price information is compiled and communicated in the marketplace, continue to retard further policy, regulatory, and commercial activity.

2.1.3.2 Lack of Competitive Service Lack of competitive service to small residential and commercial customers occurs at the end of distribution systems. Unbundling and open access to facilitate deliveries of competitive supply for smaller customers have not materialized as expected following FERC's restructuring rule. These initiatives generally are in the domain of state jurisdictions, but federal/state coordination, always an issue, is required in some instances.

2.1.3.3 Barriers to Entry of New Pipelines The certification process, already deemed to be too onerous given competitive market conditions, has been further complicated by the market disruptions of the 2000s and lack of financial capital available from distressed energy merchant businesses and parent pipeline companies.

2.1.3.4 Uncertainty with Regard to Electric Power Restructuring Following early success with natural gas, some states (notably California in 1994) and the FERC (through Orders 888 and 889), and with encouragement through the Energy Policy Act (EPAct) of 1992, proceeded to experiment with similar unbundling and open-access approaches for electricity grids. The 1992 EPAct supported creation of a bulk, wholesale market for electric power. The electric power market collapse in California and natural gas market disruptions have stymied further initiatives by the FERC for a segment of the energy sector that is considered to be crucial to growth of the natural gas industry.

2.2 Canada

The Canadian natural gas system parallels that of the United States, with an important exception. All natural gas resources in Canada are controlled by the provincial crown governments. Exploration and production activities are carried out by private, competing firms under the rules and regulations established by provincial energy ministries. This contrasts with the United States, where roughly two-thirds of natural gas resources and production are in the private domain (held either by companies or individuals).

Like the United States, Canada's transportation and distribution systems are owned and operated by private (investor-owned) companies regulated to

control for any monopoly power. Regulation of long-distance, interprovincial pipelines is carried out by the National Energy Board (NEB), which receives its authorization from the federal National Energy Board Act. The NEB, like the FERC, licenses new pipelines, sets tariffs for transportation, adjudicates disputes, and sets broad policy parameters with blanket rulings. Intraprovincial pipelines and local distribution systems are regulated by provincial energy utilities boards (EUBs). Each province has enabling legislation for its EUB. As with the state PUCs and the FERC in the United States, the EUBs and the NEB use similar methods for regulating their client industries, and are funded by these industries. The NEB and EUBs have also, traditionally, used cost-of-service ratemaking like the U.S. commissions do. Canada is a significant exporter of gas to the United States, supplying about 17% of U.S. (the lower 48 states) current demand. The NEB licenses and regulates all natural gas export activity from Canada.

Canada began to restructure its natural gas system ahead of the United States in the early 1970s with the Western Accord, which eliminated control of the natural gas supply by Canada's monopoly interprovincial pipeline, TransCanada. The Agreement on Natural Gas Markets and Prices in the 1980s was a statement in principle of support for a market-based natural gas system. The Open Access Order in 1986 unbundled the Canadian system and allowed contract carriage on Canada's pipelines. Since these steps were taken, the NEB has consistently encouraged market-based rates for transportation.

At the provincial level, EUBs followed the NEB with open access and market-based tariffs. Nearly every local distribution system in Canada offers some form of competitive supply to its core customers (residential and small commercial), with LDCs in Ontario moving toward full open-access systems for core customer service.

2.3 Britain

Like the United States and Canada, Britain's national gas grid evolved to transport "town gas" manufactured from coal by the state-owned British Gas (BG). However, unlike its North American counterparts, Britain's grid was not converted to natural gas until the 1960s. As the first gas came ashore from West Sole field in the North Sea in 1967, British Gas began the process of transforming its business. By comparison, discovery of natural gas in the United States at the turn of the 20th century, first in the Appalachians and later in the Southwest (Texas and Oklahoma), had already launched the U.S. natural gas industry. Britain has moved much more quickly than the United States to allow competition to residential and small commercial customers.

Restructuring of the British natural gas sector involved a series of steps:

1. Passage of the Oil and Gas (Enterprises) Act of 1982, which laid out the process for privatization.
2. Privatization of British Gas with the Gas Act of 1986 and creation of The Office of Gas (Ofgas) as regulator.
3. Initiation of competition in the contract market (large industrial and electric utility users who use more than 2500 therms/year) in 1989.
4. Accelerated competition in the contract market, with government targets and issuance of licenses to qualified customers taking more than 2500 therms/year at a single site in 1992.
5. Creation of the gas cost index in 1992 to limit cost passthroughs by British Gas to domestic customers who use 2500 therms/year or less.
6. Passage of the Competition and Service (Utilities) Act in 1992, which included natural gas service standards.
7. Passage of the Gas Act of 1995, which laid out targets for full competition in the domestic sector by 1998.
8. Creation of the Network Code in 1996 to ensure smooth operation of the liberalized United Kingdom gas industry.

The Oil and Gas (Enterprises) Act was passed in the year 1982 to set out the aims and objectives of the privatization of British Gas. The main issue was to break down the monopoly British Gas had in the gas supply market, so enabling the introduction of competition in gas supply. The year 1986 saw the implementation of the Gas Act, which brought about fundamental changes necessary for the privatization program to go ahead. First, Ofgas, the Office of Gas Supply, was established as the regulatory body over the gas industry. Its role is to monitor the privatization of the gas industry and to ensure customers' rights are recognized in every aspect. Second, British Gas was reorganized into a public limited company (Plc) as a monopolist with secure markets only for the medium term. BG Plc shares were released onto the stock market.

The mechanism for competition within the gas market had been implemented, with major new private sector companies created. Some were established by oil companies active in the North Sea;

others are ventures by the electricity companies and some are truly independent. The Gas Act emphasized the need for vigorous competition among the new independent suppliers with the objective of undercutting British Gas prices. The goal was to introduce competition in stages, with the industrial sector first, followed by commercial and then residential users.

2.3.1 Development of the Nonfranchise Market

In 1989, the first competition for large contract customers in industry and power generation appeared. The gas supply market did not really open up until 1992, when gas consumers buying over 2500 therms/year (million Btu, or mmBtu, per year) at a single site qualified to convert to independent suppliers of gas. The government's target was to have 60% of the contract market open to competition. By 1993, independents claimed about a 50% share of the contract market. In 1995, Ofgas reported that British Gas held a roughly 27% share. The complete breakdown of British Gas' supply monopoly occurred 1998, when every consumer of gas, including approximately 19 million domestic users, was given the option to choose their own supplier. Legislation approved in 1995 (the Gas Act of 1995) allowed liberalization of the residential market to begin in 1996.

Competition in the domestic gas supply market was introduced in stages. Under an amended Gas Act 1995, Ofgas became responsible for securing competition in gas supply to domestic customers, and issued licenses to competing companies for the transportation, shipping, and supply of gas. The Ofgas Technical Directorate enforced regulations on the quality and calorific value of gas, approved and stamped gas meters, and tested disputed meters. It also provided advice on a wide range of other technical issues. The principal job was to ensure British Gas did not take unfair advantage of its monopoly powers. This was done by limiting the prices the company could charge and setting standards for customer services. Two price controls were used (modifications have been made since restructuring was initiated). The first was a transportation and storage price control, which capped the prices TransCo, which is part of BG Plc and is the public gas transporter and operator of the pipeline system, can charge British Gas Trading and other users for transporting gas in its pipelines and storing gas. The pipeline system is operated on a contract carriage basis (suppliers arrange for transportation from beach to final customer), but with the recognition that pipeline transportation is monopolistic. The second control involved a supply price control that limited the prices British Gas Trading, now part of Centrica, could charge domestic consumers.

With the initiation of privatization in 1992, a gas cost index was used as part of the regulatory formula that limited BG's allowable revenue for the 18 million customers who use 2500 therms or less of gas per year. Ofgas introduced the index after reviewing the price control set by the government when BG was privatized in 1986. This had allowed BG to pass through to domestic customers the average actual cost of buying gas for all customers, which is about 40% of the total allowed price of gas. With introduction of the index, this part of the allowed price became based on the level of the index and was no longer linked to actual gas costs. In addition to price and service regulation, Ofgas oversaw conformance with the Network Code, established in 1996, which sets out the rights and responsibilities for TransCo and all gas shippers using the existing grid for transportation and storage. Under the code, shippers are liable for any imbalances in their daily shipments. With the network code fully operational by 1998, tariff formulas for gas suppliers will no longer apply. Gas prices will be left to market forces, including those charged to Britain's 18 million small commercial and residential customers.

2.3.2 Implementation of Domestic Competition

Key to final implementation in 1998 of domestic competition was the 1997 price control review for BG's domestic supply business. Proposals developed by Ofgas in the summer of 1996 allowed the average domestic customer to realize a reduction in gas bills, with continuing real price reductions for the following 2 years. In addition, TransCo put forth proposals for transportation/distribution tariffs. The main proposals were (1) a 3-year price control period, (2) continuation of the retail price index, (RPI) $-X$, price control on supply costs, with X set at 5% (currently 4%), (3) direct passthrough to customers of British Gas' gas purchase costs and transportation costs, (4) service standards to remain as now, but with increased compensation payments when specified standards are not met, and (5) scope for British Gas to make a profit margin of 1.5% on turnover built into prices to allow a reasonable return to shareholders, as British Gas faces the introduction of competition into the domestic market. The price of gas was made up of three components: the cost of purchasing gas from producers, the costs of transportation, and supply costs. The proposals focused on six areas in particular: the treatment of gas costs,

transportation charges, BG's operating costs in its domestic supply business, BG's profit margin, the structure of the price control, and the duration of the price control.

2.3.3 Issues

A number of primary issues were associated with Britain's gas restructuring. Take-or-pay (TOP) contract resolution was essential. As with U.S. and Canadian companies before restructuring, BG held contracts with North Sea gas producers for supply. With falling gas prices, as a consequence of competition, BG and its suppliers faced a situation in which the value of gas in the contract was higher than it was in the marketplace, rendering the contract unsustainable; new competitors in the United Kingdom market were able to contract for the cheapest gas supplies, thus renegotiation of the TOP contracts was necessary for implementation of restructuring, but the issues over reapportioning costs became politically difficult.

Setting the value of "*X*" in the price cap formula was difficult. Determination of this value relative to performance of gas companies is not simple, although it is less conflictual compared to establishment of the allowed rate base for rate of return (or cost of service) regulation traditionally used in the United States and Canada. Two other issues involved the low margins to gas suppliers and the slow implementation of domestic competition. With the onset of competition and falling gas prices, suppliers in the United Kingdom faced low and diminishing profit margins in their businesses. As in the U.S. and Canada, fear and uncertainty about reliability of gas service and the ultimate cost of service, particularly to residential customers, has delayed full implementation of domestic competition.

There was also the issue of coordination with other European initiatives. Britain leads Europe in creating a competitive natural gas market. In 1997, the European Union Council established a directive allowing large customers (above 25,000 cubic meters) to select from competitive suppliers with a target of the year 2000 for implementation by member states. Initially, each member state is to grant third-party access (TPA) to 20% of the market (reducing the customer threshold if necessary), with TPA reaching 28% after 5 years and 33% in 10 years. States have moved very slowing with this directive, with few countries establishing independent regulators or forcing incumbent monopolies to respond in spite of court actions.

TABLE II

Natural Gas Policy in Latin America

Country	Private participation in exploration and production	Private participation in pipelines	Independent regulator
Mexico	No	Yes	Yes
Colombia	Yes	Yes	Yes
Venezuela	Yes	No (pending)	No (pending)
Brazil	Yes	Yes	Yes
Bolivia	Yes	Yes	Yes
Peru	Yes	Yes	Yes

2.4 Latin American Experience

The Latin American experience with natural gas policy is summarized in Table II. During the past decade or so, experimentation in the region was active in tandem with other economic and political reforms. The disintegration of Argentina's economy and uncertainty surrounding other country regimes, as well as dissatisfaction with results of market reforms, have, as of this writing, posed a number of stumbling blocks to continued development. The region is rich in natural gas resources, but much of this supply is "stranded" as a result of inadequate domestic markets and the expense of exporting natural gas in the form of LNG (Trinidad and Tobago being a notable exception). With respect to exploration and production, Latin American countries have been characterized by the presence of sovereign, state-owned oil companies, such that privatization was an initial requirement in many cases (Mexico is unique in not pursuing this step). Argentina and Mexico represent distinct cases that reflect the range of issues in the region.

2.4.1 Argentina

Until its recent financial and economic travails, Argentina had made great strides to build a competitive market for natural gas. Most of that country's initiatives have survived the depression of the past few years, but market participants have suffered throughout the period of energy economic malaise.

In the late 1980s, the government of Argentina began to privatize state-owned energy companies as part of an economic reform drive to combat hyperinflation and a chronically underperforming domestic economy. These efforts included the

privatizations of Gas del Estado, which controlled the Argentine natural gas transportation and distribution grids, and Yacimientos Petroliferos Fiscales-Argentina (YPF-A), the national oil and gas company. Argentina now has two main transportation companies, Transportadora del Gas Norte (TGN) and Transportadora del Gas Sur (TGS), both owned and operated by consortia of Argentine, U.S., Canadian, and European companies. Eight investor-owned distribution systems are now in operation, also with combinations of Argentine and foreign direct investment. The transportation system and portions of the distribution systems operate under open-access conditions following the Canadian and U.S. systems. As in Canada and the U.S., physical, economic bypass is allowed.

The regulatory framework in Argentina is provided by Ente Nacional Regulador del Gas (ENARGAS), an independent national commission. ENARGAS maintains several objectives:

1. To protect consumers' rights.
2. To promote competition.
3. To guarantee long-term investment.
4. To regulate distribution and transport services.
5. To guarantee fair and nondiscriminatory tariffs.

For tariff regulation, ENARGAS uses a variation of the British RPI$-X$ methodology and incentive mechanisms to reward performance by the private operators. Prices to final customers are unbundled and the passthrough method is used to guarantee price transparency. The formula is specified as follows:

$$\text{Total price} = \text{gas price} + \text{transportation price} + \text{distribution margin}$$

Subsidized tariffs are allowed for certain customers but must be justified to the Presupuesto Nacional, the federal budget authority. No dumping of gas is permitted. Tariffs vary with distance and type of contract (firm or interruptible) as in the United States, Canada, and Britain. It is possible to adjust distribution tariffs as often as every 6 months in correlation with the U.S. price index and productivity factors. (Because the Argentine dollar was pegged to the U.S. dollar as an antiinflation strategy, U.S. price movements are used in a variety of Argentine economic sectors.) It is also possible to adjust distribution tariffs seasonally. The overall tariff structure is revised every 15 years.

ENARGAS has several roles (regulator, enforcer, judge) and functions principally to advise users; publish information on the industry's evolution and maintain a comprehensive library; approve transportation and distribution tariffs; authorize the building and expansion of the transportation and distribution networks; foster open access and nondiscriminatory treatment; normalize security and gas quality, measurement, and odorization processes; establish the rules for new permits; implement sanctions; perform regular inspections of sites; require periodical informs to the companies that participate in the industry; guarantee competitive business practices; and resolve controversies between companies and third interested parties through public consultations. The commission resolves disputes using public consultations and general resolutions. This counters the style of U.S. and Canadian commissions, which use open hearings and technical conferences to allow input into decision making and for dispute settlement. ENARGAS, an independent regulatory commission with no influence from Argentina's energy ministry, has three appointed commissioners. The commission uses both internal and external auditors to monitor its activities and reports to the national executive branch of the Argentine government.

Argentina's model is closest to the U.S. upstream regime. The potential exists in Argentina for a healthy gas (and power) commodity market with trading and marketing activities used by producers, marketers, and large customers (including local distributors) to hedge against natural gas price volatility. Yet, today YPF still controls around 65% of marketed natural gas production and about 75% of gas produced in fields. Thus, even the privatized YPF remains extremely powerful.

2.4.2 Mexico

Mexico has pursued a strategy of reserving upstream petroleum and gas exploration to Petroleos Mexicanos (Pemex), the national oil company. During the early days of Mexico's industry, oil and gas exploration was carried out by private foreign and Mexican companies. Disputes between the Mexican government and foreign operators, and political imperatives following Mexico's revolution, resulted in the 1938 nationalization of Mexico's oil industry. Article 27 of the regulatory law to Mexico's constitution stipulates that Pemex has sole control of the production of oil and gas and the products derived from the raw resources.

During the 1970s, hydrocarbon production did not keep pace with economic modernization, so that by 1973 Mexico found itself to be a net importer of crude oil. Critical discoveries restored Mexico's

stature as an oil producer and exporter. Investment in upstream activities continued until the early 1980s, when Mexico's external debt crisis, exacerbated by falling world crude prices, triggered a contraction in government spending. The collapse of crude prices in 1986 impacted upstream activity even more. Spending by Pemex on exploration and production dropped from its peak of approximately 86% of Pemex's total budget in 1982 to less than 60% in 1988. Historically, crude oil has been given priority because of its export potential and value. However, two factors contributed to an effort to increase natural gas production. One, in the late 1970s, was the desire to increase gas sales to the United States, which led to construction of the Cactus–Reynosa pipeline as a result of negotiations between Pemex and Border Gas, a consortium of U.S. companies. The 2-billion cubic feet (bcf)/day project was never realized because of disputes about pricing. The second factor was concern about inefficient utilization of energy. Energy use was, and is, highest in the energy sector. Expenditures were made to gather and transmit gas, especially from the huge Bay of Campeche fields, and to reduce wasteful gas flaring, which declined from 26% of production in 1970 to less than 3% by 1989. Domestic consumption of natural gas continued to grow in the 1980s, but with relatively little new investment in natural gas production and transmission made by Pemex. The result is Mexico's current situation of inadequate domestic production capacity to satisfy natural gas demand.

In the 1980s, in response to the critical economic situation Mexico faced after the oil market crash and currency devaluations, the Mexican government began to implement market reforms. Public opinion and political will for privatizing Pemex have historically been weak, but a series of major accidents, chronic shortages, and unreliable service forced the managers at Pemex to take action. The government gradually removed the obligations on Pemex to provide everything from roads to hospitals and schools as part of its social obligations to the state. Pemex began to reduce its huge employment from more than 250,000 to just over 133,000 today. In 1992, Pemex was reorganized into four functional subsidiaries for exploration and production, refining, natural gas and basic petrochemicals, and secondary petrochemicals. The government also changed Pemex's tax status by creating a corporate tax rather than controlling all of Pemex's revenues and returning some portion to the company for reinvestment. The corporate tax rate for Pemex remains high (more than 60%) and Pemex still does not have independence with respect to its budget planning.

In 1995, further, more dramatic steps were taken to reform Mexico's energy sector. The regulatory law to the constitution was changed to allow private investment in natural gas transportation, distribution, and storage, in recognition of the importance of this fuel to Mexico's economic development. A regulatory commission has been created (the Comisión Reguladora de Energía, or CRE), charged with the privatization of assets formerly controlled by Pemex. Rules have been established for pipeline tariffs and first-hand sales of imported gas from the United States (although Pemex is expected, at some point, to resume its bid to be a net exporter of gas). The CRE handles all auctions for state-owned assets (portions of the Pemex pipeline grid and local distribution networks) that are to be turned over to private operators, and uses a price cap formula similar to the Ofgas RPI$-X$ to regulate tariffs. The CRE has five appointed commissioners. A law passed by the Mexican Congress in 1995 established the CRE as an independent entity, but Mexico's energy ministry retains a great deal of influence. Like ENARGAS, the CRE handles conflicts and disputes with operators through private consultations rather than through the public meetings typical in the United States and Canada.

In spite of all of these reforms, deep problems exist in Mexico's oil and gas sector. Pemex has watched its market share of exported oil erode as other countries moved aggressively to lure private investment into their upstream businesses. The investment demands on Pemex for improvement and expansion projects are huge. Although the company has had some success with foreign placements of debt, many questions remain about Pemex's ability to finance capital improvements. Finally, although the effort to attract private investment into Mexico's natural gas pipeline and distribution segments continues, Pemex remains the sole supplier of natural gas, which will restrict growth of Mexico's natural gas market.

Glossary

acid gas The acidic constituents of natural gas, H_2S, CO_2, mercaptans (RSH), CS_2, and COS.

dew point The temperature and pressure at which a gas mixture begins condensing to form a liquid phase; for a fixed composition, the point is reached by lowering the temperature or increasing the pressure except when the mixture exhibits retrograde condensation.

ethane, propane, butanes, liquefied petroleum gas (LPG), and natural gasoline Natural gas liquid products for which there are various purity grades; they are defined by a combination of maximum and minimum compositions, vapor pressures, and boiling points.

gas conditioning The process of removal of contaminants, usually acid gases, nitrogen, and water, from natural gas.

gas dehydration The process of removal of water from natural gas to achieve a low dew point that will avoid condensation of water during further processing, transportation, and use.

gas sweetening/treating The process of removal of acid gas components from natural gas.

gas to liquids (GTL) Processes for the chemical conversion of methane to other chemicals and fuels that are predominantly liquids; most frequently refers to Fisher–Tropsch-type processes that preferably produce hydrocarbons from C_5 to C_{30}.

liquefied petroleum gas (LPG) A natural gas liquid product composed primarily of a mixture of propane and butanes.

natural gas liquids (NGL) The higher hydrocarbons separated from natural gas that are usually produced and stored as liquids under pressure at ambient temperature.

natural gasoline A natural gas liquid product that consists primarily of pentanes and higher alkane hydrocarbons (C_5^+); it is a liquid at ambient temperature and atmospheric pressure and has a low octane number.

retrograde condensation The phenomenon where a hydrocarbon gas mixture of a particular composition will pass through the dew point and begin condensation of a liquid phase when the pressure is lowered.

sour gas Natural gas that has at least a small percentage of acid gases, specifically sulfur-containing components.

Gas processing is the preparation of raw natural gas as it is produced from the reservoir for transportation to markets for utilization. Traditionally, this has been primarily the removal of chemical constituents that are not desired due to safety reasons (e.g., H_2S, Hg), operability (e.g., water due to condensation and corrosion), and/or economics (e.g., CO_2 that lowers the heating value or those components that may be profitably separated and marketed as a separate product, natural gas liquids, C_2 to C_5^+ hydrocarbons). The final product for this has been compressed gas that is fed into pipeline networks. Increasingly, the processing required to transport the gas to markets for end use has included the production of liquefied natural gas by complex refrigeration processes as well as the chemical transformation of the methane into solid or liquid chemicals and fuels that are commonly produced from natural gas, are much more easily transported than the gas itself, and satisfy significant markets for the products. The most commonly produced are ammonia and its derivative fertilizers and methanol, but there is strong promise for production of liquid hydrocarbon fuels on much larger scales to satisfy increasing demand, especially for cleaner fuels.

1. REQUIREMENTS FOR GAS PROCESSING

Feed gas to a processing plant can have extremely large variations in composition from one location to another. Produced gas, subject to removal of liquids and solids with separators only at the field locations, is frequently saturated with water due to intimate contact between gas and water in the reservoir formation. Gas associated with oil production may be saturated with hydrocarbons from ethane to C_{10}^{+}. In both cases, the amounts will vary with the pressure and temperature of the gas. In the case of water, this is commonly a proportion up to several percentage points. For hydrocarbons, this can be well above 10%. For the acid gases, primarily CO_2 and H_2S but including other sulfur-containing species such as mercaptans (RSH) and COS, reservoirs in which the majority of the gas volume is comprised of these species is possible. At some point, the high percentage of these contaminants will make the gas uneconomical for recovery, but dealing with several percentage points H_2S and CO_2 above 10% is common. The other contaminant commonly found in gas at these percentage levels and higher is nitrogen (and rarely helium). Lower levels of contaminants that must be removed are possible but less common, with mercury being one example (generally removed using solid adsorbents).

The requirements of gas processing are to remove the contaminants mentioned previously to appropriate levels. These levels are specified by contract and determined by the market for which the gas is destined as well as for safety and operability considerations. Typical "pipeline quality" gas specifications are discussed here.

Water must be removed to levels that will ensure that no condensation of the water will occur in any of the subsequent operations or distribution of the gas. This is both to minimize corrosion and to prevent damage to equipment due to two-phase flow where liquid water droplets can damage machines that compress or expand the gas and cause erosion by impingement on surfaces at high velocities. Dehydration also prevents the formation of methane hydrates, solid crystalline complexes of methane with water molecules, that can plug flow lines as well as damage equipment. To avoid condensation, a dew point for the gas is selected based on a specified temperature and pressure. This represents the combination of the minimum temperature and the maximum pressure to which the gas may be expected to be subjected, and at those conditions where no water will condense (e.g., 0°C and 6.7 MPa). Typical values of allowable water content at such conditions are in the range 50 to 110 mg/m^3 and vary by location due to climate and other factors.

For sulfur content, specifications for H_2S, mercaptans, and total sulfur are common, with H_2S and mercaptans each having limits in the range of 6 to 24 mg/m^3 and total sulfur having limits from 115 to 460 mg/m^3. These limits, although needed in part due to corrosiveness of the sulfur compounds, are due in significant part to their noxious and toxic properties.

Specifications for CO_2 and nitrogen are primarily set due to the fact that they are inert and have no heating value and, therefore, reduce the heating value of the product gas. There are typically limits of a few percentage points on each, but their amounts are also indirectly constrained by a heating value specification of the product gas.

The specifications for hydrocarbons are somewhat more complex. For methane, there is some minimum specification (e.g., 75%). For higher hydrocarbons, there may be individual maximum limits (e.g., 10% ethane, 5% propane, 2% butanes). These limits are based on ensuring against condensation, in the same fashion as for water but also for the combustion processes for which most pipeline gas is used. The presence of higher hydrocarbons changes the required air/fuel ratio for combustion and, when outside of design limits, can cause incomplete combustion with additional pollution and higher or lower temperatures, among other operational problems. From the standpoint of the gas processor, there are frequently economic incentives to recover the higher hydrocarbons from the gas. When present in sufficient quantities, the value of the hydrocarbons can exceed the cost of their recovery. Typical products of value include ethane, propane, butanes, and natural gasoline. These are collectively called natural gas liquids and, as mentioned previously, are frequently present in near saturation conditions (at their dew points) in gas associated with oil production. Each of these products has its own specifications that put minimum and maximum limits on the hydrocarbon constituents and may include heating value and boiling point ranges.

For liquefied natural gas (LNG), the product gas will have specifications with considerably lower contaminant levels to avoid contaminants that could condense or freeze at the very low temperatures involved in production of LNG (−161°C). For gas to chemicals and fuels processes, the feed gas may have similar specifications to pipeline gas except that sulfur (and possibly other trace contaminants) will be

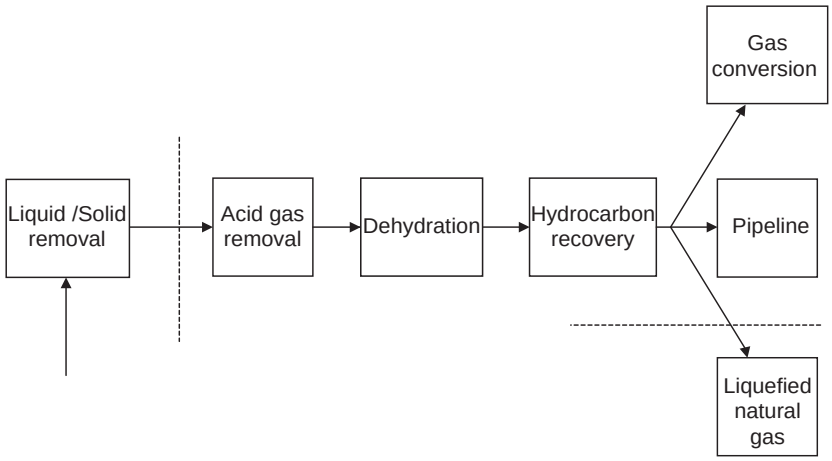

FIGURE 1 Block diagram of major gas-producing units.

further restricted due to its ability to deactivate catalysts used for the conversion reactions.

Figure 1 illustrates a block diagram of the processing units that may be found in a gas processing plant. The presence, order, and relative size of the process units will be dependent on the composition of the feed, the gas product specifications, and the specific processes selected for each unit. Gas conversion plants are considered separately given that these processes are a follow-on to the type of plant shown in Fig. 1.

2. GAS DEHYDRATION

Gas dehydration is accomplished by means of one of two primary processes (or occasionally both). Absorption of water vapor from the gas into a hygroscopic liquid is the predominant method, but adsorption of water onto solid desiccants is also used, particularly for achieving very low dew points.

The hygroscopic liquid is most frequently triethylene glycol (Fig. 2), but other glycols are sometimes used. Glycols are quite stable, but the presence of oxygen can make the solutions highly corrosive. Water is highly soluble in the glycol, and when a water-containing natural gas stream is placed in contact with a glycol solution, the water is absorbed from the gas phase into the liquid phase. The other important property is that the boiling point of the glycols, especially triethylene glycol, is much higher than that of water (288°C vs 100°C at atmospheric pressure). Therefore, the glycol–water mixture may be heated to revaporize the water at temperatures far below the boiling point of the glycol, resulting in

(1) $HO–CH_2CH_2–OH$

(2) $HO–CH_2CH_2–O–CH_2CH_2–OH$

(3) $HO–CH_2–CH_2–O–CH_2CH_2–O–CH_2CH_2–OH$

FIGURE 2 (1) Ethylene, (2) diethylene, and (3) triethylene glycol.

little covaporization of the glycol. In addition, aliphatic hydrocarbons are absorbed only in very small amounts, although aromatics are very soluble. Acid gases that may be present are also absorbed in small amounts, although their presence can affect he solubility of water in glycol during the absorption and can also result in absorption of aliphatic hydrocarbons.

Figure 3 presents a process flow diagram for a glycol dehydration system. The glycol contactor is a vertical cylindrical column with dimensions of from approximately 0.5 m up to several meters in diameter, with larger sizes required for larger gas flow rates being processed. Inside the column are usually 8 to 10 contacting trays placed above each other approximately 0.6 m apart. Although trays are common, packing materials that allow the liquid to trickle down over their surface to create a high gas–liquid contacting area are also used and can be preferred in a number of applications, particularly for increasing the capacity of existing trayed columns. The total height of the column is approximately 5 to 8 m and is not greatly affected by the flow rates. The lean (low water content) glycol solution is introduced at the top of the column and flows across each tray and down to the next. The water-containing natural gas is introduced into the

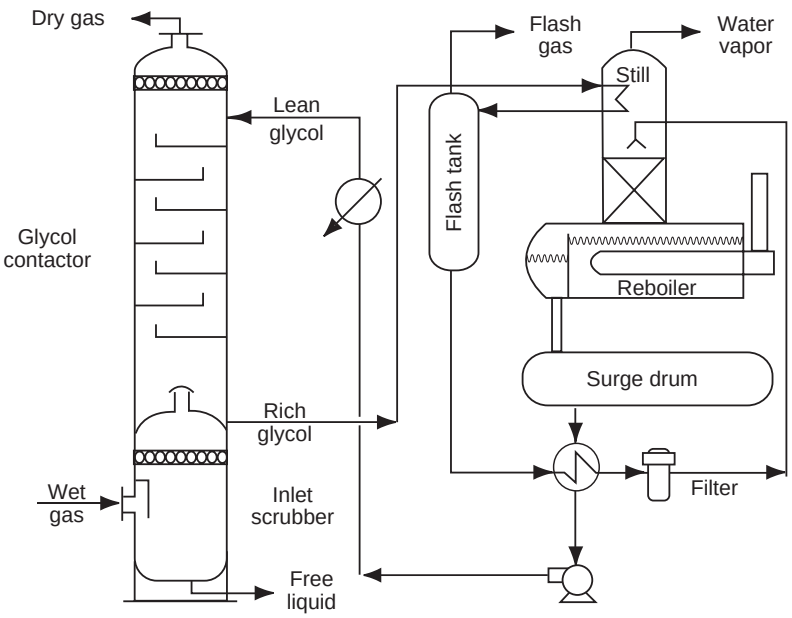

FIGURE 3 Typical glycol gas dehydration process diagram. Reprinted from Gas Processors and Suppliers Association. (1998). "GPSA Engineering Data Book," Vols. 1–2, 11th ed. GPSA, Tulsa, OK.

bottom of the column and flows upward through perforations or caps in the trays where the gas and liquid are highly mixed. This mixing provides good contact between the gas and the liquid to allow the transfer of the water from the gas to the liquid. This countercurrent flow pattern provides the best approach to equilibrium for the removal of water from the gas phase. The gas has less water remaining at each successive tray until it leaves the column at the top. The liquid increases its water content as it flows down through the column until it is discharged at the bottom. Typical applications require approximately 0.25 L of TEG/kg water removed and a lean (inlet) glycol concentration of approximately 99%. The contacting generally takes place at near ambient temperatures ($\sim 38^{\circ}$C) and at convenient pressures, with as little lowering of the gas pressure as possible (2–6 MPa).

The glycol must then be regenerated to return it to its lean concentration for reuse in this continuous process. The water-rich glycol flows from the bottom of the column to the still/reboiler, where it is heated to approximately 200°C and the water is boiled off at atmospheric pressure and vented. Any absorbed aromatics are also vaporized, and emissions handling equipment may be needed in this case. The lean glycol is then cooled and pumped back to the glycol contactor.

A number of variants of this process that improve performance, particularly under challenging circumstances such as where especially low dew points are required, are in commercial operation. In that case, a vacuum still can achieve higher lean glycol purity, say above 99%.

Solid desiccant dehydration makes use of the attraction between water in the natural gas and the surface of certain solid materials. In these adsorption processes, the surface properties are such that a weak bond will form between the solid surface and water when exposed to water during the gas phase. The bond strength is a function of temperature with high water-adsorbing capacity at ambient operating temperatures and lower capacity as the temperature increases. These materials can be fabricated into particles with diameters in the range of 1 to 5 mm and with high active surface areas and water adsorption capacities from 20% to more than 40% by weight. The most common materials are silica gels, activated aluminas, and crystalline molecular sieve zeolites.

Although it is a more expensive process than glycol dehydration, the solid desiccant process can achieve significantly lower dew points (as low as -60 to -100°C). Adsorption is also useful for simultaneous removal of acid gases.

The solid particles are placed as a bed in a vertical cylindrical column. The wet feed gas flows down through the column at a velocity designed to provide an appropriate residence time for the adsorption to take place at high rates, but it is limited by the loss of

pressure due to the friction of the gas flow through the void spaces between the particles that increases as the velocity increases. The adsorption takes place at a convenient gas pressure, say 2 to 6 MPa, at near ambient temperature.

The process operates continuously in a cyclic manner with two columns in parallel, as shown in Fig. 4. One column accepts the flow of natural gas for a period of time that allows the water-adsorbing capacity of the volume of particles in the column to be reached. A larger column of particles has a higher capacity and operates for a longer time but commonly for less than 12 h. During this time period, the other column is in the process of being regenerated, with the water removed by flowing a stream of hot ($\sim$315°C) regeneration gas over the particle bed. The regeneration gas is a portion of the dried gas that, after passing over the regenerating bed and taking up the "desorbed" water, is cooled back to ambient temperature. This stream passes below its dew point; thus, water condenses and is removed in the knockout drum. The gas, now saturated with water, is put back into the feed gas. It should be pointed out that at the high regeneration temperature, the regeneration gas can accept significantly more water than it can at ambient temperature; thus, only a relatively small portion must be reprocessed. When the adsorbing column is saturated, valves are switched to redirect the wet feed gas to the regenerated column and to begin regeneration of the "saturated" column.

Other processes for dehydration are available for commercial application; however, these are generally limited to specialty applications such as very small gas flow rates. Membrane permeation is a technology that continues to advance, although limitations on selectivity cause unacceptable losses of feed gas for dehydration. These alternative process choices are generally more costly for the most common gas dehydration applications.

3. GAS SWEETENING

A wide array of processes are available for the removal of the acid gases (primarily H_2S and CO_2 but including all sulfur compounds such as mercaptans, CS_2, and COS). The selection of the most appropriate one (both technically and economically) depends primarily on the feed gas composition, specifically which acid gases are present (or absent) and at what concentrations as well as the final product specifications. The major categories of sweetening processes are amine reaction processes, physical absorption processes, combination processes, and cyclic processes. Figure 5 shows a matrix that considers some of the criteria for process selection.

The absorption of the acid gases into aqueous solutions is low due to low solubilities, but the placement of a basic amine into the solution allows the absorbed acid gas to react to form an acid–base complex. This creates a high capacity for absorption that depends on the concentration of the amine. Figure 6 shows the dominant amines used in these solutions. For a primary amine (RNH_2), one molecule of acid gas is complexed with each amine molecule. For a secondary amine (R_2NH), two molecules of acid gas are complexed, and for a tertiary amine (R_3N), three are complexed, except that CO_2 is not complexed with the tertiary amine, giving it a preferential selectivity for sulfur (Fig. 7). In practice, only approximately one-third of the theoretical complexation capacity (moles of acid gas complexed per mole of amine) is realized.

$$RNH_2 + CO_2 \longleftrightarrow RNHCO_2^-H^+$$

FIGURE 7 Simplified amine acid gas chemistry.

Figure 8 shows a process flow diagram for an amine reaction-type gas sweetening process. The sour gas enters the column from the bottom and flows up and out the top while the lean (low acid gas content) amine solution flows down from the top to the bottom of the column. As with dehydration columns, the countercurrent flows of the two streams maximize the transfer of acid gas constituents to the liquid phase. The column internals are trays or packing in similar fashion to the dehydration column. The gas leaving the column may be passed through a water scrubber to recover more volatile amines (e.g., MEA, DEA). The gas at this point is essentially saturated with water and would then pass to a dehydration system. The column operates at near ambient temperature and a convenient gas pressure, say 38°C and 2 to 6 MPa. The acid gas-rich amine solution leaves the bottom of the column, is heated, and flows to the upper part of the stripping column. This also is a gas–liquid contactor that creates surface area between the gas and liquid phases that allow, at a higher temperature of approximately 110 to 130°C, the sour gases to be stripped into the gas phase. The bottom of the stripping column includes a reboiler where some of the heating of the amine solution occurs. The stripped or lean amine solution is then cooled and pumped back to the sweetening column. Both columns' sizes depend on the volumetric flow rates of the gas and liquid streams, with larger flow rates requiring larger diameters (in the range of 0.4 m to several meters), and on the amount of sour gas that is transferred. The amine concentration in the aqueous solution is typically in the range of 20 to 30%, and this defines the capacity of the solution and the amount that is needed to achieve the designed sweetening specification (e.g., liters of amine solution per cubed meter of gas treated). The acid gas leaving the stripper may be vented or burned if sulfur is absent or sufficiently low, but if significant amounts

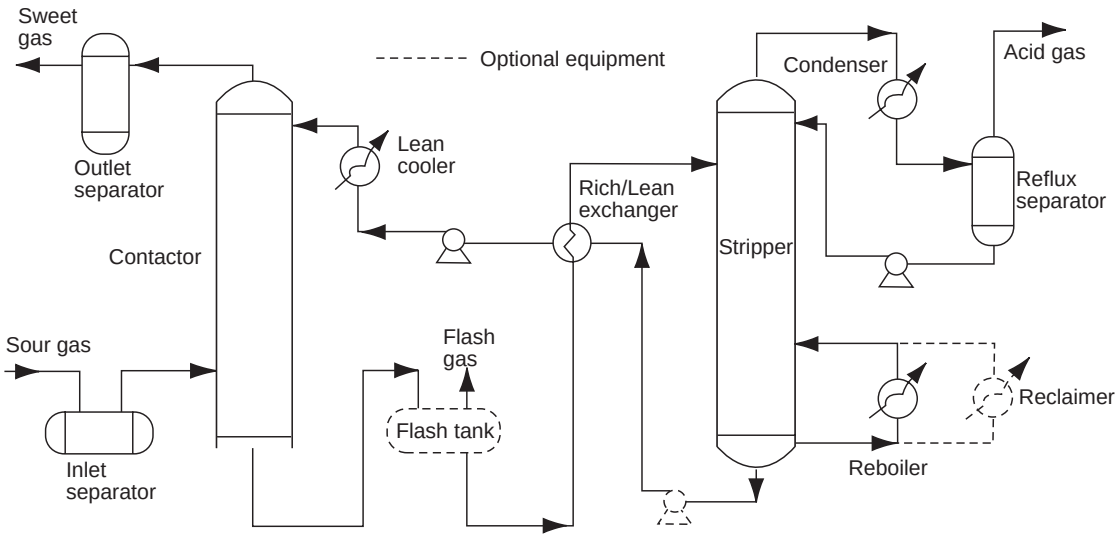

FIGURE 8 Example of an amine reaction-type sweetening process flow diagram. Reprinted from Gas Processors and Suppliers Association. (1998). "GPSA Engineering Data Book," Vols. 1–2, 11th ed. GPSA, Tulsa, OK.

are present, the sulfur-containing gas will have to be recovered.

Physical absorption processes operate in the same fashion as does glycol dehydration. A solvent that has a high capacity for acid gases is contacted with the sour natural gas in an absorption column (Fig. 3). In some cases, the solvent may be selective for sulfur compounds, may also absorb water so that the need for a separate dehydration step is eliminated, and/or may also absorb hydrocarbons advantageously. The regeneration of the solvent is generally different from the case with glycols in that it does not depend on boiling off the acid gases. Instead, pressure reductions allow the absorbed gases to vaporize, and a stripping column may be used to provide gas–liquid contacting to enhance the vaporization. Major processes using this method include the Selexol process using a polyethylene glycol derivative as the solvent, the Fluor solvent process using anhydrous propylene carbonate, and the Rectisol process using methanol.

Combined processes use both reacting and absorbing materials. Shell's Sulfinol process uses an aqueous amine along with Sulfolane, a proprietary physical solvent.

In general, cyclic processes operate by contacting with a solid adsorbent (e.g., iron sponge, zinc oxide, molecular sieve zeolites) that must be regenerated in similar fashion to the solid desiccant dehydration process or by contacting with a liquid solution (e.g., Chemsweet, Sulfa-check, Sulfatreat) that must be changed and regenerated at the end of the cycle.

Other technologies are available, including iron chelation redox-type processes and membrane permeation processes that may have applications in specific circumstances.

The major process for sulfur recovery is the Claus process with a number of possible variations. The sulfur-containing gas is first burned with air in a thermal reaction furnace to convert approximately one-third of the sulfurous gas to SO_2. At the high temperature ($\sim$1000°C), some elemental sulfur is formed. The gas is then cooled below the sulfur dew point to allow much of it to condense. The gas is then reheated to approximately 400°C and passed over an alumina-type catalyst that allows the reaction of H_2S and SO_2 to form sulfur and water. This reaction is equilibrium limited in that complete conversion is not thermodynamically feasible (lower temperature favors higher conversion) because the catalyst requires a high temperature ($\sim$400°C) to actively carry out the reaction. To achieve higher conversion to sulfur, the converted gas stream is then cooled below the dew point of sulfur that then condenses, and the remaining gas is once again heated and passed over a second catalytic reactor. This may be repeated for further conversion in a third catalytic reactor to achieve a high enough conversion to meet requirements for release of the remaining gas to the atmosphere, although further cleanup of this gas by combustion and (possibly) scrubbers may be necessary.

The primary use for the recovered sulfur is in the manufacture of sulfuric acid.

4. HYDROCARBON RECOVERY AND FRACTIONATION

The first objective of hydrocarbon recovery in natural gas processing is the reduction of the hydrocarbon dew point so that condensation cannot occur during subsequent processing, transportation, and use of the gas. Of course, the removal of these hydrocarbons causes a loss of volume of the product gas, called shrinkage, as well as a loss of heating value given that the higher hydrocarbons have a greater heat content per volume than does methane. If the higher hydrocarbons cannot be sold or used for fuel, this is a substantial loss of value that must be minimized. Historical practice frequently has been to burn those products to simply dispose of them. (Indeed, much the same could be said about natural gas found with oil, although this has changed substantially during the past decade or so.) The second objective is to maximize recovery of the higher hydrocarbons as various liquid products collectively referred to as natural gas liquids. This is now quite common, with the enhanced economic value more than offsetting the loss of value to the natural gas product.

Earlier in the article, it was mentioned that the required product dew point for water occurred at the combination of the highest pressure and the lowest temperature. For hydrocarbons, the situation is more complex in that gaseous hydrocarbon mixtures undergo the phenomenon of retrograde condensation. This is when, at a fixed temperature and composition, a lowering of the pressure may cause condensation. Thus, lowering the pressure moves the system toward the dew point rather than away from it (as is the case for most other systems, e.g., water vapor in natural gas). Thus, the operative criteria for higher hydrocarbon removal is their removal to levels that ensure that condensation cannot occur at the lowest expected temperature at any pressure. The point at which this occurs is referred to as the cricondentherm.

The removal of the higher hydrocarbons proceeds through cooling of the gas at a pressure of convenience to maintain as high a pressure for pipeline flow as possible. Figure 9 shows the normal boiling points of the major hydrocarbons found in natural gas. As can be seen, condensation and recovery of greater amounts of lighter hydrocarbons requires lower temperatures, and this is true at any pressure. Thus, the lowest temperature required will be dictated by the composition of the gas, the fractions of specific components to be recovered (or dew point to be achieved), and the operating pressure.

n-Pentane	36.07
i-Pentane	27.85
n-Butane	−0.5
i-Butane	−11.72
Propane	−42.04
Ethane	−88.60
Methane	−161.49

FIGURE 9 Boiling points of natural gas hydrocarbons at atmospheric pressure (in °C).

If the pressure is relatively low, a refrigeration process is used to chill the gas sufficiently to cause condensation of the higher hydrocarbons. These are typically propane and higher with small amounts of ethane. The condensate is then removed in a gas–liquid separator and flows to a stabilizer column that makes sure that any lighter hydrocarbons that are dissolved in the condensate, such as methane, ethane, and small amounts of higher hydrocarbons, can revaporize to an equilibrium composition and will not vaporize during later liquid processing, storage, and transportation. The stabilizer column is a vertical cylindrical column with internal trays or packing that promotes gas–liquid contact and mixing, as discussed earlier. The gas from the cold separator and the stabilizer column are then combined to form the product gas stream.

An alternative process is the use of a solvent to absorb the higher hydrocarbons, analogous to solvent dehydration. Lean oil absorption can be used as the process. The lean oil is simply another hydrocarbon stream of a sufficiently low vapor pressure that it remains in the liquid phase through the absorption and regeneration. Regeneration is carried out by heating the rich oil to allow the higher hydrocarbons absorbed from the natural gas stream to revaporize. Such plants are relatively uncommon today.

If the gas is available at sufficiently high pressures, and especially if greater recovery of natural gas liquids is desired for economic reasons, the cooling of the gas is achieved by allowing it to expand, losing some of its pressure. This is the mainstay of hydrocarbon recovery processing. There are two alternatives for this, with the simplest being the JT expansion making use of the Joule–Thomson effect where the expansion occurs as the gas flows through a restrictive valve. The design determines the degree of cooling required to achieve the amount of natural gas liquids condensation required, and additional

refrigeration can be provided if needed. This type of plant, although common, is relatively inefficient in that there can be no work recovered from the expansion.

Most newer plants, particularly those that wish to maximize recovery of gas liquids, allow the gas to expand through a turbine where the gas cooling is achieved and some work is recovered from the turbine. Usually, the turbine shaft drives a compressor also used in the process. The basic process flow diagram is shown in Fig. 10. The feed gas is first chilled by cooler gas streams in the plant, and any condensed liquids are removed in the low-temperature cooler before reaching the turbo expander. The pressure is reduced in the expander, from approximately 7 to 4 MPa in the example shown, while the temperature drops from 51 to −77°C. After the additional liquid condensate is removed in the very low-temperature separator (called the demethanizer), the cold gas is warmed by chilling the incoming feed gas. The product gas can now be partially repressurized by the compressor that is driven by the expander turbine. Additional recompression may or may not be required. There are many variations of this process to accommodate specific composition and recovery requirements, for example, the use of external refrigerants to achieve lower temperatures for greater ethane recovery. These processes can recover as much as 80 to 90% of the ethane (and virtually all of propane and higher hydrocarbons) in the natural gas.

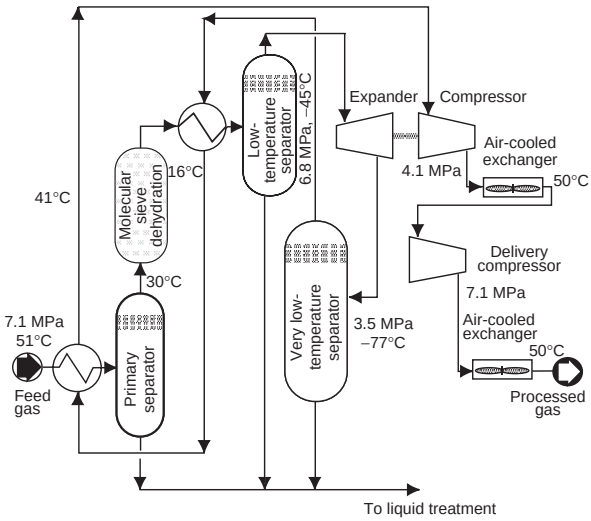

FIGURE 10 Turboexpander plant diagram. Reprinted from Rojey, A., Jaffret, C., Cornot-Gandolphe, S., Durand, B., Julian, S., and Valais, M. (1997). "Natural Gas Production Processing Transport." Editions Technip, Paris.

The processing of the gas to pipeline quality has now been completed. The liquid streams will require further separations at low temperature to produce an optimum product set. There are many possibilities for configurations that depend on both the composition of the liquids and the value of the various products. Products are defined by their composition, boiling range, and vapor pressure and may have several grades. Some major products include natural gasoline, commercial butane, commercial propane, and high-purity ethane. These products are produced by separation in one or more fractionation columns that contain trays or packing. The columns can appear in a wide range of sizes depending on the quantities of the components. Typical sizes are in the range of 0.5 to 3.0 m in diameter and 8 to 15 m in height. Higher purities require taller columns that give greater opportunity for the gas and liquid to mix. Temperatures are typically below ambient temperature, and pressures are typically in the range of 1 to 5 MPa. The conditions are selected to maximize the difference in volatilities of the components to be separated in each column. The volatility differences control whether a component appears primarily in the gas or in the liquid leaving a column. In a four-column fractionation, the raw natural gas liquids are fed to the first column, the deethanizer, with primarily ethane vaporizing and leaving from the top of the column and the remaining liquid flowing from the bottom of the column to the depropanizer, where primarily propane vaporizes and leaves from the top. The remaining liquid flows from the bottom of the column to the debutanizer, where the butanes leave from the top and flow to the fourth column that separates isobutane from normal butane. The liquid leaving the bottom of the debutanizer is the C_5^+ natural gasoline.

The product streams may flow by pipeline to subsequent processes or plants for use or to storage as liquids at ambient temperature and sufficient pressure to maintain them in the liquid state.

5. CONVERSION TO TRANSPORTABLE CHEMICALS AND FUELS

Natural gas has been a major feedstock for production of chemicals since early in the 20th century with the development of gas–solid catalytic chemistry. This is despite the intrinsic stability of the methane molecule that requires the conversion of methane to

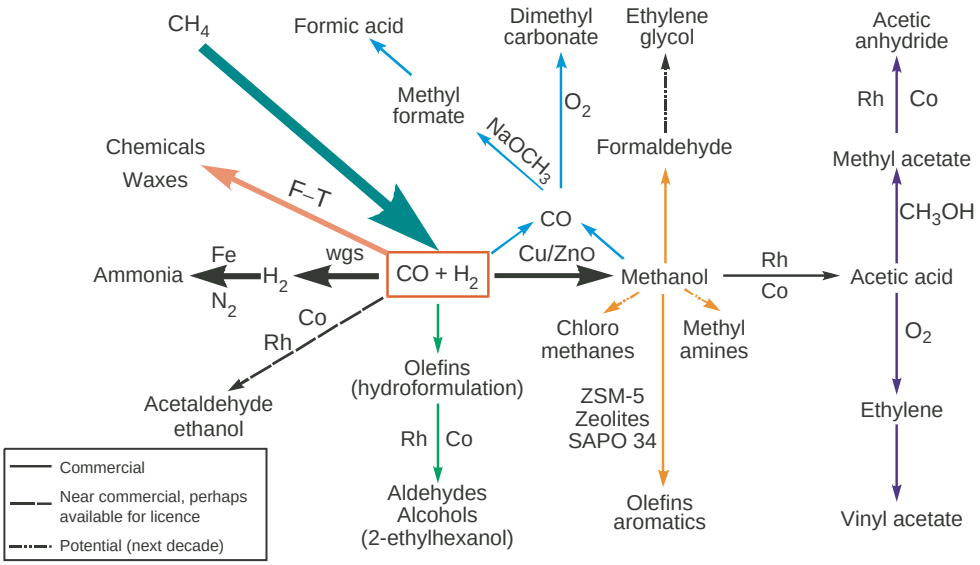

FIGURE 11 Chemical pathways for gas conversion.

carbon monoxide and hydrogen, known as synthesis gas, before further conversions to useful chemicals. Figure 11 illustrates the chemical pathways to form primary and secondary industrial chemicals from natural gas via the synthesis gas intermediate. Historically and through the current time, methanol and ammonia are among the most produced industrial chemicals. Ammonia represents the fixation of nitrogen and is the precursor for most nitrogen fertilizers. Methanol is used as a solvent as well as a feedstock for many other chemicals. Lastly, the production of liquid hydrocarbons via Fischer–Tropsch has a recent history of production from natural gas but a long history of production starting with coal. It appears that processes for production of liquid fuels from Fischer–Tropsch synthesis (FTS) are poised to undergo rapid expansion as markets for clean fuels and chemical feedstocks increase. All of these products satisfy one of the requirements for monetizing many more remote natural gas resources in that they are significantly more transportable than natural gas that is often located far from demand that can use pipelines and the relatively limited, but also increasing, markets for LNG.

The first step in the synthesis of ammonia, methanol, and liquid hydrocarbons is the production of synthesis gas. The primary means of carrying out this conversion has been methane steam reforming. This is shown in Fig. 12 as reaction 1. Steam reforming has the attribute of producing large amounts of hydrogen, one-third of which comes from the water. However, it is a very energy-intensive

(1) $CH_4 + H_2O \leftrightarrow CO + 3H_2$

FIGURE 12 Natural gas conversion chemical pathways.

reaction. The reaction takes place on supported nickel metal catalyst pellets placed in tubes through which the natural gas and water feed flows. The thermodynamics require very high temperatures to achieve good conversions, and the reaction is conducted at a temperature of approximately 800°C. In addition, the reaction is highly endothermic, requiring large heat inputs. The combination of these two requirements leads to placing the reactor tubes inside a direct-fired combustion furnace where radiative heat transfer can provide the needed heat input. Conversion remains incomplete, and a secondary reformer with a different nickel catalyst is used at temperatures of 900 to 1100°C. Less heat input is required because the remaining conversion is smaller, and this may be supplied by feeding oxygen to cause the heat-releasing exothermic partial oxidation reaction, shown as reaction 3 in Fig. 12.

For ammonia production, the secondary reformer may use air for its oxygen supply because the accompanying nitrogen will be converted to ammonia. Also for ammonia production, the CO will be

unused, so it is converted to CO_2 by the water–gas shift reaction (reaction 2 in Fig. 12) that produces another mole of H_2 for each methane that was converted (for a total of four). Newer plants may make use of molecular sieve zeolite adsorbents to adsorb only H_2 for producing a pure hydrogen stream. In many current plants, the CO must be reduced to very low levels because it is a poison for the ammonia synthesis catalyst. This is done by converting the residual CO back to methane in a methanation reactor. The CO_2 is also removed using sweetening methods discussed earlier, leaving a nitrogen and hydrogen gas stream ready for the ammonia synthesis process.

Because of the energy intensity of steam reforming and its high H_2/CO ratio that is not needed for FTS (reaction 6 in Fig. 12), large-scale FTS plants are designed to use either partial oxidation or a combined reforming to produce synthesis gas with lower energy intensity. However, partial oxidation generally uses pure oxygen that adds to process cost and complexity. Combined reforming uses less oxygen by combining partial oxidation with steam reforming in several configurations. This balances the heat required by the endothermic steam reforming reaction against the heat released by the exothermic partial oxidation reaction, although high temperatures are still required.

Research is under way on membranes that separate the oxygen, particularly on certain ceramic oxygen transport membranes. This would eliminate the need for expensive cryogenic oxygen plants and make the reforming unit very compact.

Ammonia synthesis takes place on a supported iron catalyst. The overall reaction is shown as reaction 4 in Fig. 12. This is also an equilibrium limited reaction that is favored by low temperatures and very high pressures, taking place at approximately 400°C and 40 MPa. A process diagram for ammonia synthesis is presented in Fig. 13. The feed gas is compressed and preheated before flowing to the top of the converter. The reaction is exothermic and the gas temperature increases as the reaction proceeds, so the catalyst beds are separated into two or three distinct zones. Between each zone, cool hydrogen gas is injected to mix with and cool the reacting gas so as to allow a higher conversion. The conversion remains relatively low, and the product gas is cooled to below the ammonia dew point. The product gas then passes through the separator where liquid ammonia is recovered, and the remaining gas is recycled to the reactor feed.

Methanol synthesis takes place over a Cu/ZnO catalyst at a pressure of approximately 5 MPa and a temperature of 200 to 250°C. The reaction, shown as reaction 5 in Fig. 12, requires an H_2/CO ratio of 2, but this may be higher in practice. A process diagram is shown in Fig. 14. Feed gas is compressed and flows to a multiple-bed catalytic reactor in similar fashion to that in ammonia synthesis. This reaction is also equilibrium limited, and cool feed gas is added between catalyst zones to allow higher conversion. As with ammonia synthesis, methanol synthesis achieves a relatively low conversion of the synthesis gas feed, the product gas is cooled to condense the methanol and water reaction products along with

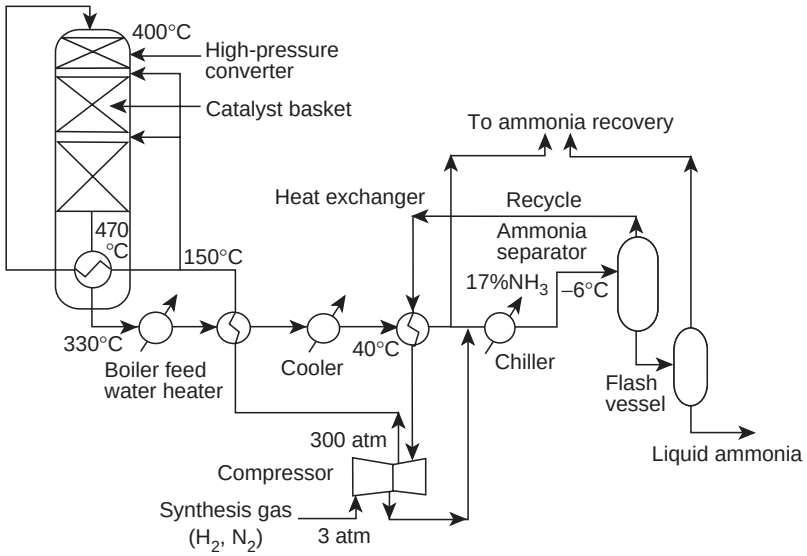

FIGURE 13 Ammonia synthesis process diagram.

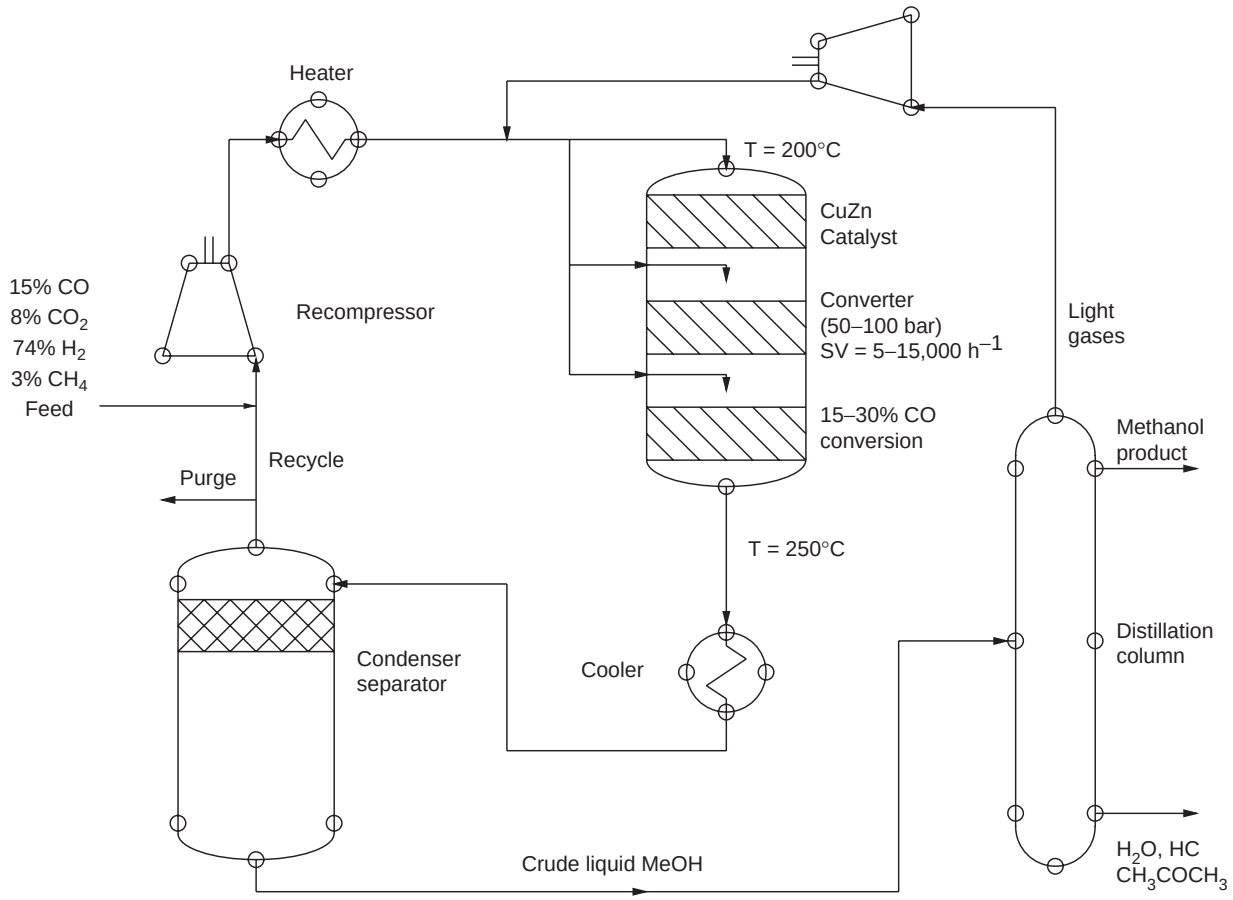

FIGURE 14 Methanol synthesis process diagram.

small amounts of by-products, and the gas is recycled to the feed. The crude product is distilled to produce various purity grades of methanol.

FTS has a complex chemistry that is simplified in reaction 6 in Fig. 12. The primary objective of large-scale Fischer–Tropsch gas-to-liquids (GTL) processes is to produce liquid hydrocarbons suitable for fuel use, and this is represented in reaction 6 by the production of the hydrocarbon-repeating unit $-CH_2-$. Under some conditions, such as high temperatures, oxygenates and olefins may be produced for specialty chemicals use. The reaction produces a wide range of molecular weight products that are predominantly straight chain alkanes. The product distribution produces some light gases (e.g., methane, ethane, propane) that are undesirable, some light liquid alkanes generally referred to as naphtha (a desirable feedstock for production of olefins), longer chain alkanes that are a suitable for diesel fuel, and even longer chain molecules that are solids at room temperature called waxes that may be converted into diesel fuel and other useful, but smaller market, products. The relative amounts of these may be adjusted by altering the catalyst and reaction conditions, but only within certain ranges. These are produced under so-called low-temperature synthesis conditions using supported cobalt- or iron-based catalysts. There are trade-offs between the two catalysts, with cobalt appearing to be more desirable despite its higher cost due to generally higher reaction rates and the fact that iron also catalyzes the water–gas shift reaction that undesirably consumes CO. A process diagram is shown in Fig. 15, which includes a complete process from natural gas to liquid hydrocarbons. The feed natural gas and oxygen both flow to the bottom of the fluidized bed synthesis gas (FBSG) reactor that uses combined reforming. The synthesis gas stream then flows to the hydrocarbon synthesis (HCS) reactor. The reactor operates with a catalyst suspended as a slurry in the liquid product with the gas feed bubbling up through the reactor. The reaction is exothermic, so heat is removed from the reactor with internal piping through which water is pumped and converted to

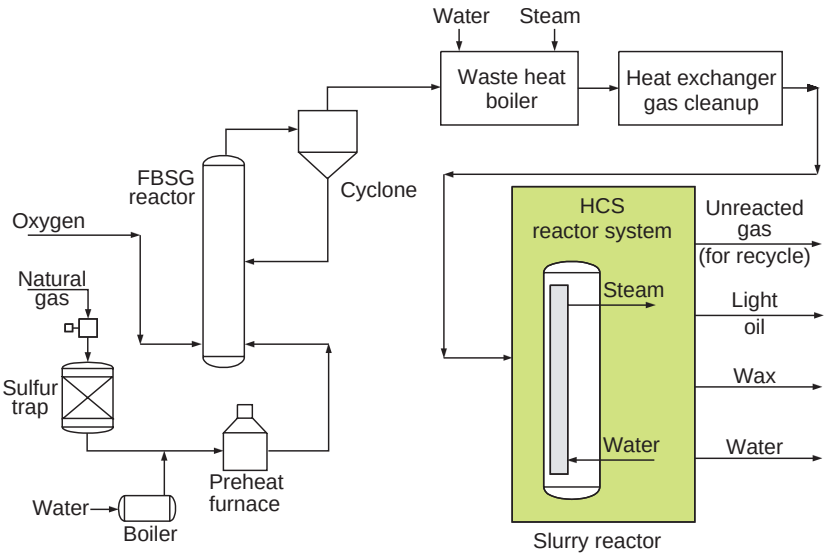

FIGURE 15 Example of a Fisher–Tropsch hydrocarbon synthesis process diagram. FBSG, fluidized bed synthesis gas reactor; HCS, hydrocarbon synthesis reactor.

steam. This maintains the desired reaction temperature of 200 to 250°C at the operating pressure of approximately 2.5 to 5.0 MPa. Relatively high conversions are achieved so that unreacted gas (and produced light hydrocarbons) is not recycled; rather, it is burned and its heat is recovered. The product liquid with catalyst flows out of the reactor, where the catalyst is separated and returned to the reactor suspended in a portion of the product hydrocarbon liquid. The water produced by the reaction is removed as a separate liquid phase, and the hydrocarbon liquid product is further refined to make final products ready for transportation by liquid pipelines or tankers.

Glossary

associated/dissolved gas The natural gas that is in or from oil fields, i.e., fields with a gas/oil volume ratio of less than 20,000 cubic feet per barrel. The natural gas may be in separate pools within the oil field, floating on the oil as a gas cap, or dissolved in the oil.

cumulative production The total volumes of natural gas that have been produced.

endowment The sum of cumulative production, reserves, reserve growth, and undiscovered resources.

future resources The sum of reserves, reserve growth, and undiscovered resources.

liquefied natural gas (LNG) The liquid form of gas; can be stored under low temperature and high pressure for transportation by ship.

nonassociated gas The natural gas that is in or from gas fields, i.e., fields with a gas/oil volume ratio of at least 20,000 cubic feet per barrel.

reserve (or field) growth The increases of estimated gas volume that commonly occur as oil and gas fields are developed and produced.

reserves The estimated quantities of natural gas, expected to be commercially recovered from known accumulations relative to a specified date, under prevailing economic conditions, operating practices, and government regulations. Reserves are part of the identified (discovered) resources and include only recoverable materials.

resource A concentration of naturally occurring natural gas in or on the earth's crust, some of which is currently or potentially economically extractable.

stranded gas Discovered natural gas that is partially or completely isolated from markets because of distances or insufficient transportation infrastructure, and thus is undeveloped or underdeveloped.

undiscovered resources Those resources postulated from geologic information and theory to exist outside of known oil and gas fields.

Natural gas is a mixture of hydrocarbon compounds that are in a gaseous state at standard conditions of temperature and pressure. Natural gas is very abundant worldwide. The greatest concentrations of conventional natural gas are in the Middle East and in the countries of the former Soviet Union. Because natural gas burns more cleanly and produces less greenhouse emissions compared to coal or oil, it is likely to provide a larger portion of the energy supply in the future.

1. INTRODUCTION

Some natural gas is found in fields that produce little or no volume of liquids. Such gas is called nonassociated gas; the fields that produce nonassociated gas have a gas/oil volume ratio of at least 20,000 cubic feet per barrel. Natural gas is also found in oil fields (fields with a gas/oil volume ratio of less than 20,000 cubic feet per barrel). In an oil field, natural gas can occur in separate pools or as a gas cap floating on the denser oil, in which cases it is termed "associated" gas. Oil field gas can also be dissolved in the oil, in which case it is termed "dissolved" gas.

1.1 Resource Classification

In the following discussion, conventional natural gas resources are classified in four categories: cumulative

production, reserves, reserve growth, and undiscovered resources. Cumulative production is that volume of natural gas that has already been produced. Reserves are those volumes remaining in already discovered oil and gas fields that are known to reasonable certainty. Reserve (or field) growth includes those volumes in already discovered oil and gas fields that are not known with certainty, but can be expected to be added to reserves in the future. Undiscovered resources are those volumes of natural gas in conventional oil and gas fields that have not yet been discovered. These volumes of gas are not static; as gas is discovered or produced, volumes shift from one category to another (e.g., from undiscovered resources to reserves, or from reserves to cumulative production). The sum of these four categories is called the endowment of natural gas. The future resources are the sum of the reserves, the reserve growth, and the undiscovered resources—that is, the endowment minus what has been already produced.

Many terms are used to identify categories and subcategories of resources. These terms are not always used consistently and must be approached with caution. The discussion here deals with conventional resources of natural gas, that is, those resources that are in discrete fields (usually with distinct gas/water or oil/water contacts). The bulk of historical natural gas production has been from conventional reservoirs. Unconventional natural gas resources, such as coal bed gas, tight gas sands, fractured shale gas, and gas hydrates, are commonly classified separately. They are treated here as unconventional gases.

1.2 Uncertainty of Estimates

Even more so than for oil, estimates of natural gas resources are subject to considerable uncertainty. This is true for all categories, including estimates of past production. Recorded gas volumes sometimes include total gas volume and at other times do not include that portion of natural gas that is noncombustible (nitrogen, CO_2, etc.). Generally, noncombustible components are less than 15% of gas volumes, but locally can be much greater. Throughout this article, total gas volumes are given (i.e., the noncombustible volume is included). Past production, as reported by the appropriate government agencies, may or may not include amounts of gas that were flared or reinjected into the reservoir to sustain pressure for additional oil recovery.

The amount of reserve growth in discovered fields is not well known, but is probably very significant. Especially in the case of stranded gas (discovered natural gas that is partially or completely isolated from markets because of distances or insufficient transportation infrastructure), there is little incentive to invest in the costs to evaluate fields fully. Although most studies of reserve growth have been based on more easily accessible data from the United States, studies of reserve growth outside the United States show that such growth occurs worldwide. Gas reserve growth outside the United States reported from 1977 to 1991 was at a rate greater than was growth of gas fields in the United States during that period.

2. WORLDWIDE DISTRIBUTION

A majority of the data used in this article on the worldwide distribution of conventional natural gas resources are from the U.S. Geological Survey (USGS) and the U.S. Energy Information Administration. The USGS provides probabilistic estimates of reserve growth and undiscovered resources, but only the mean estimates are cited here. The original USGS estimation of reserve growth was at the world level; for the analysis here, estimates of reserve growth by region were generated by allocating the USGS world reserve growth estimates proportional to the volumes of reserves in each region.

Table I and Fig. 1 show how conventional natural gas resources of the world are distributed into the eight regions used by the USGS. Note that 62% of the resource endowment is concentrated in just two regions—(1) the former Soviet Union and (2) the Middle East and North Africa. Also note that only in the North American region has a large proportion of the resource already been produced. The map in Fig. 2 shows how the resources that remain available are concentrated primarily in a part of the world that stretches from the Middle East, through the Caspian Sea, to West Siberia. Table II presents the natural gas production and consumption by region for the year 2000. The major trade movements of natural gas are shown in Fig. 3. These eight regions are discussed herein in decreasing order of their endowment; Tables I and II and Figs 1–3 should be referred to throughout the discussions.

The world distribution of unconventional gas resources is not well understood. Most of the exploration and production of unconventional resources has been in the United States. Geologic studies show that similar unconventional accumulations

[b] Numbers correspond to maps in Figs. 2 and 3.

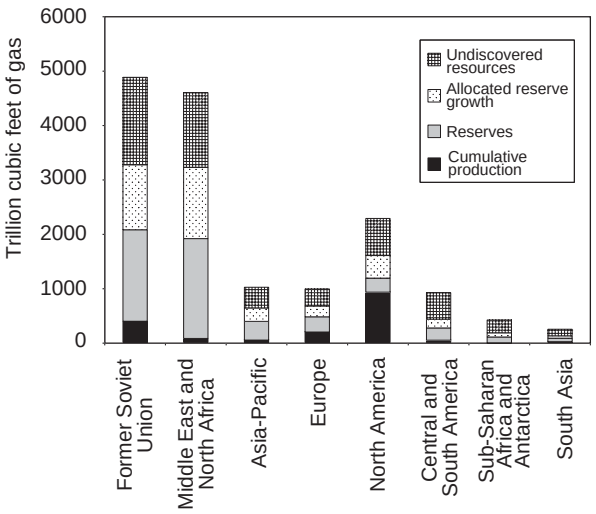

FIGURE 1 Conventional natural gas endowment (cumulative production, reserves, allocated reserve growth, and undiscovered resources) by region (see data in Table I).

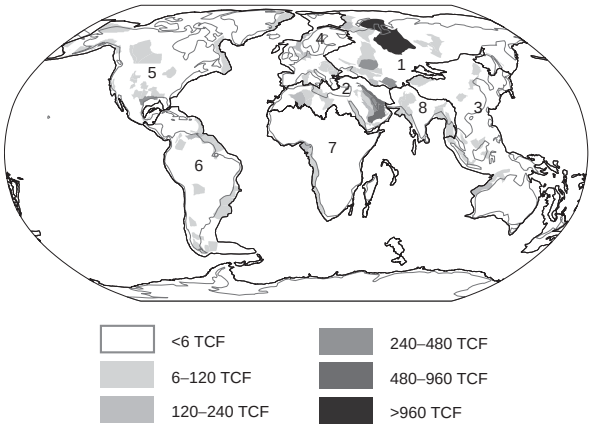

FIGURE 2 Natural gas of the world by geologic province as assessed in the *U.S. Geological Survey World Petroleum Assessment 2000*. The volumes are a sum of cumulative production, reserves, and undiscovered resources. Reserve growth was not included in the volumes. The shaded regions indicate conventional gas in trillions of cubic feet (TCF). Region key: (1) The former Soviet Union, (2) Middle East and North Africa, (3) Asia–Pacific, (4) Europe, (5) North America, (6) Central and South America, (7) sub-Saharan Africa and Antarctica, and (8) South Asia.

probably occur in many places worldwide, but quantitative estimates are not available.

2.1 Former Soviet Union

The former Soviet Union (FSU) has 33% of the world's future natural gas resources. In 2000, this region accounted for 29% of the world's natural gas production but had only 24% of the natural gas demand; thus, even though a major user of natural gas, the FSU is also a major exporter. Almost all of the export volume is to Europe through pipeline systems.

Of the 25.43 trillion cubic feet (10^{12} cubic feet, TCF) of production in 2000, 20.63 TCF (81%) was from Russia, mostly from the West Siberian Basin. The West Siberian Basin also has 63% of the FSU's natural gas reserves and 40% of the estimated undiscovered gas. The area of the Caspian Sea also contains very large estimated volumes of natural gas resources, accounting for 12% of the reserves and 21% of the estimated undiscovered gas. The Amu-Darya Basin of central Asia (Turkmenistan, Uzbekistan, Afghanistan, and Iran) has large reserves (9% of the FSU total) and estimated undiscovered gas (10% of the FSU total), but the gas is far from demand centers, so much of the gas is stranded. The Barents Sea has had few previous discoveries, but has significant estimated undiscovered gas (15% of the FSU total).

2.2 Middle East and North Africa

The Middle East and North Africa region also has 33% of the world's estimated future natural gas resources. This includes 38% of the world's reserves and 26% of the world's estimated undiscovered gas. In 2000, this region accounted for 13% of world production, but only 10% of the demand. The region is a major exporter to Europe through trans-Mediterranean pipelines and by transportation of liquefied natural gas (LNG). Much of the gas in the Arabian–Persian Gulf area is stranded, but some is exported to Japan and South Korea as LNG. The Arabian–Persian Gulf area accounts for 87% of the region's reserves and 90% of the estimated undiscovered gas. It includes the world's largest gas field, North Field (over 350 trillion cubic feet of natural gas), in Qatar. Algeria exports a significant volume of natural gas to Europe (69% of the region's exports) by both pipeline and as LNG.

2.3 North America

North America has 10% of the world's estimated future natural gas resources. Of all eight regions listed in Table II, North America is both the largest producer and the largest consumer of natural gas. Over half of the natural gas ever produced in the world has been from this region. It is the only region for which unconventional natural gas has been a significant portion of the production.

The United States is the largest producer (71% of North America's 2000 production) and the largest

TABLE II

World Natural Gas Production and Consumption in the Year 2000[a]

Region[b]	Trillion cubic feet		World production (%)	World consumption (%)	Surplus or deficit (%)
	Gas production	Gas consumption			
1. Former Soviet Union	25.43	20.54	28.89	23.51	+5.38
2. Middle East and North Africa	11.51	8.87	13.07	10.15	+2.92
3. Asia Pacific	7.29	8.20	8.28	9.38	−1.10
4. Europe	10.91	16.85	12.39	19.29	−6.90

[b] Numbers correspond to maps in Figs. 2 and 3.

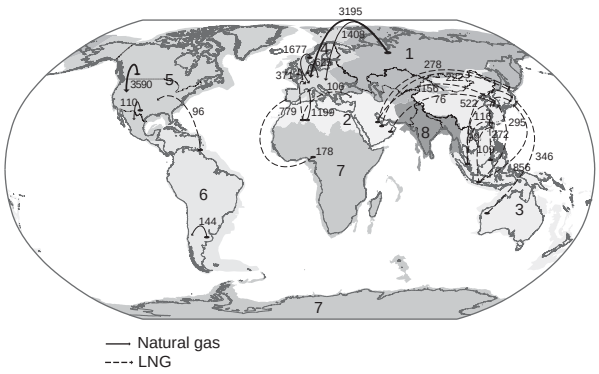

FIGURE 3 Major natural gas trade movements in billions of cubic feet (small numbers) for the year 2000. Region key (large numbers): (1) The former Soviet Union, (2) Middle East and North Africa, (3) Asia–Pacific, (4) Europe, (5) North America, (6) Central and South America, (7) sub-Saharan Africa and Antarctica, and (8) South Asia. Modified from British Petroleum Company (2002).

consumer (83% of North America's 2000 consumption). About 60% of U.S. production is from the onshore and offshore areas of the Gulf of Mexico. Almost all of the gas imported into the United States (94% of U.S. imports) comes from Canada by pipeline. Mexico imports only 3% of its demand, which is supplied by the United States.

2.4 Europe

Europe has 6% of the world's future natural gas resources. It is a net importer of natural gas, having consumed almost 6 trillion cubic feet of gas more than it produced in 2000 (35% of its consumption). Of the gas imported into Europe in 2000, 66% was from the former Soviet Union and 30% was from Algeria. Significant resources of European natural gas occur in the North Sea and adjoining areas. The largest producers in the North Sea area are the United Kingdom (35% of Europe's 2000 production), The Netherlands (24%), Norway (17%), and Germany (7%). Of these, Norway, The Netherlands, and the United Kingdom are net exporters. Almost all other European countries are net importers. Gas production in other parts of Europe is primarily from the Po Valley of northern Italy and Romania.

2.5 Asia–Pacific

The Asia–Pacific region has 7% of the world's future natural gas resources. The region accounts for 7% of world natural gas reserves, 7% of the estimated undiscovered gas, and 9% of the demand. Japan and South Korea, with little production, import LNG from Indonesia, Malaysia, Australia, and Brunei, and also from the Arabian–Persian Gulf. Areas of significant production are Malaysia and Indonesia, with 53% of the region's 2000 production. They have 42% of the reserves and 42% of the estimated undiscovered gas in the region. Northwest Australia also has significant resources—25% of the region's reserves and 29% of the region's estimated undiscovered gas—but some of the reserves are stranded. China has

significant resources also—13% of the region's reserves and 23% of the estimated undiscovered gas.

2.6 Central and South America

Central and South America have about 6% of the world's future natural gas resources. There is little interregional import or export, except for some LNG exported from Trinidad and Tobago to the United States. Argentina and Venezuela are the major natural gas producers of the region, accounting for 39 and 28%, respectively, of the region's production in 2000. Venezuela has 60% of the region's gas reserves and 21% of the estimated undiscovered gas. Argentina has 11% of the region's reserves and 8% of the estimated undiscovered gas. Other significant producers include Trinidad and Tobago, Brazil, Colombia, and Bolivia. Although Brazil currently has only 3% of the region's reserves, it has 40% of the estimated undiscovered gas, most of it in basins along the South Atlantic margin. Most of the region's natural gas is consumed in the country of production, but Argentina, Trinidad and Tobago, and Bolivia are net exporters. Chile and Brazil are net importers of natural gas.

2.7 Sub-Saharan Africa and Antarctica

Sub-Saharan Africa has about 3% of the world's estimated future natural gas resources. The Niger Delta of Nigeria dominates natural gas statistics for sub-Saharan Africa. Most (78%) of the natural gas already produced in sub-Saharan Africa was from the Niger Delta. The Niger Delta also has 82% of the reserves. Nigeria is the only major exporter of natural gas to other regions, that by transportation of natural gas liquids (NGLs). Of its exported gas, most (90%) is to Europe and 10% is to the United States.

In the past decade, deepwater oil exploration off the Atlantic coast of Africa has been very successful; several giant oil fields have been discovered. Improved geologic understanding about the South Atlantic coastal basins suggests that the undiscovered gas may be more widespread than was obtained from past production—52% of the estimated undiscovered gas is in Nigeria and 18% is in (mostly offshore) Angola. With an expansion of deepwater infrastructure and technology, gas production from these areas may become more economically viable, both from oil fields (associated/dissolved gas) and from gas fields (nonassociated gas).

No natural gas resources have yet been discovered in Antarctica. Even if exploration were allowed, any resources found would be very unlikely to be economic in the next few decades.

2.8 South Asia

South Asia has only about 2% of the world's future natural gas resources. South Asia is not well connected to other parts of the world by gas transportation routes and the gas production and consumption are roughly in balance. The region includes two of the world's largest deltas, the Indus and the Ganges-Brahmaputra, both with significant undiscovered resources of natural gas. The largest producers are Pakistan (about 40% of the region's production), India (38%), and Bangladesh (16%). Each of these countries consumes what it produces, with minimal imports or exports of natural gas. In contrast, Burma exports almost half of the gas that it produces.

3. IMPACT OF DISTRIBUTION

Although, natural gas resources are abundant and widespread, they have been underutilized compared to oil resources. Only about 11% of the recoverable conventional gas resource has been produced. Unconventional natural gas is even more abundant, but much of it is not likely to be developed in the next few decades. Tables III and IV list the major producing and consuming countries of the world. Russia and the United States dominate both lists. Russia is a net exporter of natural gas and the United States is a net importer. Some of the major consumers (Germany, Japan, Italy, and France) are only minor producers. Some major producers are only minor consumers (Algeria, Norway, Turkmenistan, and Malaysia).

The geographic distribution of supply is different from that of demand, making transportation critical. Areas such as northern Alaska, northwest Australia, and central Asia have large volumes of discovered natural gas that are poorly connected to areas of gas demand. Transportation to areas of high demand requires the construction of either natural gas pipelines or of facilities to use high pressure and low temperature to liquefy natural gas so that it can be transported by ship as LNG. The gas stranded in these areas could also become more relevant to world supply with improvements in gas-to-liquid technology.

TABLE III

Top 20 Producers of Natural Gas in Year 2000[a]

Country	Production (trillion cubic feet)
Russia	20.63
United States	18.99

4. DATA SOURCES

Information about natural gas resources is not static. Fortunately, several sources of information are easily accessible. The data about discovered resources used in this article came primarily from the U.S. Energy Information Administration. Their Web site (www.eia.doe.gov) provides extensive data on resources and energy usage for all energy sources (not just oil and natural gas) for the United States and the rest of the world. The data for reserve growth and undiscovered resources came primarily from the U.S. Geological Survey's *World Petroleum Assessment 2000*. The USGS has a Web site (energy.usgs.gov) where that assessment and additional extensive data for the United States and the rest of the world may be accessed.

Other sources of information can be found in several petroleum industry magazines (such as *Oil and Gas Journal* and *World Oil*) that publish annual statistical summaries. The British Petroleum Company (BP) also produces an annual statistical summary and has a Web site (www.bp.com) where extensive data is available.

Glossary

coalbed methane Natural gas stored within a coal seam (coal reservoir) requiring dewatering and/or lowering of pressure for its release and production.

gas hydrates Natural gas stored as a chlahrate within the molecular structure of water requiring the injection of heat or the lowering of pressure for dissociation and gas flow.

gas shales Natural gas stored within an organically rich shale interval (reservoir) requiring natural fractures and artificial well stimulation for acceptable rates of gas flow.

geopressured methane Natural gas stored as dissolved gas in highly pressured (geopressured) saline brines requiring the lowering of pressure for gas release and flow.

tight gas sands Natural gas stored within a low-permeability (tight) reservoir requiring natural and/or induced well stimulation for acceptable rates of gas flow.

unconventional gas Natural gas stored in a variety of geologically complex (unconventional) reservoirs requiring advanced exploration and production technology for their commercial development.

Unconventional natural gas has become a major source of energy supply in the United States. A large, favorable resource base, advances in knowledge, and steady progress in extraction technology have enabled significant portions of this resource to be converted to producible reserves. However, worldwide development and assessments of unconventional gas are still limited, concentrated primarily on coalbed methane and selected tight gas plays. This article provides a status report on our understanding of the size and nature of worldwide unconventional gas resources. The intent is that the information and insights in this article will be of value in accelerating the development of these large, complex natural gas resources.

1. BACKGROUND

For some time, geologists and resource analysts have known that large volumes of natural gas are locked in geologically complex, unconventional reservoirs, such as tight gas sands, gas shales, and coalbed methane (CBM). These unconventional gas reservoirs exist in the United States, Canada, and many other areas of the world. In the past, the natural gas resources stored in these geologically complex reservoirs have been judged as being too costly and technically difficult to recover to be a viable source for future natural gas supplies.

With advances in technology and understanding, the status and outlook for unconventional gas resources has become much more positive. Today, in the United States, unconventional gas provides 5.4 trillion ft^3 (Tcf) annually and accounts for 27% of domestic natural gas production, with each of the three unconventional gas sources—tight gas sands, coalbed methane, and gas shales—making a significant contribution, as shown in Fig. 1. The importance of unconventional gas is underscored by the recognition that 8 of the largest 12 U.S. natural gas fields exclusively produce unconventional gas (see Table I). Most significant, as set forth in the U.S. Department of Energy (DOE)/Energy Information Agency's Annual Energy Outlook 2003, unconventional gas is expected to become, by 2015, the largest single source of U.S. natural gas supply, surpassing

production from onshore conventional gas fields and offshore sources (see Fig. 2).

Worldwide, the pursuit of unconventional gas is also growing in importance. Significant drilling for coalbed methane is under way in Canada's Western Canadian Sedimentary Basin; Australia is actively producing tight gas sands from the Cooper Basin and coalbed methane from the Bowen Basin, and China, India, and South Africa (among other countries) are actively exploring for new coalbed methane plays.

Still, little is known about the ultimate size, nature, and producibility of these vast natural gas resources. The purpose of this article is to expand this base of knowledge.

2. *DEFINITIONS FOR UNCONVENTIONAL GAS*

Unconventional natural gas is defined as conventional natural gas (primarily methane) trapped in

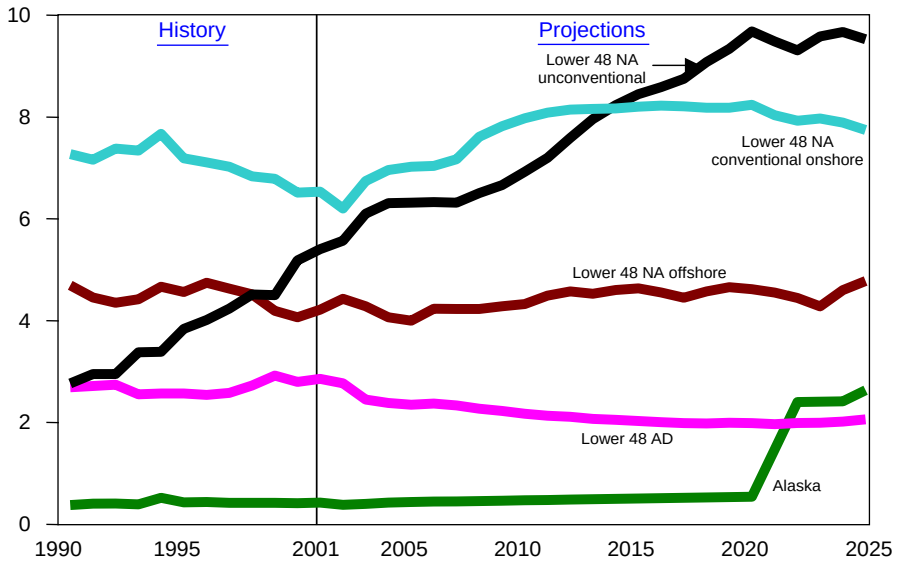

FIGURE 2 U.S. natural gas production, 1990–2025 (Tcf). *Source*: Advanced Resources International, Energy Information Agency (2003).

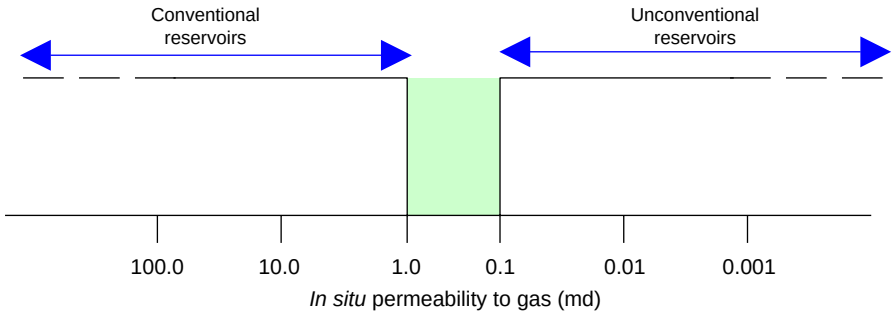

FIGURE 3 Permeability continuum for conventional through unconventional gas reservoirs.

geologically complex, nonconventional reservoirs, such as tight (low-permeability) sands, gas-bearing shales, and coalbeds. In the longer term, more speculative resources, such as gas hydrates, ultradeep gas, and geopressured methane, may be included in this resource category.

2.1 Tight Gas Sands

Tight gas sands are low-permeability (tight) gas-bearing reservoirs that have an *in situ* matrix permeability to gas of less than 0.1 md, exclusive of natural fracture permeability. Figure 3 illustrates the permeability continuum and criteria for conventional and unconventional gas reservoirs. In contrast to conventional gas reservoirs where the gas is held in structural or stratigraphic traps, tight gas reservoirs are areally extensive, often called continuous-type accumulations. These reservoirs occur in nearly all petroleum provinces, are usually abnormally pressured, and are often found in basin-center settings. Although they are commonly called tight gas sands, low-permeability reservoirs are found in a variety of rock types, including sandstone, siltstone, carbonate, limestone, dolomite, and chalk.

The porosity of lenticular and marginal-marine tight gas sand reservoirs is low, generally less than 12%, and the reservoir pores have high capillary pressure as a result of postdepositional cementation of conventional reservoir rocks. A second type of tight reservoir, such as a chalk, has high porosity of 15 to 35% but low permeability to gas because the rock is very fine-grained.

Artificial well stimulation, typically hydraulic fracturing, is required to attain commercial rates of gas flow from tight gas sands, unless the well

encounters an extensive cluster of natural fractures that enhances permeability. Identifying these naturally enhanced areas of permeability, the so-called "sweet spots" in an otherwise tight accumulation, is a major research and exploration objective for the industry.

2.2 Gas Shales

Gas shales are self-sourcing reservoirs where a major portion of the resource is adsorbed on and within the organic matter in the shale. To be productive and have adequate flow paths, the gas shale reservoir must be naturally fractured. Because of these conditions, gas shales are often called organic-rich gas shales or fractured gas shales.

Gas shale accumulations tend to be regionally pervasive, continuous-type accumulations and are abnormally pressured (generally underpressured). The quality of gas shales is judged by the total amount of organic matter (organic-rich shales are those containing more than 2% organic matter) and its degree of thermal maturity. Vitrinite reflectance values of over 1.5% are preferred for identifying areas with potential for thermogenic gas. Also important is the type of organic matter within the shales, the thickness and depth of the reservoir, and particularly the regional and local natural fracture intensity of the gas shale accumulation. These factors, in combination, determine the gas-producing potential of a gas shale reservoir.

Because the per well reserves of gas shales are often modest, low well costs, large-scale development (for economies of scale), induced fracture stimulation, and natural fracture (sweet spot) exploration are important for commercial, sustained production of natural gas from gas shales.

2.3 Coalbed Methane

Large volumes of methane, along with water and other gases, are generated in the process of converting organic matter to coal. This in-place generated gas, as well as deeper gas that may have migrated into the coal reservoir, is adsorbed (stored) upon and within the molecular structure of the coal. As such, coalbeds are both a source and a reservoir for natural gas. The amount of gas stored in the coal is a function of the coal's rank, pressure, temperature, and degree of gas saturation. High coal ranks and pressures, in general, lead to higher gas storage capacity. The storage capacity is commonly determined by using a sorption (or gas content) isotherm, as shown in Fig. 4.

The permeability of the coal matrix is nonexistent for all practical purposes. Gas moves through the angstrom-size pores in the coal by diffusion, an extremely slow flow process in most cases. As such, the primary flow paths for methane in coal seams are provided by the coal's cleat system, as well as its natural fracture overprint.

Dewatering and subsequent depressurization of the coal reservoirs are used to release the gas sorbed in the coal. Artificial well stimulation, such as hydraulic fracturing or cavitation, is used to create

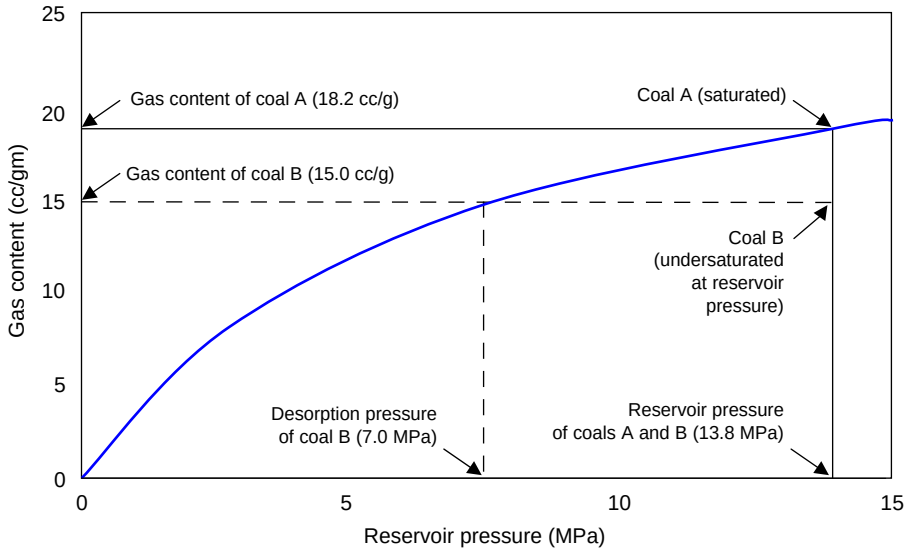

FIGURE 4 Idealized coalbed gas sorption isotherm showing relation between reservoir pressure and gas content for a saturated (coal A) and undersaturated (coal B) coal.

additional flowpaths to accelerate gas flow from the coal face and cleat systems to the wellbore.

As may be surmised from the above definitions for tight gas sands, gas shales, and coalbed methane, several features are common to unconventional gas resources:

1. First, the unconventional deposits may contain large, even massive volumes of gas in-place, often at low concentrations;
2. Second, despite the large volume of gas in-place, only limited areas will have sufficient richness and permeability for commercially developable reserves; and
3. Third, continued improvements in exploration and production technology, such as natural fracture detection, advanced reservoir diagnostics, and lower-cost well drilling and completion practices, are essential if these resources are to be effectively developed and converted to reserves.

Despite their widespread, global presence, the development of unconventional gas resources, particularly tight gas sands and gas shales, has been largely limited to the United States and much of the information in this article is based on this experience. The intent is that the information and insights in this article will be of value in developing the large, complex unconventional gas resources of the world.

3. RESOURCE ESTIMATES FOR UNCONVENTIONAL GAS

As more has been learned about the nature and location of unconventional gas, its resource estimates have increased and gained in confidence.

3.1 Initial Resource Estimates

The initial resource estimates for global unconventional gas were prepared by Kuuskraa and Meyers in the early 1980s, at a time when only limited information was available on the in-place and recoverable resource potential from tight gas formations, coalbed methane, fractured gas shales, or geopressured methane accumulations. Even less was known about methane hydrates or ultradeep gas.

As shown in Table II, the authors estimated that 570 Tcf of unconventional gas may be technically recoverable from the United States and Canada out of a gas in-place estimate of 2000 Tcf. The estimates for other areas of the world of 850 Tcf of technically recoverable resources were much more speculative and conservative and were based on analogues from the U.S. experience.

TABLE II

Technically Recoverable Resource Estimates for Unconventional Gas (Tcf)

	United States/Canada	Other areas	Total
Gas shales	50	250	300
Tight gas sands	460	400	860
CBM	60	200	260
Total	570	850	1420

Source. Kuuskraa and Meyers (1983).

3.2 Global Gas Resources Workshop

The second comprehensive set of resource estimates for unconventional gas was provided by the "Workshop on Global Gas Resources," convened in Vail, Colorado, in September 1994. The purpose of the workshop was to evaluate the worldwide gas resource base and the volume of resources that could be added with significant progress in technology. The workshop participants included presentations by 32 resource experts from 15 countries, representing international and domestic producers, state-owned energy companies, government organizations, universities, and research institutions.

The workshop participants concluded that advanced technology and unconventional resources could increase the 1993 U.S. Geological Survey (USGS) benchmark resource estimate for global natural gas by nearly 3000 Tcf, as shown in Table III and Fig. 5. Because unconventional resources in tight formations, gas shales, and coalbeds were not included in the 1993 USGS benchmark estimate (except for North America), the bulk of the 3000 Tcf of additional resource (producible with advanced technology to 2015) was estimated to be from unconventional gas.

Detailed estimates for unconventional gas were provided for the United States, Canada, and China by Fisher, Young and Drummond, and Miao, respectively. An overall review of global unconventional natural gas was provided by Kuuskraa. Of particular note were the closing remarks by Fisher on U.S. natural gas resources, setting forth long-term expectations for adding another 10,000 Tcf to the global gas resource base from unconventional gas and technology progress:

…the explicit incorporation of technology in resource estimates has doubled the U.S. estimate of ultimate recovery of natural gas…If the experience in the United States were extrapolated to the global resource base, the world reserves would exceed 20,000 Tcf, and they would be accessible at lower costs.

—Fisher, 1994

3.3 Resource Estimates

As the demand for natural gas has grown, considerably more attention has been placed on understanding the size, location, and producibility of unconventional gas.

TABLE III

Summary of Workshop Estimates for Natural Gas Resources (Tcf)

	USGS benchmark remaining resources,[a] 1993	Technology-enhanced resources, by 2015
North America	1394	2259
South America	715	987
Europe	617	783
Africa	813	1000
Middle East	2697	2799
Asia and Australasia	963	1733
Former Soviet Union	4361	4928
Total	11,560	14,489

[a] Total remaining resources are the sum of identified reserves and undiscovered gas (mean).

3.3.1 Rogner

Rogner, in 1997, published his latest assessment of global unconventional gas resources (see Table IV). Even after a considerable number of assessments, he noted that the data on unconventional gas is still limited, that estimates "are fraught with geological uncertainty," that "the technology implications for the eventual production of unconventional gas are poorly understood," and that "the data are speculative and should be read as such." Still, the information published by Rogner represented a significant step forward in quantifying both the gas in-place and the range of recoverable resources for unconventional gas. Rogner estimated the potential volume of unconventional gas in-place at over 35,000 Tcf globally.

Rogner estimated 10,000 Tcf of coalbed methane gas in-place, with over 3000 Tcf of gas in-place estimated for North and Central America. His regional distribution of coalbed methane was based on the geographical distribution of anthracite and bituminous coal deposits around the world, assuming average gas content values for these two coal types.

Rogner used the U.S. estimates for in-place natural gas from shale formations as an analogue to estimate 17,000 Tcf of global resources in gas shales, with

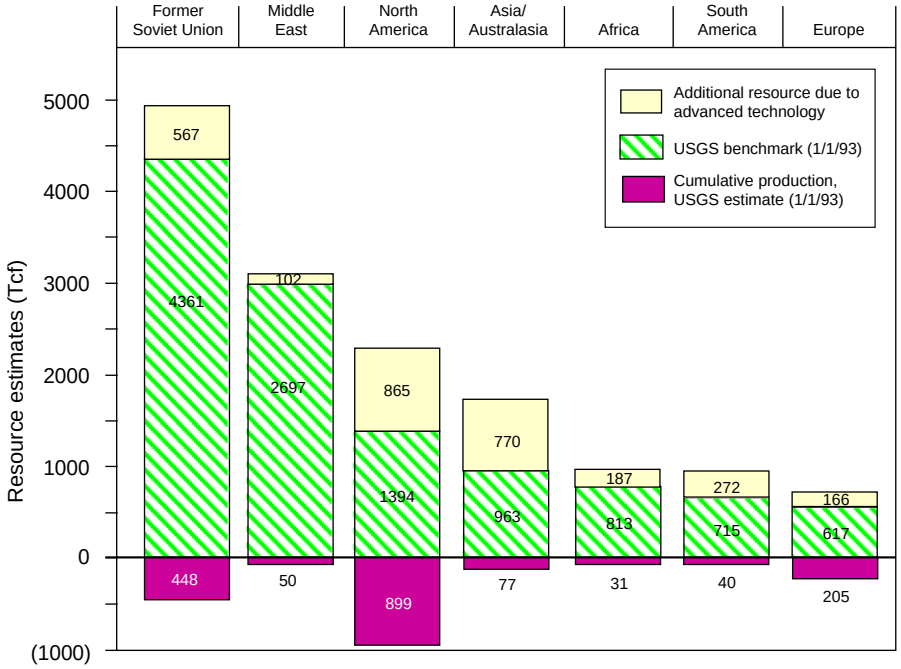

FIGURE 5 Global Gas Resources Workshop estimates for natural gas (Tcf).

TABLE IV

Estimates of Unconventional Natural Gas In-Place by Type (Tcf)

Region	Coalbed methane	Gas from fractured shales	Tight gas sands	Methane hydrates
North America	3270	4160	1480	260,000
Latin America and the Caribbean	40	2290	1400	190,000
Western Europe	170	550	380	30,000
Central and Eastern Europe	130	40	90	—
Former Soviet Union	4290	680	980	180,000
Middle East and North Africa	—	2750	890	10,000
Sub-Saharan Africa	40	300	850	20,000

Pacific OECD	510	2500	760	60,000
Other Pacific Asia	—	340	600	10,000
South Asia	40	—	210	20,000
World	9810	17,440	8020	800,000

over 4000 Tcf of gas in-place in North and Central America.

The 8000 Tcf global resource estimate and the regional distributions for tight gas sands were based on published data on conventional natural gas, with nearly 1500 Tcf estimated for North and Central America.

The global estimate for methane hydrate of 800,000 Tcf in-place was from an earlier estimate by MacDonald. A world map of locations of known and inferred gas hydrates in marine sediments and in continental permafrost was used to establish the regional distributions for this resource.

3.3.2 Nakicenovic

Nakicenovic, drawing on work by Rogner and others, published information on natural gas reserves and technically recoverable resources, including historical consumption of conventional and unconventional gas (see Table V). Reserves are assumed to be recoverable with available technologies at prevailing market conditions. Resources are technically recoverable volumes in addition to reserves, with less certain geological assurances, lacking economic feasibility, and requiring advances in technology for transforming these resources into reserves. The estimate of 33,200 Tcf of reserves and resources for unconventional gas was chosen to correspond to the highest plausible values from the literature. Nakicenovic postulated that potentially the resource base for unconventional gas could be twice as large as that for conventional gas and that the global natural gas resource base will be larger than that for oil.

3.3.3 Kuuskraa

In 1998, Kuuskraa published a country by country estimate for global coalbed methane, both for in-place and for technically recoverable resources (see Table VI). Kuuskraa estimated a CBM in-place value of 3000 to 8000 Tcf and a technically recoverable value of 510 Tcf. Kuuskraa's 1998 estimate for recoverable CBM resources is double his value published in the early 1980s. His most recent estimates were based on a combination of detailed CBM basin studies and information on the rank and depth of coal basins around the world. Future basins studies, particularly of the large CBM resources in Russia and the speculative CBM resources in Canada, the United States, and other countries, and advances in recovery technology would likely add considerably to these estimates of recoverable resources.

3.3.3.1 United States The United States has over 500 Tcf of high-quality coalbed methane resource (see Fig. 6). An additional 230 Tcf of CBM is in the deep coals of the Green River Basin and another 1000 Tcf of hypothetical CBM resource may exist in Alaska. Of this, 150 Tcf is estimated as being technically recoverable, including 29 Tcf of proved reserves plus past production. The estimates for technically recoverable CBM in the United States have steadily increased in the past 10 years and will likely continue to do so in future years. (Additional details on U.S. CBM development are provided in Section 4.)

TABLE V

Global Hydrocarbon Reserves and Resources

	Consumption		Remaining resource base		
	1860–1998	1998	Reserves	Resources	Total

Ukraine	50	N/A
Kazakhstan[a]	40	10
Total	3010–7840	510

[a] Assumes 20% recovery of gas in-place.

3.3.3.2 Australia Commercial-scale CBM projects exist in the Bowen and Gunnedah Basins, providing over 100 million ft^3 per day of production, with exploration under way in the Clarence-Moreton and Sydney Basins. The CBM resource in these four basins is estimated at 260 Tcf of gas in-place, plus 50 Tcf for the Galilee Basin, bringing the total to 310 Tcf. An additional 100 Tcf of gas-in-place may exist in the deep coals of the Cooper Basin. Approximately 60 Tcf of the CBM resource is estimated as recoverable, although considerable uncertainties exist on well productivities and economics. Given the substantial size of the resource, CBM production in Australia will likely be demand-limited. New gas pipelines to industrial gas users, such as to Mt. Isa, and the completion of a southeastern Australia gas grid are opening new markets, helping boost to both conventional gas and coalbed methane consumption.

3.3.3.3 Canada Canada has 570 Tcf of coalbed methane resources in-place, in formations that meet certain minimum reservoir parameters. This high-graded portion represents approximately one-quarter of the total Canadian CBM resource of 2280 Tcf. Using U.S. coal basins as the analogue, approximately 140 Tcf, in the higher quality reservoir settings, is judged to be potentially recoverable. The largest portion, 100 Tcf, is from the Cretaceous-age coals in the plains and foothills of Alberta. Approximately 35 Tcf of CBM is from British Columbia and 5 Tcf is potentially recoverable from Nova Scotia and Prince Edward Island.

3.3.3.4 China China has a large CBM resource base, estimated at 1150 Tcf, of which 350 Tcf is judged to be in areas geologically favorable for exploration. Of this, 150 Tcf is in eight main CBM exploration areas and perhaps 70 Tcf is technically recoverable. Much of the CBM resource, though located close to urban industrial markets in eastern China, occurs in structurally complex basins. The premier CBM area in China is the eastern margin of the Ordos Basin, where the structural setting is simpler and favorable permeability has been measured. Two new gas pipelines from the Ordos Basin to Beijing and Xian could accommodate 200 million cubic feet (MMcfd) of future CBM production. In addition, China is the world's largest coal producer and emits the highest volumes of mine-sourced coalbed methane into the atmosphere, an estimated

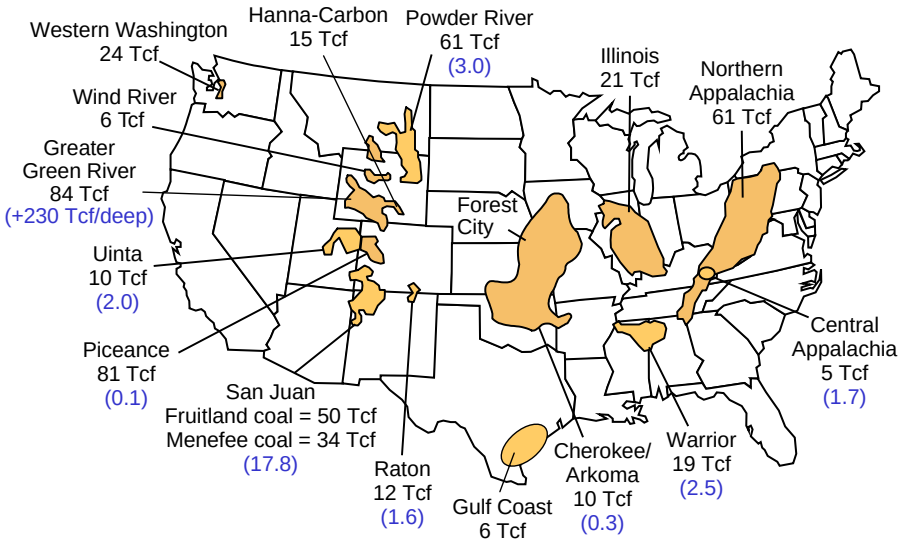

FIGURE 6 Coalbed methane resources of the United States. Values indicated (in Tcf) represent gas in-place; numbers in parentheses indicate resources that have been produced or are reserves (in Tcf) as of 2002; shaded areas indicate coal basins. *Source*: Advanced Resources Database.

2 billion cubic feet (Bcfd). Capture and use of this coal mine methane would provide a valuable source of clean energy and significantly reduce the emissions of a powerful greenhouse gas.

3.3.3.5 India India has 90 Tcf of coalbed methane resource in-place. Of this 44 Tcf is in six Damodar Valley coal fields, 40 Tcf is in the Cambay Basin of Gujarat, and 6 Tcf is in the Sohagpur and Satpura Basins. Additional CBM resources exist in other Gondwana and Tertiary coal basins of the Godavari and Mahanadi Valley that have yet to be appraised. An estimated 20 Tcf of CBM may be technically recoverable from the Damodar Valley and the Cambay Basin. Production of India's coalbed methane resource will be assisted by a strong natural gas market and plans for expanding its natural gas pipelines.

3.3.3.6 Indonesia A new entry on the world coalbed methane scene, Indonesia is estimated to have 210 Tcf of CBM resources, primarily in the Sumatra and East Kalimantan coal basins. Of this, approximately 30 Tcf is estimated as being in sufficiently high-quality settings to be potentially recoverable. Given its large conventional gas resources, uncertainties about markets, and lack of current activity, development of Indonesia's CBM may progress slowly.

3.3.3.7 Poland/Czech Republic The coalbed methane resources of Poland and the Czech Republic are estimated at 70 Tcf. This includes 47 Tcf in the Upper and Lower Silesian Basins of Poland, 20 Tcf in the Czech Republic, and 3 Tcf in the Lublin Coal Basin. Additional CBM resources may exist in the deep coals (below 1500 m) of Poland. Because of uncertainties with respect to permeability and gas saturation, no estimates of recoverable resources exist.

3.3.3.8 Russia Ultimately Russia may hold the largest volume of coalbed methane, though much of it is still poorly defined. The Kuznetsk Coal Basin (Kuzbass), on the southern slopes of the west-central Siberian plain, covers an area of 10,000 mi^2. The numerous coal seams in this basin extend to below 5000 ft in the basin center and hold an estimated 450 Tcf of CBM resource. The Pechora Basin, located on the Arctic Circle adjacent to the Barents Sea, holds an estimated 175 billion tons of high- to low-volatility bituminous coals and an estimated in-place CBM resource of 100 Tcf. Given the lack of data, no estimates are available on technically recoverable resources. The massive Tungusk Basin in the center of Siberian Russia that extends from the Arctic Circle to the Mongolian border may hold over 1000 Tcf and ultimately may become one of the largest CBM basins in the world.

3.3.3.9 Ukraine The Ukraine has 50 Tcf of coalbed methane in-place, primarily in the Donetsk Coal Basin. Given the high geologic complexity of the basin, the limited data, and the extensive past

mining in the basin, estimates of recoverable resources are still speculative.

3.3.3.10 Western Europe Western Europe is estimated to hold 120 Tcf of coalbed methane in place. The Carboniferous coal basins in Western Europe share many similarities: moderately gassy coals, concerns over natural degassing, numerous thin coal seams distributed over a large stratigraphic interval, and structurally complex settings. Coalbed methane has been tested in France, Germany, Great Britain, Belgium, the Netherlands, and Spain. Thus far, the results have been inconclusive, providing little basis for estimates of recoverable resources.

3.3.3.11 Other Counties Coalbed methane exists in numerous other countries, with still limited information on quality and producibility. Prominent are Turkey with 50 Tcf, Kazakstan with 40 Tcf, and Southern Africa with 90 Tcf of gas in-place. Approximately 20% of this in-place resource may be technically recoverable. South America (Brazil, Colombia, and Venezuela) has no publicly available assessments for CBM resources. Future exploration may add these and other countries to the world's productive CBM ledger.

3.4 Dynamic Resource Base

The review of unconventional gas resource estimates provides a valuable insight. As more is learned about the nature of these resources and the technologies by which to produce them, the resource estimates have changed dramatically.

- For geologically sound unconventional gas resources, such as tight gas sands, gas shales, and coalbed methane, the historical review shows that the recoverable resource and reserve estimates have steadily increased.
- For geologically uncertain resources, such as geopressured methane, little additional information has been obtained and the expectations for recoverable resources are low.
- For the very speculative unconventional gas resources, such as gas hydrates, much too little is known about their in-place gas concentrations and reservoir settings to provide scientifically reliable estimates on recoverable volumes.

An example of the expected growth in the U.S. unconventional gas resource base is shown in Fig. 7 and Table VII. Figure 7 shows the expected growth in tight gas sands, gas shales, and coalbed methane resource between the years 2000 and 2025, stemming from an assumed continually improving knowledge base and technology. Table VII provides an update to Fig. 7, using the latest information for the U.S. unconventional gas database maintained by Advanced Resources International.

Looking ahead, it is useful to recognize that the information and expectations for unconventional gas represent a "snapshot in time." As new plays are

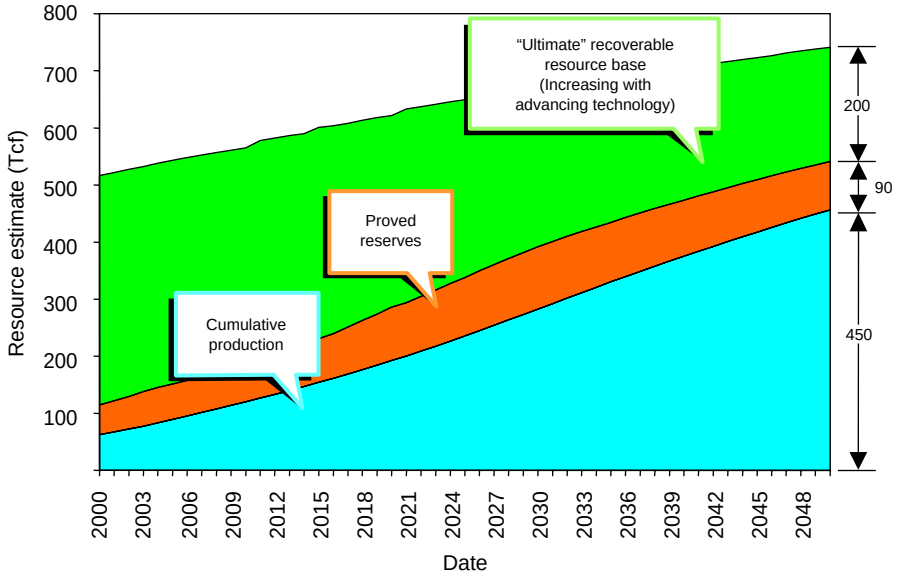

FIGURE 7 Projected growth of unconventional gas resources, years 2000 to 2050. *Source*: Modified by Advanced Resources from National Petroleum Council (1992).

TABLE VII

Estimates of Technically Recoverable U.S. Unconventional Gas Resources (Tcf)

	Year 2002 technology			Year 2025 technology:
	Proved reserves/production	Undeveloped resource	Ultimate resource	Ultimate resource
Tight gas sands	149	292	441	520
Gas shales	13	62	75	90
Coalbed methane	29	95	124	150
Total	191	449	640	760

tested, additional wells are drilled, and more efficient technologies are developed, the outlook for this complex natural gas resource will most likely improve, for two reasons:

1. First, the ultimate size or productivity of the unconventional gas resource base is not yet known. Improved geologic knowledge continues to expand its size by adding new gas plays. Technology progress helps increase recovery from the already defined plays. An example of this is the Barnett gas shale play in the Fort Worth Basin that is now estimated to have 20 Tcf of recoverable resource, up from 1.4 Tcf in the initial estimate prepared over a decade ago (as further discussed below).
2. Second, the economic outlook for unconventional gas resources, basins and plays will likely continue to change significantly with time. With the aid of technology, an unconventional gas basin or play can move from a high cost, marginal resource to a major, highly productive gas reserve. An example of this is the San Juan Basin coalbed methane play that originally was assessed by resource analysts as unaffordable, with costs of over $5 per million ft^3. Today, this important gas play accounts for 9 Tcf of remaining proved gas reserves plus 9 Tcf of past production (as of 2001).

At the other extreme is geopressured methane that was touted, 20 years ago, to hold 1000 years of natural gas supply. No production or reserves have been developed nor are any expected from this resource.

The sequence of resource assessments for the Barnett Shale gas play, illustrates the impact that improved knowledge and technology progress can have on the outlook for an unconventional gas play.

3.4.1 Initial Assessment

The first assessment for the Barnett Shale (Table VIII, column 1) was prepared using data available as of 1990, after the first group of 86 wells was drilled in this gas shale play. The initial wells had relatively low estimated ultimate reserves (EURs) of 0.35 Bcf per well, and the field was being developed on wide well spacings of 320 acres per well. Using this initial data, the Barnett Shale was estimated to have 1.4 Tcf of technically recoverable natural gas.

TABLE VIII

Successive Assessments of Recoverable Barnett Shale Gas Resources

	Initial assessment, 1990	USGS special assessment, 1996	Latest assessment, 1998
Development intensity (acres/well)	320	320	80–320
Completed wells			
Productive	74	180	300
Unproductive	12	30	50
Play (mi^2)	2439	2439	2439
Future wells	4792	4668	10,148
Success rate	0.86	0.86	0.86
EUR/well (Bcf)	0.35	0.84	0.35–1.50
Technically recoverable resources (Tcf)	1.4	3.4	10.0

3.4.2 Second Assessment

The second assessment by the USGS in 1996 (Table VIII, column 2) used a higher EUR per well, due to improved well-completion practices, of 0.84 Bcf per well but still assumed that wide well spacing of 320 acres would be the norm. The improved EUR per well raised the recoverable resource estimate for the Barnett Shale to 3.4 Tcf.

3.4.3 Third Assessment

The third assessment (Table VIII, column 3) incorporated a more optimum, "intensive development" model for the Barnett Shale. It recognized the very limited drainage being achieved by past Barnett Shale wells and that technology progress was leading to higher EURs in the naturally fractured portions of the play. This assessment established that 10 Tcf of technically recoverable gas exists for the Barnett Shale, with much of the economic potential of this resource residing in the higher productivity, sweet spots in the basin that would be developed at spacings of 80 acres per well. Recent updates place the recovery potential at 20 Tcf.

4. UNCONVENTIONAL GAS DEVELOPMENT IN THE UNITED STATES

4.1 Historical Review

Serious pursuit of unconventional gas in the United States began more than 20 years ago, following concerns that the nation was running out of conventional gas supplies. A Federal Power Commissions task force identified large volumes of tight sands gas in-place in three large Western basins. The Bureau of Mines noted that considerable volumes of methane were being vented for safety reasons from coal mines, wasting a valuable resource. In addition, public interest was stirred by major articles in *Fortune* and *The Wall Street Journal* that a new natural gas resource—geopressured aquifers—could provide gas for 1000 years.

These initial findings helped launch a series of more thorough assessments of unconventional gas and studies of how advances in technology could make these large in-place resources productive, as further discussed below.

4.1.1 Tight Gas Sands

Large quantities of natural gas resources were known to exist in geologically complex, tight (low permeability) formations. However, using available well completion technology, the production of gas from these tight formations, for the most part, was too low to support economic recovery. A handful of independents were exploring certain of the tight gas sand basins, with generally a poor record of success. The broad consensus was that significant advances in exploration and well completion technology would be required to develop this large, complex gas resource.

In response, the DOE, the Gas Research Institute (GRI), and industry established research and development programs to unlock the gas resource held in these tight rocks. Spurred by advances in technology, the development of tight gas sands expanded rapidly from the initial limited efforts in the Appalachian and San Juan Basins to the major Rocky Mountain gas basins and into Texas and the midcontinent. By 2001, tight gas sands were producing 3.3 Tcf per year. Proved tight gas reserves were 48 Tcf from a cumulative 80,000 drilled wells (not including the

4.1.2 Gas Shales

Twenty years ago, only the Appalachian Basin gas shales were being produced. Wells were being completed open-hole, with little definition of productive pay zones, and were being stimulated with nitroglycerine (a remnant of early 1900s technology). Much of the activity was centered in the Big Sandy area of eastern Kentucky. Little understanding existed about the key gas storage and production mechanisms or about geologically similar gas shale plays in other parts of the country. Gas shale drilling averaged only 200 wells per year and the play was in decline.

By 2001, annual gas shale production had reached 500 Bcf. Proved reserves are 7 Tcf, with another 6 Tcf having been produced. Stimulated by Section 29 tax credits and the expansion into new gas shale basins in Michigan and north Texas, 20,000 gas shale wells were drilled from 1978 to 2001 with a peak of 1700 gas shale wells completed in 1992. Figure 9 shows the location of U.S. gas shale basins. Table X provides estimates of the resource in-place, proved reserves, and remaining technically recoverable gas shale resources.

4.1.3 Coalbed Methane

The combination of building a scientific base of knowledge, developing appropriate technology, and providing economic incentives launched the birth of

a new natural gas industry: coalbed methane. Much of the early development was by independent producers, such as Devon Energy and Meridian Oil, who subsequently saw their gas production and reserve holdings rise sharply.

Coalbed methane production climbed from essentially zero in the mid-1980s to 1.6 Tcf in 2001. Proved reserves are 17.5 Tcf, with another 11.5 Tcf having already been produced (see Figs. 10 and 11). The development and continuing adaptation of

technology enabled the industry to remain profitable and vigorous, even after the expiration of Section 29 tax credits in 1992. Today, several new coalbed methane basins and plays are being actively developed, including the Powder River (Wyoming), Raton (Colorado), and Uinta (Utah), providing a base for continued growth. Table XI provides estimates of the in-place and technically recoverable coalbed methane resource for the United States.

4.1.4 Geopressured Methane

An aggressive research and development program assembled considerable geologic and reservoir knowledge for this resource. And, although no commercial natural gas production was established, the research and development program helped bring a strong dose of reality and understanding regarding the viability this gas resource. It also helped dispel the speculation that "1000 years of natural gas" was at hand.

4.2 Assessment of Results

Unconventional gas offers one of the great success stories of progress in technology. A poorly understood, high-cost energy resource, one that the U.S. Geological Survey had not even included in its national appraisals of future gas resources (until their 1995 assessment), is now providing major volumes of annual gas supplies and helping meet growing domestic natural gas demand.

5. CONCLUSION

The discussion and resource estimates for unconventional gas presented in this article are a snapshot in time. The ultimate size or productivity of this geologically complex natural gas resource is not yet known. However, it is useful to document what is known as the foundation for continually improving the base of knowledge and the expectations for this large potential source of future natural gas supplies.

Glossary

aquifer A porous permeable sedimentary formation located belowground and containing groundwater.
base or cushion gas The minimum quantity of natural gas that must be retained in gas storage to ensure the production of natural gas from storage at a sufficient rate and pressure; usually measured in volume expressed at 15.6°C (60°F) and 1.0 atmosphere of pressure (standard conditions).
deliverability The rate at which natural gas can be withdrawn from gas storage; usually measured in volume expressed at 15.6°C (60°F) and 1.0 atmosphere of pressure (standard conditions) per unit day.
hydrate A cagelike crystalline solid material similar to ice, formed by combining gas with water.
injectivity The rate at which natural gas can be injected into gas storage; usually measured in volume expressed at 15.6°C (60°F) and 1.0 atmosphere of pressure (standard conditions) per unit day.
inventory A survey of the total amount of gas contained in storage; usually measured in volume expressed at 15.6°C (60°F) and 1.0 atmosphere of pressure (standard conditions).
liquefied natural gas (LNG) The liquid state of natural gas, essentially containing methane and little ethane.
liquefied petroleum gas (LPG) The liquid form of propane and butane.
million British thermal units (MMBtu) A measure of heat generated by gas combustion.
permeability A physical parameter expressing the fluid (gas or water) transmitting capacity of the interconnected porous space available in depleted oil and gas reservoirs and water aquifers.
pipeline A long pipe used to transmit fluids.
porosity The volume fraction of the porous space occupied by fluids (gas and water) in depleted oil and gas reservoirs and water aquifers.
reservoir An underground geologic permeable rock formation; contains fluids such as oil, gas, and water in pore spaces.
salt cavern A cavity created in a deep salt bed or dome following the dissolution of salt by circulating hot water.
standard or base conditions Thermodynamic conditions considered as the reference conditions for volume measurement, usually temperatures of 0°, 15.6°, or 25°C and 1.0 atmosphere of pressure.
storage Facilities of various types and capacities used to store natural gas.
storage measures The various means of expressing the properties and conditions of a gas storage area and its gas content.
thousand standard cubic feet (Mscf) A measure of gas volume.
total capacity The largest quantity of natural gas that can be loaded into a particular gas storage area; usually measured in volume expressed at 15.6°C (60°F) and 1.0 atmosphere of pressure (standard conditions).
working gas capacity The difference between the total and base gas capacities of gas storage.
working (top) gas The maximum quantity of natural gas that a particular gas storage can hold and still allow for circulation; usually measured in volume expressed at 15.6°C (60°F) and 1.0 atmosphere of pressure (standard conditions).

Natural gas is an important commodity traded frequently in the energy market. It can be utilized as a source of energy by direct consumption as fuel or

 © 2004 Elsevier Inc. All rights reserved.

by other means, including after conversion to hydrogen for use in fuel cells or after conversion to various chemicals. Because it is a gas and a low-density substance at ambient pressure and temperature conditions, safe and economic handling of natural gas during transportation, storage, and utilization requires special measures and sophisticated technologies. Therefore, the worldwide trade and utilization of natural gas is inherently limited by the difficulty of handling gas between the source and market.

1. INTRODUCTION

Natural gas is gaining increasingly great potential as an abundant and environmentally friendly energy source; it is available worldwide from onshore and offshore reserves in various forms, including as gases or as condensates in underground geological reservoirs, and as solid hydrates in hydrate-bearing sedimentary formations present in permafrost regions and ocean floors. Thus, technologies are being developed rapidly for its economical production and utilization. Although transportation is necessary as a means of delivering gas from production to market, gas storage ("parking" gas temporarily) at appropriate locations is instrumental in compensating between the surge and peak effects in the gas supply-and-demand value chain. Accurate measurement of natural gas using reliable meters is another important issue involved in custody transfer and inventory accounting in natural gas trading. Effective engineering and management of the gas transportation and storage facilities also include strategic security measures and emergency response procedures. Capacity and location of the source and the user, available and feasible technologies, and economics determine the means of transportation and storage used. The various types and capacities of transportation and storage facilities involved in natural gas handling and value chain are summarized in Table I.

2. NATURAL GAS

Natural gas is a mixture of hydrocarbon and nonhydrocarbon gases; these gases are produced from petroleum and hydrate-bearing formations present in geological sedimentary formations located below the ground surface and the ocean floor. Typical hydrocarbon components of natural gas

TABLE I

Means of Transportation and Storage of Natural Gas[a]

Natural gas compression	Direct gas liquefaction	Conversion to hydrate blocks or hydrate-in-oil slurry	Dissolution of petroleum gas in pentane-plus-heavier fractions of crude oil	Chemical conversion to liquid products	Electric power generation

[a] From oil and gas reservoirs, as coal bed methane, as ocean–floor and permafrost hydrates, and gathered from wells.

include a significantly large percentage of methane, and relatively smaller percentages of ethane, propane, isomer and normal butanes and pentanes, hexane, heptane, and other heavier hydrocarbons. The typical nonhydrocarbon components can be classified as acid gases, such as hydrogen sulfide and carbon dioxide; inert gases, such as nitrogen and helium; odorous sulfurous gases, such as hydrogen sulfide and various mercaptans; and other impurities, such as water and mercury vapors and sulfur dissolved in gas.

The composition of natural gas dictates its behavior during the chain of processes involved in gas handling, including its transportation and storage. Its density ρ or specific volume v are given by the real gas equation of state as in Eq. (1):

$$\rho = \frac{1}{v} = \frac{m}{V} = \frac{MP}{ZRT}, \tag{1}$$

where m, V, P, and T denote the mass, volume, pressure, and temperature of the gas, M is the gas molecular mass (16 kg/kmol for methane), R is the universal gas constant (8308 J/kmol°K), and Z is the real gas deviation factor, a function of the pressure, temperature, and composition of gas, usually given by empirical correlations or charts. The density of the methane gas is about 0.65 kg/m^3 at 25°C and 1 atm under ambient conditions. The density of natural gas relative to the density ρ_a of dry air of standard composition, at standard conditions, is referred to as the specific gravity G, given by Eq. (2):

$$G = (\rho/\rho_a)_b = M/M_a, \tag{2}$$

where the molecular weight of air is $M_a \cong 29$ kg/kmol. The standard conditions b are defined as zero or 15.6°C (60°F) temperature and 1.0 atmosphere of pressure. The gravity of methane gas is 0.55. The gravity of typical natural gas is about 0.64, hence it is lighter than air. Therefore, the transportation and storage of natural gas in large mass present a challenging engineering problem, requiring sophisticated and expensive technologies. This is because the volume of natural gas per unit mass (referred to as the specific volume) is very large and its density is very low at ambient conditions. For example, 1 kg of methane gas occupies 1.5 m^3 at 25°C and 1.0 atm of pressure. Consequently, natural gas should be compressed or converted to smaller volumes by suitable means in order to be able to handle the large quantities in a convenient manner.

At elevated pressure and sufficiently low temperature conditions, natural gas can liquefy and produce a multiphase system, including a liquid phase, referred to as condensate, and a solid phase (when combined with water), referred to as a natural gas hydrate. Production of condensates and hydrates of natural gas creates various difficulties during transportation and storage of natural gas. Coping with such problems is an important issue in natural gas transportation and storage, and an economic and technological headache.

3. NATURAL GAS TRANSPORTATION

Transportation facilities of various types are used for collecting gas from distributed sources and for delivering it to end users (the customers), who utilize gas for various purposes. The worldwide trade and utilization of gas greatly depend on the availability and economics of gas transportation and distribution facilities. The primary gas transportation technologies are based on compressed gas transport, direct pipeline transfer, gas-to-liquid conversion, gas-to-solid conversion, and gas-to-power conversion.

3.1 Compressed Gas Transport in High-Pressure Tanks

Natural and petroleum gases can be transported as compressed gas in small quantities inside high-pressure tanks for use at residences, in industry, and in gas-powered vehicles. Based on Eq. (1), the volume of compressed gas at the prevailing pressure P and temperature T can be estimated by Eq. (3):

$$V = V_b Z \frac{T}{T_b} \frac{P_b}{P}, \tag{3}$$

where P_b and T_b denote the base or standard pressure and temperature, respectively, and V_b is the standard gas volume.

3.2 Direct Pipeline Transfer

Pipeline transportation is the oldest and most common technology; pipelines are widely utilized worldwide for transportation of gas. Pipeline transportation of natural gas involves a variety of equipment and instrumentation, such as a pipeline network to carry gas from different sources to the end users; meters to measure the gas quantity and flow; valves to control the gas flow; regulators to control the gas pressure; safety devices, expansion systems, and storage facilities for temporary storage

TABLE II
Worldwide Natural Gas Pipeline Extent[a]

Location	Length (km)
North America	405,980
Latin America	35,041
Europe	267,846
Africa	7160
Middle East	6854
Asia–Oceania	145,519
World total	868,400

[a] Estimated based on data in *The World Factbook* (available on the Internet through the Central Intelligence Agency Web site at http://www.cia.gov).

of gas; dehydrators to remove the moisture and prevent water condensation, hydrate plug formation, and corrosion; compressors to pressurize and "flow" the gas; prime movers and electrical control systems to operate these systems; and remote data acquisition, monitoring, and transmission systems. Table II provides worldwide statistics about the extent of natural gas pipelines based on information provided by *The World Factbook*.

One of the frequently used pipeline flow equations is the Weymouth equation, expressing the gas flow rate q_b at the base pressure and temperature conditions, given by Eq. (4):

$$q_b = \frac{\pi}{4}\frac{T_b}{P_b}\left[\frac{R(P_1^2 - P_2^2)D^5}{M_a G \bar{Z} T \bar{f} L}\right]^{1/2}. \quad (4)$$

The symbol L denotes the length of the pipeline, the gas pressures at the inlet and outlet ends of the pipeline are P_1 and P_2, D is the internal diameter of the pipe, M_a is the molecular weight of standard air, and $\bar{Z}$ and $\bar{f}$ are the average values of the real gas deviation factor and the pipe friction factor over the pipe length.

3.3 Gas-to-Liquid Conversion

Liquids can be more conveniently, safely, and economically transported in large quantities than can gases. Natural and petroleum gases can be transformed into liquids either by direct cryogenic condensation, by mixing, or by chemical conversion. Cryogenic condensation forms liquefied gases, such as liquefied natural gas (LNG), which essentially consists of methane and little ethane, and liquefied petroleum gas (LPG), which consists of the propane and butane cut. Liquefaction occurs by mixing natural or petroleum gas with the pentane-plus-heavier hydrocarbon fractions separated from an associated gas of crude oil. Chemical conversion yields liquid products such as methanol and gasoline. Chemical conversion of natural gas to liquid products requires the application of a series of complicated and expensive chemical processing methods. Therefore, chemical conversion is not a generally preferred option. Nevertheless, the liquids produced by chemical conversion are stable at ambient conditions and can be conveniently carried and safely stored at moderate near-ambient conditions. Following liquefaction, intercontinental and marine transport of liquids is accomplished by means of specially designed tankers or ships.

Transportation of gas in liquefied form is a broadly exercised option. However, this combines a series of delicate technological issues, including compression, Joule–Thomson expansion turbines, cooling and heating, fractionation, and specially designed storage tanks for tankers. Liquefied natural gas is transported as a cryogen at the normal boiling temperature at atmospheric pressure. This temperature is -161.5°C for pure methane. However, natural gas also contains small quantities of other hydrocarbon gases. Therefore, the liquefaction process undergoes a gradual condensation by cooling from heavier to lighter components at different temperatures, ending with the condensation of methane at -161.5°C. The density of the liquid methane is about 420 kg/m^3 at this condition. This means that 1 kg of liquid methane occupies a volume of only 0.0024 m^3. Hence, the volume of the liquid methane is 625 times less than the volume of the methane gas at ambient conditions.

The LNG tankers for marine transport are specially designed and constructed to carry large quantities of liquefied natural gas safely. The hull of LNG tankers usually is double, consisting of outer and inner hulls, separated with a space sufficient to protect against damage by contact or collision of tankers with other objects. Essentially, integrated and self-supporting tanks are used as containers in the conventional LNG tankers. The LNG tankers incorporating the integrated-tanks technology contain a series of rectangular tanks containing a membrane to resist the external forces. The LNG tankers incorporating the self-supporting tanks technology contain a series of individually reinforced tanks, usually spherical in shape, designed to resist the hydrostatic force of their fluid content. These tanks are placed at sufficient distances from the neighboring tanks and are insulated

individually. LNG transport by tankers also requires auxiliary services for liquefaction of natural gas, and LNG loading, storage, discharging, and regasification.

3.4 Gas-to-Solid Conversion

Under proper conditions, natural gas combines with water to form a cagelike crystalline solid material similar to ice, called a gas hydrate. The gas and water molecules are held together because of the molecular interaction forces. Hydrates can hold approximately 150 to 180 standard (at 15.6°C or 60°F and 1.0 atm) volumes of natural gas per unit hydrate volume and they are stable in the −10° to −15°C temperature range at atmospheric conditions. Natural gas hydrates exist in ocean floor and permafrost regions. Gas hydrates can also be artificially manufactured in the form of rectangular and cylindrical blocks and transported conveniently via ships and other means. Hydrates can also be transported through pipelines in the form of slurry with oil. For this purpose, the gas and water are placed into contact at conditions near 5°C and 50 atm in stirred-tank or spray-tower reactors to produce gas hydrates. This process generates some heat, which must be removed by appropriate cooling technologies. This rather new technology is under development. Hydrate transportation requires additional processes to form and dissolve the hydrates.

3.5 Gas-to-Power Conversion

Conversion of gas to electric power is accomplished in gas-powered combined-cycle electric power plants. Electricity is the most convenient means for transport, using electric transmission cables of various types. However, electric storage is a challenging technological barrier. Theoretically, 1.0 kg of methane can generate 14 kilowatt-hours (kWh) of electric energy if all the chemical energy can be converted to electric energy with 100% conversion efficiency. However, the actual energy generated by combustion of methane is less than this quantity, because of the loss of energy by friction and other means.

4. NATURAL GAS STORAGE

Temporary natural gas storage capability is essential in order to balance out the supply of natural gas with demand, and as a backup reserve to compensate for shortages and temporary interruptions of gas supply

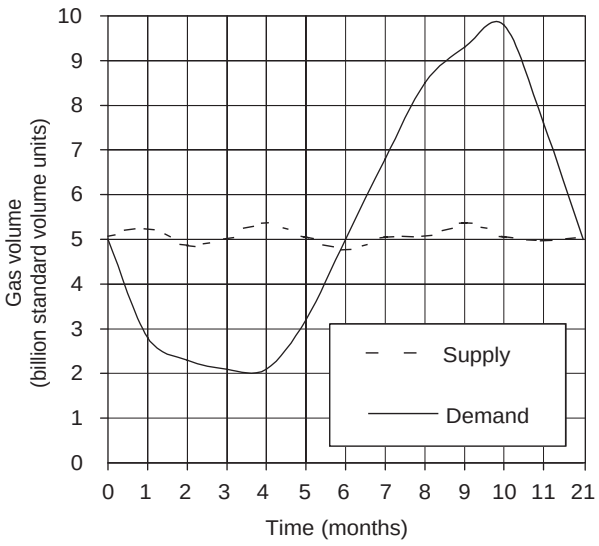

FIGURE 1 Natural gas storage and consumption based on the supply and demand trends.

or demand. Gas storage provides a convenient leverage and advantage in risk management, combating and dealing with peaks in the gas supply-and-demand chain, and accommodating gas price fluctuations. Natural gas is temporarily stored when the market is unfavorable and/or demand is low, and the stored gas is made available under favorable market and demand conditions. For example, as a heating fuel, gas is stored during summers and consumed during winters (Fig. 1). Companies providing various gas utilization services, local distribution, and intra- and interstate pipeline transportation rely on gas storage in order to alleviate the variations in the supply-and-demand chain. When storage cannot meet the demand for natural gas, liquefied natural or petroleum gases are regasified for the market.

Various features, such as capacity, accessibility, and gas injection and production rates, determine the type of gas storage for particular applications and requirements. The conventional gas storage options can be broadly classified as aboveground and underground storage facilities.

4.1 Aboveground Natural Gas Storage

The primary means of aboveground gas storage involve pipelines, cryogenic tanks, and gas hydrates.

4.1.1 Pipeline Storage

Pipeline networks can be used to provide temporary gas storage when they are not needed for gas

transmission purposes. This helps in coping with the rapid surge and peak situations in the supply-and-demand value chain over short time frames. Applying the Weymouth equation given by Eq. (4), the total quantity of gas stored in a pipeline after closing its ends can be estimated as follows:

$$V_b = \frac{\pi D^2 T_b L}{6 P_b T}\left(P_1 + P_2 - \frac{P_1 P_2}{P_1 + P_2}\right). \qquad (5)$$

4.1.2 Storage in Cryogenic Tanks

Tank storage affords small capacity and is expensive, but can be facilitated practically anywhere. Natural gas can be stored cryogenically in small quantities in specially designed storage tanks at –155° to –160°C temperatures. These tanks are well insulated against heat influx from the surroundings and therefore cooling is not required. Further, the storage tanks can be placed inside specially designed dikes to confine the liquefied gas in case of accidental spills. Cryogenic storage tanks may be constructed as double-wall or membrane tanks.

Prolonged storage of liquefied gas in storage tanks may create a hazardous condition resulting from external heating at the bottom of the tank over time. Heating can cause a density difference and stratification of the stored liquid, eventually leading to rollover and rapid mixing of the colder and heavier upper layer with the warmer and lighter lower layer of the cryogen. The rollover phenomenon can be avoided by maintaining a uniform-density liquid throughout the tank; this can be accomplished by various methods, including proper loading and discharging procedures, continuous recirculation of the liquid in the tank, and reliquefying the vapors generated by boil-off and refluxing of the liquefied vapors back into the tank.

4.1.3 Storage as a Gas Hydrate

Gas can be conveniently stored in the form of hydrate blocks. As explained for transporting gas as hydrates, typical hydrates can hold approximately 150 to 180 standard volumes of natural gas per unit hydrate volume, and they are stable in the −10° to −15°C temperature range at atmospheric conditions. This technology enables storing large quantities of natural gas in the hydrate state.

4.2 Underground Gas Storage

There are various options for underground gas storage, varying in capacity and performance, such as in-ground storage tanks, depleted and abandoned oil and gas reservoirs, aquifer storage, salt and hard-rock caverns, and abandoned mine shafts. Table III provides several statistics about the worldwide disposition of underground gas storage capacity.

4.2.1 In-Ground Storage Tanks

In-ground storage tanks and aboveground tanks are constructed similarly, but in-ground tanks are partially or fully buried in the ground.

4.2.2 Depleted and Abandoned Oil and Gas Reservoirs

Oil and gas reservoirs with their existing wells and surface handling facilities are widely used for underground gas storage after their economically recoverable hydrocarbon content has been depleted. Depleted gas reservoirs are preferred because their

TABLE III

Worldwide Underground Gas Storage Capacity[a]

Location	Storage sites (number)	Working capacity (10^9 m^3)	Total capacity (10^9 m^3)	Peak withdrawal rate (10^6 m^3/day)
United States	386	102	228	1894
Western Europe	66		86	782
Central Europe	17	7.3	—	—
New independent states	46	80.5	—	—

[a] Based on data from an international association of natural gas industries and the Institut Français du Pétrole (IFP-CEDIGAZ). (Available at the Web site http://www.cedigaz.com.)

structure is more likely to be leakproof compared to oil reservoirs. The injectivity and deliverability of gas storage will vary with the prevailing condition and quantity of stored gas and with several other factors, including the energy or driving mechanisms (such as water drive) of the reservoir storage for gas transport; the gas and storage formation rock compressibility; the amount of base gas; the number, arrangement, and performance of the wells completed into storage; and effectiveness of the surface gas handling facilities.

Reservoir rock is a compacted sedimentary porous formation, often naturally fractured. Fractures form the highly conductive flow paths, and the interconnected pores of the rock blocks (separated by the fractures) provide the essential gas storage capability. Permeability of the storage rock formation determines the rate of gas flow through it. High-permeability reservoirs are preferred for gas storage because these can allow for high rates of injectivity and deliverability. However, over time, the performance of depleted reservoir storage can be reduced by impairment of permeability due to various damage mechanisms, such as clay swelling, fine aggregate ("fines") migration, and precipitation of scales. The performance can be restored by costly special measures, such as acid flushing and hydraulically created fracture stimulation. Depleted reservoir storage requires careful operation and mitigation in order to avoid the possibility of coproduction of water; water production can occur due to the coning phenomenon, because most reservoirs contain an underlying water table. A large quantity of base gas should be retained in underground storage in order to avoid this problem. The possibility of facilitating inert gases is being explored for use as a base or cushion gas. Typically, depleted reservoir storage involves ten to hundreds of wells, 5 million to 10 million standard cubic feet per day deliverability capability, only 33–50% of the total gas content available as working gas, a significant amount of water, and inflexibility, allowing only one to two cycles of injection and production per year with 100 to 150 days of withdrawal periods. Applying the leaky-cylindrical tank model depicted in Fig. 2, the relationship between gas flow rate and pressure is given by Eq. (6):

$$q_b = C(\bar{P}^2 - P_w^2)^n, \tag{6}$$

where $\bar{P}$ and P_w denote the average reservoir gas pressure and the gas pressure at the well bottom, respectively, and C and n denote the performance coefficient and exponent, respectively, which have

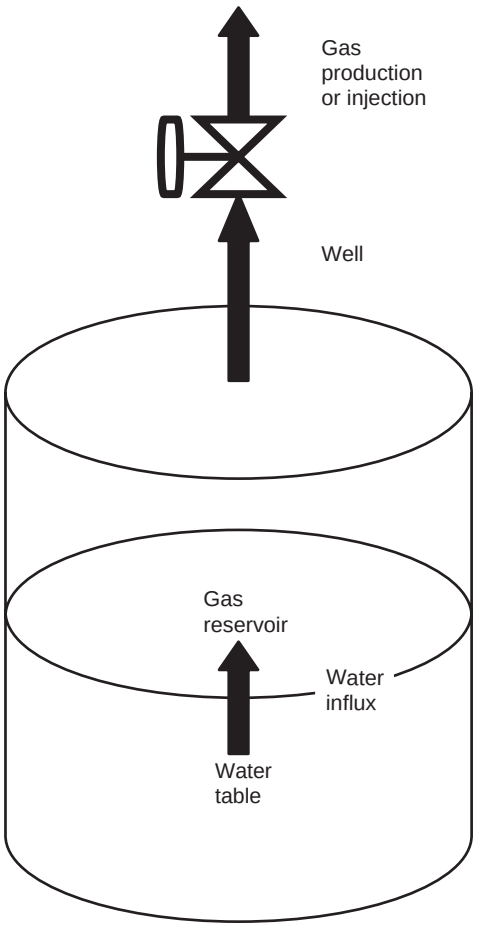

FIGURE 2 Underground gas storage reservoir and water table.

empirically determined specific values for specific storage reservoirs. Assuming constant flow rate, the cumulative production/injection gas volume is given by Eq. (7):

$$G_p = q_b t, \tag{7}$$

where G_p and q_b denote the cumulative volume and volume flow rate of the gas under standard conditions (15.6°C or 60°F and 1.0 atm), and t denotes the total elapsed time.

4.2.3 Storage in Aquifers

Suitable underground water aquifers, leakproof for gas, can be used for gas storage. Aquifer storage must have an impermeable cap rock formation to avoid gas leakage. The injectivity and deliverability of this storage depend on the gas solubility in water and the water-drive potential of the aquifer. Generally, use of aquifer storage requires a large quantity of base gas to be retained in place. Such storage needs careful

operation and mitigation in order to avoid the possibility of coproduction of water with gas. The other features of aquifer storage (including typical inventory) and the injection and production capabilities of aquifers are similar to those of depleted reservoirs.

Based on Fig. 2, the storage gas balance equation can be expressed as follows in order to relate the gas pressure in the storage to the cumulative gas production or injection:

$$\frac{P}{Z} = \frac{P_i}{Z_i}\left(1 - \frac{G_p}{G_i}\right) \Big/ \left(1 - \frac{W_e E_i}{G_i}\right), \tag{8}$$

where the subscript i denotes the values at initial or reference condition of the gas storage, and E is the gas expansion factor, given by Eq. (9):

$$E = \frac{T_b}{P_b}\frac{P}{Z}\frac{1}{T}. \tag{9}$$

The water content of the aquifer is denoted by W_e, and G_i and G_p denote the initial volume of gas stored in the storage and the cumulative volume of gas produced from the storage, respectively, both expressed at standard conditions. The water rises when gas is produced from the storage, and recedes when gas is injected. The water influx or efflux rate q_w is given proportionally to the pressure difference between the aquifer water and storage gas as

$$q_w = \frac{dW_e}{dt} = J(\bar{P}_a - P), \tag{10}$$

where W_e is the aquifer water content, t is time, J is an aquifer productivity index, P is the storage reservoir gas pressure, and $\bar{P}_a$ is the average water pressure in the aquifer.

4.2.4 Storage in Salt Caverns or Cavities

Salt caverns are created by dissolution of salt in deep salt beds and domes by hot water circulating through wells drilled into the salt formation. Storage capacity is significantly smaller in these cavities compared to the depleted reservoirs and aquifers, but cavern storage is flexible and allows for multiple cycles of gas injection and production in a year. The construction of salt cavern storage is expensive and is preferred usually only when depleted reservoir or aquifer storage opportunities are unavailable. Cavern storage provides significantly greater gas injectivity and deliverability rates in comparison to the depleted reservoirs and aquifers, and requires holding a much smaller amount of base gas in the storage to be effective. Typically, salt cavern storage involves one to three wells, 8.5 million to 17 million standard cubic meters per day deliverability capability, about 65% of the total gas content available as working gas, a negligible amount of water, and 6 to 12 cycles per year with 10 days of withdrawal periods. Simplifying Eq. (8) by neglecting the water influx effect, the gas pressure and cumulative gas production or injection at isothermal conditions are related by Eq. (11):

$$\frac{P}{Z} = \frac{P_i}{Z_i}\left(1 - \frac{G_p}{G_i}\right). \tag{11}$$

4.2.5 Hard-Rock Caverns and Abandoned Mine Shafts

The possibility of storing natural gas in properly conditioned and prepared hard-rock caverns and abandoned mine shafts is under consideration. Refrigerated mined caverns operating in the -29° to -40°C temperature range and specially lined rock caverns that can store compressed gas at elevated pressures are being explored in order to increase the capacity of flexible gas storage. However, the gas industry has not yet implemented such storage for conventional applications. The operational equation for this type of storage is similar to that for the salt cavern storage.

5. GAS TRANSPORTATION AND STORAGE SERVICES, OPERATION, AND ECONOMIC VALUE

The economic value of gas transportation and storage depends on many factors, including supply and demand trends; means of transportation and storage; measures for deliverability assurance; operational and management strategies; ability of accommodation for seasonal price fluctuations; measures for management of uncertainty, risk, surge, peaks, and pricing options; and conditions and types of available services. Mitigation of the uncertainty in natural gas price, investment, decision-making, and supply and demand is the challenge in the marketing and management issues. Development and implementation of best strategies for effective coordination of various gas sources, flexibility of transportation and storage facilities, measures for absorbing and managing peaks, and dealing with price volatility and seasonal price spreads are among the important problems. Typically, the price of natural gas remained close to $5.00 per million British thermal units (MMBtu), or $5.00 per thousand standard cubic feet (Mscf) during the most of the year 2003.

Pipeline operation is a dynamic industry, providing creative services such as gathering, lending, parking, pooling, wheeling, and interruptible and backhaul services. The cost of pipeline transportation depends on the expense, usage, distance, and types of services rendered. While providing valuable service to the suppliers and end users of gas, the gas marketing and trading industry makes a profit from the seasonal buying and selling of gas price differentials, by managing risk and taking advantage of creative services such as options, swaps, and futures.

Gas storage ensures adequate and reliable gas supply with less price volatility. Inventory accountability, deliverability assurance, and gas leakage mitigation are some of the measures of the technical, economic, and environmental performance of natural gas storage. Selection of the gas storage type, location, and operation mode is a delicate and strategic engineering issue. Dictated by the supply, demand, and market price trends, gas storage facilities can be operated at different gas injection and withdrawal modes. Simultaneous injection and production as well as consecutive injection and production modes are often resorted to in this practice. Hence, various gas storage facilities can be broadly classified as having flexible or inflexible storage capabilities with respect to the ability of providing different storage services, gas deliverability, and yearly cycling frequency. Flexible storage (e.g., salt caverns) allows multiple cycles during a year and high injection and deliverability rates, accommodating widely varying intra- and interday gas rates. Gas can be withdrawn quickly from a flexible storage within as short a time frame as a week This makes it possible to have more than 12 cycles in a year. As a result, flexible storage can capture the price differentials quite effectively over short periods of time according to the trends in the market conditions. Therefore, flexible storage has a beneficial market value when it can take advantage of small price fluctuations, but it would not have an economic value under stable market conditions. In contrast, inflexible storage (e.g., a depleted reservoir and water aquifer) may be cycled only once a year, typically with injection during summer for storage and production during winter for consumption. Consequently, while providing an advantage of storing significantly large quantities of natural gas in the storage place, depleted reservoir and aquifer storages can capture only the long-term seasonal spreads in the gas market. Hence, flexible and inflexible gas storage facilities may have different response dynamics and economic values under certain market trends.

6. HAZARDS FROM NATURAL GAS TRANSPORTATION AND STORAGE

Natural gas transportation and storage systems can create various pollution and safety problems and should be monitored, inspected, and controlled carefully in order to avoid the escape and emission of dangerous natural gas. Gas storage facilities may undergo significant variation in the gas pressure and storage stress conditions as a result of frequent injection and production under different scenarios associated with various services. Frequent overpressuring and underpressuring of gas storage can induce aging of and various types of damage to the storage facility, creating and increasing the potential for gas leak and hazards.

From the point of gas storage, depleted reservoirs, aquifers, and salt domes often contain natural defects, including natural fractures and faults, which may provide escape routes for gas. Escape, migration, and accumulation near the ground surface of large quantities of gas from storage create potential hazardous situations, such as fire and explosion, and environmental pollution problems, including noxious odors and other health hazards. Nevertheless, gas leaks from underground storage facilities are natural and unavoidable, and should be monitored carefully in order to avoid potential health and safety hazards.

7. NATURAL GAS SECURITY AND RISK ISSUES

Natural gas supply and transportation in parts of the world may be limited and/or interrupted because of political instability and unrest and frequent changes in local governments, customs, and regulations. The security and risk issues in the post-9/11/2001 world are of great concern, and ensuring the accessibility and availability of natural gas reserves and the safe operation and economic viability of natural gas transportation and storage facilities are issues of importance. Liquefied natural gas tankers, facilities for on- and offshore natural gas liquefaction, regasification, and storage, and gas pipelines are particularly vulnerable to sabotage and other man-made damages. Attacks impacting any of the storage

components may lead to rapid release of large gas clouds and to dangerous fires and explosions. Implementation of carefully designed surveillance techniques can avert such problems, and security and emergency response plans and methods for detection and deterrence of unwanted activity inside and around gas transportation and storage facilities have become an integral part of the overall natural gas handling and management task. Effective security measures require the use of highly sophisticated tools and approaches, such as the development and application of vulnerability assessment models, security vulnerability assessment of gas handling facilities, properly selected and installed security equipment, and training of personnel about safety and emergency procedures.

Glossary

absolute energy ratio (**AER**) Energy produced/energy required, including energy from the ground or the sun (dimensionless).
end use Consideration taking into account the efficiency of use of energy produced.
incremental energy ratio (**IER**) Energy produced/energy required, excluding energy from the ground or the sun (dimensionless).
internal rate of return (**IRR**) The implied interest rate if energy inputs are considered an investment and energy produced is considered a payoff (units = 1/time).
payback time The time for the accrued energy produced to balance the energy inputs (units = time).
power Energy per unit time.
power curve A graph of power inputs and outputs vs time.
premium fuel An energy type considered especially valuable. For example, oil is usually considered premium relative to coal because it is more flexible in use, less polluting, etc.

Net energy analysis of an energy technology is a comparison of the energy output with the energy needed to supply all inputs—the energy source, materials, and services—to construct, operate, and dispose of the technology.

1. INTRODUCTION AND BACKGROUND

At first glance, net energy analysis (NEA) is a natural, intuitively sensible extension of the idea of energy cost. Everything requires energy somewhere along the chain of production, including the equipment and services used to find and extract energy. In addition, energy seems to be harder to get with time: efforts to drill, dig, and dam must be in deeper and in more forbidding places for our oil, gas, coal, and hydropower (offshore for oil and gas, in mountainous terrain for coal, and into the sub-Arctic for hydropower). This in turn probably implies more energy cost, and shifts the time when this trend will hit the breakeven point. NEA seeks to find out. Some proponents of NEA claim that standard economics will not always indicate this problem (especially if subsidies to energy industries are involved, as they usually are) and that therefore net energy analysis should be carried out largely independent of economic analysis. However, the more common argument is that energy analysis is a supplement to, not a substitute for, economic analysis in decision making.

Net energy concerns peaked in the 1970s and early 1980s following the oil embargo/energy crisis years of 1973 and 1979–1980. Many NEA studies covered oil made from coal or extracted from tar sands and oil shale, geothermal sources, alcohol fuels from grain, biomass plantations, solar electricity from orbiting satellites, and nuclear electricity from ambitious proposed plant-building programs. In 1974, Federal legislation requiring net energy analysis of federally supported energy facilities was enacted. It required that "the potential for production of net energy by the proposed technology at the state of commercial application shall be analyzed and considered in evaluating proposals" [Public Law No. 93-577, Sect. 5(a) (5)]. Since that time, interest in net energy has diminished, but continues sporadically. Adherence to Public Law 93-577 was abandoned early by the U.S. Department of Energy (DOE). In 1982, responding to a criticism from the U.S. General Accounting Office that it was not performing NEAs, DOE said "[it is]

 © 2004 Elsevier Inc. All rights reserved.

DOE's view that the benefits of [NEA] are not worth the time and effort involved for general application." Net energy analysis is a type of life cycle analysis. The past decade has seen an increase in applications of the latter, but usually these have been applied to consumer products rather than to energy facilities, using toxic and other materials, water, etc., rather than energy, as numeraire.

The DOE had a point; the devil is in the details. NEA is an elusive concept subject to a number of inherent, generic problems that complicate its application. Some of these problems persist, not because they are unstudied, but because they reflect fundamental ambiguities that can be removed only by judgmental decision. The problems include all of those with energy analysis as well as others specific to the "net" question. The difficulty of specifying a system boundary, the question of how to compare energy produced and consumed at different times, and the problem of how to compare energy types of different thermodynamic qualities, density, and ease of storage all make NEA harder to perform and interpret. Some analysts therefore reject net energy analysis but support energy analysis. The latter considers the energy output to be a good or service and attaches no special significance to the fact that it is energy. In this view, it is reasonable and useful to determine how much energy is required to keep a room warm, or to produce a head of lettuce or even a ton of coal, but it is confusing at best and misleading at worst to compare outputs and inputs of a coal mine purely on the basis of energy cost. This fundamental objection attacks the very basis of NEA: NEA assumes that the economic/human life-support system can be separated into the "energy system" and the "rest of the system" and that studying the energy system as a distinct entity is valid. For many applications, this separation, although not perfectly defensible, seems to be acceptable. For others, there are stronger objections.

Little has occurred since 1982 to challenge DOE's dismissive pronouncement, and in this author's opinion NEA has very seldom, if ever, been used as a critical decision criterion. In the Grain Belt, NEA arguments have sometimes been quoted regarding ethanol production from corn, but the sorting out that occurred (with small operators using dry-milled corn shutting down while larger operators using wet milling flourished) can be understood on the basis of the monetary economies of scale, of the role of economic subsidies, and of the details of the flexibility of the two milling processes. In fairness, there is a large debt owed to NEA as a stimulant to proper thinking about resources. Predicting resource availability on the basis of past trends has been shown to be fallacious by the example of domestic U.S. oil, where increased drilling in "Project Independence" did not reverse the fact that all-time production peak was in 1971. To the extent that prediction by linear extrapolation is an economics technique and that prediction by incorporating the physical aspects of the resource is a net energy analysis technique, NEA deserves credit. But anything can be done poorly, and proper economics should incorporate physical realities. Once that is granted, the question of usefulness lies in the details of NEA.

In advance, it can be anticipated that two specific outcomes of NEA will be least controversial. If the technology appears to be a clear energy loser even after all uncertainties of technique and data are accounted for, the result is useful; the program should be scrapped. Likewise, if the technology appears an unambiguous energy producer, it is likely that NEA can now be deemphasized and the decision to proceed based on other criteria. If the technology is close to the energy breakeven point, NEA seems more appealing. Of course, in this case, a higher degree of accuracy in the result, and hence in the needed data, will be required.

2. *QUANTITATIVE ENERGY BALANCE INDICATORS*

The statement that an energy technology can be an energy winner or loser implies three assumptions. First, because energy is not created or destroyed (mass–energy in the case of nuclear energy), it would seem that at best an energy (conversion) technology can only break even. NEA usually assumes that the energy in the ground (or coming from the sun) is not to be counted as an input, i.e., is outside the system boundary. This is discussed in detail later. Second, it is usually assumed that high-quality energy (in the thermodynamic sense) is desirable, whereas low-quality energy is not. This would be covered properly if "free energy" were used instead of energy. The common (mal)practice is followed here, i.e., using "energy" actually to mean thermodynamic free energy. Third, it is assumed here that all material and service inputs to an energy facility are expressible in terms of the energy needed to produce them.

Figure 1 shows the basic NEA framework, assuming only one energy type. It is useful to have a normalized indicator of the net energy balance; two are the incremental energy ratio and the absolute

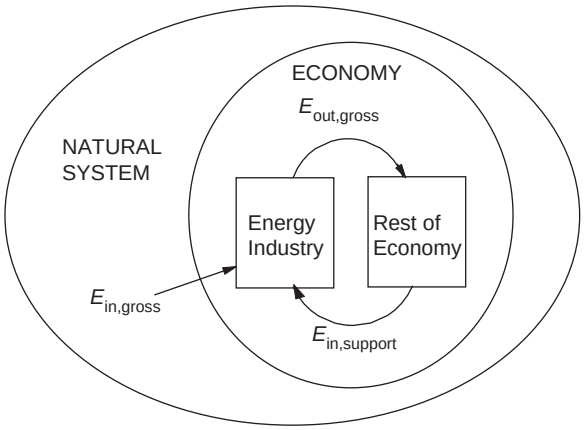

FIGURE 1 Energy flows for net energy analysis.

energy ratio:

$$\text{Incremental energy ratio} = \frac{E_{\text{out,gross}}}{E_{\text{in,support}}}$$

$$\text{Absolute energy ratio} = \frac{E_{\text{out,gross}}}{(E_{\text{in,gross}} + E_{\text{in,support}})}$$

Support energy is that obtained directly from the rest of the economy or used by the economy to provide necessary materials and service inputs. $E_{\text{in,gross}}$ is the energy from the ground or sun, that energy usually referred to as "resource." $E_{\text{out,gross}}$ is the energy supplied to the rest of the economy. The difference between the two ratios depends on the system boundary. The incremental energy ratio (IER) parallels standard economic practice in that the "cost" of exploiting a resource is the cost of extraction, and includes as inputs only those taken from the rest of the economy. The latter can be thought of as "invested" energy, and the IER is called by some workers "energy return on investment." An IER > 1 means that we have a net energy producer. The absolute energy ratio (AER) is appropriate to the more global question of the physical efficiency with which a given (say) fossil or renewable energy source can be converted into useful energy. The AER (which never exceeds 1) is useful for determining how much of a given stock of energy resource can be used by the rest of the economy.

Figure 2 illustrates the interplay of the IER and AER. Because of the possibility of energy consumption within the boundary of the energy technology, knowledge of the IER does not uniquely specify the AER, and vice versa. To exhibit how the energy flows vary and cumulate over the facility's lifetime, we can use a "power curve," shown in Fig. 3. The power curve tells "everything" (assuming that the system boundary is properly stated, etc.) but is cumbersome. It is desired to have some summary indicator of the whole time path,

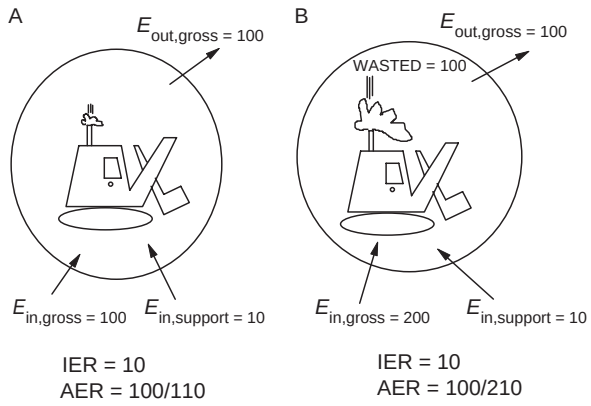

FIGURE 2 Incremental energy ratio (IER) and absolute energy ratio (AER) for two hypothetical coal mines. Both mines have the same IER, but mine B has a lower AER because of energy waste within the system boundary.

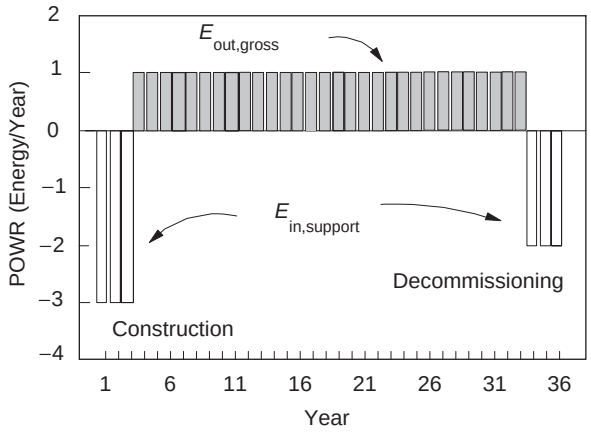

FIGURE 3 Hypothetical power curve for an energy facility through construction, operation, and decommissioning. IER = 30/[(3 × 3) + (2 × 3)] = 2. Payback time = 12 years, but it is not really "simple" because the concept does not apply to a power curve with costs following benefits. IRR = 9.1%/year.

such as (1) the energy ratio (already defined), (2) the energy payback time (the time for the accrued energy produced to balance the energy inputs), and (3) the energy internal rate of return (IRR; the implied interest rate if energy inputs are considered an investment and energy produced is considered a payoff). The formal statement is that the IRR is that value of r for which

$$\frac{\sum_{t=1}^{N} \frac{E_{\text{out,gross}_t}}{(1+r)^{t-1}}}{\sum_{t=1}^{N} \frac{E_{\text{in,support}_t}}{(1+r)^{t-1}}} = 1.$$

All three of these indicators have analogues in economics. All require summing energy over many years, and it is necessary to decide how to weigh the present against the future. The IRR by definition

explicitly assumes the standard economic practice of geometric discounting. However, for energy ratio and payback time there is no fixed rule. Most energy analysts do not discount, and that convention will be followed here. Summary indicators will be used for ease of communication but they sacrifice detail and introduce ambiguity. For example, consider simple payback time (i.e., payback time with no discounting), which is defined as that time at which the energy facility has produced as much energy as it has consumed. This definition implicitly assumes a power curve that is negative at first and then becomes, and remains, positive during facility operation. It would be less useful, and even misleading, for more complicated power curves, such as for a facility that requires significant energy inputs late in the lifetime, as for repair, maintenance, or decommissioning (see Fig. 3).

The energy ratio is also subject to difficulties in interpretation. For example, if an electric plant uses some of its own output, should that be added to the inputs or subtracted from the output? This makes no difference to payback time or to the internal rate of return, but does affect energy ratio. If the power curve is well behaved, i.e., negative at first and then positive over the whole lifetime, then the following statements are equivalent statements of positive net energy production:

- IER > 1.
- Simple payback time $<$ facility lifetime.
- Internal rate of return > 0.

3. CONCEPTUAL AND PROCEDURAL ISSUES

Several of the conceptual and procedural difficulties of NEA are summarized in Table I. It should be noted that there is considerable overlap between issues, and that several also plague economic analysis. Most are

TABLE I

Conceptual and Procedural Difficulties with Net Energy Analysis

Issue	Example	Remedied by careful statement of problem?	Comment
1. Specification of system boundary	Is sunlight "free"?	Yes	Differences of opinion persist among both analysts and users
a. Spatial	Is soil quality maintained in biomass energy production?		
b. Temporal	How much of a passive solar house is functional vs decorative?		
c. Conceptual	Should the energy cost of decommissioning a nuclear plant be included?		
	Should energy costs of labor be included?		
2. End-use consideration	Should NEA of a coal–electric plant be influenced by the efficiency of residential refrigerators? If a car gets better miles per gallon than expected, is the benefit allocatable to the ethanol-from-grain process?	No	An example of the fundamental question of to what extent the energy system is separable from the rest of the economy
3. Opportunity cost	Can energy conservation measures be thought of as producing (saved) energy and then subjected to NEA?	Yes	Difficult-to-set ground rules that are not situation-specific
4. Dynamic problem	Will a rapid buildup of many energy facilities produce net positive energy? The answer can be "no," even if the IER for each facility is >1	Yes	Raised regarding nuclear and solar energy in the 1970s but shown not to be not significant (rapid buildup did not occur)
5. Existence of more than one kind of energy	Should oil and coal be equally weighted in NEA?	Not completely	Very vexing
6. Average vs. marginal accounting	New oil wells often have a lower IER compared to old wells	Yes	Generic problem
7. Dependence of NEA on economic factors	Energy requirements for steel production depend on price of energy	No	Unavoidable because NEA is based on real technology

problems with energy analysis in general as well as with NEA specifically.

3.1 End-Use Considerations

Should NEA take into account the efficiency of use of $E_{out,gross}$ to provide an energy service such as cooling a space (e.g., a refrigerator) or moving people (e.g., an automobile)? An example of this problem is the gasohol miles-per-gallon question. It was observed in the late 1970s that cars using gasohol (a mixture of 90% unleaded gasoline and 10% ethanol) got more miles per gallon than would be expected on the basis of the enthalpy of combustion ("energy content") of the mixture as compared with that of pure gasoline. For the purpose of NEA, this could be viewed as a production of extra energy, i.e., an increase in $E_{out,gross}$. Should the credit for this increased output be allocated to the ethanol-producing process? If so, the IER increased from 1–1.7 to 1.5–2.4. Or, because the improvement is really due to the existence of the mixture, should it be inadmissible to perform the NEA of ethanol only? And what if the ethanol goes to an end use other than gasohol, for which this issue is moot? Further, this is all dependent on the type of engine. Research provides no definite answer. The user must decide, being attentive to the likelihood that in the event of controversy, different interest groups will tend to select the interpretation that best supports their cases.

3.2 Energy Conservation

NEA can be applied to energy conservation, in which case $E_{out,gross}$ is the energy saved ("neg-a-watts"), and $E_{in,support}$ is the energy required to make the insulation, the more efficient motor, etc.

3.3 The Dynamic Problem

This is an age–structure demographic issue, of concern with the rapid buildup of an energy technology. Even though a single facility may have a (lifetime) IER > 1, a program of building many facilities may be a net energy sink for many years. If the program is growing fast enough, the average facility is not even completely built! Concern over this problem was stimulated by exponential program goals for nuclear power plants (in the United States and Great Britain, doubling time $= 5$ years) and solar heating (United States, doubling time $= 3$ years). The exponential growth did not occur, and the concern has largely gone away. But it is always a potential problem.

3.4 Energy for Human Labor

There is disagreement on whether to include the energy to support human labor. The two following reasons argue against inclusion:

1. It is difficult to agree on how much of it to include. Is it the energy consequences of a worker's whole paycheck or just that portion spent for food and lodging?
2. Including labor means that the economy is viewed as producing goods only for government consumption, exports, and capital purchases. Consumption by residences is assumed to be fixed in amount and, especially, in "mix." Other energy research (for example, energy conservation) exploits the flexibility of personal consumption patterns (to purchase more insulation and less natural gas, for example). This flexibility seems to be preferable.

3.5 Different Energy Types and Premium Fuels

Not all energy types are equally useful. On average, we consider oil and natural gas more useful than coal, and the price reflects this (gasoline retails for about $10 per million Btu; coal is about $1.50 per million Btu). Various analysts have accounted for this by giving different weights to different energy types based on criteria such as scarcity or economic price. One example is calculating the IER for "premium" fuels only. Thus, if liquid fuels are defined as premium and an ethanol-from-grain plant can burn coal or crop residues, the IER will be increased over one that burns oil. This explicit introduction of nonenergy criteria again blurs the boundary of NEA.

3.6 Facility Lifetime and Other Sensitivity Issues

In Fig. 3 we see that if the energy facility has a productive life of only 15 years, instead of 30, the IER is reduced to 1, which is the breakeven point. Besides lowered lifetime, lack of reliability could cause diminished output and increased energy inputs for maintenance. Similarly, increased energy costs of decommissioning would reduce the IER; this is a real issue for nuclear power. Of course, the IER could be increased by the opposite of these trends. Explicit treatment of the uncertainty of IER is often performed. An example is an NEA of the proposed solar power satellite (SPS) of the late 1970s. This involved arrays of solar cells in geosynchronous orbit, on which electricity was

converted to microwaves and beamed to terrestrial antennas, for conversion back to electricity. Uncertainties of the lifetime and performance of photovoltaic cells in a space environment, plus relatively high energy requirements for heavy, crystal-grown silicon, which in turn required higher energy costs to place them in orbit, resulted in an IER of 2.1 ± 0.8 for the SPS. The project was not funded, though monetary issues probably dominated net energy questions. Today's solar cells are lighter and more efficient and durable, so that portion of the system would likely be more energetically favorable now.

4. RESULTS AND TRENDS

NEA has changed little since the spate of work in the 1970s and 1980s. A literature search today shows relatively few studies, and these tend to emphasize window coatings to manage solar gain and loss, a continued interest in solid biomass fuels and liquids-from-biomass, and photovoltaic units. Thus, the data in Table II, showing results for several conventional and unconventional technologies, are dominated by 25-year-old results. Table II indicates that coal tends to have IERs on the order of several 10s. Crude oil and natural gas are on the order of 10. Electricity from a fossil plant is on the order of 3 to 10. Geothermal electricity is of order 4 to 10. For solar technologies, we see that direct combustion of biomass has IERs of 3 to 20, with the energy cost of fertilization a dominant factor at the low end. Biomass liquids have IERs of 1 to 5. One study of ethanol from corn found an lER from 1 to 1.4 for total energy, which increased to 2.3–3.8 when calculated for premium fuel (liquids) only (another study 25 years later similarly found IER = 1.5). Solar space heat has IERs from 2 to 15. The high variation is partly due to climate, partly due to the boundary issue of how much of a solar house is the solar system (especially for passive solar), and partly due to the degree of coverage. The latter is another boundary

TABLE II

Selected Net Energy Results

Technology	Date	IER (unless otherwise stated)	Comment
Coal, U.S. average	1970s	37	
Eastern surface coal	1970s	43	Surface mining tends to have a higher IER compared to deep mining
Crude petroleum delivered to refinery	1970s	7	
Natural gas delivered through gas utility to user	1970s	11	
Coal mine-mouth electric power plant	1977	8	
Solar power satellite	1979	2.1 ± 0.8	Very uncertain; the IER for the photovoltaic cells alone would likely be higher today
Ethanol from corn for gasohol (gasoline:ethanol = 90:10)	1979, 1995	$\approx$1.5 to 2.5	Extremely sensitive to issues in Table I
Ceiling insulation as source of saved energy	1970s	136	Best case, previously uninsulated house
Geothermal–electric plant (vapor dominated)	1981	13 ± 4	Geothermal heat is not counted in the IER
Geothermal–electric plant (liquid dominated)	1981	4 ± 1	Geothermal heat is not counted in the IER
Short-rotation ($\approx$5-yr) trees for direct combustion	1980s	10 to 20 if unfertilized; 2 to 4 if fertilized	Unfertilized is likely unsustainable
Short-rotation biomass (trees, $\approx$5 yrs; grass, 1 yr) for direct combustion	1980s	6 if unfertilized; 2 if fertilized	Unfertilized is likely unsustainable
Residential solar space heat	1980s	2–15	Depends on climate and how well insulated the structure is (climate dependent); passive (no moving parts) tends to have higher IER compared to active
Residential solar hot water	1980s	2–5	Climate dependent
Photovoltaic cells	1976	Simple energy payback time $\approx$12 yr	
Photovoltaic cells	2000	Simple energy payback time = 1.1 to 4 yr	Payback time must be compared with device lifetime; this study concludes that the IER $\approx$30, implying a lifetime of at least 30 + yr

issue. A solar heating system that can supply year-round heat, including that one continuously overcast 5°F week in January, will require more inputs (such as more glass, thermal mass, and storage tanks). This system's IER will be lower than the IER for a system that is not expected to cover the worst periods—for which there is, say, a backup propane furnace that is not considered part of the solar heating system.

A similar comment applies to conservation as an energy source. The IER > 100 for ceiling insulation is for the first few inches of insulation in a totally uninsulated house. Putting that same insulation in a house already somewhat insulated would save less energy and give a lower IER. Also, photovoltaic cells have become better net energy producers over time as reliability has increased and material inputs have decreased.

5. CONCLUDING COMMENTS

Interpreting net energy information such as that in Table II almost instantly raises questions of the details and assumptions, which the critical reader must embrace. In spite of these, the concept (and the specter!) of the energy breakeven point and hence exhaustion is compelling enough for continued study. Perhaps the most vivid way to address this is by asking how IERs are changing over time.

Glossary

artificial intelligence The science devoted to the reproduction of the methods or results of human reasoning and brain activity.

artificial neural network A network of artificial neurons interacting with one another in a concerted manner that achieves "intelligent" results through many parallel computations without employing rules or other logical structures.

artificial neuron Element of a neural network that behaves like a neuron of the brain that possesses a number of input values to produce an output value.

backpropagation A method of supervised learning applied in multilayer feedforward neural networks. The error signal between the actual output and target is fed back through the processing layer, which tries to reduce this error by changing the connection weights.

biological neuron A brain cell that processes data and controls the response of the body. Neurons are connected to the brain and other nerve cells by transmitting connectors (axons) and receiving connectors (dendrites).

epoch A complete pass through the neural network of the entire set of training patterns.

hidden layer A neural network layer of nodes between input and output layers that contains the weights and processing data.

layers A group of neurons in a network. Layers can be input, output, or hidden.

pattern A single record or row of variables, also called an observation, that consists of inputs and outputs.

training In neural networks, training is synonymous to learning. During training, the system adapts in a specified manner so that some parts of the system suggest a meaningful behavior, projected as output.

weights Parameters for which their values are adapted during training in order to perform a task.

Artificial neural networks, or simply neural networks, are collections of small, individual interconnected processing units. Information is passed between these units along interconnections. An incoming connection has two values associated with it, an input value and a weight. The output of the unit is a function of the summed value. Neural networks, although implemented on computers, are not programmed to perform specific tasks. Instead, they are trained with respect to past history data sets until they learn the patterns presented to them. Once they are trained, new unknown patterns may be presented to them for prediction or classification.

1. ARTIFICIAL INTELLIGENCE AND NEURAL NETWORKS

For the estimation of the flow of energy and the performance of energy systems, analytic computer codes are often used. The algorithms employed are usually complicated, involving the solution of complex differential equations. These analytic programs usually require large computer resources and need a considerable amount of time to achieve convergence and thus to give accurate predictions. Instead of complex rules and mathematical routines, artificial neural networks are able to learn the key information patterns within a multidimensional information domain. In addition, neural networks are fault tolerant, robust, and noise immune. Because they are inherently noisy, data from energy systems represent good candidate problems to be handled with neural networks.

The possibility of developing a machine that would "think" has intrigued humans since ancient times. In 1637, the French philosopher–mathematician Rene Descartes predicted that it would never be possible to make a machine that thinks as humans do. However, in 1950, the British mathematician and computer pioneer Alan Turing declared that one day there would be a machine that could duplicate human intelligence in every way.

Artificial intelligence (AI) is a term that generally indicates the ability of a machine or artifact to perform the same kinds of functions that characterize human thought. The term AI has also been applied to computer systems and programs capable of performing tasks more complex than straightforward programming but still far from the realm of actual thought. Thus, AI is the study of how to make computers do things similar to the way human beings do them. This term is often misinterpreted, and in order to avoid misunderstandings scholars usually employ the term computational intelligence.

It should be noted that solving a computation does not indicate understanding, something a person who solved a problem would have. Human reasoning is not based solely on rules of logic. It also involves perception, awareness, emotional preferences, values, the ability to generalize and weigh many options, evaluating experience, and many more.

Machinery can outperform humans physically. Similarly, computers can outperform mental functions in limited areas, particularly in the speed of mathematical calculations. The fastest computers are able to perform approximately 10 billion calculations per second. However, making more powerful computers is probably not the way to create a machine capable of thinking because computer programs operate according to set procedures, or logic steps, called algorithms. In addition, most computers do serial processing and operations such as those of recognition and computation are performed one at a time. The brain, however, works in a manner called parallel processing—that is, it performs a number of operations simultaneously. To achieve simulated parallel processing, supercomputers have been developed that have multiple processors that follow several algorithms at the same time.

During the past 15 years, there has been a substantial increase in interest in artificial neural networks. Neural networks are suitable for some tasks while lacking in some others. Particularly, they are good for tasks involving incomplete data sets, fuzzy or incomplete information, and for highly complex and ill-defined problems, for which humans usually decide on an intuitional basis. Additionally, they can learn from examples and are able to deal with nonlinear problems. They also exhibit robustness and fault tolerance. The tasks that neural networks cannot handle effectively are those requiring high accuracy and precision, such as in logic and arithmetic.

Neural networks have been applied successfully in various fields—engineering, mathematics, economics, medicine, meteorology, psychology, neurology, and many others. Some of the most important applications are in pattern, sound, and speech recognition; the analysis of electromyographs, cardiographs, and other medical signatures; the identification of military targets; the identification of explosives and other illegal substances in passenger suitcases; and the prediction of mineral exploration sites. They have also been used in market trends and weather forecasting, electrical and thermal load prediction, adaptive and robotic control, and many others. Neural networks are also used for energy systems process control because they can build predictive models of the process from multidimensional data routinely collected from sensors.

2. BIOLOGICAL AND ARTIFICIAL NEURONS

The basic building blocks of the nervous system are called neurons. A schematic of a biological neuron is shown in Fig. 1. Neurons are excitable cells composed of the cell body or soma (where the cell nucleus is located) and projections branching out from the soma. Each neuron has incoming fibers called dendrites and an outgoing fiber called an axon. Dendrites are input devices through which the neuron receives signals from other neurons. There is usually a single axon per neuron, and it serves as its primary output device. This may be connected to other neurons or may terminate in a muscle tissue, serving as a control signal for the muscle activity. The points of contact between an axon branch and a receiving neuron are called synapses. The change of synaptic transmission efficiency acts as a memory for past experiences. In the brain, there is a flow of coded information (using electrochemical media, the so-called neurotransmitters) from the synapses (having a density of approximately 10^4 synapses per neuron) toward the axon. The axon of each neuron transmits information to a number of other neurons. The neuron receives information at the dendrites from a large number of other neurons. It is estimated that

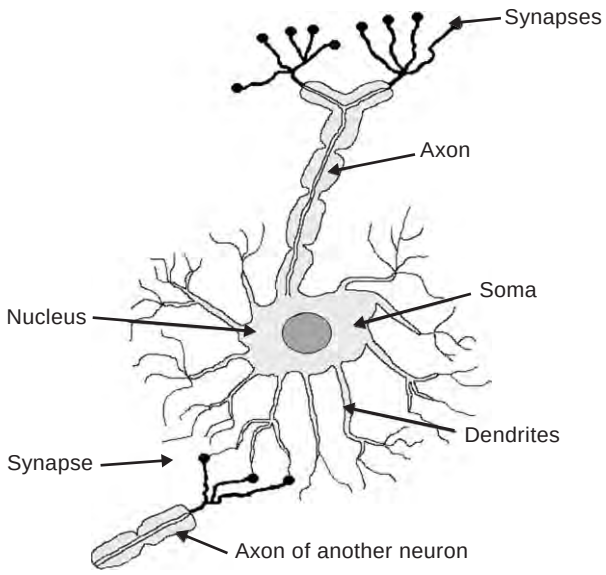

FIGURE 1 A simplified model of a biological neuron showing the soma with nucleus, the axon, dendrites, and synapses. The axon is the neuron output device and the dendrites are the input devices. The point of contact between an axon branch and a receiving neuron is called a synapse.

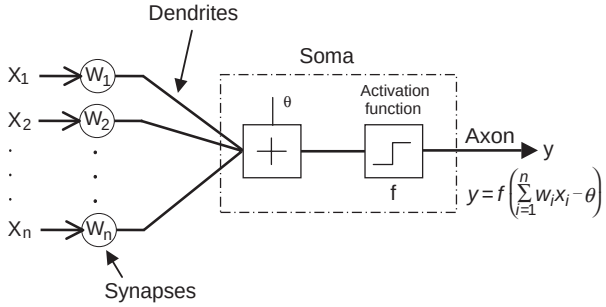

FIGURE 2 A simplified model of an artificial neuron used to model the features of the biological neuron. The synapses are the connection weights, the soma includes the summation and activation units, and the axon represents the output of the artificial neuron as in the biological counterpart. The unit step function is equal to 1 if $x \geq 0$ and is equal to zero otherwise.

each neuron may receive stimuli from as many as 10,000 other neurons. Groups of neurons are organized into subsystems and the integration of these subsystems forms the brain. It is estimated that the human brain has approximately 100 billion interconnected neurons.

Computing networks are far simpler than their biological counterparts. The first simplified neuron model was proposed by McCulloch and Pitts in 1943. Figure 2 shows a highly simplified model of an artificial neuron that may be used to stimulate some important aspects of the real biological neuron. The artificial neuron has all the features of a biological neuron (i.e., synapses, dendrites, soma, and one output line representing the axon of the neuron). The neuron is considered to be a binary threshold device with n inputs $x_1, \ldots, x_n$, one output y, a threshold level θ, and n synaptic weights $w_1, \ldots, w_n$. In such a system, excitation is applied to the input of the network. Following some suitable operation, it results in a desired output. At the synapses, there is an accumulation of some potential, which in the case of the artificial neurons is modeled as a connection weight. These weights are continuously modified during training, based on suitable learning rules.

3. PRINCIPLES OF ARTIFICIAL NEURAL NETWORKS

An artificial neural network is a group of interconnected artificial neurons interacting with one another in a concerted manner. It is in fact a massively parallel distributed processor that has a natural propensity for storing experiential knowledge and making it available for use. It resembles the human brain in two respects: The knowledge is acquired by the network through a learning process, and interneuron connection strengths known as synaptic weights are used to store the knowledge.

Artificial neural network models may be used as an alternative method in engineering analysis and predictions. They operate like a "black box" model, requiring no detailed information about the system. They imitate somewhat the learning process of a human brain because they learn the relationship between the input parameters and the controlled and uncontrolled variables by studying previously recorded data. In this way, they operate similarly to nonlinear regression, but they are much more powerful than regression analysis. Neural networks are able to handle large and complex systems with many interrelated parameters. They seem to simply ignore excess input parameters that are of minimal significance and concentrate instead on the more important inputs.

A schematic diagram of a typical multilayer feedforward neural network architecture is shown in Fig. 3. The network usually consists of an input layer, some hidden layers, and an output layer. In its simple form, each single neuron is connected to other neurons of a previous layer through adaptable synaptic weights. Knowledge is usually stored as a set of connection weights (presumably corresponding to synapse efficacy in biological neural systems).

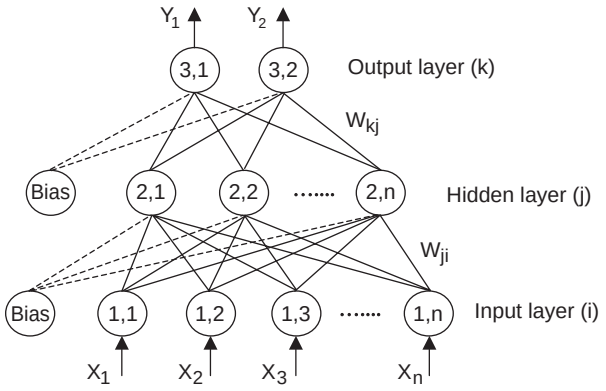

FIGURE 3 Schematic diagram of a multilayer feedforward neural network with an input layer (*i*), a hidden layer (*j*), and an output layer (*k*).

Training is the process of modifying the connection weights in some orderly fashion using a suitable learning method. The network uses a learning mode in which an input is presented to the network along with the desired output and the weights are adjusted so that the network attempts to produce the desired output. Before training, the weights are random and have no meaning, whereas after training they contain meaningful information.

Figure 4 illustrates how information is processed through a single node. The node receives weighted activation of other nodes through its incoming connections. These are first added (summation) and the result is passed through an activation function; the outcome is the activation of the node. For each of the outgoing connections, this activation value is multiplied by the specific weight and transferred to the next node.

A training set is a group of matched input and output patterns used for training the network. The outputs are the dependent variables that the network produces for the corresponding input. When each pattern is read, the network uses the input data to produce an output, which is then compared to the correct or desired output. If there is a difference, the connection weights (usually but not always) are altered in such a direction that the error is decreased. After the network has run through all the input patterns, if the error is still greater than the maximum desired tolerance, the neural network runs through all the input patterns repeatedly until all the errors are within the required tolerance. When the training reaches a satisfactory level, the network holds the weights constant and the trained network can be used to define associations in new input data sets not used to train it.

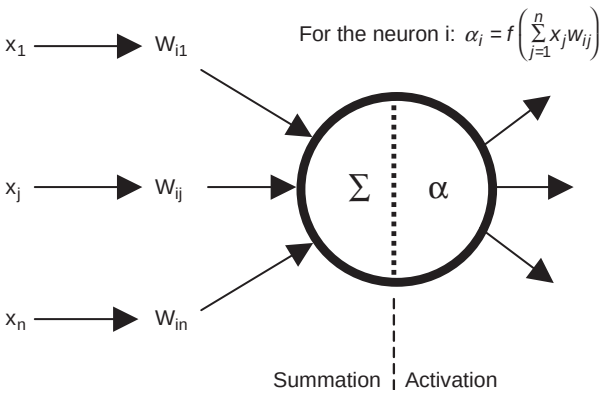

FIGURE 4 Information processing in a neural network unit.

By learning, it is meant that the system adapts (usually by changing suitable controllable parameters) in a specified manner so that some parts of the system suggest a meaningful behavior, projected as output. The controllable parameters have different names, such as synaptic weights, synaptic efficacies, and free parameters.

The classical view of learning is well interpreted and documented in approximation theories. In these, learning may be interpreted as finding a suitable hypersurface that fits known input/output data points in such a manner that the mapping is acceptably accurate. Such a mapping is usually accomplished by employing simple nonlinear functions that are used to compose the required function.

Generally, learning is achieved through any change in any characteristic of a network so that meaningful results are achieved. Thus, learning may be achieved not only through synaptic weight modification but also by modifications in network structure and through appropriate choice of activation functions, number of neurons in hidden layers, number of input parameters used, and others. By meaningful results, it is meant that a desired objective is met with a satisfactory degree of success. The objective is usually quantified by a suitable criterion or cost function. It is usually a process of minimizing an error function or maximizing a benefit function. In this respect, learning resembles optimization.

The information processing at each node site is performed by combining all input numerical information from upstream nodes in a weighted average of the form

$$\beta_i = \sum_j w_{ij}\alpha_{pj} + b_1, \tag{1}$$

where b_1 is a constant term referred to as the bias. The final nodal output is computed via the activation

function. There are many such functions, but the most common one is the logistic

$$\alpha_{(pi)} = \frac{1}{1 + e^{-\beta_i}}. \tag{2}$$

The most popular learning algorithms are backpropagation and its variants. The backpropagation algorithm is one of the most powerful learning algorithms in neural networks. Backpropagation training is a gradient descent algorithm. It tries to improve the performance of the neural network by reducing the total error by changing the weights along its gradient. The error is expressed by the root mean square value (RMS), which can be calculated by

$$E = \frac{1}{2}\left[\sum_p \sum_i \left|t_{ip} - o_{ip}\right|^2\right]^{1/2}, \tag{3}$$

where E is the RMS error, t is the network output (target), and o is the desired output vectors over all pattern (p). An error of zero indicates that all the output patterns computed by the artificial neural network perfectly match the expected values and the network is well trained. In brief, backpropagation training is performed by initially assigning random values to the weight terms (w_{ij}) in all nodes, where j is a summation of all nodes in the previous layer of nodes, and i is the node position in the present layer. Each time a training pattern is presented to the artificial neural network, the activation for each node, α_{pi}, is computed. After the output of the layer is computed, the error term, δ_{pi}, for each node is computed backwards through the network. This error term is the product of the error function, E, and the derivative of the activation function; hence, it is a measure of the change in the network output produced by an incremental change in the node weight values. For the output layer nodes and for the case of the logistic-sigmoid activation, the error term is computed as

$$\delta_{pi} = (t_{pi} - \alpha_{pi})\alpha_{pi}(1 - \alpha_{pi}). \tag{4}$$

For a node in a hidden layer,

$$\delta_{pi} = \alpha_{pi}(1 - \alpha_{pi}) \sum_k \delta_{pk} w_{kj}, \tag{5}$$

where k is a summation over all nodes in the downstream layer (the layer in the direction of the output layer), and j is the weight position in each node. The parameters δ and α are used to compute an incremental change to each weight term via

$$\Delta w_{ij} = \varepsilon(\delta_{pi}\alpha_{pj}) + m w_{ij(old)}, \tag{6}$$

where ε is the learning rate, which determines the size of the weight adjustments during each training iteration, and m is the momentum factor. It is applied to the weight change used in the previous training iteration, $w_{ij(old)}$. Both of these constant terms are specified at the start of the training cycle and determine the speed and stability of the network.

In the past few years, a large number and variety of commercial neural network programs have become available. These vary from user-friendly, step-by-step, easy to implement programs to general-purpose programs such as Matlab, in which the user must set up the neural network in the program environment and perform the necessary operations of training and testing of the network. In this case, the neural network component is a special module of the program (toolbox in Matlab) that can use the capabilities of the main program in order to input and manipulate data and produce graphs.

4. NETWORK PARAMETERS SELECTION

Although there are differences between traditional approaches and neural networks, both methods require preparing a model. The classical approach is based on the precise definition of the problem domain as well as the identification of a mathematical function or functions to describe it. However, it is very difficult to identify an accurate mathematical function when the system is nonlinear and there are parameters that vary with time. Neural networks are used to learn the behavior of the system and subsequently to simulate and predict this behavior. In defining the neural network model, first the process and the process control constrains have to be understood and identified. Then the model is defined and validated.

The neural network model and the architecture of a neural network determine how a network transforms its input into an output. This transformation is in fact a computation. The neural network architecture refers to the arrangement of neurons into layers and the connection patterns between layers, activation functions, and learning methods. Often, success depends on a clear understanding of the problem regardless of the network architecture. However, in determining which neural network architecture provides the best prediction, it is necessary to build a good model. It is essential to be able to identify the most important variables in a process and generate best-fit models. How to identify and define the best model is very controversial.

When building the neural network model, the process has to be identified with respect to the input and output variables that characterize the process. The inputs include measurements of the physical dimensions, measurements of the variables specific to the environment, and equipment-controlled variables modified by the operator. Variables that do not have any effect on the variation of the measured output are discarded. These are estimated by the contribution factors of the various input parameters. These factors indicate the contribution of each input parameter to the learning of the neural network and are usually estimated by the network, depending on the software employed.

The selection of training data is vital in the performance and convergence of the neural network model. An analysis of historical data for identification of variables that are important to the process is important. Plotting graphs to determine whether the charts of the various variables reflect what is known about the process from operating experience and for discovery of errors in data is very helpful.

The first step is to collect the required data and prepare them in a spreadsheet format with various columns representing the input and output parameters. If a large number of sequences/patterns are available in the input data file, and to avoid long training times, a smaller training file may be created to select the required parameters and the complete data set can be used for the final training.

Three types of data files are required: a training data file, a test data file, and a validation data file. The former and the latter should contain representative samples of all the cases that the network is required to handle, whereas the test file may contain approximately 10–20% of the cases contained in the training file.

The training of all patterns of a training data set is called an epoch. The training set has to be a representative collection of input/output examples. During training, the network is tested against the test file to determine its prediction accuracy, and training should be stopped when the mean average error remains unchanged for a number of epochs. This is done in order to avoid overtraining, in which case the network learns perfectly the training patterns but is unable to make predictions when an unknown training set is presented to it.

The input and output values need to be normalized. All input and output values are usually scaled individually such that the overall variance in the data set is maximized. This is necessary because it leads to faster learning. The scaling that may be used is either in the range -1 to 1 or in the range 0 to 1 depending on the type of data and the activation function used.

When using a neural network for modeling and prediction, the following steps are crucial. First, a neural network needs to be built to model the behavior of the process. Second, based on the neural network model built, the output of the model is simulated using different scenarios. Third, the control variables are modified so as to control and optimize the output.

The basic operation that has to be followed to successfully handle a problem with neural networks is to select the appropriate architecture and the suitable learning rate, momentum, number of neurons in each hidden layer, and the activation functions. This is a laborious and time-consuming method, but as experience is gathered some parameters can be predicted easily, thus shortening tremendously the time required.

In backpropagation networks, the number of hidden neurons determines how well a problem can be learned. If too many are used, the network will tend to try to memorize the problem and thus not generalize well later. If too few are used, the network will generalize well but may not have enough "power" to learn the patterns well. Determining the correct number of hidden neurons is a matter of trial and error since there is no science to it.

5. MODELING OF ENERGY SYSTEMS USING NEURAL NETWORKS

Neural networks have been applied successfully in a number of applications. The following are some of the most important:

Function approximation: In this type of problem, mapping of a multiple input to a single output is established. Unlike most statistical techniques, this can be done with adaptive model-free estimation of parameters.

Pattern association and pattern recognition: Neural networks can be used effectively to solve difficult problems in this field, such as in sound, image, or video recognition. This task can even be performed without an a priori definition of the pattern in which the network learns to identify totally new patterns.

Associative memories: This is the problem of recalling a pattern when given only a subset clue. In these applications, the network structures used are

usually complicated, composed of many interacting dynamical neurons.

Generation of new meaningful patterns: This general field of application is relatively new. Some claims have been made that suitable neuronal structures can exhibit rudimentary elements of creativity.

Neural networks have been used by various researchers for the modeling of energy systems. This section presents various such applications in a thematic rather than a chronological or any other order.

5.1 Renewable Energy Systems

In the field of renewable energy, neural networks have been used for the modeling of various components of a concentrating solar collector and for the prediction of the mean monthly steam production of a solar system. They have also been used to model the starting up of a solar steam generator, which is a particularly difficult problem because the system is working in transient conditions. In all these models, experimental data were used to train the neural networks, which were used subsequently to provide predictions for unknown cases.

Neural networks have also been used for the modeling of solar domestic water heating systems and for long-term performance prediction of the systems. In these models, performance data for 30 systems, obtained by testing the systems with the procedure suggested in international standards, together with weather conditions and some physical characteristics of the systems such as the collector area, storage tank volume and heat loss coefficient, tank type (vertical or horizontal), and type of system (open or closed) were used to train the neural network. A large variety of weather conditions were used to enable the network to accept and handle unusual cases. The trained model could be used to provide the useful energy extracted and the increase in storage tank water temperature of other unknown systems using only their physical characteristics and typical weather conditions, which reduces the experimentation required.

Other applications of neural networks in this field include the identification of the time parameters of solar collectors, photovoltaic systems, and solar radiation and wind speed prediction, which are the driving sources of renewable energy systems.

5.2 Heating, Ventilating, and Air-Conditioning Systems

In the field of heating, ventilating, and air conditioning, neural networks have been used for the modeling of houses and the estimation of the heating and cooling load, for the prediction of the air flow and pressure coefficients of naturally ventilated rooms, for the prediction of the energy consumption of passive solar buildings, and for the energy consumption optimization. The data required for the training of the neural networks were obtained from experimental measurements in actual buildings. Although most of the previously mentioned models were performed for a particular building construction, these can be developed to have a more general usefulness provided that the training databases are enriched with a variety of building constructions, orientations, and weather conditions. In such cases, neural networks need to be retrained to "learn" the new patterns.

Other applications in this field include the use of neural networks for the energy consumption prediction in commercial buildings and modeling of a room storage heater. In these models, the neural networks were used as an expert system.

Neural networks have also been used to control specific systems such as the temperature in a bus air-conditioning system according to the ambient temperature, number of passengers, and time of day. Neural networks can also be used for the modeling of refrigeration systems. In one such application, neural networks were used to model the amount of frost on the coil of a refrigerator, and based on the network results a demand defrost method was proposed.

5.3 Combustion and Incineration

In combustion, neural networks have been used mainly for the modeling and prediction of the combustion emission products. In particular, they have been used for the monitoring of combustion pollutant emissions, for the prediction of the gaseous emissions from a chain grate stocker boiler, and for the estimation of NO_x emissions in thermal power plants. They have also been used for the development of controllers for combustion systems. Applications include the predictive control of unstable combustion systems, process control for fluidized bed combustion, and optimal control of an industrial stoker-fired boiler.

For the latter application, data collected during 300 h of experiments on an actual 0.75-MW chain grate stocker boiler were used to train two neural networks. The control strategy, shown in Fig. 5, is to provide the minimum airflow required for combustion without incurring unacceptably high CO emissions and carbon in ash losses, thus improving the combustion efficiency. The system detects changes in load required and gives the matching coal feed and

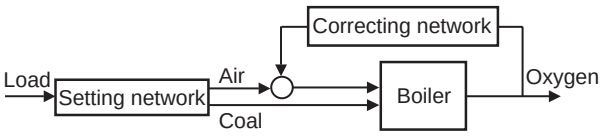

FIGURE 5 Chain grate stocker-fired boiler controller strategy.

airflow. Initially, the "setting network" acts as a look-up table to provide near optimum settings of coal feed and airflow for the desired load. After quasi-steady-state conditions are reached, the "corrective network" is activated to fine tune the airflow rate in order to optimize the combustion process on the grate.

Neural networks have also been used for the modeling of the combustion process in incineration plants, modeling of the temporal evolution of a reduced combustion chemical system, representation of the chemical reactions of combustion flames, and turbulent combustion modeling. In all the previously mentioned models, past history experimental data were used for the training of the neural networks to learn the required behavior and, according to the application, to provide the expected emissions so as to take corrective actions or to control a processes.

5.4 Internal Combustion Engines

Neural networks have been used to design engine controllers, such as a controller for idle speed regulation in internal combustion engines, a knock detector, spark advance control using cylinder pressure, and the control of combustion parameters such as spark ignition timing of petrol engines.

Neural networks have also been used for engine modeling, such as for the nonlinear time series analysis of combustion pressure data, modeling of the emissions and performance of a heavy-duty diesel engine, modeling of the volumetric efficiency and performance prediction of internal combustion engines, and modeling of a gas engine. In these models, experimental data were used for the training of the neural networks and the developed models are applicable to the particular type of engine used to collect the data. More general models can be produced by combining data from a number of engine capacity sizes and retraining the networks in order to produce general-purpose tools for the modeling of these engines.

Neural networks have also been used for the fault diagnosis of small to medium-sized diesel engines and marine diesel engines by providing an early warning of combustion-related faults. In a marine diesel engine model, the neural network was used to classify combustion quality on the basis of simulated data.

5.5 Energy Prediction and Forecasting

In the field of forecasting and prediction, neural networks have been used in power systems load forecasting and in electric power forecasting. They have also been used in tariff forecasting and energy management and in electric load forecasting in smaller capacity units such as supermarkets. The neural network models were trained with a sequence of past data recorded at the utilities and can provide either short-term or long-term predictions. Such systems can be used as effective management tools to regulate the operations of power utilities and other smaller enterprises.

6. CONCLUSIONS

From the applications described previously, it can be seen that neural networks have been applied for modeling and prediction in a wide range of fields of energy systems. Required for setting up such a neural network system are data that represent the past history and performance of the real system and a suitable selection of a neural network model. The selection of the model is usually done empirically after testing various alternative solutions with respect to network architecture and parameters. The performance of the developed neural network model is tested with unknown data collected from a real system that were not used for the training of the network.

The number of applications presented here is neither complete nor exhaustive but merely a sample that demonstrates the usefulness of artificial neural networks for modeling and prediction of energy systems. Artificial neural networks, like all other approximation techniques, have advantages and disadvantages. There are no rules regarding when this particular technique is more or less suitable for an application. Based on work published to date, neural networks offer an alternative modeling method that should not be underestimated.

3. Conclusion

Glossary

nongovernmental organizations (**NGOs**) National and international nonprofit organizations as well as local membership organizations, often referred to as grassroots or community-based organizations, that represent the public interest (or the interests of groups of citizens).

The term nongovernmental organization (NGO), as used in this article, refers to national and international nonprofit organizations as well as local membership organizations that are often referred to as grassroots or community-based organizations. NGOs can basically be thought of as being a third sector—separate from the state and the market—that represents the public interest (or the interests of groups of citizens). In this context, NGOs fill gaps in services provided by governments and firms and also enhance the accountability and responsiveness to citizens of these two sectors.

1. INTRODUCTION

Organizational goals of nongovernmental organizations (NGOs) include empowering people socially, economically, or politically; serving underserved or neglected populations; and protecting the local or global environment. To fulfill these objectives, NGOs are involved in a range of activities, including delivering welfare and development services, monitoring, critiquing and advocating policies, and providing information to citizens (and even to policymakers).

Although such citizens organizations have been a part of the landscape of societies for centuries, there has been a marked and rapid growth of this sector during recent years. The number of NGOs in most countries, as well as those operating transnationally, has increased substantially during the past couple of decades, as have the functions of these organizations. Consequently, these NGOs are playing an increasingly prominent role in many aspects of domestic affairs (within industrialized and developing countries) as well as in the international arena, resulting in what Edwards and Hulme referred to as the "rise and rise of NGOs" and what Salamon referred to as a "revolution." Nowhere is this transformation more prominent than in the environment and development arena. Whereas fewer than 300 NGOs attended the Stockholm Conference on the Environment in 1972, approximately 1400 NGOs registered for the Earth Summit in Rio de Janeiro, Brazil, in 1992 and roughly 18,000 NGOs attended the parallel NGO forum. More recently, more than 8000 NGOs attended the World Summit on Sustainable Development (WSSD) in Johannesburg, South Africa, and approximately 30,000 NGOs participated in the related Civil Society Forum. By now, NGOs and their networks are central players on the landscape of environmental politics and action.

At the same time, the finances underlying NGO operations have also been bolstered markedly. For example, Edwards and Hulme estimated that in

 © 2004 Elsevier Inc. All rights reserved.

1975 only 0.7% of the total development aid given by Organization for Economic Cooperation and Development (OECD) countries was channeled to NGOs, whereas by 1985 NGOs received 3.6% of development aid and by 1993–1994 they received 5.0%—with this last figure corresponding to roughly $5.7 billion. Other sources of NGO funding could have accounted for another $3 billion by the early 1990s. Of course, these numbers pertain only to funds channeled by aid and development agencies. NGOs in industrialized and developing countries also raise money from other sources, including membership fees, private foundations, individual donors, sales of publications (e.g., *State of the World* by the Worldwatch Institute), and technical services (e.g., organizing conferences and technical consulting). For example, Greenpeace raised more than four-fifths of its $143 million income in 2000 through personal donations, and the U.S. NGO Natural Resources Defense Council (NRDC) has more than 500,000 dues-paying members (see subsections on Greenpeace and NRDC in Section 2.4).

Another indicator of the growing influence of NGOs is the increasing movement of their personnel into governmental positions. This is particularly true in Western European countries, such as Germany, where members of environmental organizations formed the Green Party that has participated in governing coalitions. There have also been notable examples in the United States under Presidents Clinton and Carter, where individuals from environmental NGOs were nominated for senior governmental positions. This movement is not only into the government, as there are many former government officials now working in NGOs.

Broadly speaking, NGO activities include the following:

- Identification and articulation of needs and concerns that are being overlooked, or that are not receiving sufficient attention, by the state and the market
- Research and analysis to examine specific issues as well as potential solutions
- Advocacy, information, and technical assistance provision (e.g., coalition building) to citizens, policymakers, politicians, media, NGOs, and other groups
- Agenda setting
- Policy development
- Policy change and alternative policy formulation
- Policy implementation
- Delivery and provision of services to citizens or groups of society
- Capacity building in other groups, individuals as well as state and market actors
- Monitoring and critiquing state and market actors and activities.

The scale of NGO operations can also vary from the local (as may be common for many grassroots organizations) to the national and global. Furthermore, to fulfill their function better, NGOs often establish a wide variety of formal and informal links with other NGOs, individuals, governments and intergovernmental organizations (IGOs), development agencies, corporations, and transnational issue networks. For example, NGO relationships with governments and IGOs can be such that the NGOs may assist these latter institutions, take on tasks that have been ignored by them, lobby them to do things differently, evaluate their performance, or even challenge them, and sometimes the same NGOs may exhibit different kinds of linkages on different issues. Another important facet has been the emergence of networks and coalitions of NGOs at the national and transnational levels that have been useful for mobilizing and leveraging resources of a number of groups with common agendas or ideologies.

1.1 Greenpeace

Greenpeace is an environmental nonprofit organization that was founded in 1971 and now has a presence in 41 countries across Europe, the Americas, Asia, and the Pacific. The Greenpeace organization consists of Greenpeace International (Stichting Greenpeace Council) in Amsterdam, Netherlands, and Greenpeace offices around the world. The organization has a large base of individual supporters; as of January 2002, 2.8 million people had taken out or renewed their financial memberships within the previous 18 months.

As with many other major environmental NGOs, Greenpeace is engaged in a number of campaigns, including climate change, through which it draws attention to major environmental problems and possible solutions to them. Given the intimate relationship between energy use and climate change as well as other environmental issues, many of Greenpeace's activities focus on energy issues and, in turn, the organization has had a significant impact on various components of the energy system.

Greenpeace is actively engaged in increasing the public profile of a range of energy-related issues,

including renewable energy, nuclear energy, oil exploration, and climate change. It prepares detailed reports, commissions studies, analyzes policies, and disseminates information to the public on such issues. It also campaigns against, debates, and engages with industry (as needed). For example, whereas Greenpeace has led campaigns to prevent oil exploration in remote areas by firms such as BP or to challenge Shell on Brent Spar (the oil platform in the North Sea), it has also worked with other firms to develop new refrigeration technology. It also seeks to influence governments in international forums, such as those on climate change, as well as in the domestic arena.

Greenpeace was instrumental in the development of Greenfreeze, the world's first climate and ozone safe technology. In 1992, it brought together scientists who had extensively researched the use of propane and butane as refrigerants with an East German company, DKK Scharfenstein (now Foron), to develop this technology. It also gathered tens of thousands of preliminary orders for this new refrigerator from environmentally conscious consumers in Germany. Greenfreeze refrigerators are now sold in Western Europe, China, and Latin America.

Greenpeace does not solicit or accept funding from governments, corporations, or political parties. It relies on the voluntary donations of individual supporters and on grant support from foundations. Greenpeace's net income in 2001 was 112 million Euros (nearly exclusively from grants and donations). It spent approximately 10 million Euros on its climate campaign that year.

1.2 Natural Resources Defense Council

NRDC was founded in 1970 and now has more than 500,000 members in the United States. The organization is active in a number of areas, including clean air, energy, and water; forests and wildlife; toxics; nuclear weapons and waste; and green cities. It uses scientific analysis, legal actions, public education, and targeted grassroots efforts to promote policy changes in all of these areas.

NRDC's efforts to ensure clean air include targeting local, state, and federal governments as well as using legal avenues to promote strict pollution standards and compliance with them. NRDC also uses market-based strategies to promote new, less-polluting technologies. It also aggressively promotes renewable energy sources, such as wind and sun, as well as energy efficiency improvements in appliances, business equipment, and buildings through new and existing laws, better regulations, and financial incentives. Recently, NRDC has been paying particular attention to deregulation and restructuring of the electric industry to ensure incorporation of incentives for clean energy and efficiency.

NRDC's "earthsmartcars" campaign aims to put cleaner cars on the road by focusing on the demand side (i.e., consumer demand) as well as on the supply side (i.e., new technologies). It advocates for laws and regulations governing vehicle pollution as well as for promotion of public transportation and local planning to reduce vehicle use. NRDC has also been active in targeting diesel-fueled trucks and buses due to the particular health and environmental hazards posed by them. NRDC was instrumental in the efforts to phase out lead from gasoline, reduce acid rain, and help win adoption of national efficiency standards for consumer appliances, all of which have had a major impact on the energy system in the United States.

NRDC also has a major effort on climate change focusing on greenhouse gas (GHG) reduction domestically and internationally.

Nearly three-quarters of NRDC's 2001 operating income of $40.6 million came from membership and contributions, with foundations accounting for most of the remainder (nearly $9 million).

2. NGOs AND ENERGY

The main path through which NGOs shape the energy system is by influencing policy processes of governments and IGOs (e.g., the World Bank) that have an impact on the energy system as well as on the pace and direction of technological innovation. These include the following:

- National energy policy frameworks, including regulations, taxes, and publicly funded research
- Local and national environmental policies such as air quality regulation and GHG abatement policies
- Global environmental regimes such as the climate convention
- Contextual policies such as trade policy, export credit, and bilateral and multilateral aid that have indirect influences on global energy supply and demand

NGOs also directly participate in efforts to enhance and improve the delivery of energy services by working on relevant technologies and products as

well as on their deployment and diffusion in energy projects.

2.1 NGO Influence on National Energy Policies

Over the past few decades, NGOs have had a significant influence on shaping national or regional energy policies in most industrialized countries as well as in many developing countries. In industrialized countries, there is by now an established tradition of (mostly environmental) NGOs lobbying for domestic environmental regulations, and energy is often a priority on the agenda. In developing countries, an increasing number of NGOs have played a leading role in promoting sustainable energy technology transfer as well as the recognition of local knowledge and "home-grown" solutions in the South, critiquing existing national or local energy policies and proposing alternative policies, and participating in the design, implementation, and monitoring and evaluation of energy-related development projects. The pathways to influence have also been different in various countries. NGOs, although often with limited resources, are generally quite adroit at working within the institutional, policy, and cultural contexts within their countries and exploiting opportunities to shape energy policies through various mechanisms, as illustrated by the following examples from various countries.

2.1.1 United States

Some of the largest environmental NGOs, such as NRDC, were formed when citizens organized to fight power plants and other energy projects. Energy issues consistently appear high on the agenda for many of the largest NGOs. For example, the Sierra Club, one of the largest U.S. membership NGOs, has for years been a strong opponent of oil drilling in Alaska and a strong proponent of more stringent fuel economy standards.

The ability of NGOs to use courts as a means of influencing energy policy has been particularly important in the United States, where citizen suits to protect the environment were first permitted by judicial decisions and then enshrined in legislation such as the Clean Air Act. Environmental litigation has been used to challenge procedural deficiencies, such as lack of notice and opportunity to participate in decision making, as well as substantive outcomes, such as whether regulations are sufficiently protective of the environment consistent with legislative requirements. Litigation has also been an important educational tool in that it often generates publicity and public awareness. For example, environmental groups went to court in 2002 seeking to identify participants in meetings on energy policy with the vice president in an effort to show undue influence by industry.

An example of the high impact of environmental litigation in the United States on energy policy is a lawsuit filed by NRDC in 1983 to contest a decision by President Reagan to oppose the implementation of a law that required energy efficiency standards for refrigerators, air conditioners, and other appliances. NRDC was joined in the lawsuit by several states, including California and New York, as well as other NGOs, including a national consumer organization. The lawsuit was decided in favor of NRDC and resulted in negotiations between the plaintiffs (NGOs and state governments) and appliance manufacturers on national standards that were ultimately adopted through national legislation in 1987. It has been estimated that the standards will save U.S. consumers $200 billion through reduced energy consumption and avoided investments in power plants. U.S. appliances, which had been among the least energy efficient in the world during the 1970s, are now among the best available.

Although U.S. NGOs receive financial support from members, resources provided by private foundations have been particularly helpful in many cases. This source of funding is generally not available in other industrialized countries or is restricted from supporting litigation. The impact of foundation support for NGO efforts related to energy policy was enhanced in the United States by the founding of the Energy Foundation in 1991. The Energy Foundation was created by the McArthur, Pew, and Rockefeller foundations to provide more strategic support for utility regulatory reform and other technical issues. (Since that time, it has also received support from other foundations.) This more coordinated funding facilitated a network of lawyers and activists, at the state level, who could develop a common strategy; share data, witnesses, and legal materials; and generally work much more effectively. The Energy Foundation was also able to identify gaps in NGO work and support the creation of new organizations such as the Regulatory Assistance Project (RAP) and the Renewable Energy Policy Project (REPP).

2.1.2 Europe

NGOs have influenced domestic energy policies in many Western European countries. In Italy,

Legambiente, a leading grassroots environmental NGO, has worked on energy issues in various spheres. Started with the intellectual support of a group of scientists, many of them associated with the University of Rome "La Sapienza," Legambiente was initially very active in the antinuclear campaign. In 1986, after the accident at Chernobyl, Legambiente and other Italian NGOs promoted a referendum that resulted in a nuclear moratorium. During the 1990s, Legambiente's scientific committee, as well as its legal office, supported the work of green parliamentarians who designed and proposed Laws 9 and 10, subsequently approved by the Italian Parliament in 1991. Laws 9 and 10 introduced the "avoided cost principle" for purchase of power from nonutility generators and created significant economic incentives to produce and distribute renewable energy.

In The Netherlands, the ratio of NGOs to population is the highest in the world. Dutch NGOs have engaged in a number of activities on domestic energy policy, including public awareness, financial and fiscal incentives, and demand-side management programs. For example, in 1997, the Dutch government, the World Wildlife Fund (WWF, a major international NGO), and energy distribution companies decided to coordinate their public information campaigns. In addition, the three stakeholders joined efforts in the "Dutch Green Electricity Project" aimed at introducing a new product: "green electricity." Consumers paid 20% more, and the energy utility, in partnership with WWF, guaranteed that that this amount of electricity came from wind, small-scale hydro, biomass, and solar sources.

In Central and Eastern Europe, energy and climate NGOs have been active since the early 1980s and have significantly increased in number and activities during subsequent decades. Terra Millennium III, engaged at both the domestic and international levels, successfully lobbied the Romanian government toward an early ratification of the Kyoto Protocol. Green Action in Croatia, the Energy Club in Hungary, the Energy Efficiency Program and the Renewable and Energy Savings Center in Czech Republic, and the Polish Foundation for Energy Efficiency in Poland are among many NGOs in the region working to promote energy efficiency, renewable energy, and GHG reduction through policy research, training and education, and joint venture development.

2.1.3 India

NGOs play a prominent role in public discourse on India's development activities, including numerous aspects of the energy sector. For example, NGO opposition to the country's policy on independent power projects (IPPs), and on specific IPPs (including Enron's Dabhol project) for environmental, social, or economic reasons, has contributed to the government's reexamination of its power policies. The long and ongoing protest by the Narmada Bachao Andolan against a major dam (the Sardar Sarovar), citing reasons of insufficient attention to resettlement and rehabilitation issues as well as overall long-term effectiveness of the project, forced the World Bank to withdraw its support from the project and has rendered impossible a business-as-usual approach on hydroelectric development within the country. The International Rivers Network (IRN) has helped to support and lead a discussion on these kinds of issues in other countries as well (see subsection on IRN in Section 2.4).

Environmental NGOs have also influenced indirectly aspects of energy policy in India. For example, the Center for Science and Environment released a major study on urban air pollution to highlight the urgency of tackling transport-related pollution in Delhi and other major cities in the country. It followed this up with a strong and sustained public campaign that helped to catalyze the transition (with the support and intervention of a determined and activist judiciary) toward cleaner public transport in these cities.

2.1.4 NGOs and Nuclear Energy

No energy technology has been the subject of more NGO focus and influence than has nuclear power. The development of nuclear power has been heavily subsidized, and its further refinement and deployment is supported by a well-financed industry lobby. Nevertheless, since around 1970, nuclear energy's expansion has been blocked and even reversed (in the form of plant closures) in response to public pressure in Europe, the United States, and Japan. As noted in the World Energy Assessment, many official projections of nuclear power in 2020 envision no more, and perhaps less, total output than is the case today. NGO campaigns, coupled with the devastating accident at Chernobyl, have had a major and lasting influence on public attitudes toward nuclear power in Europe. NGOs have engaged in demonstrations (sometimes violent) at plant sites throughout Europe and the United States to highlight concerns about plant safety and waste disposal. They have also used legal means to challenge licensing and construction of plants and have prepared detailed analyses critical of the economics of nuclear power. The result has

been a significant contribution to public skepticism about the technology, ultimately leading to a refusal to accept new plants and, in some cases, pressure to cancel plants under construction or even those already operating.

A further indication of NGO influence is the widespread perception that the future revival of the nuclear industry depends as much on changes in public attitudes as on actual changes in plant operation and safety. As the World Energy Assessment states,

> *Decisions on future nuclear power will be made largely at the political level rather than on narrow technical and economic grounds. Gaining broad public support … is not simply a matter of better educating the public on the issues, which is what many in the nuclear industry believe is needed most. The industry should also seek to better understand public concerns. The industry should also consider opening up the nuclear decision-making process to diverse interest groups, so that a well informed public could ensure that its concerns are addressed every step of the way.*

2.2 Role of NGOs in Shaping International Environment/Development Policy Frameworks

A major role of NGOs in shaping energy policy is through their influence on international policy frameworks that have implications for energy systems. These include frameworks that are both legally binding, such as the UN Framework Convention on Climate Change (UNFCCC), and nonbinding, such as the Agenda 21 (the sustainable development action plan that includes significant sections about energy policies).

Energy plans and policies, previously seen as domestic issues, now have a transnational dimension with the clear recognition that the way in which energy is consumed and produced affects the regional and global environment through phenomena such as acid rain and greenhouse warming. Hence, agreements have been negotiated at the regional level, such as the Convention on Long-Range Transboundary Air Pollution (LRTAP), as well as at the global level, such as the UNFCCC.

NGOs have played a pivotal role in these negotiations and in the domestic implementation of related energy policies. At the global level, this has occurred thanks to the inclusive policy of the UN system, which allows nongovernmental groups to participate as observers in international forums. Since 1945, NGOs have been involved in consultation arrangements with the Economic and Social Council (ECOSOC) of the United Nations. Notwithstanding many difficulties and constant debate for decades with some governments that were not in favor of public participation, NGOs have increasingly gained recognition, credibility, and consensus on their involvement in UN processes, to the extent that by the early 1990s ECOSOC already included approximately 1000 NGOs. The UN Conference on Environment and Development (UNCED), or Earth Summit, held in Rio de Janeiro in 1992 was an unprecedented event with respect to NGO participation in global environmental politics. A record number of NGOs participated in the UNCED process (more than 1420 NGOs were accredited) and had the opportunity to influence the outcome of the negotiations. The UNFCCC and Agenda 21 are, among the outcomes of the Rio summit, the most relevant with respect to energy. NGOs are now considered as a major force in environmental politics. At various levels, they have helped governments and other stakeholders to identify issues and set agendas, have provided policy analysis as well as normative and regulations criteria, and have carried out monitoring and implementation activities.

Over the years, the level of expertise of NGOs has been increasingly recognized, thanks also to credible and independent policy analyses and scientific reports. Many governments, especially in developing countries, now rely on NGOs' expert support to help negotiate global environmental treaties and to help translate such agreements into domestic (energy) policies.

Worldwide, most NGOs active in global environmental politics fall into one of three categories: international NGOs (e.g., Friends of the Earth, Greenpeace, WWF, Third World Network), national organizations and think tanks, or (more recently) small and local NGOs. The last ones are particularly helped by joining umbrella organizations that work on thematic issues such as the Climate Action Network (CAN) (see subsection on CAN in Section 2.4).

2.2.1 NGOs' Involvement in the UNFCCC

The UNFCCC was adopted by more than 160 countries at the Earth Summit in Rio de Janeiro, and this agreement forged the first international work plan to address climate change. The ultimate objective of the treaty is the "stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system." In practical terms, this statement implies a significant drop in

GHG emissions that cannot occur without significant changes and reforms in energy policies and technologies worldwide, inevitably leading to complex and contentious negotiations among countries.

NGOs have interfaced with this negotiation process in a number of ways, including directly lobbying government delegates, presenting "position papers" to the climate convention secretariat and parties, making statements during the plenary and organizing thematic "side events," using the media to exert public pressure on the delegates, and providing technical, policy, and scientific advice to the delegations (as appropriate). Although it is generally difficult to quantify the impact of NGOs, their relevant contributions to the debate, including policy analysis, position papers, fact sheets, scientific research, and economic analysis of mitigation options in the energy sector, among other inputs, have been recognized by the UNFCCC secretariat as well as by governments, which are gradually including a larger number of NGOs in their official delegations.

For example, in 1991, the Center for Science and Environment (CSE), an Indian NGO based in Delhi, published a report called "Global Warming in an Unequal World," that expressed the frustration of both Southern governments and many NGOs about the lack of attention given to the equity issue in the climate deliberations and that forcefully injected the topic into the international discussions. CSE was also asked to advise the Indian government on climate change, and it continues to have a significant influence on the country's climate policies. On the other end of the policy process, ENDA Energy, the energy branch of ENDA Tier Monde from Africa, is helping to implement the UNFCCC in African countries (see subsection on ENDA Energy in Section 2.4).

During the climate negotiations, NGOs have found numerous ways in which to exert influence. CAN NGOs publish a daily newspaper, *ECO*, that reports and comments on the details of the negotiations and is considered by many negotiators and observers to be a key source of information, policy analysis, and humor. CAN representatives also organize a daily press conference and distribute press releases commenting on the status of the climate negotiations. A Canada-based NGO, the International Institute of Sustainable Development (IISD), also publishes a more journalistic report on the negotiations, the *Earth Negotiations Bulletin*.

Over time, NGOs have gradually become more effective at networking by working together with their counterparts from various parts of the world. Increased funding from foundations and from bilateral, multilateral, and private sources, combined with North–South joint fund-raising, has increased NGOs' ability to travel and ensure a continued and consistent presence during more than a decade of climate negotiations.

2.2.2 NGOs and Agenda 21

The influence of NGOs was even more relevant in the Agenda 21 than in the climate convention due to its non-legally binding nature. Agenda 21 is intended to set out an international program of action for achieving sustainable development during the 21st century. Agenda 21 is a report of more than 500 pages and comprising 40 chapters. Energy issues are explicitly spelled out in many chapters, although there is no single energy overview or focus reflecting political differences on this topic. In the section on changing consumption patterns, NGOs provided language proposing to improve production efficiency to reduce energy and material use and to minimize the generation of waste concepts reflected in the final text of Agenda 21. The text of Agenda 21 is a particularly positive example of a collaborative approach and mutual tolerance among governments and civil society, represented mostly by NGOs.

Agenda 21 also explicitly recognizes, in its chapter 27, the role of NGOs in implementing the agenda:

> *Nongovernmental organizations play a vital role in shaping and implementing participatory democracy. Their credibility lies in the responsible and constructive role they play in society. Formal and informal organizations, as well as grassroots movements, should be recognized as partners in the implementation of the Agenda 21. … Nongovernmental organizations … possess well-established and diverse experience, expertise, and capacity in fields which will be of particular of particular importance to the implementation and review of environmentally sound and socially responsible sustainable development.*

2.2.3 NGOs and Multilateral Development Banks

During the 1980s, NGOs launched a major campaign to reform the environmental policies of the multilateral development banks (MDBs). Such a targeted reform campaign on MDBs was based not only on the size of their loan portfolios but also on the fact that MDBs act as a catalyst for additional funding from the private sector and other banks.

Energy was a key issue in this campaign. The lending decisions of the World Bank and other MDBs often favored large-scale, capital-intensive, centralized projects (e.g., large dams, fossil fuel power plants) as opposed to more decentralized,

small-scale, renewable energy or energy efficiency technologies.

Because of the significant influence of the U.S. government on the World Bank and other MDBs, a coalition of U.S.-based NGOs launched a strategy based on lobbying the U.S. Congress to influence the MDBs' lending policies through an evaluation of their environmental practices and policies. The NGOs started their campaign by convincing members of the U.S. House and Senate and their staff to hold hearings on the environmental performance of the MDBs. The U.S.-based NGOs testified, together with colleagues from developing countries, on the environmental and social impacts of the projects, especially in the energy and agriculture sectors. Recommendations on new procedures for MDB lending decisions drafted jointly by NGOs and staff of the House Banking Subcommittee were proposed to, and accepted by, the Department of the Treasury.

During the late 1980s, the campaign expanded to include an increasing number of NGOs from developing countries, economies in transition, and Western Europe. Although the campaign had a tangible influence on environmental policies of the World Bank, within the energy sector it resisted shifting its landing policy from conventional energy sources (e.g., fossil fuels, large dams). In 1989, only 2% of the World Bank's energy portfolio included end-use energy efficiency components.

Many developing country NGOs gradually increased their participation in areas of action traditionally handled by Northern NGOs. Protest against international aid agencies has demonstrated to be a very successful means to raise media, public, and political attention. In the MDB campaign, monitoring and denouncing project activities in the field became a key element of the campaign, giving developing country NGOs a pivotal role to play. In some cases, thanks to the testimony of developing-country NGOs about negative local environmental and social impacts, Northern NGOs managed to stop or at least question the project funding.

The NGO initiative calling for a World Bank reform further expanded during the 1990s, especially in 1994 when Friends of the Earth International took the lead with the "50 Years Is Enough" campaign.

The relationship between MDBs and NGOs has also changed dramatically during recent years as a result of such campaigns. The World Bank and other aid agencies have included public participation and disclosure guidelines to give more access to information and participation at all stages of project design, implementation, monitoring, and evaluation, and formalized consultations are now sometimes done on the Internet. The ongoing NGO campaign that embraces a number of MDBs' initiatives is called the "Campaign for the Reform of the World Bank," where development groups, such as Both Ends, have a leading coordinating role.

In the context of aid agencies, it is also relevant to mention the interaction between the Global Environmental Facility (GEF) and NGOs. GEF has allocated $580 million in renewable energy during the past decade or so and has engaged in bilateral consultations with NGOs since its inception. GEF public participation policy consists of information dissemination, consultation, and stakeholder participation, including those potentially affected by GEF-financed projects. The GEF Small Grant Program also includes a project portfolio that involves NGOs as central proponents, designers, and implementing stakeholders.

2.2.4 NGOs and International Finance/Aid Flows

NGOs have recently started to examine the activities of export credit and investment insurance agencies that play a major role in financing infrastructure projects in developing countries. Many of these infrastructure projects are in the energy area and, hence, have important long-term climate as well as other environmental and social implications. Many export credit agencies (ECAs) have no formal policies to evaluate such implications of the projects they fund; hence, many NGOs are building on their past work on World Bank projects to direct attention to filling this gap.

Recent examples include advocacy (so far unsuccessful) in the United States to include renewable energy targets in legislation reauthorizing the Export–Import Bank's charter and budget, establishment by the Export–Import Bank of a renewable energy advisory committee (REAC) that was pushed by advocacy groups, and greater integration of the ECA issue into climate advocacy group efforts both within the context of climate negotiations and in the runup to the WSSD.

2.3 NGOs and Energy Service Delivery

Given the centrality of energy services in improving the human condition, numerous development NGOs have, not surprisingly, been involved in efforts to increase and improve the delivery of essential energy services to poor people in many developing countries.

Thus, the main thrusts of these activities have been on improving the availability and use of energy for basic human needs, such as lighting and cooking, as well as for enhancing health services and opportunities for basic economic development. Hence, NGO efforts have aimed to enhance, and make more reliable, supplies of electricity using renewable resources (biomass, microhydro, and solar photovoltaic [PV]) as well as to make available technologies for economically or socially productive uses of energy (e.g., biomass gasifiers for small-scale industrial applications, refrigeration for health clinics) and improved cooking stoves for reducing health-adverse impacts of traditional stoves.

The presence and sophistication of NGOs involved in such activities have grown significantly over the past few decades and have often compensated for the inadequacies of the public sector in many developing countries. As mentioned earlier, given the local nature of many NGOs, development agencies interested in improving energy service delivery have also recognized their value, as have many actors in the private sector. Thus, NGOs continue to play an increasing role in this arena.

NGO involvement in energy service delivery takes many forms, but these organizations have been particularly useful at overcoming some of the major barriers—technology, finance, information—that often impede efforts to increase access to energy in rural areas.

Effective implementation of small-scale energy projects in rural areas often hinges on the availability of appropriate energy technologies. Although specific components of these technologies may be available in the commercial markets, often the development of the overall system is dependent on local resources and constraints. This necessitates making careful choices about technology design, possibly carrying out modifications to existing designs or developing new designs or components altogether. NGOs can play a useful role in such technology modification or development processes.

This is well illustrated by the case of improved cooking stove programs where, to be successful, the designs of the new stoves have had to take into account the locally available energy sources, the preferences of the users in terms of stove characteristics (not only functional but sometimes also aesthetic), and the skills and materials available locally for stove manufacture. For example, the successful Kenyan *jiko* stove was based on a design from Thailand that was modified to make it useful and appealing to local users. The training and demonstration work that underlay the development of the jiko was carried out with the assistance of the Kenya Energy and Environment Organization (KENGO), an indigenous NGO. Similarly, in the case of the improved cooking stove program in Sri Lanka, the Intermediate Technology Development Group (ITDG), a U.K.-based NGO that has been involved in energy technology projects for many decades (see subsection on ITDG in Section 2.4), played an important role in working with local firms to identify appropriate production materials and processes for indigenous production of cooking stoves. As another example, The Energy and Resources Institute (TERI, formerly known as Tata Energy Research Institute), a major NGO in India (see subsection on TERI in Section 2.4), has been involved in the development of biomass-gasifier–based technologies for thermally productive uses such as silk dyeing and cardamom drying where the design of the system, to be successful, is very much dependent on the specific needs of the small-scale enterprises that are its eventual users.

The success of the Grameen Bank in Bangladesh highlighted both the importance of microcredit in rural areas and the feasibility of NGOs and community organizations in bridging the financing gap for poor people who are deemed credit risks by banks and other traditional lending agencies. The resulting microcredit revolution has had an impact on the energy sector also where rural users were often unable to purchase energy systems for lack of financing options. NGOs, often with the help of development agencies, have begun to play a role by helping to provide microfinance to individual users or local entrepreneurs for promoting energy access. For example, Grameen Shakti (GS), a subsidiary of the Grameen Bank, has been quite successful at promoting energy service delivery through the provision of microcredit and other services (see subsection on GS in Section 2.4).

NGOs also provide other kinds of assistance to entrepreneurs and other actors in the energy service delivery arena by providing training and building capacity in technical as well as business issues. They can also play a critical role through public education and dissemination of information about energy options. In some cases, NGOs can be involved in the actual delivery of energy services. And in some of these cases, they may have functions similar to those of private energy service companies (ESCOs), although presumably maintaining their nonprofit character.

2.4 Illustrative NGOs

2.4.1 The Climate Action Network

CAN is a global network of more than 330 environment and development NGOs from some 80 countries working to promote equitable measures to limit human-induced climate change to ecologically sustainable levels. CAN is the largest recognized environmental nongovernmental network through which environmental groups coordinate on climate and energy policy at the national and international levels. CAN members work to achieve this goal through the coordination of information exchange and NGO strategy on international, regional, and national climate issues. CAN has seven regional coordinating offices that coordinate these efforts in Africa, Central and Eastern Europe, Europe, Latin America, North America, South Asia, and Southeast Asia. Diverse environmental organizations from around the globe, ranging from large international groups, such as WWF, Greenpeace, and Friends of the Earth, to small local groups in developing countries, such as Terre Vivante in Mauritania and the Green Coalition in The Philippines, work collaboratively within CAN. Its members place a high priority on both a healthy environment and development that "meets the needs of the present without compromising the ability of future generations to meet their own needs." CAN's vision is to protect the atmosphere while allowing for sustainable and equitable development worldwide.

Established in March 1989, CAN has been actively monitoring and seeking to influence the climate negotiations as well as climate-related policies and measures at the national and international levels. Member organizations include noted experts on issues of climate change science and policy. CAN is the recognized umbrella NGO in the international negotiations through which environmental groups work. CAN's credibility has been built over years of involvement at both the international and national levels. The organization's flexible structure provides an NGO forum to get together and share ideas, advocacy strategies, and information on climate change. Membership is open to nonprofit public interest organizations that are active on the global warming issue and that subscribe to the mission of CAN.

CAN's major objectives include assisting the global community in reaching the goals of the climate convention, promoting awareness and capacity building of governments and citizens worldwide on the climate issue, developing an objective understanding of climate change and its causes, sharing this information with all people (especially all members), and organizing, supporting, inspiring, and coordinating its members to take effective action on climate change.

2.4.2 ENDA Energy

ENDA Energy is a branch of the organization ENDA Tiers Monde (Environnement et Développement du tiers-monde), an association of autonomous entities coordinated by an executive secretariat, and collaborates with grassroots groups in search of alternative development models on the basis of the experience, expectations, and objectives of marginalized peoples.

ENDA Energy's work focuses on energy use and management in the African context, with an emphasis on the linkages between energy and development. ENDA Energy is also helping with the implementation in Africa of the United Nations Conventions on Climate Change and Desertification, with both areas being intimately related to the energy issue in Africa. It is also involved in the development of alternative energy technology, collecting information on energy, and implementing projects on both local and regional levels. ENDA Energy often works in partnership with other groups and through networks and jointly led projects.

ENDA Energy's team has approximately 10 permanent members, engineers, economists, and environmentalists focusing on the knowledge and planning of energy systems, the promotion of alternative energy systems suitable for the African context, and the broader challenge of integrating energy with environment for sustainable development.

Although the program originally focused mainly on energy use by grassroots communities, over time it has become involved in maintaining databases, undertaking direct fieldwork and training, and lobbying African policymakers. ENDA Energy has also helped to set up an African network, RABEDE (African Network on Bioresources–Energy–Development–Environment), which circulates information, advice, and experience on these topics through a variety of mechanisms, including the *Bulletin Africain,* the journal of the RABEDE network.

2.4.3 Grameen Shakti

GS is a subsidiary of Bangladesh's Grameen Bank, a member-owned organization founded in 1976 that provides microcredit to its members. GS was founded in 1996, when only 16% of the 21 million households were covered by the national electric

grid, to help provide renewables-based energy to rural households in Bangladesh.

By mid-2001, GS had installed more than 5800 PV home systems, with an installed capacity of 290 kWp, and planned to install 8000 systems within the subsequent 3 years. GS provides soft financing for customers as well as maintenance of its system for a year after sales. GS provides training to customers so that they can take care of minor problems themselves, and its intention is bring all customers under this program. GS also provides training to develop skilled technician-cum-retailers in the rural areas who will be able to install solar systems, provide accessories and after-sales services to PV systems buyers, and educate the rural people in renewable energy technologies. GS has trained more than 300 PV technicians under this program. GS also engages in promotion and demonstration efforts to build awareness of solar PV technology and also encourages customers to develop income generation schemes.

Under its wind program, GS is developing micro-enterprise zones using wind-based electricity generation systems; it has installed at least six turbines so far. Under its biogas program, GS is promoting the use of biodigesters to produce clean-burning biogas from cow dung and other waste biomass. GS has installed 30 biogas plants in northern Bangladesh and also provided training to customers for producing biogas from their own resources.

GS also has a research program that explores ways in which to develop appropriate renewable energy technologies (RETs) and their uses, develop methods to popularize renewable energy systems and make them accessible to large number of people, innovate financial services to facilitate rapid expansion of RETs, and develop and fabricate solar home system accessories and components to reduce total system cost.

A number of organizations have provided financial support to GS, including the International Finance Corporation, the U.S. Agency for International Development, the Swedish International Development Agency, Grameen Trust, and Grameen Fund.

2.4.4 International Rivers Network

IRN was established in 1985 in the United States as a nonprofit, all-volunteer organization of activists experienced in fighting economically, environmentally, and socially unsound river intervention projects. IRN collaborates and coordinates with local river activists worldwide. It sees itself as part of a larger citizen-based movement working on these issues and believes that its legitimacy is to be derived from the respect of individuals groups all over the world with whom it works.

IRN has a two-pronged approach that combines work on changing global policies with campaigning on specific key projects around the world. Through this approach, its campaigns for policy change are informed by specific project examples while also recognizing that a project-only approach does not address the root causes and policies that underlie unsound river interventions.

IRN works with groups from around the world on cooperative campaigns for community-based river development. This has included campaigns on the Sardar Sarovar project in India, the Three Gorges project in China, and the Lesotho Highlands Water project.

IRN also undertakes in-depth research and provides project critiques, analyses of alternatives, and activist briefings. It monitors and critiques the policies of financial institutions, including the World Bank, and provides analyses and recommendations for reforming their practices.

IRN helped to establish and continues to coordinate the International Committee on Dams, Rivers, and People (ICDRP), an informal network of NGOs and peoples movements from 13 countries. ICDRP monitored the World Commission on Dams (WCD) and facilitated civil society input into the process, and it continues to advocate for the implementation of the WCD guidelines. IRN has also supported the formation of regional networks to promote progressive change in water and energy policies.

IRN's support and revenue for the year ended December 2000 amounted to $1.2 million, of which nearly 80% came from grants and approximately 14% came from contributions. Nearly 70% of its expenses were directed toward campaigns, and just over 7% of its expenses were directed toward information and media.

2.4.5 The Intermediate Technology Development Group

ITDG, an NGO registered in the United Kingdom, was founded in 1966 by E. F. Schumacher. It has a presence in Latin America, East Africa, Southern Africa, and South Asia and focuses particularly on Peru, Kenya, Sudan, Zimbabwe, Sri Lanka, Bangladesh, and Nepal.

In these countries, ITDG works with poor communities to develop and disseminate appropriate technologies in a number of sectors, including energy,

transport, and small enterprise development. In the energy area, ITDG's efforts focus on increasing poor people's access to energy technology options. It has done this through the development and commercialization of low-cost cooking stoves as well as small-scale, off-grid, sustainable energy supply technologies such as microhydro plants, small-scale wind generators, affordable solar lanterns, and biogas plants.

As an example, in Peru, ITDG has been promoting the dissemination of microhydro energy for the past 20 years. Its integrated approach has included technology development, training, pilot projects, research on institutional issues, and advocacy work. This approach allowed ITDG to overcome the main barriers to rural electrification in Peru, namely, lack of appropriate technology, financial mechanisms, local capacity, and legal frameworks. Through a program with the Inter-American Development Bank (IDB), ITDG has implemented a small hydro revolving fund consisting of soft loans and technical assistance for isolated communities. Between 1994 and 2000, there were 21 small hydro schemes (more than 1 MW total) benefiting 15,000 people with an allocation of $700,000 that, in turn, leveraged $2.5 million from local, regional, and central governments as well as other NGOs. ITDG also helped to open a training center to build local capacity and actively disseminated the results of its effort. This program won the CTI World Climate Technology Award in 2000.

Lessons from ITDG's grassroots experience are spread through consultancy services, publishing activities, education, policy, research, and an international technical inquiries service. Thus, dissemination is an explicit part of ITDG's focus.

ITDG's income for the financial year ended March 2000 was £12.9 million (U.S. $20.8 million at then prevailing exchange rates), of which £3.6 million was from donations by individuals, companies, and trusts; £6.5 million from grants from the U.K. government, multilateral development agencies, NGOs, companies, and trusts; and the remainder from its in-house consulting, publishing, and manufacturing activities. More than half of ITDG's expenditures were devoted to its technology programs.

2.4.6 The Energy and Resources Institute

TERI was established in 1974. Although during the initial period its focus was mainly on documentation and information dissemination activities, research activities in the fields of energy, environment, and sustainable development were initiated toward the end of 1982. With a staff of some 500 drawn from multidisciplinary and highly specialized fields, TERI is the largest developing country institution focusing on issues relating to energy and environment and is involved in an enormous range of activities in these areas. Not only does TERI play a prominent role in energy, environment, and other related issues in India, it also has an international presence through its international offices and affiliate institutes.

TERI engages in research and analysis, technology development, consultancy, training and capacity building, and information collection and dissemination. It also organizes numerous seminars and workshops that bring together various stakeholders and experts on assorted topics. It also set up the TERI Institute of Advanced Studies, a degree-granting institution focusing on energy and environment technology, regulation, and governance, among other things.

TERI is also involved in analyzing policy issues on various aspects relating to energy such as global environmental issues, oil and gas resources, urban and transport systems, and economic modeling and statistical analyses.

Through its energy–environment technology division, TERI is involved in the development and dissemination of energy technologies as well as efforts to promote energy conservation, biomass energy technologies, rural energy (development and implementation of renewable energy-based programs as well as building capacity for doing so), and chemical and hydrogen energy (with a particular focus on fuel cells).

TERI's revenues have grown rapidly during the past decade or so. During the year 2000–2001, it received approximately Rs. 170 million (~U.S. $3.7 million at then prevailing exchange rates) from international sources and Rs. 110 million (~U.S. $2.4 million) from domestic sources.

3. CONCLUSION

The energy sector is often a high priority on NGOs' agendas due to the increasing demand for energy services in both developed and developing countries and its high environmental and social impacts. Consequently, NGOs from many developed and developing countries have played a substantial and generally effective role in shaping international and domestic energy agendas.

Importantly, NGOs' influence on the energy system comes through their engagement in a range of activities—from grassroots activism, to policy research, to technology development and dissemination.

TABLE I

Some Examples of NGOs That Have Had an Influence on the Energy System and/or Its Potential Trajectory within Their Home Countries or Globally and Their Main Modes of Influence

	CAN	ENDA	GS	Greenpeace	IRN	ITDG	NRDC	TERI
Research	X	X	X	X	X	X	X	X
Advocacy	X			X	X		X	
Agenda setting	X	X		X			X	X
Policy development		X						X
Policy reorientation/alternative policy formulation	X			X			X	
Policy implementation		X						
Service delivery			X			X		X
Information provision		X		X	X		X	
Technical assistance			X			X		X
Capacity building		X			X	X		
Watchdog	X			X	X		X	

Through their bottom-up approach, NGOs have shown increasing expertise, technical knowledge, and capability to monitor the implementation of energy policies, highlight problems, and suggest solutions to governments, UN agencies, multilateral aid agencies, and other energy stakeholders. And on the other end of the spectrum, many NGOs have helped local and national governments, as well as other organizations, to design improved energy policies.

Although most NGOs are involved in a number of activities at the same time (as Table I illustrates), the emphasis of their efforts is generally of a limited set of core activities that are in line with the organizations' foci. However, there are significant synergies and complementarities between the efforts of NGOs that aim to influence the energy sector within their home countries and those that aim to do so internationally. Although NGOs may collaborate and network with other like-minded NGOs in the North and South (e.g., in the MDB reform campaign), they also form partnerships with government agencies, donor organizations, and academic organizations.

Given the range of energy-related activities in which NGOs are involved, their creative strategies for influencing the energy system, and their responsiveness to the needs of citizens and marginalized stakeholders, these organizations occupy an important niche in the energy field. Through their advocating, opposing, negotiating, and consulting activities, NGOs have contributed to strengthening the links among the general public and governments, aid agencies, and other key stakeholders that act as decision makers in the energy sector and to catalyzing change. These organizations, in turn, have begun to realize the value of NGOs as allies in the design, implementation, monitoring, and evaluation of energy projects. If anything, over time, the roles played by NGOs in contributing to an evolution toward an improved, effective, and sustainable energy system will only increase.

Glossary

boiling water reactor A direct-cycle power system that produces steam for a turbine-generator set by boiling water in a nuclear reactor core.

breeder reactor A nuclear reactor that breeds fissile fuel through neutron absorption in nonfissile isotopes.

containment building A large concrete- and steel-reinforced building that houses a commercial nuclear steam supply system.

passive safety systems A system that provides nuclear core or containment cooling by natural processes such as buoyancy, condensation, and evaporation or by a system of prepressurized tanks filled with coolant.

pressurized water reactor A power system that produces steam for a turbine-generator set by transferring heat from a nuclear core filled with high-pressure, subcooled water to an intermediate heat exchanger, known as a steam generator.

The methods developed in 1942 by Enrico Fermi to design, construct, operate, and control the first nuclear reactor formed the basis of a new discipline in engineering, nuclear engineering. It is the purpose of this article to introduce the reader to this exciting field. Today, nuclear engineers are active throughout the world, designing a new generation of nuclear reactors that can be safely used to produce electricity or medical isotopes or even to provide the power needed for deep-space exploration. However, the guiding principle for the nuclear engineer has remained the same, to find creative ways of safely harnessing and using the energy of the atom for the benefit of mankind.

1. NUCLEAR POWER AND WORLD ELECTRICITY GENERATION

> *I am going to tantalize you with a vision of vast supplies of energy far surpassing the wildest desires of the engineer-resources so illimitable that the idea of fuel economy is not to be thought of.*
>
> *—Sir Arthur Eddington, Berlin, 1930*

Sir Arthur Eddington's general address on subatomic energy at the 1930 World Power Conference in Berlin stirred the imagination of every scientist and engineer present. The challenge was clear: find a practical means of accessing, controlling, and using the enormous energy locked in the atom as predicted by Einstein's remarkable mass–energy relation, $E = mc^2$. On December 2, 1942, Enrico Fermi transformed Eddington's visionary challenge into reality by producing the world's first controlled, self-sustaining nuclear reactor, Chicago Pile 1. Six decades later, nuclear energy now produces 16% of the world's electrical power. As shown in Fig. 1, this amount compares to 40% for coal, 15% for natural gas, 10% for oil, and 19% for renewables such as hydro, solar, wind, and geothermal power. Although the percentages for nuclear power are relatively high in countries such as France (78%), Japan (35%), Germany (32%) and the United Kingdom (27%), the United States and Canadian nuclear shares are only 20% and 15%, respectively. Although the percentage is somewhat lower in the United States, it actually boasts the largest number of nuclear power reactors in the world. That is, 104 of the 441 nuclear power reactors in the world are operating in the United

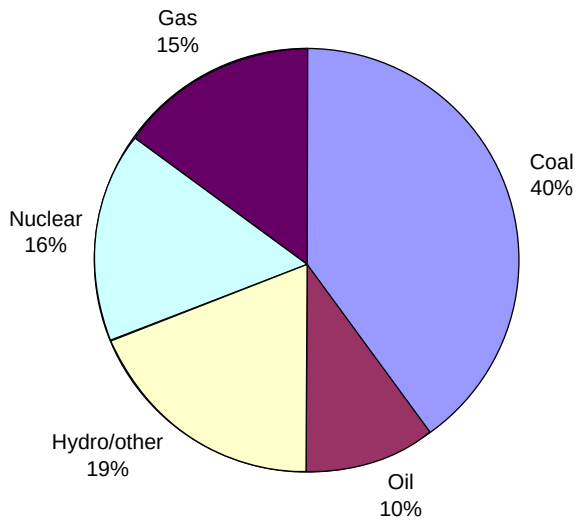

FIGURE 1 World electricity generation (statistics from the World Nuclear Association, World Energy Needs, and Nuclear Power, July 2002).

States. These reactors have a combined power output of 98.2 gigawatts (GW) of electricity, more than any other nation in the world.

2. SOME BASICS OF NUCLEAR SCIENCE

Before discussing nuclear engineering and the technology it has created, it is necessary to explain some basics of nuclear science. To this end, an atom is composed of negatively charged electrons that orbit around a positively charged nucleus. The nucleus, in turn, consists of positively charged protons and electrically neutral neutrons, both of which have masses approximately 1800 times greater than that of an electron. Thus, the preponderance of the atomic mass lies in the nucleus, which forms the tiny, central core of the atom.

Because the atom is electrically neutral, the number of electrons is identical to the number of protons, but the number of neutrons can and does vary. However, for any given chemical element, the number of protons is constant and serves to identify the element in question. For instance, all hydrogen atoms have 1 proton; all helium atoms have 2 protons, and all uranium atoms have 92 protons. Because the number of protons is uniquely linked to each element, this quantity is referred to as the atomic number Z. As already mentioned, however, for any given chemical element (i.e., for constant Z), the number of neutrons may vary. Thus, whereas all hydrogen atoms have a single proton and a single

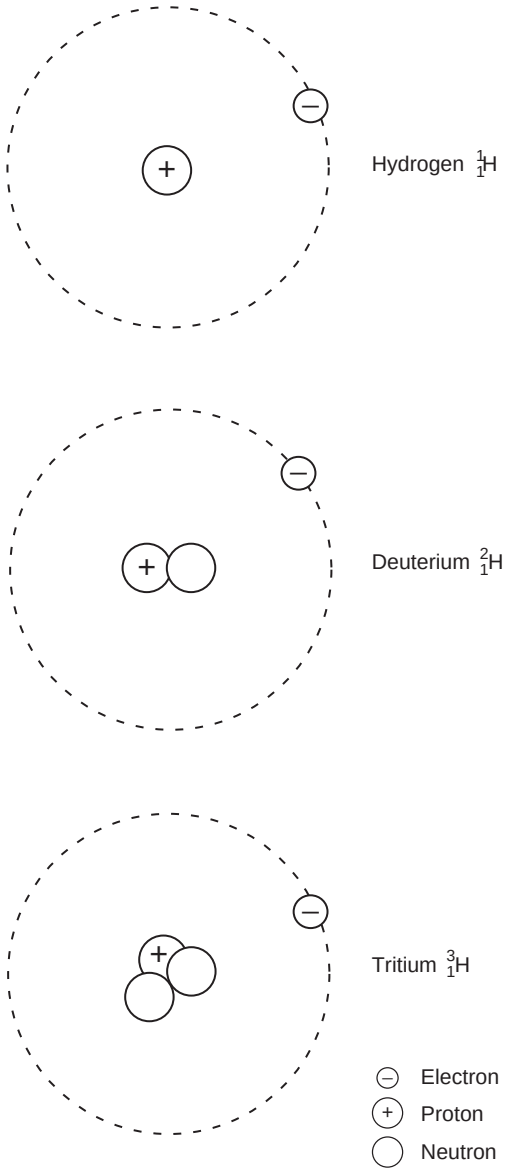

FIGURE 2 Isotopes of hydrogen.

electron, the number of neutrons varies from 0 to 2, as shown in Fig. 2. Given this fact, to uniquely specify a specific nucleus, it is necessary to specify both the number of protons (and hence the element) and the number of neutrons. Alternately, because the nuclear mass number A is specified by the total number of protons and neutrons, the nucleus can be uniquely specified by the combination of the atomic number Z and the mass number A. For instance, because all hydrogen atoms have a single proton ($Z = 1$), but can have 0, 1, or 2 neutrons, the mass number A will assume values of 1, 2, or 3, respectively. Accordingly, using the Z value for the subscript and the A value for the superscript, the

three types of hydrogen nuclei can be represented as $^{1}_{1}H$, $^{2}_{1}H$, and $^{3}_{1}H$. Moreover, because the Z value is implicit in the chemical symbol H, these nuclei may be represented more compactly as ^{1}H, ^{2}H, and ^{3}H, known as hydrogen-1, hydrogen-2 (or deuterium), and hydrogen-3 (or tritium), respectively. Finally, because these various nuclei all have the same Z value, they are all forms of hydrogen and will therefore occupy the same place in a periodic table of the elements. For this reason, they are referred to as isotopes, a word derived from the Greek terms *isos* (same or equal) and *topos* (place), which literally means "same place."

If all the isotopes of the various elements are plotted on a graph of N (the number of neutrons) vs. Z, a chart of the nuclides is obtained, a portion of which is shown in Fig. 3. The chart identifies the stable isotopes and lists essential data for each radioisotope, such as its decay constant, the type of radiation emitted, and the energy of the emitted particle. For nuclear engineers and physicists, the chart of the nuclides provides a direct means of visualizing nuclear reactions and therefore functions as a nuclear analogue of the chemists' periodic table. The known nuclides fall within a narrow band, which becomes more horizontal as N increases. Accordingly, only certain combinations of N and Z are possible, and the ratio of N to Z increases for the larger nuclei. The reason for this latter effect is that the number of protons must remain sufficiently small relative to the total number of nuclear particles, to prevent the electrostatic repulsion from exceeding the nuclear binding force.

As mentioned previously, the mass of the atom is approximately equal to the nuclear mass due to the relative lightness of the electrons. However, if the nuclear mass is measured, it is found that the actual nuclear mass is less than the total mass of its individual particles. The reason for this mass defect is that, in forming a nucleus, the particles achieve a lower energy state together than they would separately. The absolute value of this energy difference is called the binding energy of the nucleus and it is related to the mass defect through Einstein's famous formula: $E = mc^2$ (or in this case, $\Delta E = \Delta mc^2$).

To put the nuclear binding energy on a specific particle basis, the binding energy of every isotope may be obtained and divided by its mass number A to obtain the binding energy per nucleon (i.e., per nuclear particle), as shown in Fig. 4. From Fig. 4 it is seen that the binding energy per nucleon is maximized for nuclei around $A = 60$. Thus, for light nuclei, energy can be liberated by bringing the nuclei together. On the other hand, for heavy nuclei, energy can be released by splitting them apart. The former process, known as fusion, is operative in the sun and in the explosion of hydrogen bombs, but cannot yet be controlled and sustained at the moderate rates needed for power generation. The second process, by contrast, known as fission, was utilized in the first

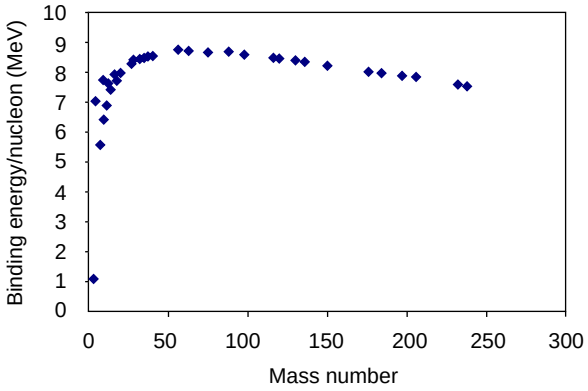

FIGURE 4 Binding energy of isotopes.

atomic bombs. Unlike fusion, fission can be controlled at sustained, moderate rates and is therefore currently utilized in nuclear power plants. For this reason, the subsequent discussion is restricted to fission technology.

With respect to fission, all nuclei are theoretically fissionable because they can be made to undergo fission by high-energy neutrons. However, some nuclei are said to be fissile, because they will undergo fission through the absorption of even slow-moving neutrons. Such slow neutrons are referred to as thermal neutrons because they have reached thermal equilibrium with their surroundings and are therefore moving as slowly as the local temperature will allow. The kinetic energy of particles is typically expressed in units of electron volts (eV), where 1 eV is the energy obtained in passing an electron or a proton through a potential difference of 1 V. Natural uranium is composed of 0.7% uranium-235, which is fissile, and 99.3% uranium-238, which is merely fissionable. Given this low percentage of the fissile isotope, natural uranium must be enriched to approximately 3% uranium-235 to serve as fuel in most reactor types. However, although the uranium-238 is not fissile, it may be transformed into fissile plutonium-239 by the absorption of a neutron. Thus, uranium-238 is said to be fertile because it can be used to breed fissile material. Given this fact, both isotopes of uranium may be utilized through special reactor designs known as breeder reactors (see later).

In addition to man-made transformations, some nuclei disintegrate spontaneously through a process known as radioactivity. As a result of radioactive decay, such nuclei emit three main types of radiation, denoted by the Greek letters α, β, and γ. In α decay, a nucleus emits an α particle, which consists of 2 protons and 2 neutrons and is identical to a helium-4 nucleus. As a result of α decay, the nuclear charge and mass decrease by 2 and 4 units, respectively. In β decay, the nucleus emits either an electron (β^-) or a positron (β^+). In β^- decay, a neutron transforms itself into a proton by emitting an electron and an antineutrino. In β^+ decay, a proton becomes a neutron by emitting a positron and a neutrino. Thus, in β decay, the nuclear charge is either increased (β^-) or reduced (β^+), but the nuclear mass remains constant. By contrast, neither the charge nor the mass of the nucleus is changed in γ decay. Rather, the nucleus gives off a high-energy photon (i.e., electromagnetic radiation) known as a γ ray. Finally, it should be mentioned that some nuclei decay by neutron emission, although this form of decay is least common. Obviously, in neutron emission, the nuclear mass is reduced without affecting the nuclear charge. As a result, the nucleus changes to a different isotope of the same element.

TABLE I

Biological Quality Factors for Various Types of Radiation

Type of radiation	Biological quality factor
X rays and γ rays	1
β particles	1–1.7
Neutrons	2–11
α particles	10
Heavy nuclei	20
