Apart from imposing extremely high (and continuously increasing) levels of fuel taxation, which in many countries may be one of the least politically feasible of available strategies, reigning in travel probably can be accomplished only through a coordinated, but ambitious, package of measures. This package must both discourage personal vehicle travel and encourage use of alternative modes and alternatives to travel altogether. Strong packages should include several of the following elements:

- Widespread electronic roadway pricing, at least throughout all limited-access highway systems. Cordon pricing in urban areas, such as has recently been implemented in London, may also be an important element.
- Increased parking costs and better enforcement in many areas.
- Much stricter land use controls. These could potentially include growth boundaries, improvements in pedestrian and nonmotorized travel (e.g., bicycle) infrastructure, restrictions on parking supply in new construction, strong incentives for mixed-use multimodal developments, and other elements that can help to end the current practice of building car-dependent communities.
- Incentives to speed the rate of adoption of telecommuting, especially 1- or 2-day-a-week home-based telecommuting. The latter may have relatively small secondary impacts on relocation and generation of increases in other types of travel. These incentives could include tax breaks to businesses and individuals for telecommuting equipment and even straight tax breaks to businesses per employee who telecommutes.
- Carefully coordinated improvements to public transit that include measures to increase average ridership and "load factors" for existing systems. New concepts in transit, embodied in the term "bus rapid transit" (BRT), are emerging. BRT typically includes features such as conversion of traffic lanes into dedicated bus lanes (and enforcing this measure), better bus stops or even bus "stations" with prepayment of fares and rapid boarding, and bus priority treatment at traffic signals. These features can increase transit capacity, improve service (faster travel times), and discourage personal vehicle travel in the same corridors, potentially yielding high load factors and significant reductions in overall system CO_2 emissions. However, simply expanding transit service by adding more routes may lead to situations with more nearly empty busses with relatively high CO_2 emissions per passenger-kilometer of travel, and net increases in CO_2.
- A strong education/publicity campaign to encourage society to collectively take actions to move toward a much less car-oriented society. The seeds of such efforts are now being planted in many places, as reflected by "car-free" days and the like.

All of these measures are already well known and often considered by planners and have been implemented in various forms in many cities around the world. But few places have taken an aggressive strategy of coordinating these measures and implementing them at levels of policy intensity sufficient to come anywhere near ending the growth in personal vehicle travel. Even in cities with good transit service and good facilities for nonmotorized travel, such as in The Netherlands, significant problems remain with automobile traffic congestion and air pollution. A relatively laissez-faire attitude about the car and levels of personal vehicle travel is still evident in nearly every city in the world.

4.2 Improving Technical Efficiency of Vehicles

Currently available technology offers a large potential for improving vehicle efficiency at a relatively low cost. But in many countries, fuel prices have not given a strong signal to consumers to demand vehicles with higher fuel economy or to producers to provide vehicles with better fuel efficiency. Trends in car size and power are moving in the opposite direction; as consumers around the world become wealthier, they tend to choose ever larger, more powerful vehicles at the expense of fuel efficiency. The net effect is fairly flat, or even deteriorating, fuel economy in most regions of the world.

Recent estimates of the penetration of various technologies in new vehicles in three OECD countries suggest that many technologies have only just begun to be used (Fig. 4). Even without using advanced technologies (e.g., fuel cells), there is still a large scope for technical improvements to vehicles. Many of these technologies would pay for themselves in fuel savings. Most of these will eventually be added to most vehicles, but at a pace that is much slower than possible with an aggressive fuel economy policy.

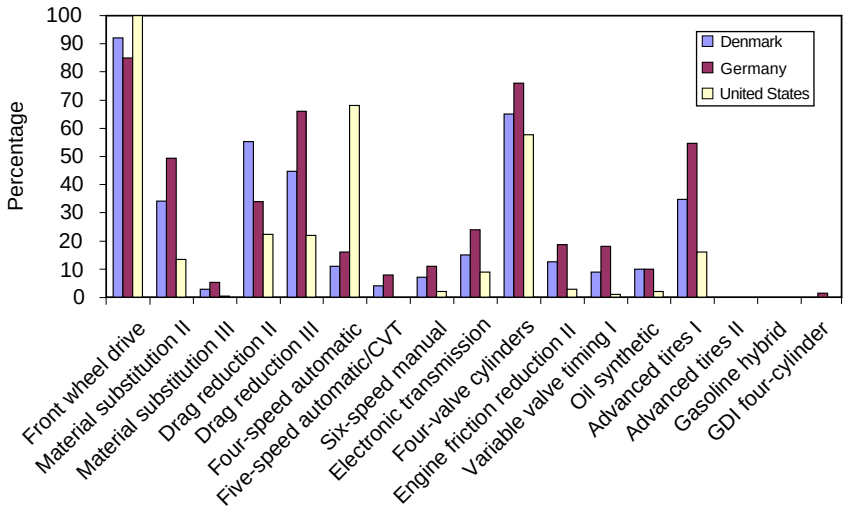

FIGURE 4 Market penetration of selected technologies in compact cars: Denmark, Germany, and the United States, 1998. Reprinted from International Energy Agency (2001).

Various recent studies estimate that there is considerable potential for cost-effective improvements in light-duty vehicle fuel economy during the next 10 years and beyond. Using just conventional technologies such as those shown in Fig. 4, studies estimate anywhere from a 20 to 50% potential reduction, albeit at varying costs. A recent IEA study estimated that low-cost reductions in new car fuel use per kilometer on the order of 25% are possible by 2010 compared with the late 1990s. This estimate is similar to the goals of the EU manufacturer association (ACEA) voluntary agreement to improve fuel economy. Increasing sales of diesel cars and avoiding purchase shifts to larger, heavier cars could contribute to these targets. After 2010, introduction of some advanced technology vehicles with radically improved engine and drivetrain efficiency (e.g., advanced hybrid electric and fuel cell vehicles) could provide significant additional fuel economy improvements.

Figure 5 shows that although implementing a full set of technologies could result in much lower fuel consumption per kilometer from new cars in the future, much of this improvement is likely to be lost to shifts in consumer purchases to larger heavier vehicles. The figure, which shows the U.S. scenario, focuses on just one size class of vehicles: compact cars. Further erosion in fuel economy improvements is likely to come from purchase shifts from this car class to larger heavier classes such as large cars, minivans, and SUVs.

Thus, although the availability of cost-effective technologies holds promise, these technologies might not be deployed to save energy and CO_2 without strong market signals in that direction. An IEA examination of automobile advertising in virtually every OECD country in 1997 confirms that CO_2 reduction is not a major marketing theme.

The existing EU voluntary agreement and the Japanese "Top Runner" fuel economy program are policies already in place that appear likely to help achieve much of the available cost-effective potential by 2010. In the EU agreement, automakers have committed to a 25% reduction in the CO_2 emissions of new vehicles between 1995 and 2008. As of 2001, they were on track to meet their target. The Japanese program identifies the most fuel-economic vehicles in each vehicle weight class and requires all new vehicles to approach this level over time. In North America, there is not currently any policy that appears to be pushing the market toward taking advantage of these new technologies given that the U.S. corporate average fuel economy (CAFÉ) standards have not changed significantly in nearly 20 years. Without additional policy efforts, much of the available technology may be used to increase vehicle size, weight, and horsepower while holding fuel economy constant, as has occurred over the past 10 years or so.

There are several types of policies that could be implemented to help maximize the fuel economy benefit of existing technology. In addition to voluntary agreements and "top runner"-style policies, implementing fuel economy-based fees and rebates (also called "feebates") and market incentives for the adoption of advanced technologies could play useful roles in North America and elsewhere.

To achieve early market penetration of advanced technologies, such as hybrid electric and fuel cell

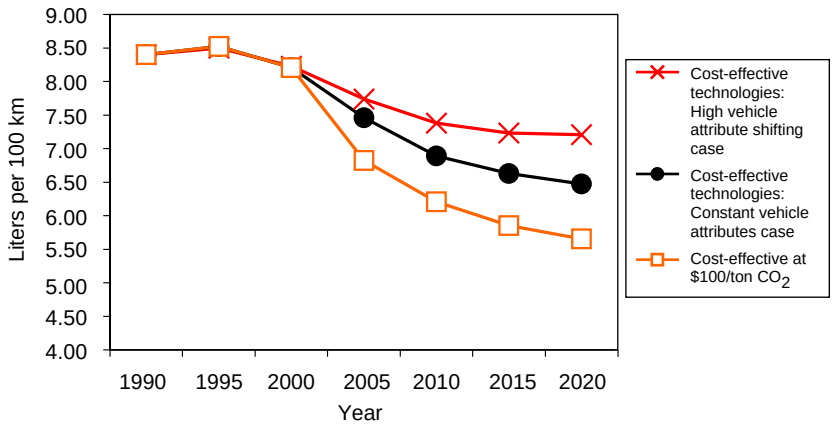

FIGURE 5 Cost-effective technologies implemented in cars over time in the United States: Three scenarios. Reprinted from International Energy Agency (2001).

propulsion systems, governments might need to provide relatively large rebates on these vehicles so as to make them attractive to consumers (and attractive to producers to build). As an alternative to a broad feebate program (which could itself provide significant rebates for very fuel-efficient cars), more targeted incentives could be used to overcome the very high initial capital costs and risks of producing such vehicles and to encourage consumers to purchase vehicles containing such technologies. Vehicle purchase incentives could be implemented in the form of price subsidies, either for vehicles possessing specific technologies or simply for vehicles meeting a certain standard for fuel economy or CO_2 emissions per mile. The latter approach has the advantage of encouraging the development of new technologies to meet societal goals. Such subsidies could also be designed to target both reductions in CO_2 and reductions in pollutant emissions.

An example of "next generation" technology price incentives is found in Japan, where there is a rebate of U.S. $3500 per vehicle for purchases of hybrid electric vehicles. Japan is the first country with significant sales of these advanced technology vehicles. A time-phased approach, which includes large initial subsidies per vehicle that decline through time as vehicle sales increase (and as vehicle costs decline), may produce a much more rapid buildup in production volumes and the rate of learning than a scenario where expensive vehicle technologies must compete on their own during the early phases.

4.3 Shifting to Alternative Fuels

Alternative fuels continue to hold promise, but for a variety of reasons none has yet significantly penetrated the vehicle market around the world. There are several fuels and propulsion systems that offer the possibility of displacing oil and lowering vehicle CO_2 emissions, including natural gas, liquefied petroleum gas (LPG), alcohol, and biodiesel for internal combustion engine vehicles; electricity for battery-powered vehicles; and hydrogen (produced from any number of different fuels) for fuel cell-powered vehicles. All of these options are making only slow progress in the marketplace due to factors such as higher costs of the vehicles and/or fuel, lack of available vehicle models, and lack of widespread retail fuel availability. Most fuels and accompanying vehicle technologies also have one or more other drawbacks such as lower driving range, longer refueling times, smaller trunk space, and poor acceleration performance. As a result, consumers have so far been reluctant to embrace any of these options. Without strong regulations or the creation of significant price advantages, alternative fuels are making little headway.

Although all alternative fuels offer an opportunity to displace petroleum fuel, many offer only relatively small CO_2 reductions on a life cycle or well-to-wheels basis (Fig. 6). Only four options clearly can provide greater than a 50% reduction in CO_2-equivalent emissions per kilometer of driving: alcohol derived from cellulosic biomass (and using biomass as the process fuel), biodiesel from oil crops, hydrogen produced from a low-GHG source (e.g., renewably powered electricity) and used to run fuel cell vehicles, and low-GHG electricity itself when used with electric vehicles. These options all are relatively expensive, and the latter two would require large investments in new types of vehicles and refueling infrastructure.

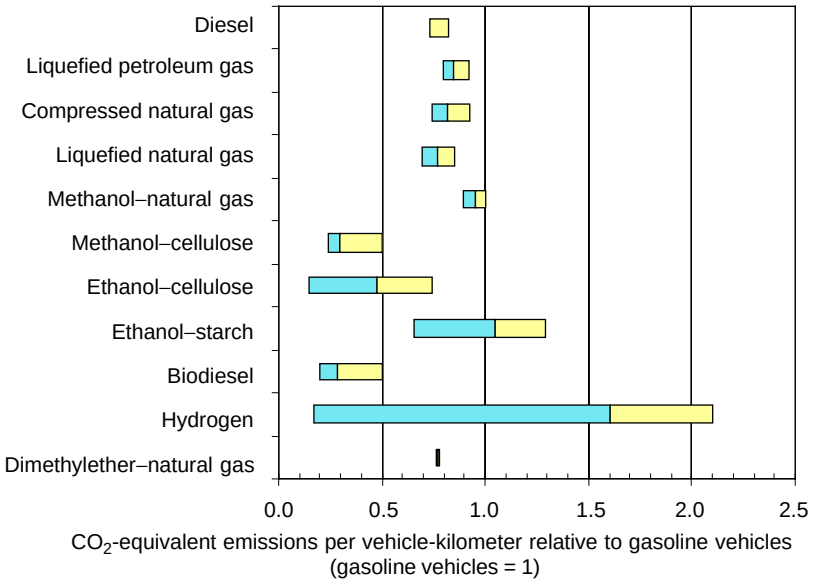

FIGURE 6 Alternative fuels: Near-term CO_2-equivalent reduction potential compared with conventional gasoline vehicles (well-to-wheel). The shaded and hatched areas represent bands of uncertainty around the middle vertical line on each bar, with the middle line being considered the "reference" case. Reprinted from International Energy Agency (2001).

As a result, few OECD countries consider alternative fuels as an important near-term option for mitigating energy security concerns and GHG emissions. Because the best alternatives would be expensive and would require substantial (and risky) investment, most countries are taking a longer view of these options—focusing on developing niche markets, funding research and development (R&D), and taking other preparatory actions.

Although not strictly an alternative fuel—or at least not a nonpetroleum fuel—diesel can provide significant potential for lower net fuel intensity and CO_2 emissions and does as well as many alternative fuels such as compressed natural gas (CNG) and LPG. New light- and medium-sized diesel cars in Europe with turbo-direct injection (TDI) offer up to 25% lower fuel consumption than do similar gasoline vehicles. On the other hand, diesel fuel is taxed much more lightly than gasoline in some countries; not surprisingly, its consumption is associated with significantly higher car travel. Diesel TDI is also appearing on heavier American-style vans in Europe, bringing fuel-driving costs for such larger vehicles down to more affordable levels. Thus, the net impact of Europe's trend toward "dieselization" is difficult to determine after its "behavioral" impacts are taken into account.

Over the longer term, perhaps the most promising option is the fuel cell vehicle running directly on hydrogen fuel. With renewably or nuclear power-derived hydrogen, this technology could provide near-zero life cycle CO_2 emissions. However, during the 2000–2010 time frame, fuel cells are not likely to be produced in large numbers due to ongoing technical hurdles, their current very high cost, and lack of hydrogen refueling infrastructure. The refueling infrastructure problem could be alleviated by using hydrogen-rich fuels (e.g., methanol, gasoline) and reforming these fuels on-board fuel cell vehicles to produce hydrogen, but this option appears to be falling out of favor with most car companies. The complexity and cost of on-board reforming appear to offset the benefits it may provide. Furthermore, vehicles with on-board reforming will not be zero emissions for either pollutants or GHGs (because reforming fuels on-board produces some emissions), significantly reducing the benefits of switching to fuel cells.

Whether or not electric vehicles ever reach a commercial stage of production (prevented so far primarily due to shortcomings in battery technology), electric drive systems (including electric transmission systems and even motors) are likely to become a feature on all vehicles in the future. Although hybrid electric vehicles now being sold in OECD countries run on gasoline, with the hybrid system used to boost fuel economy, these vehicles introduce motors and larger battery systems into vehicle propulsion design and help to pave the way for future electric or fuel cell systems. If battery

technology improves, hybrid vehicles could take on larger battery storage systems and eventually be "pluggable" (rechargeable), offering a bridge to electric vehicles.

Electric- or hydrogen-powered propulsion systems may offer attractive ways in which to eliminate internal combustion, and the emissions it produces, from vehicles, but they may simply move this process to central power plants (which produce the fuel). This would help to move pollutant emissions away from cities, but unless electricity or hydrogen is produced in a manner with low carbon emissions, the net GHG benefits may be small. The most obvious options for low-carbon production of electricity and hydrogen are renewable fuels and nuclear power. These currently account for less than 20% of electricity generation around the world.

How could a low-carbon hydrogen or electric vehicle scenario come about? One transition path is for governments to strongly encourage development and commercialization of fuel cell (or electric) vehicles, especially demonstration programs and small-scale production to speed learning. Concurrent with (or slightly preceding) the beginnings of significant vehicle sales in targeted areas, a strong push toward developing hydrogen (or electric) refueling infrastructure will be needed. Policies such as tax credits for installation of refueling infrastructure could be applied, or governments could invest directly in infrastructure. The level of investment needed over 30 years to pay for refueling infrastructure and other support systems (e.g., garages that are trained to repair the vehicles) and the incremental costs of fuel cell vehicles over this time both are likely to be quite large. Society must be prepared to help pay these costs if it is to have a reasonable chance to achieve the desired transition. Willingness to pay these costs will largely reflect the level of determination of the public to move transport onto a more sustainable course. Of course, ongoing R&D programs can help to reduce costs before a transition begins, especially in the areas of fuel cell system production cost and on-board hydrogen storage. But chances are that the initial costs of both vehicles and refueling infrastructure will be high.

Biofuels, such as ethanol from crops, holds the potential for substantial oil displacement and GHG reduction, although current production practices fall far short of this potential. An important advantage of biofuels over most other alternative fuels is that they can be blended with conventional fuels and used, to a point, in current vehicles. In the United States and the EU, a small share of transport fuel is blended up to 10% with ethanol fermented from the sugars in grain crops (e.g., corn, wheat). The processes used require substantial fossil fuels to drive them, and the net displacement of petroleum fuel is less than 30% in most cases (i.e., it takes 0.7 unit of fossil fuel to produce 1 unit of ethanol). As a result, GHG reductions are also generally no better than 30% per liter of gasoline displaced by ethanol.

However, considerable research is under way to develop new conversion processes that would allow ethanol to be produced from "cellulosic biomass," specifically the green portions of plants made of cellulose. Using advanced enzymes and processes for conversion of cellulose to alcohol, and using cellulose as the process fuel (rather than natural gas or another fossil fuel), cellulosic ethanol could bring life cycle GHG emission reductions of 80% or more compared with fossil fuels on a well-to-wheel basis. This approach is still in the R&D phase of development, and although it appears to have strong cost reduction potential, it is unclear when it will become cost-effective or even more cost-effective than current grain-to-ethanol processes (which themselves cost up to twice the cost of producing conventional gasoline).

Biodiesel fuel, typically a methyl ester produced from oil crops such as rapeseed, can be blended with conventional diesel fuel in any proportion and used in today's diesel vehicles. Biodiesel has been estimated to provide anywhere from 30 to 70% reductions in well-to-wheel GHG emissions, but it is very costly. Biodiesel in countries such as Germany and France, where it is publicly available, costs up to three times the cost of conventional diesel fuel.

Even if substantial cost reductions in biofuel production costs are achieved, a separate question is whether biomass resources are best used for transportation fuels (as opposed to using them, e.g., to produce electricity). Liquid fuel production requires substantial energy input per output unit of useful energy, and biomass feedstock might have more cost-effective use elsewhere.

4.4 The Role of Fuel Taxation

Fuel taxation plays an important role in all of the policy areas covered here. Fuel price at the pump provides an incentive to consumers to drive less, to choose more efficient cars, and (potentially) to choose cars running on alternative fuels. Increases in taxation can help to limit the "rebound" effects of other policies that reduce fuel costs, for example, by making vehicles more efficient. Differentiated fuel taxes can

be applied to support or limit the use of specific fuels. Fuel tax increases help to restrain growth in transport activity and have ramifications for the relative competitive advantages of various modes.

Yet one should not overstate the role of taxation, especially as an isolated measure, or the potential to increase its role in the future. The response to fuel tax increases tends to be very limited in the short term, although it is somewhat greater in the long term. Many studies across the OECD have estimated that a 10% increase in fuel taxes will reduce travel by only 1 to 3%. Furthermore, in many countries, fuel taxes appear to already be at levels that are not politically popular, and significant additional increases in the near future may be problematic. It may be that more selective pricing mechanisms, such as congestion charges and other road user charges, may be more viable.

4.5 Increasing the Efficiency of Freight Movement

There are four ways in which freight travel (at least truck travel), energy use, and GHG emissions could be dramatically reduced:

- Increasing investment in rail and waterborne transport modes and increasing investments in intermodal facilities around the world to allow as much use of these modes as possible, reserving truck transport for relatively short-distance trips. Pricing incentives can also play an important role in pushing such shifts to the maximum extent feasible.
- Fuel shifting in medium and heavy trucks. Just as hydrogen fuel cell propulsion systems is probably the closest thing to a "silver bullet" for light-duty vehicles, this is also true for most types of heavy-duty vehicles. Fuel cell engines are being developed for many types of heavy-duty vehicles, including trucks, buses, and trains, and applications in some market niches (e.g., urban transit buses) may become cost-effective before light-duty vehicle applications. On the other hand, diesel engines are very cost-effective and durable and are very popular with truck operators.
- Incentives and government infrastructure support to rapidly develop much more sophisticated systems and linkages between suppliers and their clients, and with each other, to significantly increase the efficiency of goods delivery in metropolitan areas. Truck load factors, the numbers of "back haul" trips where trucks run empty, and the sizes of trucks for various applications all could be improved significantly, resulting in far fewer kilometers of truck travel and much less fuel use per ton-kilometer of goods movement. Systems are now being installed in many places to improve freight logistics, but the relative fragmentation of the truck industry impedes the types of cooperation needed to maximize the potential efficiency gains. Governments could take a much more active role to change this in the future.
- Rationalization of locations of goods producers, distributors, and end users. There is some evidence to suggest that many "upstream" (nonretail) activities could be moved much closer to other steps in the chain of taking a product through various stages of production and, in some cases, delivery to the end user. However, this is a particularly difficult problem to address because shipping costs are typically such a small part of location decisions that they are not likely, even with much higher taxes placed on transport costs, to drive significant changes in many location decisions. But there may be other ways in which to assist companies in optimizing location decisions that should be pursued aggressively.

5. CONCLUSIONS

This article has sketched out some of the key issues regarding transport energy sustainability, outlined where transport energy use and GHG emissions appear to be heading over the next 30 years, and identified a variety of potential technologies and policy areas that could be used to move transport away from its current trends. The current path is far from any reasonable characterization of a sustainable path.

Among the first steps for moving in a new direction will be for governments to convince citizens of the need for aggressive action and to educate people about the risks associated with the current path and how important a role transport must play in reducing oil dependence and CO_2 emissions. Without strong public support and understanding, there will be little political will to enact policies. Under such conditions, even low-cost actions that provide clear societal benefits beyond fuel savings and CO_2 reductions can be blocked by individual stakeholders who may stand to lose. Governments also need to overcome "traditions" that no longer make sense such as company car policies, very high fixed (but low variable) taxation, and traditions of generally cheap fuel (in a few countries). Governments need to become more entrepreneurial. The

presence of good transit or walking/biking facilities does not necessarily translate into high use of such facilities; the public has to be convinced that the benefits that these modes offer—lower traffic congestion, cleaner air, and lower CO_2 emissions—are worthwhile and that they will be attainable only if people are willing to make changes to their lifestyles.

Governments would be well served to identify their own points of sustainability and sketch out sustainable pathways, such as the ones presented here, to help develop a plan of action that has any hope of yielding the desired path. Sharing such scenarios with the public—indeed, involving the public in a meaningful way and investing in widespread dissemination of such efforts—may also be a critical element in generating a social consensus on what pathway the public most supports, taking into account both the benefits of achieving such a pathway and the costs of getting there.

Glossary

biodiesel Soybean, rapeseed, and sunflower oils can be burned in compression ignition engines, but cause deposits and considerably higher maintenance requirements. Esterification with methanol or ethanol can largely eliminate these problems. The modified ester is called biodiesel. The more common form is a methyl ester. Soy-based biodiesel is used in the United States, while rapeseed based biodiesel is used in Europe.

carbon dioxide (CO_2) CO_2 is the leading greenhouse gas. Volumes of CO_2 produced as a result of combustion account for well over 99% of the volume of exhaust gases.

carbon monoxide (CO) Tailpipe pollutant that is a primary pollutant, which is worst in winter and at high altitude. Per unit of fuel burned, gasoline-fueled vehicles produce more CO than diesel-fueled vehicles.

catalytic converter Device used to convert hydrocarbons, carbon monoxide, or nitrogen oxides to innocuous chemicals such as carbon dioxide, water, oxygen, or elemental nitrogen. The need for unleaded fuel to allow catalytic converters to successfully reduce tailpipe emissions of gasoline-fueled motor vehicles is one of the major factors (aside from health damages of lead itself) causing removal of the highly effective octane enhancer tetraethyl lead from gasoline and the exclusive U.S. use of unleaded gasoline. Ethanol was one of the octane enhancers that got its start in part from this sequence of events (see E10). The next wave of improvements in fuel composition to enhance the performance of catalytic converters is reduction of fuel sulfur content. The World Fuels Charter provides recommended fuel specifications for areas of the world as a function of seriousness of need for emissions control. The greater the need for (or requirements for) emissions control, the lower the recommended lead and sulfur content of the fuel. Lead is scheduled to be completely removed.

cetane An indicator of the combustion quality of fuel for CI engines, such as diesel fuel. As cetane rises, the top speed (rpm) of compression ignition engines designed for the fuel rises. This, however, does not necessarily correspond to engine efficiency. Low-speed diesels are usually more efficient than high-speed diesels. The cetane rating of diesel fuels used for low-speed CI engines (100 to 500 rpm) is 25 to 35. For medium speed engines (300 to 1500 rpm), cetane can range from 35 to 45, while for high-speed diesels such as those found in heavy trucks and passenger cars, cetane ranges from 45 to 55.

Clean Air Act (CAA) and Clean Air Act Amendments (CAAA) The original CAA preceded the oil price shocks of the 1970s and CAFE. One of the sets of amendments occurred in 1990. The CAA and its amendments created the rules and regulations that are largely responsible for the removal of tetraethyl lead from gasoline and the introduction of alternative octane enhancers, including ethanol and, to a lesser extent, MTBE, for blending into gasoline. The unintended introduction of ethanol blends in the early 1980s followed the first CAA by many years and preceded AMFA and EPACT by about a decade.

compressed natural gas (CNG) CNG has high octane and is readily used as a fuel for spark-ignited (SI) engines, but only with diesel fuel ignition assist in compression ignition engines. Because NG displaces air (oxygen) in the cylinder, NG engines of a given technology have less peak power than gasoline or diesel-fueled versions.

compression ignition (CI) A method of initiating combustion in an internal combustion engine (ICE) in which heat of compression causes ignition. The CR of CI engines can range from 16 to 22 when diesel fuel is used. Suitable CRs for natural gas, EtOH, or MeOH fall

 © 2004 Elsevier Inc. All rights reserved.

between those for gasoline and diesel fuel. These fuels are more naturally suited to use in SI engines.

compression ratio (CR) CR is a measure of the degree of expansion of volume in a cylinder of an ICE from minimum to maximum, with the ratio being maximum/minimum volume. As a rule of thumb, the higher the CR of an engine, the greater is the efficiency.

corporate average fuel economy regulations (CAFE) These are government regulations originally adopted in the 1970s. The adoption of these regulations, along with oil price shocks in the 1970s, led to a doubling of new light-duty vehicle fuel economy from the early 1970s to mid-1980s.

E10 A blend of 90% gasoline and 10% volume ethanol, also called gasohol.

E85 A blend of 15% gasoline-like hydrocarbons and 85% volume ethanol introduced in the 1990s, after M85-fueled vehicles failed in the market.

electric vehicle (EV) Since very little of electricity is generated by use of petroleum products, electric vehicles are effectively alternatively fueled vehicles.

Energy Policy Act of 1992 (EPACT) This act "required" purchases of alternatively fueled vehicles by many classes of industry and government, as a way of starting a movement away from petroleum. Like AMFA, it "required" alternatively fueled vehicles but not use of alternative fuel. Further, it contained a broad exception that requirements need not be met if the alternative fuels and vehicles were not economically competitive. It had a goal (unrealized) of 10% replacement of gasoline in 2000, 30% by 2010.

ethanol or ethyl alcohol (EtOH) (also called E100) Produced in the United States from corn and in Brazil from sugarcane. Selected woods and grasses, urban waste, sugar beets, and rice straw are candidate feedstocks for expanded ethanol production.

Fischer-Tropsch (FT) processes Processes used to convert natural gas or coal to liquid fuels that can be used in conventional vehicles. These processes—particularly for planned facilities—primarily produce fuel suitable for use in compression ignition (diesel) engines. Due to need for much lower cost natural gas than available in North America, none of the announced plants are in North America. The diesel fuel produced (FTD) is high quality with respect to sulfur content (very low or zero) and cetane (high).

flex fuel vehicle (FFV) A vehicle that can switch between gasoline and an alcohol fuel (E85 or M85) in the same tank.

fuel cell (FC) Instead of combustion, FCs use chemical reactions to directly produce electricity. The proton exchange membrane (PEM) FC, the leading FC candidate for vehicle propulsion, reacts hydrogen and oxygen to produce electricity and water.

greenhouse gas (GHG) For purposes here, a gas specified in the Kyoto international protocol on global warming whose emissions are to be calculated and weighted to estimate the contribution of an individual signatory nation (the United States is not a signatory). Six gases are so specified. The most important by far is carbon dioxide, the predominant gas emitted as a result of combustion, and the predominant GHG. However, methane (CH_4) and nitrous oxide (N_2O) are also specified GHGs. The former is somewhat important to account for in use of natural gas fuels, the latter in ethanol fuels.

heavy oil Approximately, crude oil with American Petroleum Institute (API) gravity degrees in the low 20 s is heavy. Concentrations and most production from heavy oil are from California, Canada, and Venezuela.

hybrid electric vehicle (HEV) A hybrid is a vehicle that uses both electrical and mechanical systems to provide power to drive the vehicle. Many configurations are possible. Commercially available light-duty vehicle HEVs run on gasoline, while heavy-duty vehicle HEVs run on diesel. It is possible to configure a hybrid so that it can be plugged in to the electric grid, to provide part of the energy used to move the vehicle. When electrically operated, such a vehicle would be alternatively fueled. This type of hybrid is not presently receiving much attention, but the Electric Power Research Institute continues to evaluate it. Also, the California Air Resources Board provides incentives in its emissions regulations (see CALEV) for future plug-in hybrids.

hydrocarbons (HC) Chemical constituents of gasoline and diesel that are also a tailpipe and evaporated pollutant. Gasoline is more volatile than diesel fuel and contributes more hydrocarbons to air pollution than diesel fuel. The chemicals in gasoline (and those in alternative fuels) have a wide variation in "reactivity" in ozone formation. Many regulations of gasoline and alternative fuels are designed to change the composition of the fuel to reduce its reactivity and contribution of hydrocarbons to ozone.

hydrogen (H_2) There are many technologies and feedstocks from which hydrogen can be extracted, one of its great potential advantages. It is presently predominantly produced from natural gas. Hydrogen is a gas with very low energy per unit volume. It is costly to transport and store, and it causes significant power loss relative to gasoline or diesel fuel used in engines of comparable technology. It is the fuel that allows the fuel cells presently considered the leading candidate for use in motor vehicles to work.

liquefied natural gas (LNG) LNG is created when natural gas is cooled to -127°C. LNG tends to be used instead of CNG on heavy-duty trucks to reduce fuel storage volume. An LNG fuel storage system requires about half the volume of a CNG system. Still, LNG contains only about 50% of energy per unit volume as diesel fuel. For ocean shipping of NG, liquefaction is used in especially designed tankers.

liquefied propane gases, or liquefied petroleum gases (LPG) Despite the latter name, these gases are primarily

derived from condensing out NGLs from natural gas. The process that condenses these gases results in two streams. The lighter of these streams is primarily propane, with small amounts of butane and ethane. This is marketed as LPG. The heavier fraction is generally added to gasoline to control volatility. Some of the propane used in LPG is also a by-product of refining. Among gaseous fuels, a major advantage of LPG is that it can be liquefied with relatively little pressure. As stored in a lightly pressurized vehicle fuel tank, it has a much higher energy density than CNG or hydrogen. LPG is used exclusively in spark-ignited internal combustion engines.

M85 A blend of 15% gasoline-like hydrocarbons and 85% volume methanol introduced in the late 1980s. The hydrocarbons are included for flame luminosity, cold starting, and as a denaturant.

methane The predominant gas in natural gas. Relative to the many different hydrocarbons in gasoline, methane is nonreactive when it comes to forming ozone and is therefore not a regulated air pollutant in the United States. However, methane is a greenhouse gas that is included for control in other nations according to the international Kyoto protocol on greenhouse gases contributing to global warming.

methanol or methyl alcohol (MeOH) (also called M100) Predominantly produced from natural gas, but also producible from any hydrocarbon containing feedstock.

methyl tertiary butyl ether (MTBE) A gasoline octane enhancing and emissions reducing additive made primarily from methanol and isobutylene. Isobutylene in turn uses butane from NG processing and excess butane from petroleum refining.

natural gas (NG) A combination of gases that is predominantly methane. Larger volumes of other (condensable) gases include ethane, propane, and butane.

natural gas liquids (NGL) NGLs are condensable liquids from natural gas production. Propane is a leading NGL. Ethane is another. By the definition used here, when used by refiners to expand the volume of products, NGLs are alternative fuels.

nitrogen oxides (NO_x) Tailpipe pollutant resulting from combination of oxygen and nitrogen during combustion. Per unit of fuel, diesel fuel tends to contribute far more NO_x to air pollution than gasoline. NO_x is also a primary pollutant (itself regulated).

octane Index of ability of a fuel to resist preignition (knock) in a SI ICE. As octane rises, compression ratio can rise, and thermodynamic efficiency can also rise. There are two methods of measuring octane, the research (R) and motor (M) methods.

ozone Air pollutant for which standards exist that are typically violated in major urban areas on clear hot summer days. Ozone is created primarily by reactions of hydrocarbons and nitrogen oxides. Carbon monoxide is also a minor contributor.

reformulated gasoline (RFG) This term arose after the Clean Air Act Amendments of 1990. This law mandated changes in gasoline used within nine areas of the United States that were and are in violation of ozone air quality standards. The blending agent most commonly used in RFG is MTBE. Sulfur content of RFG was lowered, as was reid vapor pressure (RVP). In addition to summertime gasoline reformulation for ozone, wintertime reformulation to reduce carbon monoxide (CO) required 2.7% oxygen in gasoline. This was met with either MTBE or ethanol.

shale oil A much lower quality source of hydrocarbons than heavy oil or tar sands. Early 1980s estimates indicated that "high-quality" (a misnomer) shales contained the energy equivalent of about half of that of conventional crude oil. Such shale oil reserves were estimated to be concentrated in the United States (12 gigatonnes), Canada (6.5), Brazil (7), the former Soviet Union and Eastern Europe (4), and China (4).

tar (or oil) sands These have an API gravity of less than 12° and could be called very heavy oil. Venezuela was estimated in the early 1990s to have 4000×10^9 bbl of reserves; Canada, 1350; Russia, 600; and the United States, 28.

tetra-ethyl lead (TEL) The predominant gasoline octane-enhancing additive used from the late 1920s to mid-1980s in the United States. MTBE and EtOH have been the predominant octane enhancing additives used since TEL was phased out of gasoline in the 1980s.

Alternative transportation fuels are here defined as fuels produced from feedstocks other than petroleum. For petroleum, both conventional and unconventional oils are included in the umbrella term petroleum. Thus, unconventional oils such as oil sands in Canada and heavy crude oils in Venezuela are not alternative fuels, even though they can allow extension of the time that transportation can rely on refined liquid fossil fuels while continuing to use the same types of powertrains and fuel delivery infrastructure now in use. Oil shale—also an unconventional oil—is also defined here as petroleum. Oil shale is the most costly source of petroleum feedstock that would provide petroleum for refineries producing diesel or gasoline. Accordingly, oil shale is not presently a feedstock used in refined petroleum products. Since gasoline and diesel fuel can be produced from hydrocarbon feedstocks other than the sources defined here as petroleum, we use the terms petro-gasoline and petro-diesel to refer to gasoline or diesel fuel refined from conventional or unconventional oil.

The distinction here relies on replacement of refining capacity as the dividing line that defines alternative fuels. For example, in the 1970s, Mobil Corporation developed a process to produce gasoline

from methanol that was in turn produced from natural gas and built a plant in New Zealand. New Zealand has a slow turnover of its vehicle fleet and does not produce its own vehicles. Accordingly, the discovery of natural gas offshore at a time when oil prices were high (1970s) led to implementation of the gasoline from natural gas choice, rather than attempt to use methanol (an intermediate, cheaper product) directly in newly purchased vehicles designed for use of methanol. However, following the decline of world oil prices in the mid 1980s, gasoline production from this plant ceased. There is no discussion at the present time of reviving this inefficient method of producing transportation fuel. By this discussion's definition, this gasoline was an alternative fuel, though its properties as a vehicle fuel were nearly identical to gasoline refined from petroleum.

Similarly, by this discussion's definition, transportation fuels produced from coal or natural gas via the Fischer-Tropsch process are also alternative fuels. South Africa long produced a diesel fuel substitute from coal with the Fischer-Tropsch process, but this was done for political reasons, since inexpensive oil was not available to South Africa. Though an inconsequential alternative fuel at this time, Fischer-Tropsch diesel fuel from natural gas feedstock is in production and is scheduled for rapid expansion (from a small base) worldwide. This fuel is similar, though not identical, to diesel fuel processed from petroleum. Negligible sulfur content is a distinct advantage for future environmental needs.

1. BLENDS VERSUS NEAT AND NEAR-NEAT FUELS: 1970s TO PRESENT

If a fuel produced from a nonpetroleum feedstock is substantially like gasoline or diesel fuel, it is evident that it could be blended into such a fuel, and perhaps not recognized as having any difference from petro-gasoline or petro-diesel. In fact, number of chemicals other than gasoline or diesel fuel are blended into those fuels in order to alter their properties. In particular, for gasoline, properties such as octane, sulfur content, and volatility can be altered by blending chemicals—often produced from feedstocks other than petroleum—into the gasoline in relatively small percentages. For diesel fuel, the key properties that can be affected are cetane and sulfur content. Blending for improved properties also generally involves removal of some chemicals from gasoline, such as highly volatile butane.

Table I lists the leading alternative fuels in the United States, by our definition. The first two—methyl tertiary butyl ether (MTBE) and ethanol—are each separately used in considerably larger quantities as blending agents in gasoline than are all other alternative fuels combined. To supplement corn-based ethanol, the U.S. Department of Energy is developing technology to produce ethanol from other biomass feedstocks, including grasses and trees. On a percentage and total volume basis, Brazil uses more ethanol in gasoline than any nation, producing it from sugarcane. In 1989, Brazil consumed 11.9×10^9 liters of ethanol, while the United States consumed 3.6×10^9 liters in 1990. Quantities have varied in Brazil since that time, while quantities have moved relatively steadily upward since then in the United States. However, 2002 U.S. consumption is still well below the 1989 level in Brazil.

Vehicles designed to use only ethanol were the majority of SI ICE-powered vehicles produced in Brazil in the mid-1980s, but this program was reversed after ethanol shortages occurred and oil prices dropped sharply from the historical highs of the early 1980s. However, production of ethanol from sugarcane and use in motor vehicles has been estimated to allow significant reductions in greenhouse gases, and oil prices are high as this discussion is written, so interest in a second wave of expansion of ethanol use in Brazil is under way.

MTBE—a common gasoline additive to reformulated gasoline in the 1990s—is produced, on average, from additional processing of a combination of petroleum-derived and natural-gas-derived chemicals. The predominant natural gas derived chemical feedstock for conversion to MTBE is another alcohol, methanol. Early in the 20th century, methanol was produced from wood and called wood alcohol. However, now it is predominantly produced from natural gas feedstock and is an important industrial chemical. The U.S. EPA has funded past research to produce methanol from biomass, as was done early in the 20th century, but funding for this approach has been dropped. Since MTBE is produced from a combination of chemicals derived from petroleum and natural gas (methanol and isobutylene from butane), with natural gas likely contributing more than half of the available energy, it does qualify as an alternative fuel under the definition used here.

The term neat, or near-neat, refers to a fuel used in its pure form (neat) or with a small percentage of additives (near neat). Among such fuels, E95 (a blend

TABLE I

Some Key Alternative Fuel Attributes

Name	Primary feedstock (s)	Cetane/octane (motor/ research)	2002 Sulfur content	Energy/ volume (kj/L)	Pressure for storage	Vapor pressure at 38°C
Gasoline	Petroleum	80–90 (M)	300 ppm (40 in CA)	30–33	N/A	54–62 after 1992 (48 in CA)
		88–100 (R)				
Diesel No.2	Petroleum	40–55	300 ppm	35–37	N/A	<1
Methyl tertiary butyl ether (MTBE)	Natural gas, Isobutylene from natural gas or refining	100–118 (pure state)	Max. 10 ppm by weight	Not obtained	N/A	Lower than gasoline
		98–120 (M)				
		115–135 (R) (blending)				
Ethanol (EtOH)	Corn, sugarcane, or beet, switchgrass, poplar and other biomass	96–130 (pure state)	None unless included in denaturant	21.1	7–21 kPa	15.9 kPa at 38°C (pure state); causes nonlinear increase in gasoline vapor pressure in blends.
		100–104 (M)				
		132–135 (R) (blending)				
LPG (Propane data)	Natural gas liquids, refining byproducts	112/97	Not obtained	23	43.5 kPa	1303
Methane (CNG, LNG)	Processed natural gas	120	Not in methane, varies in CNG	9 at 20700 kPa	(CNG) at 17–25000 kPa	N/A
Electricity	Numerous.					
	Oil % in U.S. only 2 to 3%	Not applicable	Not applicable		N/A	N/A
Methanol (MeOH)	Natural gas	89 (M)	Near zero	15.8	7–21 kPa	32 kPa at 38°C (pure state); causes nonlinear increase in gasoline vapor pressure in blends.
		109 (R) (purestate)				
		98–100 (M)				
		132–134 (R) (blending)				
Fischer-Tropsch diesel	Natural gas		Near zero		N/A	<1
Biodiesel	Soybeans, rapeseed, waste cooking oils	52	None	32	N/A	<1
Hydrogen	Many	No rating	None	2 as gas, 7 liquid	>25000 kPa	N/A

Note. Values in this table are for illustration only. See state, federal, and national regulations and industry association and professional society recommendations before making any technical judgments about these fuels. Some cited values vary considerably, depending on local requirements and needs, or even test equipment capability.

of 95% ethanol and 5% hydrocarbons) and M100 (100% methanol) are both compression ignition engine fuels. Both may be regarded as failures, having been tried in urban buses in the early 1990s and found wanting. Neither of these fuels is currently of any importance in the United States. The alcohol-fueled urban buses were abandoned due to considerable maintenance problems emerging after several tens of thousands of miles of operation and disappointing fuel economy. Ethanol and methanol have very low cetane ratings and do not ignite well in CI engines at low loads (idling conditions). Since urban buses spend a high percentage of engine hours idling, this experiment was ill fated. Attempts to develop economically competitive cetane-enhancing additives for alcohols in CI engines were not successful.

LPG and CNG are used as neat fuels in spark ignited light-duty vehicles. CNG and LNG are used in both spark-ignited and compression-ignited engines in heavy-duty vehicles. Both CNG and LPG enjoy far greater success in 2002 than E95 and M100. M85 was used in FFVs in light-duty vehicles with spark-ignited engines in the early 1990s (but no longer), while E85 can be used (but generally is not) in the numerous E85 FFVs sold in the late 1990s and at the present time. Electricity was used for electric vehicles, especially in California, but also more aggressively than elsewhere in Georgia and Massachusetts. However, automakers are no longer producing full-function electric vehicles, after marketing several models in the late 1990s. Fischer-Tropsch diesel is blended into petro-diesel in very small quantities, if it is used at all. However, a few large Fischer-Tropsh plants are scheduled for construction in Southeast Asia and the Middle East, so this fuel may be used increasingly in the next decade. It can be used in existing compression ignition engines, especially when blended with petro-diesel fuel. The Alternative Fuels Data Center provides information on numbers and locations of five neat or nearneat alternative fuels—CNG, E85, LPG, electricity, biodiesel, and LNG. Presently the fewest stations nationally among these five types are those providing biodiesel.

For motor vehicles used worldwide, there tends to be a correspondence between fuel properties, engine types, and size (duty) class of vehicle. Gasoline is used in engines that use sparkplugs to initiate combustion (spark ignition). Such engines use fuels that have high-octane ratings. Except in Europe, where diesel fuel is taxed at a much lower rate than gasoline, gasoline tends to be the dominant fuel in light-duty vehicles used primarily for movement of persons.

Diesel fuel tends to be used in engines that do not use sparkplugs and instead use heat from compression of air to ignite injected fuel—so called compression ignition (CI) engines—which are more commonly known as diesels. Diesel-fueled CI engines are generally used in trucks (heavy-duty vehicles), locomotives, and ship engines to move freight, or in buses to move large numbers of people. Diesel fuels use cetane rating as the figure of merit rather than octane. Among candidate fuels for use in internal combustion engines (ICEs), octane and cetane tend to be inversely related.

Some analysts distinguish engines by normal operating speed, in revolutions per minute (rpm). Generally, as the size and power of an engine drops, its normal operating speed rises. For petroleum-based fuels, the quality of fuel used and degree of refining needed tends to increase as normal engine operating speed increases. Ship engines use one of the lowest quality refined petroleum products, residual oil, and operate in the hundreds of rpm. Locomotive engines also use low-quality distillate oil, while truck engines use relatively high-quality distillate oil and are capable of peak rpm of about 4000. Light-duty passenger cars and trucks generally use spark-ignited engines and gasoline fuel, which is more highly refined than diesel fuels. These engines can peak at 5500 rpm and greater. The sulfur content of refined petroleum fuel declines as its quality increases. Volatility is important for spark ignition engines. Gasoline is more volatile than diesel fuel. Volatility is an environmental problem leading to evaporative emissions, so the volatility of gasoline was required to be reduced considerably since the 1970s. It remains true, however, that the volatility of gasoline (RVP, Table I) is considerably higher than diesel fuel. The mix of engines used has actually been adapted over the years to the mix of products that can be (and is) produced via refining.

One of the problems of near neat alternative fuels is that they consistently have different properties than gasoline or diesel fuel. Gases have to be compressed for convenient storage and behave differently if they leak. Alternative fuels have different octane or cetane ratings, requiring an engine to be adapted to make best use of such fuels. Natural gas, ethanol, and methanol all have higher octane ratings than petro-gasoline and lower cetane ratings (if there is a cetane rating) than petro-diesel. Unfortunately, if the engines are adapted to make best use of the properties of the alternative fuels, then they may not be able to run on available refined petroleum products. Thus, using alternative fuels most efficiently, in engines optimized and exclusively suited for them, creates a fuel supply

problem. Dedicating the engine to a scarce alternative fuel makes it improbable that an average consumer would use vehicles designed to use only that alternative fuel because of a lack of refueling stations.

The response to this is to design what are called dual fuel or flex fuel vehicles, or to limit target markets to fleets of vehicles that use the same refueling facility. Gaseous fuels in a dual fuel vehicle that can use refined petroleum products require two separate fuel tanks. Thus, the term dual fuel is applied to these vehicles. Vehicles that can switch between near-neat alcohol fuels and gasoline in the same single tank are called flex-fuel vehicles. Many flex fuel vehicles sold are capable of using both E85 and gasoline, but there are relatively few E85 stations, and it almost always costs more to run on E85 than on gasoline. Public policy is responsible for the existence of these vehicles, since the vehicle manufacturer is allowed under the AMFA to assume that the rated fuel economy is doubled from its gasoline rating. Since fuel economy is regulated under the Corporate Average Fuel Economy (CAFE) regulation, and consumers are buying larger and less fuel-efficient vehicles, the incorrect assumption that these E85 flex fuel vehicles actually use E85 is beneficial to automakers wishing to provide larger vehicles to U.S. consumers.

On the other hand, should oil supplies become tight and oil prices rise sharply, having these vehicles on the road could allow biomass-based ethanol production facilities to be built, and a refueling infrastructure, during the approximate average 13-year lifetime of these vehicles. The prior sales of E85 FFVs could then allow successful marketing of biomass-based ethanol. Such ethanol would also reduce greenhouse gases significantly, so the existence of these vehicles does provide the United States with some degree of energy security and an additional environmental option, should it need these in the early 21st century. However, in the short run, these options are made available by selling vehicles that consume more refined petroleum products than would otherwise be the case under CAFE regulations. If significant expansion of ethanol fuel for transportation is to be achieved, biomass-based ethanol production must move from corn to woody biomass or switchgrass feedstock. There is little evidence that plans are under way to accomplish such an expansion in the United States within the lifetime of the E85 FFVs that have been placed in the fleet in the early 21st century. This contrasts with plans for expansion of FTD production from natural gas outside the United States and considerable expansion of production of Canadian oil sands.

Among nations, the United States has required more sophisticated and highly refined fuels for purposes of low emissions and pays more for suitable oil than other nations. One exception to the rule of thumb that the United States requires the most refined and cleanest fuel is Sweden, where a very clean (low-sulfur) diesel fuel is required for use in urban areas. Within the United States, cities with severe air quality problems use the most sophisticated and highly refined petroleum products for emissions control. As a result of the Clean Air Act Amendments of 1990, nine areas with severe ozone air quality violations were required to introduce reformulated gasoline to reduce the emissions of the light-duty gasoline burning fleet of vehicles in those areas.

The state with the worst air quality problems has been California. As a result of uniquely severe problems, California developed the first emissions regulations, followed by the federal government. California has since retained the legal authority to set more strict regulations. One result is that the most costly and most highly refined reformulated gasoline in the country is required in California. Prior to the Clean Air Act Amendments of 1990, California adopted regulations that included a requirement for zero-emissions vehicle sales, starting in 1998. The states containing the nine regions required to use reformulated gasoline in the Clean Air Act Amendments of 1990 were allowed to adopt the California standards if they chose to do so. New York, Massachusetts, and other New England states attempted to do so, but legal challenges by the automobile industry were fought throughout the 1990s. Nevertheless, as a result of a negotiated agreement with California, electric vehicles were produced and test-marketed by major manufacturers through the latter part of the 1990s, and electric refueling infrastructure was set up by several states. Most noteworthy, of course, was California.

During the 1990s, the additive MTBE, an alternative fuel by the definition used here, was the dominant additive in reformulated gasoline. Expanded use of reformulated gasoline led to expanded use of MTBE and, in effect, expansion of the amount of natural gas feedstock used in transportation fuels. The oil and automobile industries have exhibited and continue to exhibit a strong preference for MTBE as an octane-enhancing and emissions-reducing additive rather than ethanol. It can even be safely asserted that, absent regulation to the contrary, tetraethyl lead remains the preferred octane enhancer. However, lead removal regulations are spreading worldwide,

and only the lowest income nations still allow their refiners to take advantage of its powerful octane-enhancing effects. Footnotes in the World-Wide Fuel Charter make it clear that lead is still not gone and its content must be regulated. This publication by automakers (no oil companies are coauthors) states, "leaded gasoline should be removed as soon as possible." Recommendations for gasoline are for unleaded gasoline, not gasoline generically. For the dirtiest of the four unleaded gasoline types, lead content equal to a "maximum level of 0.005 g/l is acceptable during the transition period."

At the same oxygen concentrations, blending ethanol causes an increase in volatility and, as a result, refining severity must be greater to obtain a specified volatility for the gasoline-oxygenate blend. Further, ethanol has an affinity for water and is a stronger solvent than gasoline. As a result, it cannot be blended at the refinery and piped to customers, while a gasoline MTBE blend can. Ethanol is often splash-blended at a location close to the final customer. Ethanol and associated impurities are more likely than MTBE to have materials compatibility problems with fuel systems. Accordingly, the World Fuels Charter explicitly indicates a preference for ethers rather than ethanol. This preference is stated despite the fact that the dominant ether MTBE is being removed from gasoline in the United States because of its contribution to water pollution.

In the Midwestern United States, the political support for blending of ethanol produced from corn into gasoline was very strong starting in the 1980s, after the two oil price shocks of the 1970s. It must be remembered that, although most analysts focus almost exclusively on the politics of support for ethanol, ethanol and tetraethyl lead were the two competing additives to increase octane in 1920s gasoline. Tetraethyl lead won the first battle to be the octane enhancer of choice, but by the 1980s it was being removed from gasoline both because of its toxic side effects and its poisoning of the newly required tailpipe emissions reducing catalytic converters. After 1975, all gasoline marketers were required to provide at least one grade of unleaded gasoline. The removal of lead from gasoline meant that refiners needed other additives or additional refining investment to provide octane that was being lost as lead was removed. So one of the technical arguments that could properly be brought to bear by ethanol advocates was its ability to provide octane that was needed as tetraethyl lead was phased out. Similarly, ethanol is a domestically produced fuel, so its substitution into gasoline also was correctly argued to reduce dependence on foreign petroleum. The political advantage of these arguments in states in which corn production is a major part of the economic base is clear. As a result of this combination of factors, and one more, the E10 blend of 10% ethanol by volume and 90% gasoline—so called gasohol—has become prevalent in the Midwestern United States. EPA rules revisions in 1979 and 1981, at the peak of real oil prices since World War II, allowed gasohol to be marketed as a gasoline substantially similar to industry average gasoline. Ethanol use in gasoline has reasonably steadily expanded since that time.

The other factor that played an important role in the success of ethanol was the 1980s discovery that gasohol reduced the wintertime emissions of carbon monoxide in the front range of Colorado, helping that area deal with its wintertime air quality problems. This was also true of MTBE. The reduction occurred primarily in older vehicles using carburetors, but the timing was such that this reduction was perhaps the final winning argument in favor of ethanol expansion in Colorado and elsewhere in the cold Midwestern United States. Though the amount of reduction of carbon monoxide by using gasohol in modern fuel injected vehicles is negligible, the 1980s proponents did not wish to wait for the advanced fuel injected 1990s vehicles to reduce carbon monoxide, and they further pushed ethanol (along with MTBE) into the gasoline blend market.

Ethanol also had opponents who estimated that it required so much energy to produce that it was actually a loser in terms of energy use and greenhouse gases. However, in the 1990s, reinvestigation of the efficiency of production of corn and of ethanol led to estimates that corn ethanol produced in the 1990s and since actually reduces greenhouse gases. While it was true that ethanol of the 1980s increased greenhouse gases, the experience with production of ethanol led to improvements in plant design, and refinement of existing plants, increasing efficiency of ethanol production. In the meantime, the productivity of corn growing rose steadily, and fertilizer use per bushel produced dropped (reducing emissions of the greenhouse gas nitrous oxide), so the contribution of corn farming to the greenhouse gas emissions of ethanol also dropped significantly. Thus, ethanol's success in getting into the market and staying there has been the result of a diverse set of factors and to evolving emphasis on key attributes. For the early 21st century, it appears that the absence of negative effects of ethanol on groundwater is going to give it an advantage relative to MTBE, and it will

likely expand in use as a gasoline additive for yet another reason.

Ethanol is only blended into gasoline. However, research is ongoing on blending ethanol into diesel. Many problems have been noted (often similar in nature to those for adding ethanol to gasoline), so the World-Wide Fuels Charter recommends that more research is needed before motor vehicle and engine manufacturers and governments could acceptably agree that ethanol blends in diesel fuel are technically suitable for use.

There are multiple state and federal subsidies or tax relief programs for ethanol. Generally, in the Midwest, there are state subsidies and tax exemption programs that supplement federal subsidies/exemptions, leading to a much higher market penetration of ethanol blends into the Midwest. In addition to regulations and subsidies promoting gasohol throughout the Midwest, there is a federal oxygenate requirement for reformulated gasoline. Since both MTBE and ethanol contain oxygen, this requirement can be met with either. Since ethanol contains a higher proportion of oxygen, a lesser proportion of ethanol blended into reformulated gasoline can meet a given gasoline oxygen percentage requirement. The percentages of ethanol in reformulated gasoline, when ethanol is present, are often considerably less than the 10% portion in gasohol.

Compared to most refined petroleum products, alternative fuels are generally less complex chemicals. Refined petroleum products are a soup of chemicals tailored to match the attributes of the engines and fuel delivery system developed for them over the years. If alternative fuels cannot fit into this preexisting system with little required modification, then a significantly different system has to be developed. This is known as the infrastructure problem. Blends that allow alternative fuels to make use of existing fuel delivery infrastructure obviously represent the easiest way to get alternative fuels into the system, but they nevertheless have limitations. Generally these limitations are defined by their chemical properties in interaction with the gasoline (or diesel fuel) with which they are blended. A mixture of gasoline and an alternative fuel never has the properties of either fuel. Since the fuel delivery and maintenance systems (as well as vehicles) are designed for gasoline or diesel fuel properties, the limiting factors tend to be set by rules, regulations, and practices originally established for the existing dominant fuels. Usually, the alternative fuels are blended into gasoline or diesel fuel because they provide desired enhancement in various properties, but the extent of their addition is limited by undesirable deterioration in other properties. In particular, the octane blending benefits of tetraethyl lead, ethanol, and MTBE are highly nonlinear, and these components are almost always considerably more costly than gasoline. Thus, the amount blended into gasoline tends to be minimized to give the desired properties. In the case of gasohol, governments got around this attribute by specifying subsidies only for a 10% blend. This property also meant that it was more difficult for refiners to cope with the last small amounts of tetraethyl lead removed from gasoline than the previously removed quantities.

Another important point is that the blending octane of ethanol and MTBE tends to be higher than the octane rating of the pure compound. Accordingly, when used primarily for purposes of providing octane, ethanol and MTBE have a higher value blended into gasoline than used in near-neat form in a vehicle (see Table I).

To a far greater extent than alternative fuels that are suitable blending components, neat fuels will have properties that require significant adaptation of the system. Mechanics have to be retrained. New fuel infrastructure has to be built or existing facilities adapted. For example, diesel fuel pools on the floor if it leaks and is quite difficult to ignite. Natural gas rises in the air if it leaks and ignites readily in the presence of a spark if its concentration is high enough. Electric resistance heaters at the roof of a diesel bus maintenance garage could not ignite leaked diesel fuel, but if natural gas were to leak, an explosive fire could easily result. For this and other reasons, conversion of bus maintenance facilities to safely maintain natural gas buses can be costly. This is but one example.

2. *FUEL PROPERTIES AND FUEL SWITCH EFFORTS*

The 1980s and 1990s show that introduction of alternative fuels is quite difficult. At the time of publication, energy security was a major concern, due to high oil prices and elevated dependence on oil from politically unstable nations. Interest in alternative fuels waxes and wanes as oil prices rise and fall. When the United States Energy Policy Act (EPACT) of 1992 was passed, memory of a 1988–1990 oil price shock heightened by the Iraq-Kuwait war of 1990, followed by a recession, had caused elevated concerns with petroleum dependence by the

United States. This act nominally called for the United States to be using 10% alternative fuels in highway transportation by 2000, and 30% by 2010. The act was exhortative and had loopholes if economics did not support use of alternative fuels. For most of the 1990s, oil prices were well below the levels that induced the writing of the EPACT, and economics did not support use of alternative fuels to the extent envisioned in the EPACT. Nevertheless, one may take a glass partially full perspective toward the 1990s, since expansion of use of alternative fuels did occur, and numerous potentially valuable attempts to implement alternative fuels were made.

While it is possible to emphasize the perspective that energy security was the primary driver behind the EPACT, this would be misleading. Prior to the EPACT, the Clean Air Act Amendments of 1990 (CAAA90) were passed. At the time, alternative fuels were also regarded as cleaner fuels than gasoline. Prior to these amendments, California had developed low-emission vehicle regulations with far-reaching implications for automobile makers. The California regulations included requirements for introduction of zero-emissions vehicles, as well as other low-emissions vehicles much cleaner than the motor vehicle industry could produce. Prior to writing of the California zero-emissions vehicle requirements, General Motors had announced that it would develop a commercial electric vehicle. Zero emissions at the time implied electric vehicles. California had also been experimenting with methanol as an alternative fuel and anticipated that methanol vehicles would have considerably lower emissions than gasoline vehicles. An extremely clean experimental vehicle dedicated to the use of methanol was highlighted in research of the time. This vehicle was contrasted with a methanol FFV that had less power, slower acceleration, and higher emissions. The automobile industry had worked with California to develop versions of its standard vehicles capable of running on M85 and gasoline.

The summer of 1988 had been an unusually hot summer. As the environmentally motivated removal of the toxic but highly effective octane enhancer tetraethyl lead from gasoline was coming to an end, oil companies added volatile chemicals such as butane to keep the gasoline octane at levels previously offered to consumers. This caused greater amounts of evaporation of hydrocarbons, which tended to cause ozone air quality to deteriorate. Combined with the hot summer, this led to a reversal of years of consistent declines of summertime ozone concentrations and an alarmed response by environmentally concerned citizens. The CAAA of 1990 resulted directly from this reversal of progress. California and others thought that M85-fueled vehicles and electric vehicles might be used to address the need for even lower vehicle and refueling delivery system emissions. However, as work progressed on the CAAA, oil prices were rising, and a war between Iraq and Kuwait occurred, increasing the interest in alternative fuels for energy security reasons. EPACT followed 2 years later, and alternative fuel advocates were excessively optimistic.

The share of alternative fuels in use in highway transportation in 2000 fell far short of the 10% EPACT goal, and the probability of falling short of the 30% goal for 2010 is almost 100%. Instead of electric and M85 vehicles, the more successful alternative fuels are ethanol and MTBE blended into gasoline. Such fuels are termed replacement fuels in the Energy Policy Act of 1992, while they are referred to here as alternative fuels. The more successful neat and near neat alternative fuels are compressed natural gas (CNG) and ethanol, not electricity and methanol, the seeming leaders when EPACT was written. But the true success of ethanol and natural gas to date are not as neat or near-neat fuels, but as a constituent of gasoline. The vast majority of ethanol fuel produced in the United States is blended into gasoline. The amount of natural gas as a feedstock making its way into light-duty vehicles is considerably greater in MTBE than in CNG.

2.1 Status of Alternative Fuels and Trends Under Way

The U.S. Department of Energy's Energy Information Agency began compiling the amount of alternative fuels and alternatively fueled vehicles sold in the United States, by region, by fuel type, and by vehicle class since passage of the EPACT. Thus, there is a record of what has happened during the 1990s. The Alternative Fuels Data Center, maintained by the National Renewable Energy Laboratory, lists refueling stations by type of alternative fuel and provides technical details on alternatively fueled vehicles. The Electric Vehicle Association of America, since renamed to the Electric Drive Vehicle Association, provides data on the history of electric vehicles, by class of vehicle. The Natural Gas Vehicle Coalition provides information on natural gas vehicles and public policy (incentives) information for consumers. The Fuel Economy Guide, maintained by the U.S. EPA and Department of Energy, provides fuel

economy ratings of alternatively fueled vehicles in its published version of the guide. In the Web version, a weighted ranking from zero to ten (ten is best) is provided on "criteria pollutant" emissions (emissions for which standards exist). Information on full fuel cycle greenhouse gas emissions is also provided on the Web site.

2.1.1 Blended Alternative Fuels

According to Energy Information Agency (EIA) data, in the early years of the 21st century, the share of MTBE in gasoline was about 2.5%. The share of natural gas feedstock versus petroleum feedstock for MTBE is not available, but 50% is a good rough estimate. Thus, about 1.25% of gasoline is derived from natural gas feedstocks. Ethanol is blended into about 0.8% of gasoline. Thus, by the definition of alternative fuels used here, a little over 2% of gasoline is presently alternative fuel. Note, however, that diesel fuel, residual oil, and jet fuel are also petroleum products used in transportation, so the share of alternative fuel blended into refined petroleum products is probably a bit over 1%. However, this does not account for the use of hydrogen and natural gas liquids to produce other blendstocks used in refined petroleum products. These are not reported by EIA in its alternative fuel statistics. Hydrogen produced for such purposes is usually derived from natural gas, so the percentage of nonpetroleum feedstocks in refined petroleum products probably exceeds 1% by a significant margin.

The future for MTBE in the United States is troubled. It was adopted to reduce tailpipe emissions. The risks of its leakage and its effects if it did leak into aquifers were mistakenly judged to be small relative to the air quality benefits. In *very* small quantities it ruins the taste of water. It also is highly resistant to biodegradation and has negative health effects at small concentrations. The flaw in regulatory analyses of MTBE were that the concerns over concentrations in water were based on health effects rather than taste, which has a considerable economic value, even if the water is safe to drink. Health effects of concern are not reached until concentrations reach those well above the point where it fouls the taste of water. The effect on taste appears to be the Achilles' heel of MTBE. Due in part to leaks of underground storage tanks and in part to unburned fuel in two stroke boat motors, MTBE has tainted the water supplies of a number of localities, leading to a backlash against it and widespread concern over its long-term environmental effects. Small quantities are being found in many locations as a result of unburned MTBE emitted from motor vehicle tailpipes, so its gradual buildup, in light of public alarm over taste of MTBE contaminated water at several prominent locations, has led to widespread concern, and movements to remove MTBE from gasoline. Early in the 21st century, ethanol use as a blending component of gasoline will increase, while MTBE use will decrease. The net effect will likely be a significant tapering off of growth of alternative fuels blending into gasoline —perhaps even a decline.

2.1.2 Neat and Near-Neat Alternative Fuels

Liquefied petroleum gases (LPG) are the leading neat or near-neat alternative fuels in the United States Despite the name, a large fraction of the fuel is derived from natural gas liquids, propane in particular. LPG technically can be a mix of gases. The mix is generally butane and propane, with the percentage of butane limited. The abbreviation sometimes stands for liquefied propane gas, because propane is the primary constituent. Only two models of light-duty LPG vehicles are listed in the 2002 Fuel Economy Guide. Both are versions of the Ford F150 pickup truck, the leading selling vehicle model. Among vehicle body types, pickups are sold in higher quantities in rural areas than any other. There is also a medium-duty truck that uses LPG. In any case, LPG is predominantly an alternative fuel sold in rural areas. Vehicles are often converted to use LPG. These are generally in areas where air quality is not a problem and vehicles are not inspected for emissions. According to EIA, LPG sales in the United States for transportation have been about 250 million gallons of gasoline equivalent since about 1994. For comparison purposes, 1% of the 2001 gasoline market was 1260 gallons, about five times as much as the gasoline equivalent sales of LPG. Thus, sales of LPG, at about 0.2% of gasoline, are far less than ethanol blended into gasoline (about 0.8%) or natural gas used in MTBE blended into gasoline (about 1.25%). Further, sales are not growing. Thus, according to earlier calculations, merchant hydrogen is probably already used in refined petroleum products to an extent similar to the leading neat alternative fuel, LPG. The use of merchant hydrogen by refiners is probably rising.

Among neat and near-neat alternative fuels, natural gas is second in sales to LPG. In 2001, sales of natural gas in transportation were estimated to be about 105 million gallons of gasoline equivalent, up from about 20 in 1993. So growth of sales of natural gas is significant, but in 2001, natural gas as a neat fuel represented 0.1% of gasoline sales, far less than

the 1.25%-plus share of natural gas feedstock that works its way into refined petroleum products via MTBE and hydrogen.

After natural gas, not one of the remaining alternative fuels constitutes more than about 0.01% of gasoline sales. This includes liquefied natural gas, M85, E85, M100, E100, and electricity.

According to the 2002 Fuel Economy Guide, the mix of new 2002 light-duty alternative fuel vehicles offered to consumers was considerably out of balance with the relative success of alternative fuels to date. Twenty-seven E85 FFV models were offered, versus eight CNG models. As noted, there were two LPG models and two electrics. The number of electric vehicles offered had dropped sharply from earlier years, and the number of CNG models had dropped moderately. Numbers of E85 vehicles had expanded rapidly. No M85 vehicles were offered in 2002. Such vehicles had been available early in the decade. Methanol and electricity, at the end of a decade or so of experimentation, appear now to be abandoned as alternative fuels for vehicles designed to clean the environment or to provide energy security.

It has been pointed out that a prime motivator for several of the alternative fuels has been emissions reduction rather than energy security. MTBE has been used in reformulated gasoline for that purpose. Ethanol's ability to reduce carbon monoxide emissions in the 1980s fleet of vehicles helped it expand its market share. Electric vehicles were the hoped for zero-emissions vehicle for California and other states that wished to adopt the California low-emissions vehicle standard under rules written into the Clean Air Act amendments. Natural gas was also advocated as a clean fuel. Compressed natural gas vehicles designed to use only natural gas have proven to be very clean, on average. Figure 1 illustrates an average rating emissions index rating from the Fuel Economy Guide's 2002 models. It shows that CNG vehicles obtain almost the same rating as electric vehicles. It was stated that LPG tends to be a rural fuel, and few clean LPG vehicles are available from manufacturers.

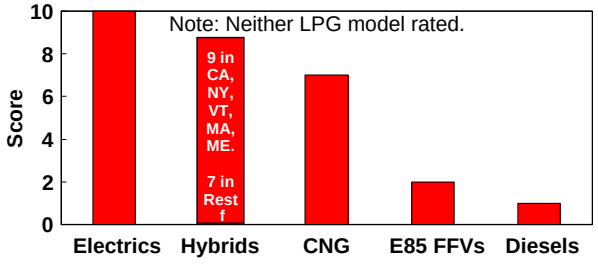

FIGURE 1 Average air pollution score of non-gasoline light-duty vehicles and hybrids on the EPA Fuel Economy Guide Web site (10 is best, 0 is worst).

2.2 Location Patterns

Since EPACT was enacted, efforts to introduce alternative fuels have included installation of refueling stations to provide the fuels. Electric refueling stations and E85 refueling stations are highly concentrated geographically, while natural gas refueling stations are not.

The cleanest of vehicles, the CNG and electrics, have had infrastructure for them preferentially installed within a 25-mile radius of large metro areas. The share of LPG stations rises sharply in the 25- to 50-mile annular ring outside metro areas. Small metro areas have a higher proportion of LPG stations than the nation as a whole, and they have a considerably larger share than within a 25-mile radius of large metro areas. The proportion of electric vehicle stations drops far more sharply in the small metro areas than does the other clean fuel, CNG. Where electric vehicle stations exist, the proportion of electric refueling stations found within the 25-mile radius of the metro area is consistently greater than for other fuels. It is fair to say that attempts to introduce electric vehicles have focused on the core of large urban metro areas with ozone air quality problems. It is also clear that the mix of fuels being sold is far different from the mix of refueling stations available to refuel them with an alternative fuel.

Various states and metro areas choose different fuels for primary emphasis and have different levels of effort at developing an alternative fuel infrastructure. The shares of electric stations in major metro areas of California are greater than elsewhere. California has the most electric vehicles in the nation. However, California is also listed as the state with the most LPG vehicles, amounting to about nine times as many as electrics. California also leads the nation in number of CNG vehicles and has about five times as many CNG vehicles as electric vehicles. In fact, California is estimated to have over twice as many methanol vehicles as electrics, as a result of methanol vehicles remaining from the methanol programs of the early 1990s and small numbers of electric vehicles sold since then.

Metro areas outside of California that also have electric vehicle refueling stations have not emphasized electric stations to the degree that California has. There, CNG is the fuel with the largest

proportion of alternative fuel stations, not electricity. The only metro area that has chosen to emphasize E85 refueling stations is Minneapolis. Minneapolis has no ozone violations, but it is in violation of the CO standard. Minnesota is the state with the most E85 FFVs actually using the fuel.

Among the metro areas examined, those not including electric vehicles also generally have fewer alternative fuel stations. Milwaukee, Chicago, and Houston have about the national proportion of LPG stations and a considerably higher proportion of CNG stations than the average. Texas is the leader in LPG vehicle totals, while Illinois is third. California, Texas, and New York lead in implementation of CNG vehicles, consistent with their populations.

Only a few states are estimated to have more alternatively fueled vehicles using ethanol, natural gas, or electricity than LPG. For Arizona, Arkansas, Delaware, Nevada, Utah, and West Virginia, natural gas vehicles are the leaders. Delaware, the District of Columbia, Maryland, New Jersey, Utah, and West Virginia have more CNG stations than any other type. The District of Columbia, Hawaii, Minnesota, and North Dakota are estimated to have more E85 vehicles than any other type. Only Minnesota has more E85 stations than any other type. Only Puerto Rico is estimated to have more electric vehicles than any other type. California, Georgia, and Puerto Rico have more electric refueling stations than any other type.

3. FUEL PROPERTIES AND CENTURIES-LONG TRANSPORTATION FUEL SWITCHES

Clearly, many detailed properties of alternative fuels are important to their success or failure. Nevertheless, it is also necessary to consider the overarching general properties and their role when taking a long view. Cost, a function of abundance of feedstock for the fuel, is, of course, a primary consideration. However, whether a fuel is a solid, liquid, or a gas is also important. Use of solid fuels in 19th century transportation (grains for horses, wood, and coal for steam locomotives) gave way to use of refined liquids from petroleum in the 20th century. Some energy forecasters hold the belief that the transportation fuel of the 21st century will be a gas—hydrogen. One argument in favor of the logic of a transition to hydrogen is that there is a natural transition from fuels with higher carbon content toward lower carbon content, with hydrogen at the end of the sequence. As far as the percentage of carbon versus hydrogen in the molecular weight of past and candidate future transportation fuels is concerned, the percentage declines as one moves from wood to coal to petroleum to natural gas (methane) to hydrogen. There are debates about a transition to hydrogen. Some argue that natural gas will be the next major alternative transportation fuel, followed by hydrogen. Others assume that natural gas will not be used in significant quantities in transportation and hydrogen will be the next major neat fuel.

The primary argument for an expectation that nonpetroleum fuels will be dominant in the 21st century is that petroleum will be depleted. Those who advocate this argument generally use a depletion model known as the Hubbert curve. By this model, petroleum will first be depleted, then natural gas depletion will follow within a very few decades. If natural gas were to be more abundant than presently estimated, then perhaps methane could be a significant worldwide transportation fuel well into the 21st century. If not, then the argument that hydrogen will be the dominant fuel can be based on the projection that *both* petroleum and natural gas will be depleted.

Hydrogen is seen as an energy carrier that can be produced via a large number of feedstocks and processes. A hydrogen delivery infrastructure for the 21st century would be analogous to the present electricity transmission and distribution system, where electricity fed into the system comes from many different primary sources. Presently, hydrogen is produced predominantly from natural gas, which is the cheapest resource for high-volume hydrogen production. In fact, the hydrogen production capacity in existence is as large in energy terms as most alternative fuels. Hydrogen production outside of refineries was estimated in 1995 to be equivalent to two days of gasoline consumption. Expressed on a percentage basis, this would be 0.55%. The leading use of hydrogen in 1988 was for ammonia production, while the second leading use was as a refinery input. Worldwide, in that time frame, 77% of hydrogen was estimated to be produced from natural gas, 18% from coal, and less than 1% from oil. In 1988, it was estimated that 37% of hydrogen was used by refineries. Thus, hydrogen production dedicated to transportation fuel may be on the order of 0.2% of gasoline production or more. Since 1988, use of hydrogen in refining has likely increased significantly. A large portion of the hydrogen

produced is actually used in petroleum refining to upgrade refined petroleum products to the tighter specifications being imposed largely for environmental reasons, and these restrictions have become tighter in the 1990s. In this sense, petroleum feedstock is already being replaced by natural gas feedstock for production of gasoline and diesel fuel in ways completely transparent (unknown) to the average consumer.

Another way that domestic natural gas use in refining has likely increased is through the expanded use of natural gas liquids. While oil production in the United States has typically declined, production of natural gas liquids has increased. One of the markets for these liquids has traditionally been in gasoline refining.

Even if the transportation system were to make a transition directly to hydrogen-fueled vehicles instead of an intermediate transition to methane-fueled vehicles, it is probable that natural gas would be the primary feedstock for the hydrogen used. Past and recent research on the costs of hydrogen production and delivery indicate that hydrogen will be significantly more costly than gasoline or diesel fuel, a clear drawback. Hydrogen is also more costly per unit of energy than natural gas or ethanol, but it has the potential advantage of being converted to tractive energy in a fuel cell vehicle more efficiently than these two fuels in spark ignited internal combustion engines. The high cost per unit of delivered hydrogen is directly related to the fact that hydrogen is a gas with a low amount of energy per unit volume. It would also be possible instead to use the natural gas directly in vehicles rather than convert it to hydrogen. Credible sources obtain differing estimates of the relative total full fuel cycle energy and greenhouse gas emissions of future transportation technologies. Depending on the source consulted and time frame examined, one can find estimates that (1) petro-diesel used in advanced hybridized conventional compression ignition engine vehicles, (2) natural gas used in advance hybridized spark ignited engine vehicles, (3) hybridized hydrogen fuel cell vehicles, or (4) electric vehicles will result in the least greenhouse gas emissions. Electric vehicles, however, have limited driving range relative to the other three types. This has proven to be a show-stopper for electric vehicle experiments of the 1990s.

When one considers a half century or full century time frame, then the issue of adequacy of natural gas supply as a feedstock for hydrogen production leads some to argue that there is no sense in attempting three transitions—first to methane and CNG, second to methane and hydrogen, and third to multiple primary sources of hydrogen. By this argument, transitions themselves are inherently difficult, so avoiding intermediate transitions and jumping to a long-term solution is desirable. Economists do not make such an argument, but some scientists, environmentalists, and motor vehicle manufacturers (for which transitions are indeed costly) do, for different reasons. Some environmentalists tend to stress the opportunities to produce hydrogen from nonfossil primary sources such as wind, hydro, and solar power. Some scientists stress production of hydrogen via nuclear power as a source of abundant supply. Some in the automobile industry want to spend scarce research dollars to develop reliable, reasonable cost hydrogen powertrain technology for vehicles before proceeding to a hydrogen-based transportation system.

An argument against hydrogen is that liquids are the ultimate fuel for transportation because of their energy density and ease of handling in a fuel system. In this regard, the advantage of a liquid is clear for internal combustion engines (ICEs). Gases tend to reduce the peak power output of an ICE of a given size and also require bulky pressurized tanks that require a lot of physical volume relative to liquids. Converting an ICE to hydrogen does offer promise of elimination of hydrocarbon and carbon monoxide emissions, but not nitrogen oxides. Further, the effective efficiency of the vehicle will decline due largely to the power loss, which will require a larger and heavier powertrain. While projections indicate that hydrogen powered ICEs could be advanced to have considerably lower greenhouse gas emissions than present ICEs, it is also true that present ICEs can also advance. At any level of technology, Ricardo Consulting Engineers estimated in 2002 that hydrogen-fueled ICEs using hydrogen from natural gas will cause higher greenhouse gas emissions than comparable technology petro-diesel vehicles. So according to Ricardo's estimate, unless there is some unequivocal great long-term advantage to immediately starting to convert to a natural gas derived hydrogen fuel infrastructure, there is no clear reason to switch to hydrogen ICEs instead of petro-diesels. Ricardo constructed estimates of two pathways to hydrogen, with the early introduction pathway taking advantage of ICE engines converted to use hydrogen and the late introduction pathway waiting until fuel cell vehicles are ready for the market, estimated by Ricardo to be about 2020. Still, by Ricardo's estimates, very advanced hydrogen ICEs could compete with hydrogen fuel cell vehicles in terms

of efficiency, so they may be worth examining on a research basis since they may be considerably cheaper than hydrogen fuel cell vehicles.

It should be pointed out that technology exists and has been demonstrated to produce gasoline and diesel fuels from unconventional oils, from shale, and from coal. However, use of these technologies in their demonstrated forms would increase greenhouse gas emissions and probably would cause other environmental difficulties. One possible solution to this problem would be to sequester carbon dioxide produced when coal or other heavy fossil fuels are converted to hydrogen. If this could be done at reasonable cost and in an otherwise environmentally acceptable manner with abundant coal, then coal might actually again provide significant quantities of transportation fuel. The effort to develop hydrogen fuel cell vehicles is, in effect, a long-term effort to reduce urban motor vehicle emissions to inconsequential amounts. Without environmental concerns over ambient air pollution and greenhouse gases to drive this process, it is likely that reliance on fossil fuels could and would continue perhaps through the entire 21st century. Given these concerns, energy sources such as nuclear, biomass, wind, hydro, and solar could provide original energy for hydrogen production for transportation instead of fossil fuels.

It is quite likely that if the clean fuel of the future is hydrogen, it will bring with it an entirely new powertrain. Just as steam and coal were matched for the 19th century and petroleum and the ICE for the 20th, the advocate of hydrogen will note that hydrogen and the fuel cell will be matched for the 21st century. The fuel cell is the prime mover (a generic term for the primary power source for a motor vehicle) for highway vehicles for which pure hydrogen is clearly the ideal fuel from a thermodynamic efficiency perspective. In particular, at this time, a type of fuel cell called a polymer electrolyte membrane (PEM) fuel cell is the candidate of the future. It is possible to obtain a jump in peak efficiency with FCs relative to ICEs—especially SI ICEs—if hydrogen is the fuel. FC powertrains using liquid fuels—methanol in particular—are also being developed, but such a powertrain's efficiency is not as high as for one equipped with PEM cells fueled by hydrogen stored on board. This is because, in addition to the fuel cell, the methanol fuel cell vehicle requires a reformer—a chemical processing device to convert methanol to hydrogen and carbon dioxide. So the perceived need to evolve toward gaseous hydrogen is promoted by the estimated high efficiency of the PEM FC using hydrogen stored on board the vehicle.

Thus, many think, with good reason, that the hydrogen-fueled PEM FC vehicle powertrain will be the prime mover and fuel combination for transportation in the 21st century. To the extent that this combination relies on natural gas feedstock, most analysts estimate that it will extend the life of natural gas resources relative to use of CNG in ICEs. As previously noted, using wind, solar, geothermal, biomass, coal, or nuclear electric power to produce hydrogen would also be technically possible. Compared to use of CNG in ICEs, the hydrogen-fueled PEM FC could significantly reduce urban emissions of carbon monoxide, hydrocarbons, and nitrogen oxides (the hydrogen ICE can also eliminate the former two and probably sharply reduce the latter). Some see the hydrogen PEM FC as the zero-emission vehicle that can succeed, now that electric vehicles have failed to garner consumer support.

Counterarguments against a switch to hydrogen essentially involve cost. Arguments that hydrogen is excessively costly imply many decades of reliance on the technologies and fuels discussed in the prior section. High overall hydrogen transportation system cost is because of the shift to an entirely new powertrain type that presently appears inherently more costly than ICEs and a shift of fuel delivery infrastructure, which is inherently more costly than for refined petroleum products or natural gas. The cost of the needed fuel infrastructure shift could be avoided to some degree if the fuel feedstock to be used in all cases is natural gas, while the powertrain could be reduced in cost by using NG directly in a natural gas-fueled internal combustion engine. In this regard, CNG can be burned in either spark-ignited engines for light-duty vehicles or in compression-ignited engines for heavy-duty vehicles. An extensive natural gas delivery infrastructure exists, but it would be completely inadequate for the significant use of natural gas in transportation as long as other users of natural gas continue to use it. Thus, the cost issue would be the cost of new natural gas infrastructure versus new hydrogen infrastructure, unless a single infrastructure compatible with either natural gas or hydrogen could be developed.

Fischer-Tropsch diesel fuel produced from natural gas can be used in compression ignition engines, which are presently dominant in the United States in heavy-duty vehicles. It is, of course, suitable for light-duty diesels as well, which are common in Europe.

Fischer-Tropsch diesel fuel is very clean with respect to sulfur and tailpipe emissions, and in present applications it is generally a premium-priced fuel stored in separate tanks from normal diesel. However, this is only necessary where emissions are problematic. Otherwise, Fischer-Tropsch diesel can be shipped and stored in the same equipment presently used for diesel fuel. According to most studies of light-duty vehicles, natural gas and Fischer-Tropsch diesel fuel pathways use more energy and cause greater greenhouse gas emissions than hydrogen in fuel cell vehicles. However, the differences are not large, and the cost of hydrogen is presently estimated to be considerably greater. A third nonhydrogen option is biomass-based ethanol (not corn-based). This fuel could be burned in the many E85 flex fuel vehicles being sold into the market. It does require a separate infrastructure for delivery of the fuel. This option can actually reduce greenhouse gases by more than hydrogen fuel cell vehicles for which the hydrogen is produced from natural gas. A comparison of a scenario heavily dependent on hydrogen and fuel cells versus one using the more conventional technologies discussed in this paragraph was one evaluated in 2003 in a joint U.S. Department of Energy and Canadian Energy Mines and Resources study.

The results of that study indicated that it is quite possible to envision an evolutionary shift of fuels for ICE engines that would make use of a combination of CNG and Fischer-Tropsch diesel fuel from natural gas feedstocks and ethanol from biomass. This shift could well provide the same level of service as if a single hydrogen with FC transition pathway were pursued, provide greenhouse gas emissions as low as for the hydrogen pathway, and use no more natural gas. The CNG would most likely be used predominantly in spark ignited ICE engines in urban areas with more severe air quality problems. As such, it would be the clean gaseous fuel used where air quality needs are greatest, instead of hydrogen. E85 would also be used in spark-ignited ICE engines, in areas where air quality was less of a concern. Fischer-Tropsch diesel fuel would be used in compression ignition engines in heavy-duty vehicles.

The two drawbacks of this latter option, which relies far more heavily on liquids than the hydrogen transition, are (1) once natural gas was depleted, a transition to hydrogen and fuel cell vehicles would probably still be necessary, and (2) there would be no zero-emissions vehicles in the mix of vehicles available to deal with air quality problems.

4. CONCLUSION

Neat and near-neat alternative fuels and alternatively fueled vehicles contribute very little to the transportation services of the United States. Where there has been a small degree of success, the states, localities, and businesses involved have generally chosen to emphasize only one or two alternative fuels. LPG is the largest neat alternative fuel in the market to date, but where cleaner natural gas or electric vehicles have been pursued, LPG seems to have been deemphasized. Natural gas and ethanol fuels have a tiny share of the market, but are still growing. Electric vehicles attained an even tinier share of the market and appear now to have been an experiment that will be abandoned.

One reason for abandoning electric vehicles is the promise that hydrogen fuel cell vehicles can also provide zero tailpipe emissions with far more consistent reductions in greenhouse gases and at a cost less than for electric vehicles, with considerably greater overall satisfaction to the consumer. Beyond this, many anticipate hydrogen to be the leading candidate fuel for light-duty vehicles for the 21st century. Nevertheless, for the next few decades the role of petroleum as the leading transportation fuel seems secure. However, projections that this cannot continue for the entire century are now conventional wisdom.

One question to ask at this time is whether it is wise to abandon the alternative fuels experiments of the 1990s and wait another decade or two until hydrogen is technically (and, it is hoped, economically) demonstrated, or should ongoing trends be reinforced, refined, and expanded via public policy or corporate investment. Another is whether improved transportation energy efficiency—largely ignored in this discussion—should instead be the primary goal for the next two decades.

5. Gas Turbine Usage

Glossary

Aeroderivative An aviation propulsion gas turbine (jet engine) used in a nonaviation application (e.g., an electric power plant) to provide shaft power.
Brayton Cycle Ideal gas cycle that is approximated by a gas turbine simple cycle.
Cogeneration A gas turbine operating to produce shaft power and to supply heat from its exhaust for some useful purpose.
Combined-Cycle Power Plant The combination of a gas turbine power plant and a steam turbine power plant. The gas turbine exhaust energy is used as heat input to generate steam.
Gas Generator The compressor, combustor, and turbine components of a gas turbine.
Isentropic A process that is reversible and adiabatic; having constant entropy.
Jet Engine An aviation gas turbine used for aircraft propulsion thrust power.
Rankine Cycle Ideal gas cycle that is approximated by a simple steam turbine power plant cycle.
Thermal Efficiency Useful output power divided by costly input energy rate, expressed as a percentage.
Working Fluid In the case of gas turbine, the gas (usually air) that flows through the machine to produce work or power.

The first jet engine-powered aircraft flight and the first electric power produced by a land-based gas turbine both occurred in 1939, making the gas turbine one of the youngest energy conversion devices. A gas turbine consists of a rotating assembly of a compressor to draw in a gas (usually air) and a turbine to extract power from the gas flow. Energy (usually combusted fuel) is added in a combustor between the two rotating components to heat the gas flow and power the turbine. Gas turbines are used to produce either thrust power (e.g., an aircraft jet engine) or shaft power (e.g., to turn an electric generator). The thermal efficiency and power output of a gas turbine are dependent on the compressor pressure ratio and on the gas flow temperature at the inlet to the turbine. Gas turbines range in size from hand-held units to whale-size units, weighing from a few kilograms to 300,000 kg, and producing power from tens of kilowatts up to 250 MW.

1. INTRODUCTION

In the broad sense, a turbine is any kind of spinning device that uses the action of a fluid to produce work or power (work per unit time). Typical fluids are air, water, steam, gaseous combustion products, and helium. Windmill turbines, water turbines in hydroelectric dams, and steam turbines have been used for decades to turn electrical generators to produce electrical power for both industrial and residential consumption. Simple turbines date back centuries, with the first known appearance in ancient Greece (Hero's turbine).

In the history of energy conversion, the gas turbine is a relatively new energy converter, or prime mover. The first practical gas turbine used to generate electricity ran at Neuchatel, Switzerland, in 1939 and was developed by the Brown Boveri firm. The first gas turbine-powered airplane flight also took place in 1939 in Germany using the gas turbine developed by Hans P. von Ohain. In England in the 1930s, the invention and development of the aircraft gas turbine by Frank Whittle resulted in a similar British flight in 1941.

Table I presents a list of energy converters and the year in which a first working device was successfully

 © 2004 Elsevier Inc. All rights reserved.

run. The gas turbine is by far the "youngest" of the energy converters listed. Note that the common automotive gasoline engine (Otto engine) has been around a long time (1876), as has the fuel cell (1839).

The name "gas turbine" is somewhat misleading, for it implies a simple turbine that uses gas as a working fluid. Actually, a gas turbine (as shown schematically in Fig. 1) has a compressor to draw in and compress gas (usually air), a combustor (or burner) to add combusted fuel to heat the compressed gas, and a turbine (or expander) to extract power from the hot gas flow. The gas turbine is an internal combustion (IC) engine employing a continuous combustion process, as distinct from the intermittent combustion occurring in a Diesel or Otto cycle IC engine.

TABLE I

History of Energy Converters

Energy converters	Date of first working device
Steam engine	1769
Fuel cell	1839
Otto engine	1876
Steam turbine	1884
Diesel engine	1897
Gas turbine	1939

Because the 1939 origin of the gas turbine lies both in the electric power field and in aviation, there has been a profusion of "other names" for the gas turbine. For land and marine applications, it is generally called a gas turbine, but also a combustion turbine, a turboshaft engine, and sometimes a gas turbine engine. For aviation applications, it is usually called a jet engine, and various other names (depending on the particular aviation configuration, or application), such as jet turbine engine, turbojet, turbofan, fanjet, and turboprop or prop jet (if it is used to drive a propeller) are also sometimes used. The compressor–combustor–turbine part of the gas turbine (Fig. 1) is commonly termed the gas generator.

2. GAS TURBINE APPLICATIONS

In an aircraft gas turbine, all of the turbine power is used to drive the compressor (which may also have an associated fan or propeller). The gas flow leaving the turbine is then accelerated to the atmosphere in an exhaust nozzle (Fig. 1A) to provide thrust or propulsion power. Gas turbine or jet engine thrust power is the mass flow momentum increase from engine inlet to exit, multiplied by the flight velocity.

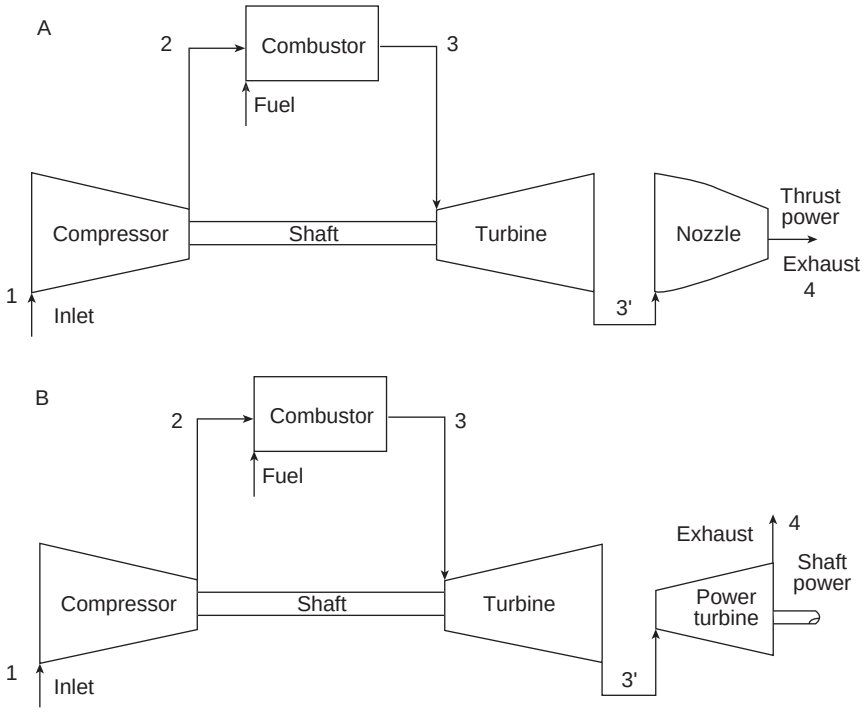

FIGURE 1 Schematic for (A) an aircraft jet engine and (B) a land-based gas turbine.

A typical jet engine is shown in Fig. 2. Such engines can range from approximately 100 lbs of thrust (445 N) to as high as 100,000 lbs of thrust (445,000 N), with dry weights ranging from approximately 30 lbs (134 N) to 20,000 lbs (89,000 N). The jet engine shown in Fig. 2 is a turbofan engine, with a larger diameter compressor-mounted fan. Thrust is generated both by air passing through the fan (bypass air) and by air passing through the gas generator itself. With a large frontal area, the turbofan generates peak thrust at low (takeoff) speeds, making it most suitable for commercial aircraft. A turbojet does not have a fan and generates all of its thrust from air that passes through the gas generator. Turbojets have smaller frontal areas and generate peak thrusts at high speeds, making them most suitable for fighter aircraft.

In nonaviation gas turbines, part of the turbine power is used to drive the compressor. The remainder, the "useful power," is used as output shaft power to turn an energy conversion device (Fig. 1B), such as an electrical generator or a ship's propeller. As shown in Fig. 3, shaft power land-based gas turbines can become very large (as high as 240 MW). The unit in Fig. 3 is called an industrial or frame machine, used mostly for electric power generation. It is constructed for heavy duty, ruggedness, and long life, where weight is not a major factor as it is with a jet engine. Typically, frame machines are designed conservatively and have made use of jet engine technical advances when it has made sense to do so.

Lighter-weight gas turbines derived from jet engines (such as in Fig. 2) and used for nonaviation applications are called aeroderivative gas turbines. Aeroderivatives are used to drive natural gas pipeline compressors, to power ships, and to produce electric power. They are particularly used to provide peaking and intermediate power for electric utility applications. [Peaking power supplements a utility's normal electric power output during high-demand periods (e.g. summer air conditioning in major cities).]

Some of the principle advantages of the gas turbine are as follows:

(1) It is capable of producing large amounts of useful power for a relatively small size and weight.

(2) Since motion of all its major components involves pure rotation (i.e., no reciprocating motion as in a piston engine), its mechanical life is long and the corresponding maintenance cost is relatively low.

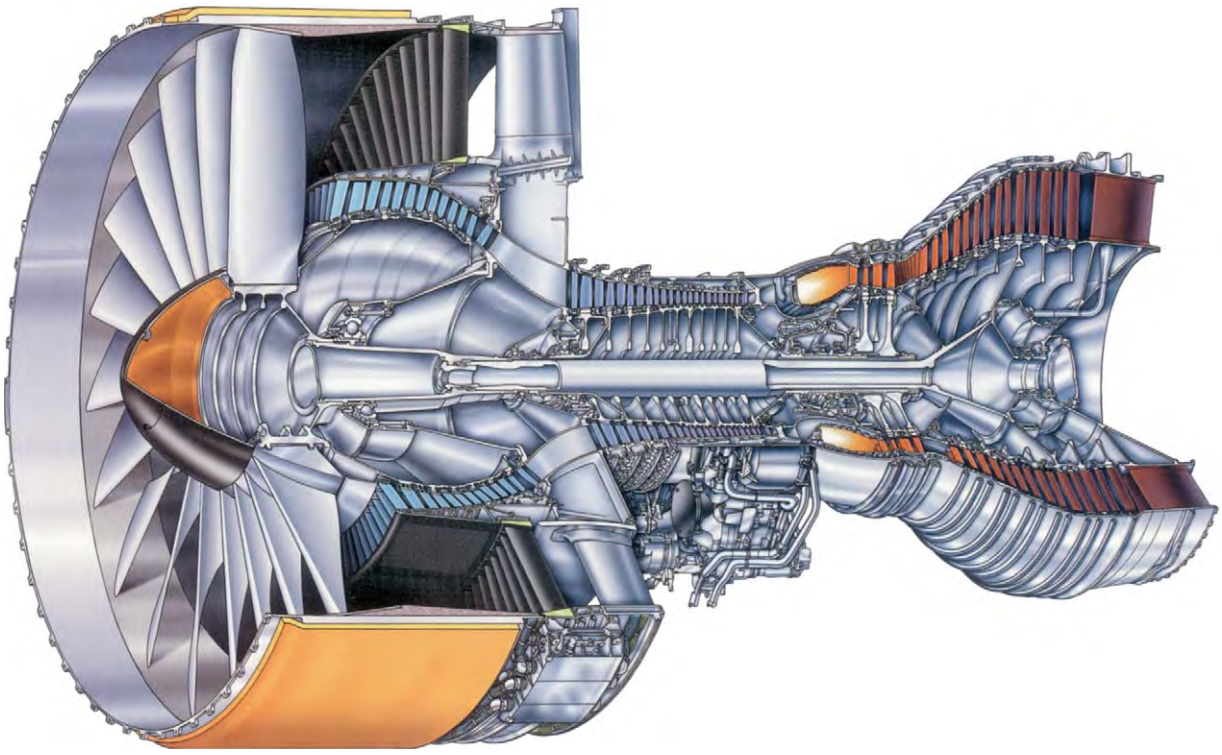

FIGURE 2 A modern jet engine used to power Boeing 777 aircraft. This is a Pratt and Whitney PW4084 turbofan, which can produce 84,000 lbs (374 kN) of thrust (~ 63 MW at 168 m/s). It has a front-mounted fan of 112 in. (2.85 m) in diameter, a flange-to-flange length of 192 in. (4.87 m), and a mass of ~ 15,000 lbs (6804 kg).

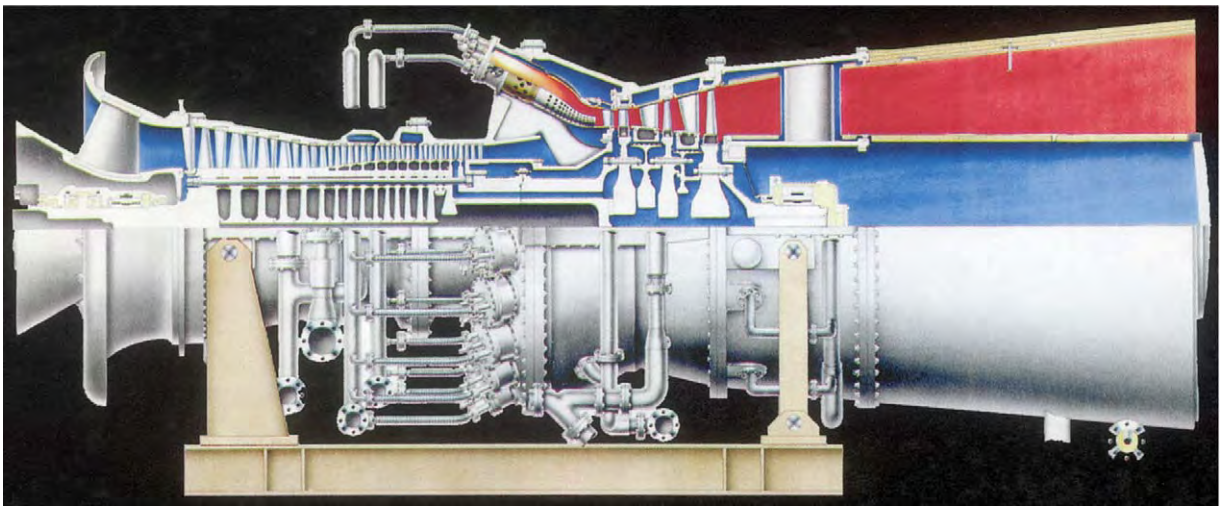

FIGURE 3 A modern land-based gas turbine used for electrical power production and for mechanical drives. This is a General Electric MS7001FA frame machine with a length of ~61 ft (18.6 m) and a mass of ~377,000 pounds (171,000 kg). It produces shaft power of 159 MW (213,140 hp) at 3600 rpm.

(During its early development, the deceiving simplicity of the gas turbine caused problems, until aspects of its fluid mechanics, heat transfer, and combustion were better understood.)

(3) Although the gas turbine must be started by some external means (a small external motor or other source, such as another gas turbine), it can be brought up to full-load (peak output) conditions in minutes, as contrasted to a steam turbine plant, whose startup time is measured in hours.

(4) A wide variety of fuels can be utilized. Natural gas is commonly used in land-based gas turbines, whereas light distillate (kerosene-like) oils power ship and aircraft gas turbines. Diesel oil or specially treated residual oils can also be used, as can combustible gases derived from blast furnaces, refineries, land fills, sewage, and the gasification of solid fuels such as coal, wood chips, and bagasse.

(5) The usual working fluid is atmospheric air. As a basic power supply, the gas turbine requires no coolant (e.g., water).

In the early days of its development, one of the major disadvantages of the gas turbine was its lower efficiency (hence higher fuel usage) when compared to other IC engines and to steam turbine power plants. However, during the past 50 years, continuous engineering development work has pushed the thermal efficiency (18% for the 1939 Neuchatel gas turbine) to approximately 40% for simple-cycle operations and up to 60% for combined-cycle operations (i.e., when combined with a heat-recovery steam-generation unit and a steam turbine). Even more fuel-efficient gas turbines are in the planning stages, with simple-cycle efficiencies predicted as high as 45–47% and combined-cycle machines in the >60% range. These projected values are significantly higher than those for other prime movers, such as steam power plants.

3. GAS TURBINE CYCLES

The ideal gas Brayton cycle (1876, and also proposed by Joule in 1851), shown in graphic form in Fig. 4A as a pressure–volume diagram, is an idealized representation of the properties of a fixed mass of gas (working fluid) as it passes through a gas turbine in operation (Fig. 4B).

A unit mass of ideal gas (e.g., air) is compressed isentropically from point 1 to point 2. This represents the effects of an ideal adiabatic (isentropic) compressor (Figs. 1 and 4B) and any isentropic gas flow deceleration for the case of an aviation gas turbine in flight (Fig. 1A). The ideal work necessary to cause the compression is represented by the area between the pressure axis and the isentropic curve 1–2.

The unit gas mass is then heated at constant pressure from 2 to 3 in Fig. 4 by the exchange of heat input, Q_{23}. This isobaric process is the idealized representation of heat addition caused by the combustion of injected fuel into the combustor in Figs. 1A, 1B, and 4B. The mass flow rate of the fuel is very much lower than that of the working fluid (approximately 1:50), so the combustion products can be neglected as a first approximation.

The unit gas mass is then isentropically expanded (lower pressure and temperature and higher volume) from 3 to 4 in Fig. 4, where $P_4 = P_1$. In Fig. 4B, this represents flow through the turbine (to point 3′) and then flow through the exit nozzle in the case of the jet engine (Fig. 1A) or flow through the power turbine in Fig. 1B (point 4). In Fig. 4, the area between the pressure axis and the isentropic curve 3–3′ represents the ideal work, $W_{33'}$, derived from the turbine. This work must be equal to the ideal compressor work W_{12} (the area bounded by curve 1–2). The ideal "useful work," $W_{3'4}$, in Fig. 4 (the area bounded by the isentropic curve 3′–4) is that which is available to cause output shaft power (Figs. 1B and 4B) or thrust power (Fig. 1A).

The Brayton cycle is completed in Fig. 4 by a constant pressure process in which the volume of the unit gas mass is decreased (temperature decrease) as heat Q_{41} is rejected. Most gas turbines operate in an open cycle mode, in which, for instance, air is taken in from the atmosphere (point 1 in Figs. 1 and 4) and discharged back into the atmosphere (point 4), with exiting working fluid mixing to reject Q_{41}. In a closed-cycle gas turbine facility, the working fluid is continuously recycled by ducting the exit flow (point 4) through a heat exchanger (shown schematically in Fig. 5) to reject heat Q_{41} at (ideally) constant pressure and back to the compressor inlet (point 1).

Because of its confined, fixed-mass working fluid, the closed-cycle gas turbine is not an internal combustion engine. The combustor (shown in Fig. 1) is replaced with an input heat exchanger, supplied by an external source of heat. Closed-cycle designs were developed in the 1960s for providing power to space satellites on deep space missions, using a radioisotope heat source to heat helium gas

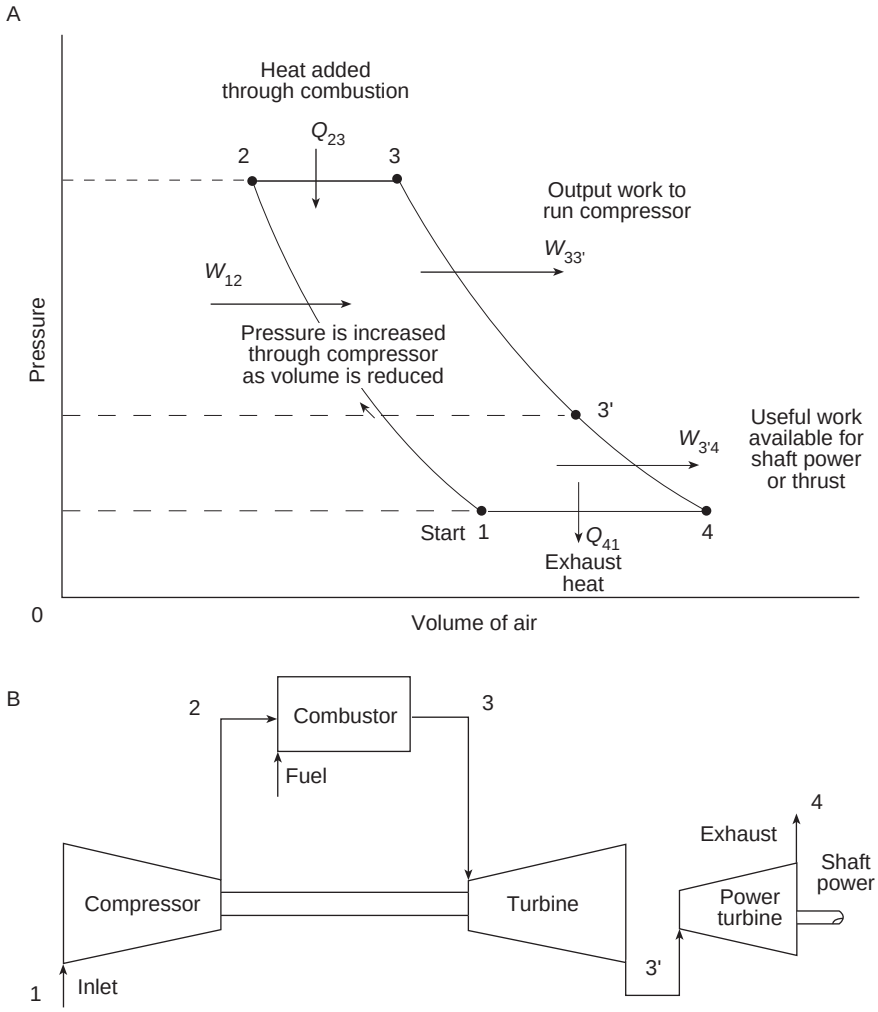

FIGURE 4 (A) Brayton cycle pressure-volume diagram for a unit mass of working fluid (e.g., air), showing work (W) and heat (Q) inputs and outputs. (B) Gas turbine schematic showing relative points from the diagram for the Brayton cycle.

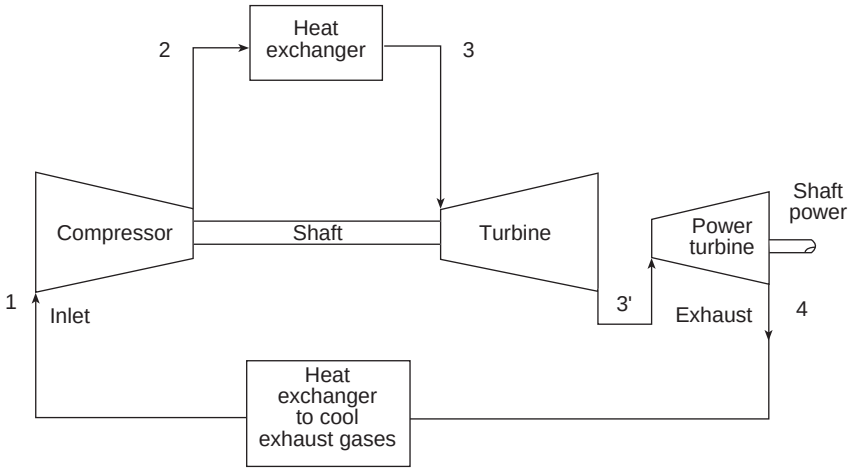

FIGURE 5 Closed-cycle system. Heat exchangers interact with external heat reservoirs.

as the gas turbine working fluid and a space radiator for cycle heat rejection. Development work to use a nuclear reactor (e.g., a pebble bed reactor) to heat helium gas in a closed-cycle gas turbine to be used for electric utility power generation in the 100 MW range is in progress.

The ideal Brayton cycle thermal efficiency, η_B, can be shown to be

$$\eta_B = 1 - \frac{T_4}{T_3} = 1 - \frac{1}{r^{(k-1)/k}}, \tag{1}$$

where the absolute temperatures T_3 and T_4 correspond to points 3 and 4 in Fig. 4, $k = c_p/c_v$ is the ratio of specific heats for the ideal gas, and r is the compressor pressure ratio,

$$r = \frac{P_2}{P_1}. \tag{2}$$

Thus, the Brayton-cycle thermal efficiency increases with both the turbine inlet temperature, T_3, and compressor pressure ratio, r. Modern gas turbines have pressure ratios as high as 30:1 and turbine inlet temperatures approaching 3000°F (1649°C).

The effect of real (nonisotropic) compressor and turbine performance can be easily seen in the expression for the net useful work $W_{net} = W_{3'4}$

$$W_{net} = \eta_T c_p T_3 \left[1 - \frac{1}{r^{(k-1)/k}}\right] - \frac{c_p T_1}{\eta_C}[r^{(k-1)/k} - 1], \tag{3}$$

where c_p is the specific heat at constant pressure, and η_T and η_C are the thermal (adiabatic) efficiencies of the turbine and compressor, respectively. This expression shows that for large W_{net} one must have high values for η_T, η_C, r, and T_3. For modern gas turbines, η_T can be as high as 0.92–0.94 and η_C can reach 0.88.

A gas turbine that is configured and operated to closely follow the ideal Brayton cycle (Figs. 4 and 5) is called a simple-cycle gas turbine. Most aircraft gas turbines operate in a simple-cycle configuration since attention must be paid to engine weight and frontal area. However, in land or marine applications, additional equipment can be added to the simple-cycle gas turbine, leading to increases in thermal efficiency and/or the net work output of a unit. Three such modifications are regeneration, intercooling, and reheating.

Regeneration involves the installation of a heat exchanger (shown in Fig. 6A) through which the turbine exhaust gases (point 4 in Fig. 6A) pass. The compressor exit flow (point 2 in Fig. 6A) is then heated in the exhaust gas heat exchanger (regenerator, and also called a recuperator) before the flow enters the combustor. If the regenerator is well designed—that is, if the heat exchanger effectiveness is high and the pressure drops are small—the cycle efficiency will be increased over the simple-cycle value. However, its relatively high cost must also be taken into account. Regenerated gas turbines can increase efficiency by 5–6 percentage points and are even more beneficial for part-load operation.

Intercooling also involves the use of a heat exchanger. An intercooler, as shown in Fig. 6B, is a heat exchanger that cools compressor gas during the compression process. For instance, if the compressor consists of a high-pressure unit and a low-pressure unit, the intercooler can be mounted between them (Fig. 6B) to cool the flow and decrease the work necessary for compression in the high-pressure

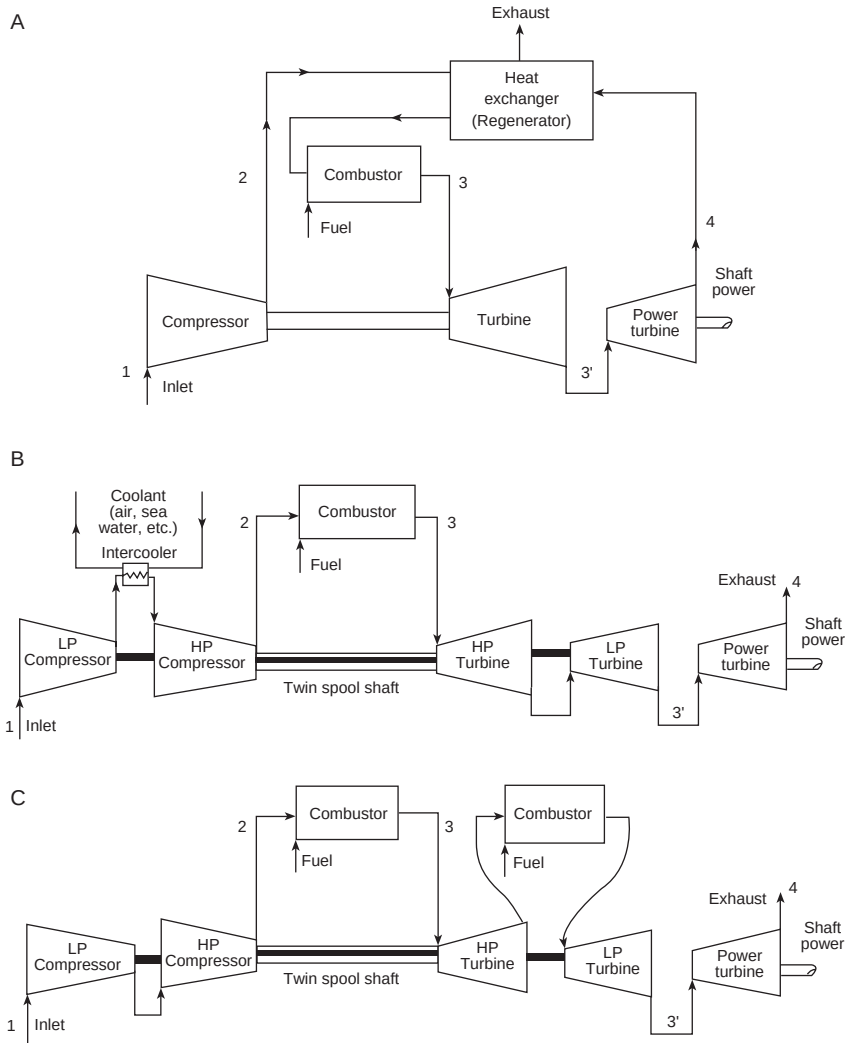

FIGURE 6 Modifications available for the simple Brayton cycle.

compressor. The cooling fluid could be atmospheric air or water (e.g., sea water in the case of a marine gas turbine). The net work output of a given gas turbine is increased with a well-designed intercooler. Studies of gas turbines equipped with extensive turbine convective and film cooling show that intercooling can also allow increases in thermal efficiency by providing cooling fluid at lower temperatures, thereby allowing increased turbine inlet temperatures [T_3 in Eq. (1)].

Reheating, as shown in Fig. 6C, occurs in the turbine and increases turbine work without changing compressor work or exceeding the material temperature limits in the turbine. If a gas turbine has a high-pressure turbine and a low-pressure turbine, a reheater (as shown in Fig. 6C, usually another combustor) can be used to "reheat" the flow between the two turbines. Reheat in a jet engine is accomplished by adding an afterburner at the turbine exhaust, thereby increasing thrust, with a greatly increased fuel consumption rate.

A combined-cycle gas turbine (CCGT) power plant, shown schematically in Fig. 7, is essentially an electrical power plant in which a gas turbine provides useful work (W_B) to drive an electrical generator. The gas turbine exhaust energy (Q_{BR}) is then used to produce steam in a heat exchanger (called a heat recovery steam generator) to supply a steam turbine whose useful work output (W_R) provides the means to generate more electricity. [If the steam is used for heat (e.g., heating buildings), the unit would be called a cogeneration plant.] Figure 7 is a simplified thermodynamic representation of a CCGT and shows it to be two heat engines (Brayton and Rankine) coupled in series. The "upper" engine is the gas turbine (represented as a Brayton-cycle heat

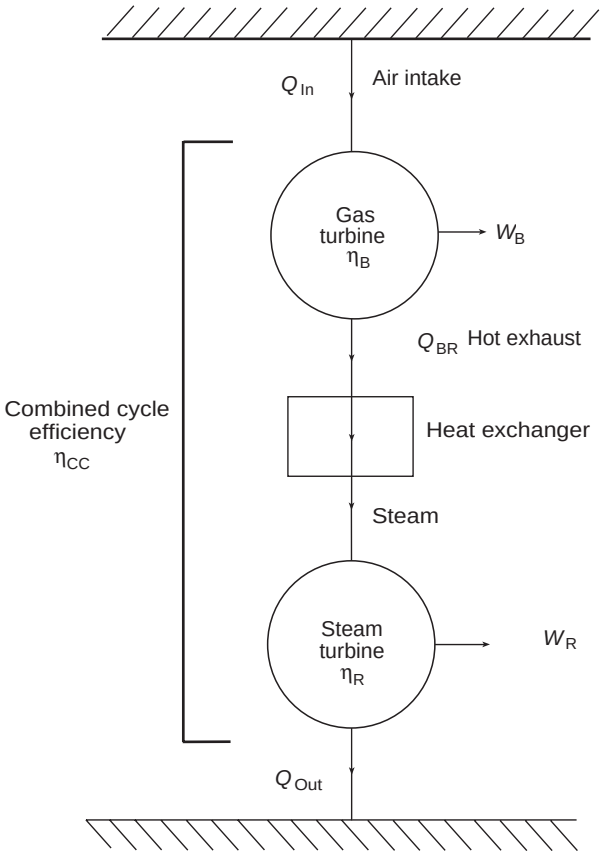

FIGURE 7 Schematic of a combined-cycle gas turbine plant. Overall efficiency (η_{cc}) is a combination of the efficiency of the Brayton gas turbine cycle (η_B) and the Rankine steam turbine cycle (η_R). Total combined-cycle efficiency $\eta_{cc} = \eta_B + \eta_R - \eta_B\eta_R$.

engine), whose energy input is Q_{In}. It rejects heat (Q_{BR}) as the input energy to the "lower" engine (the steam turbine, represented as a Rankine-cycle heat engine). The Rankine heat engine then rejects unavailable energy (heat) as Q_{Out} by means of a steam condenser. The combined thermal efficiency (η_{CC}) can be derived fairly simply and is given as

$$\eta_{CC} = \eta_B + \eta_R - \eta_B\eta_R, \tag{4}$$

where $\eta_B = W_B/Q_{In}$ and $\eta_R = W_R/Q_{BR}$ are the thermal efficiencies of the Brayton and Rankine cycles, respectively. Taking $\eta_B = 40\%$ (a good value for modern gas turbines) and $\eta_R = 30\%$ (a reasonable value under typical CCGT conditions), the sum minus the product in Eq. (4) yields $\eta_{CC} = 58\%$, a value of combined-cycle efficiency greater than either of the individual efficiencies.

This remarkable equation gives insight into why CCGTs are so efficient. The calculated value of η_{CC} represents an upper bound on an actual CCGT, since Eq. (4) does not account for efficiencies associated with transferring Q_{BR} (duct losses, irreversibilities due to heat transfer, etc.). Actual efficiency values as high as 52 to 57% have been attained with CCGT units during the past few years, thus coming close to values given by Eq. (4).

4. GAS TURBINE COMPONENTS

A greater understanding of the gas turbine and its operation can be gained by considering its three major components (Figs. 1, 2, and 3): the compressor, the combustor, and the turbine. The features and characteristics of these components are briefly examined here.

4.1 Compressors and Turbines

The turbine and compressor components are mated by a shaft, since the former powers the latter. A single-shaft gas turbine has but one shaft connecting the compressor and turbine components. A twin-spool gas turbine has two concentric shafts, a longer one connecting a low-pressure compressor to a low-pressure turbine (the low spool), which rotates inside a shorter, larger-diameter shaft (e.g., see Figs. 6B and 6C). The latter connects the high-pressure turbine with the higher pressure compressor (the high spool), which rotates at higher speeds than the low spool. A triple-spool engine would have a third, intermediate-pressure compressor-turbine spool.

Gas turbine compressors can be centrifugal, axial, or a combination of both. Centrifugal compressors (radial outflow) are robust, generally cost less, and are limited to pressure ratio of 6 or 7 to 1. They are found in early gas turbines or in modern, smaller gas turbines.

The more efficient, higher capacity axial flow compressor is used on most gas turbines (e.g., Figs. 2 and 3). An axial compressor is made up of a number of stages, with each stage consisting of a row of rotating blades (airfoils) and a row of stationary blades (called stators) configured so the gas flow is compressed (adverse or unfavorable pressure gradient) as it passes through each stage. It has been said that compressor operation can founder on a metaphoric rock, and that rock is called stall. Care must be taken in compressor operation and design to avoid the conditions that lead to blade stall, or flow separation. The collective behavior of blade separation can lead to compressor stall or surge, which manifests itself as an instability of gas flow through the entire gas turbine.

Turbines are generally easier to design and operate than compressors, since the flow is expanding in an overall favorable pressure gradient. Axial flow turbines (Figs. 2 and 3) will require fewer stages than an axial compressor for the same pressure change magnitude. There are some smaller gas turbines that utilize centrifugal turbines (radial inflow) but most utilize axial turbines (e.g., Figs. 2 and 3).

Turbine design and manufacture are complicated by the need to ensure turbine component life in the hot gas flow. The problem of ensuring durability is especially critical in the first turbine stage, where temperatures are highest. Special materials and elaborate cooling schemes must be used to allow metal alloy turbine airfoils that melt at 1800 to 1900°F (982 to 1038°C) to survive in gas flows with temperatures as high as $T_3 = 3000$°F (1649°C).

4.2 Combustors

High-pressure air leaves the compressor (Figs. 1, 2, and 3) and enters the gas turbine combustor, where, in a very short space and at high flow rates, heat is added to it by the combustion of fuel (gas or liquid). Modern gas turbine combustors are of three types: cans (individual cylindrical chambers arranged circumferentially), annular (consisting of a cylindrical single inner and single outer shroud), and can–annular (a fusion of the can and annular geometrics). Because of the high temperatures in the combustors, combustor parts are regularly inspected and will require repair and/or replacement during the lifetime of the gas turbine.

Compared to some other energy converters [such as the Diesel or Otto (gasoline) engines listed in Table I], gas turbines produce very low levels of combustion pollution, such as unburned fuel, carbon monoxide, oxides of nitrogen (NO_x), and smoke. New electric power plants using gas turbines drastically reduce area pollution when they replace older steam- or diesel-powered plants. For instance, due to new strict environmental restrictions being placed on Alaskan cruise vessels, new cruise ships are installing gas turbines, as the only means available to comply with the emission levels that have been put in place.

Gas turbine combustion systems must have very low pressure losses and be carefully designed to provide a stable flow, free of pressure pulsations and characterized by uniform exit temperatures (flow "hot spots" can damage turbine gas path parts, such as stationary vanes). New electric power gas turbines have experienced serious pressure oscillations with new "lean premixed" combustion systems designed to meet lower NO_x emission regulations. System pressure oscillations brought about by combustion mechanisms that not yet fully understood have been given descriptive names ranging from humming to hooting, screech, chub, buzz, and rumble. Manufacturers have taken a number of paths to deal with this problem (which, if left unattended, can shake a machine apart), such as the use of catalysis, resonators, fuel schedule timing, active controls, or simple cutting back on power output levels.

5. GAS TURBINE USAGE

Although they are used in an ever-increasing variety of applications, gas turbines are used extensively in two areas: aviation and electric power generation.

It is difficult to remember a time when the aviation gas turbine—the jet engine—was not part of aviation. Before jet engines, an aviation piston engine manufacturer could expect to sell 20–30 times the original cost of piston engines, in aftermarket parts. With the advent of the jet engine, this aftermarket value dropped to 3–5 times the original cost (an important reduction that made air travel affordable and reliable, and airlines profitable). Technology and airline/military demands made on jet engine manufacturers have resulted in even longer lasting engine components, dropping the aftermarket value even lower.

A well-managed airline will regularly try to keep a jet-powered plane in the air as much as 18 h per day, 365 days a year, to produce revenue. The airline expects the engines, if well-maintained, to remain in service and on the wing for up to 15,000–20,000 h of operation, depending on the number of takeoffs and landings experienced by the plane. After this period (or time between overhauls), the jet engine will be taken off of the wing and overhauled and usually hot-section (combustor and turbine) parts will be replaced as needed. (An experienced air traveler can generally believe the numbers presented here, by reflecting how few (if any) times he or she has experienced an in-flight shutdown of a jet engine while flying.)

The life of electric power gas turbines are much longer that those of their aviation counterparts, because they run at constant speeds and are not usually subjected to the wide range of power settings experienced by jet engines. Modern power plant operators expect trouble-free units to run as long as 30,000–50,000 h, depending on load conditions, maintenance procedures, and the level of turbine

inlet temperatures. Overhauls usually involve replacement or refurbishment of hot-section parts in the combustor and turbine sections. Normally, these will take place approximately three or more times during the life of a gas turbine unit.

In summary, the power spectrum of the gas turbine units produced is larger than that of most other prime movers, spanning a range that varies by a factor of 10,000. New microturbines [weighing little more than 100 pounds (45 kg)] are being produced in the range of ~25 kW to provide electrical power and heat for fast-food restaurants. Base-load electric power gas turbines as large as 250 MW [weighing as much as 330 tons (300,000 kg)] are being installed to drive electric generators and to supply heat for steam turbines in combined-cycle operations, with resultant thermal efficiencies approaching 60%. In an evolving role as the engineer's most versatile energy converter, gas turbines produce thrust power [as much as 120,000 pounds thrust (534,000 N) for the largest commercial jet engines] to propel most of the world's military and commercial aircraft. In closing, it can be noted that at the time this article is being written, the annual worldwide value of production of gas turbines for shaft power applications (electric power, ship propulsion, natural gas pipeline compression) is approximately equal to that for aviation thrust power applications.

Glossary

back-pressure turbine A steam turbine that discharges the steam (usually at $p > 1$ bar) into a pressurized system.
condensing turbine A steam turbine at whose exit the steam is condensed in an air- or water-cooled condenser; the pressure in the condenser (and at the turbine exit) is usually less than 1 bar.
degree of reaction (R_ρ) Ratio of the static enthalpy drop in the rotor to the total enthalpy drop in the stage.
dimensional analysis A mathematical theory that derives dimensionless groups by proper combination of dimensional parameters, with the goal of extracting from these groups further and more general physical information.
extraction turbine A steam turbine in which a portion of the working fluid is tapped between stages and used for purposes other than generating mechanical power.
flow coefficient (φ) Ratio of the local average meridional absolute velocity component to the local peripheral velocity.
head coefficient (ψ) Ratio of the local average tangential absolute velocity component to the local peripheral velocity.
impulse stage A stage with zero degrees of reaction.
isentropic A thermodynamic transformation in which the initial and final points have the same specific entropy.
reaction stage A stage with a degree of reaction larger than zero.
secondary flows Conventionally defined as all fluid motions extraneous to the ideal "mean" flow path.
similarity The property of two "objects" (physical dimensions, components, or flow patterns) that have the same ratio of a certain number of homologous characteristic features.
solidity (σ) At a certain radius, the ratio of the blade chord to the interblade spacing.
specific diameter (d_s) A dimensionless group linking one characteristic dimension, volumetric flow rate, and stage enthalpy drop.
specific speed (n_s) A dimensionless group linking angular velocity, volumetric flow rate, and stage enthalpy drop.
supercritical A steam turbine in which the feed steam is above the critical conditions.
swirl The tangential component of the absolute or relative velocity.

Turbines are machines that convert the energy carried by a continuous flow of fluid into mechanical shaft rotational power. Their essential feature is that they do not contain parts in alternating motion; therefore, the flow of both mass and energy through them, except for secondary transitory phenomena, may be considered steady. This is in contrast to piston-based machinery, where the energy exchange is fundamentally linked to the alternating motion of the piston. Traditionally, and in spite of the fact that the basic physics of the energy exchange is not much different, hydraulic turbines, where the working fluid is incompressible, are treated separately from gas and steam turbines, where compressibility phenomena play a major role in the fluid/machine coupling. In compressible flow turbines, it makes little difference, from a theoretical point of view, whether the working fluid is a "gas" that follows an ideal gas law or a "steam" described by one of the variants of van der Waals's equation of state. Physically, the only difference is that gases are farther away from their two-phase region, so that the variation of their specific heat with temperature is less complicated. But in practice, there are enough differences in the

design procedures to grant separate treatment of gas and steam turbines.

1. SOME BASIC CONCEPTS

1.1 The Flow through a Turbine

Figure 1 shows a schematic cross section of an axial (Fig. 1A) stage and a radial stage (Fig. 1B) of a modern steam turbine. High-pressure steam enters the machine at station "in" (throttle valve exit section), passes through the inlet channel, and reaches the stator inlet (station "0"). The stator accelerates the flow by expanding it by a fraction $\beta_{st}\,(1 \geq \beta_{st} > 0)$ of the total stage pressure drop and introduces a tangential velocity component (inlet swirl). The steam jets exiting the stator (station "1") impinge on the rotoric blades that deviate the flow so as to decrease this inlet swirl and, thus, absorb rotational momentum. At rotor exit (station 2), the steam is at a lower pressure and energy level than at station 0 and is discharged through the outlet scroll or diffuser channel. Station "out" is the outlet section of the stage. The purpose of the inlet channel is to guide the flow from the turbine inlet port to the statoric vanes with the minimum possible loss in total pressure. If the first stage after the admission throttle is axial, the inlet is usually shaped as a pseudo-conical transition piece between the inlet duct and the (larger in diameter) stator. In this case, no flow deviation is imposed and only a modest acceleration is attained. For intermediate axial stages, the inlet is missing and the flow from the exit of the previous stage flows directly onto the stator of the following stage. Radial turbines can be centripetal (flow inward) or centrifugal (flow outward). Because the only significant centrifugal application is the Ljüngstrøm turbine, shown in Fig. 2 and discussed at the end of this section, "radial turbine"

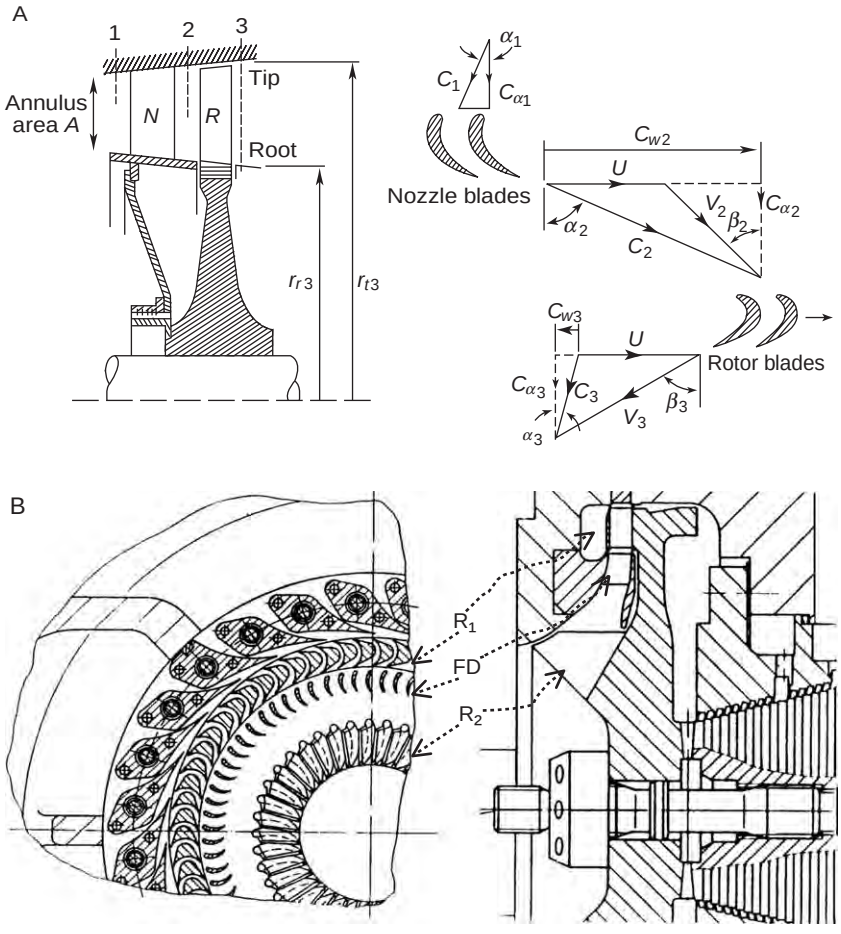

FIGURE 1 (A) Axial turbine stage. (B) Radial turbine stage. Notice the two-stage rotor (R_1 and R_2) and the flow deviator (FD).

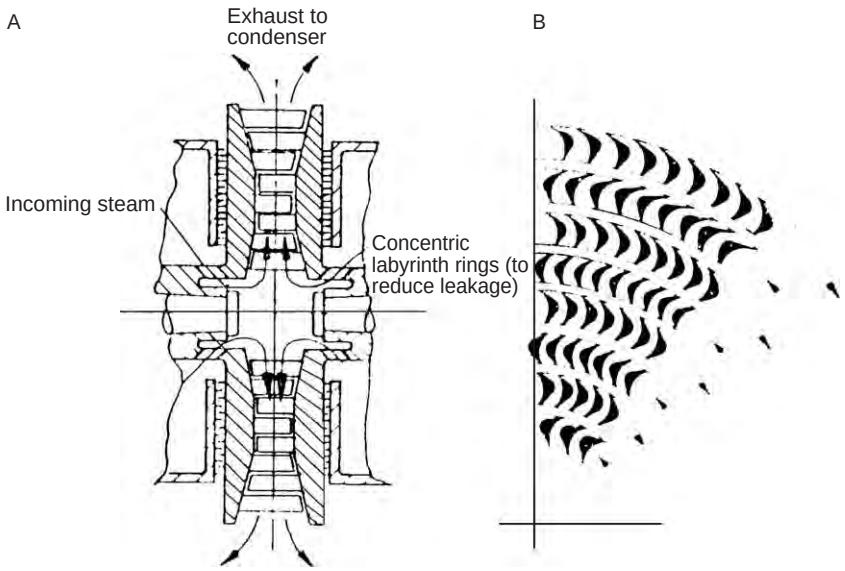

FIGURE 2 The Ljüngstrøm radial turbine. (A) Meridional section through turbine. (B) Blading arrangement and directions of rotation.

implies centripetal in the remainder of this article. Radial turbines are usually single-staged with a tangential inlet. The flow is admitted into the statoric vanes through a scroll of variable cross section that accommodates the decreasing mass flow rate in the tangential direction.

The purpose of the stator is as follows:

- To induce a tangential velocity component (swirl) in the flow
- To transform a portion β_{st} of the stage expansion ratio $\beta = p_{in}/p_{out}$ into kinetic energy
- To attain the above with the minimum possible irreversible dissipation
- To serve as an auxiliary structural support for the casing

Stators consist of a large number of rather thick, curved, airfoil-like blades that turn the oncoming flow, whose main flow component is parallel to the turbine axis, in the tangential direction. Axial and radial stators differ in shape, as shown in Fig. 3. If large variations of the steam mass flow rate are foreseen, variable geometry stators are often employed where the individual vanes may rotate about a radial (in axial turbines [Fig. 3C]) or meridional (in radial turbines [Fig. 3D]) axis.

The purpose of the rotor is as follows:

- To extract energy from the main flow by recovering its tangential velocity component
- To transfer this energy to a rotating shaft
- To attain the above with the minimum possible irreversible dissipation

Rotors consist of a large number of curved, airfoil-like blades that turn the oncoming flow so as to cause a decrease in its angular momentum, thereby generating a tangential force on each blade. The blades are solidly attached to the turbine shaft by a disk whose only purpose is to transfer the resulting torque. Axial blades resemble twisted airfoils, with their chord decreasing from hub to tip, and are attached to the disk on their hub side. Radial blades look more like paddles attached to the disk on their hub side and strongly twisted in three dimensions. Axial blades can be forged onto the disk, but more commonly they are individually inserted into proper circumferential grooves machined on the external surface of the disk and are firmly held in position by spacers and stiffeners. For smaller rotors, they may be machined together with the disk from a single, cylindrical, forged "raw" disk. Radial blades are most commonly an integral part of the rotor, being forged or machined from one initial pseudo-conical billet.

It is often convenient, for design reasons, to let the flow exit the stage with substantial kinetic energy. This lowers the stage exit pressure and increases the stage expansion ratio β_s. In addition, it allows handling the same mass flow rate with a smaller flow passage area (a smaller diameter implies a less costly machine). The kinetic portion of the total enthalpy can be partialy recovered in the diffuser, which is a passage of increasing flow area (visible in

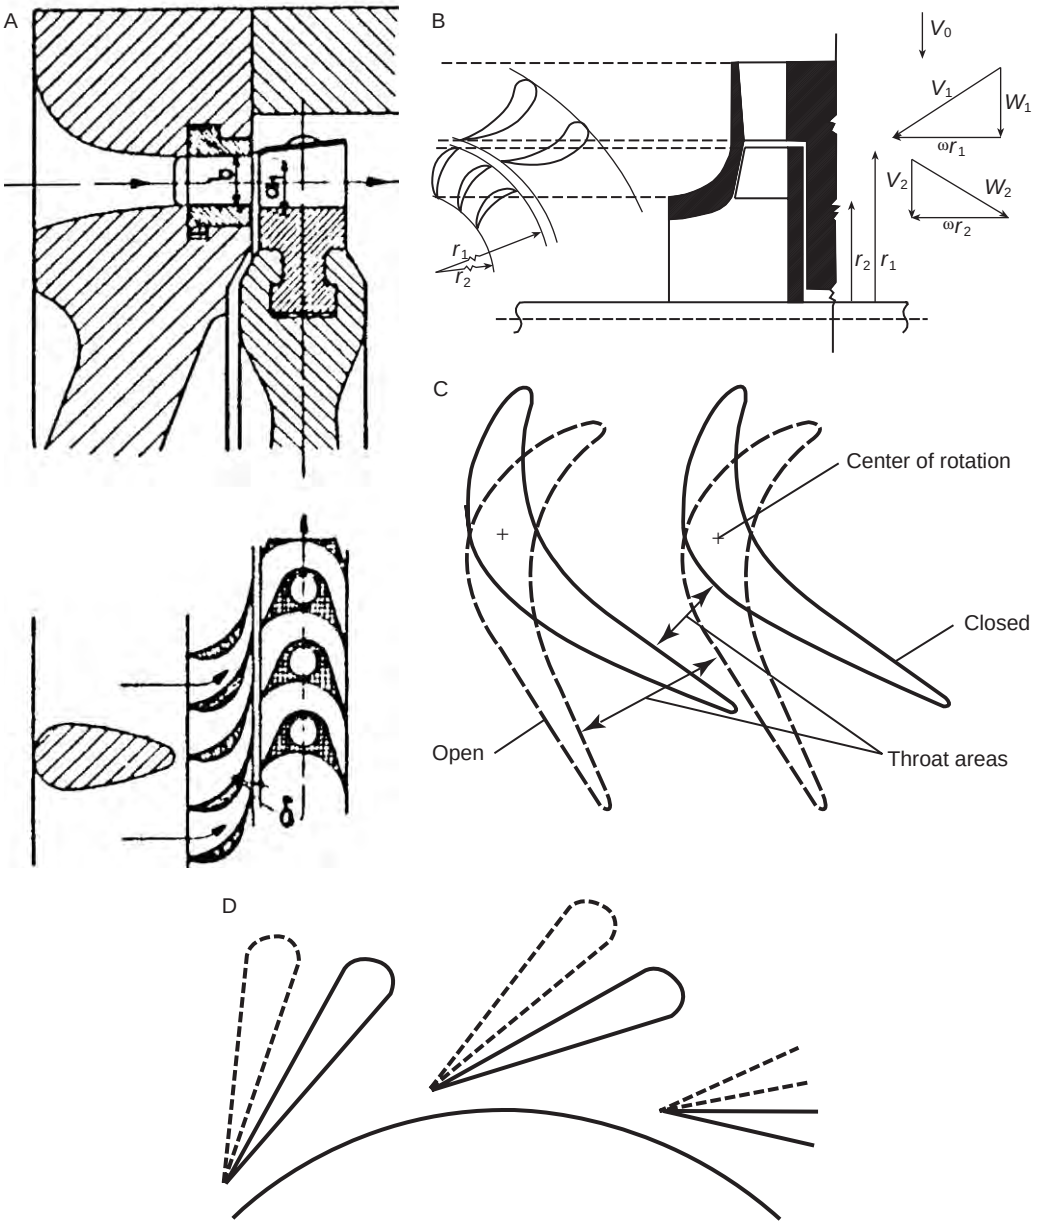

FIGURE 3 (A) Axial stage geometry. (B) Radial stage geometry. (C) Variable geometry axial stator. (D) Variable geometry radial stator.

Figs 1A and 1B). If the area increase is obtained by increasing the average radius, there is the additional advantage that the exit swirl is recovered as well.

Ljüngstrøm turbines (Fig. 2), are atypical in more than one sense. The steam enters the machine radially from slots in the casing or in the shaft and proceeds radially outward. The wing-like blades are inserted in two counterrotating disks, with the arrangement being such that each blade row rotates between two rows attached to the opposite disk. Each blade row is a rotor in the sense that it extracts energy from the flow and provides it to the shaft, and is a stator in the sense that it introduces a (relative) tangential velocity component for the next blade row. Ljüngstrøm turbines are used when axial size constraints are very stringent because their power density is higher than that of other types of turbines. However, their use is restricted to lower mass flow rates due to blade length limitations.

1.1.1 Partial Admission

If the throttle pressure is very high, the incoming steam into the first stage has a very high density;

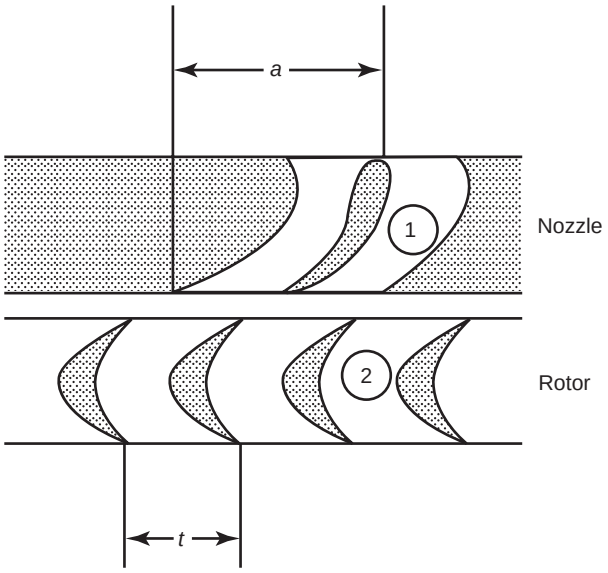

FIGURE 4 Partial admission.

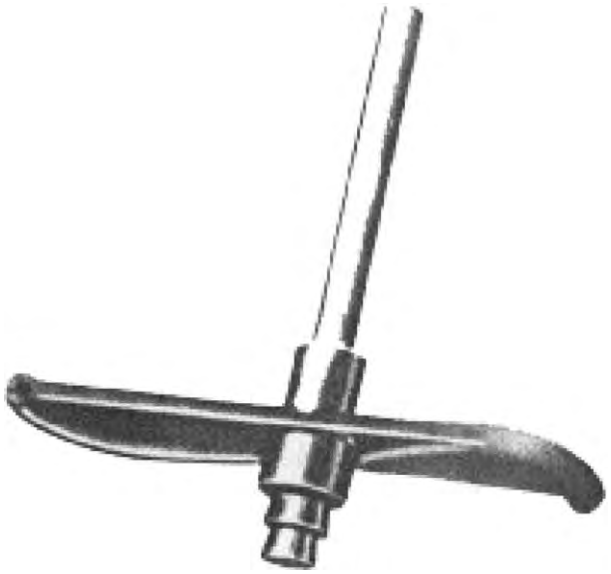

FIGURE 5 Avery's 1831 reaction turbine.

therefore, even for large flow rates, the required passage area may be relatively small. Because the external diameter (both in axial and radial stages) is selected on the basis of the best attainable efficiency and provides an optimal d_s, this may lead to extremely low blade heights, which increase the end wall losses and decrease the practical stage efficiency. To uncouple (at least to a certain extent) the blade height from the external diameter, the statoric nozzles of the first stage of class 4 and 5 turbines are so constructed as to limit the steam injection angle to a value $a < 360^\circ$ (Fig. 4). Thus, only the statoric channels within this angle a will be active, and for a given external diameter, the blade height can be increased of $1/a$ without efficiency penalties. This configuration is called partial admission and can be introduced only in pure impulse stages, where the steam in the rotoric passages is not subject to a streamwise Δp (otherwise, massive leakage into the inactive adjacent channels would destroy the regularity of the flow).

1.2 Brief Historical Background

The word "turbine" was first proposed in its modern usage by the French Claude Burdin in 1820, with reference to hydraulic machines. Although the first steam turbines in commercial service were those installed in the northern United States by William Avery in 1831 to power some sawmills (Fig. 5), the idea of exploiting the "motive power" of live steam is much older. In the first century BC, Hero of Alexandria, in his treaty "De Re Pneumatica" (literally "On Fluid Flow"), described what in modern terms would be defined as a "single-stage, pure reaction turbine" (Fig. 6). Hero, who seemed to imply that the "turbine" had been actually built prior to his description of it, provided no indication about practical uses for this device, although other sources indicate that similar machines were used to power the opening mechanisms of the heavy bronze doors of some Egyptian or Babylonian temples. (This indicates that the turbine provided ~ 0.5 kW with a steam mass flow rate of ~ 0.01 kg/s, which seems unfeasible for those times because it implies a nozzle diameter of ~ 15 cm.) Be that as it may, the technological level of those times clearly had no use for such machines, and for centuries hydraulic and wind turbines were the only turbomachines employed in power generation. Much later, there were isolated attempts to convert the motive energy of steam (now called stagnation exergy) to mechanical shaft power. Giovanni Branca's machine (in Italy in 1629 [Fig. 7A]) was actually inspired by an earlier illustration (from 1551) contained in a sort of technological almanac compiled by the Arab historian Taqi-al-Din. John Dumbell's proposal (in England in 1808 [Fig. 7B]), although in essence based on the same principle, was technologically much more advanced. However, neither machine ever produced any net power. In 1848, the Scot Robert Wilson patented a series of steam turbines, one of which

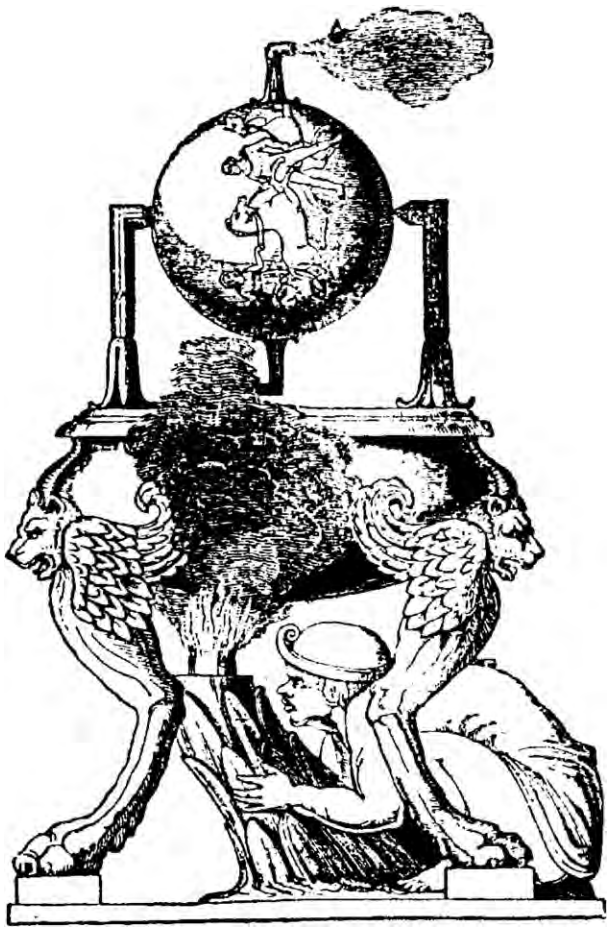

FIGURE 6 Hero's "steam turbine" (probably conceived before the first century BC) in a 16th-century rendering.

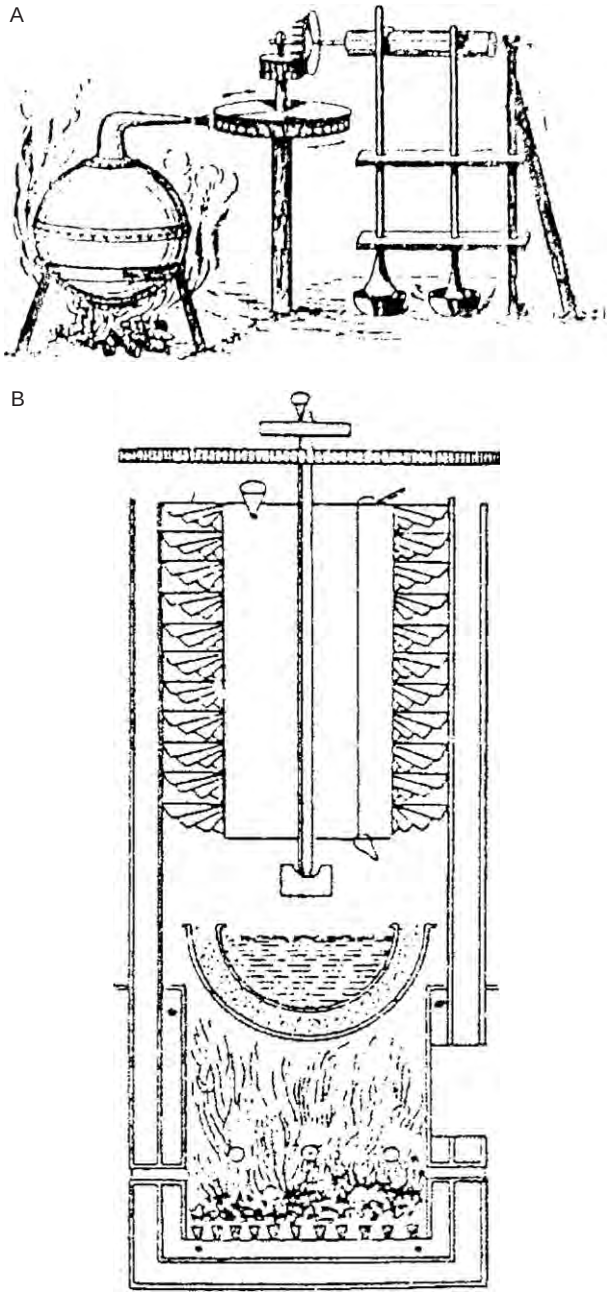

FIGURE 7 (A) Branca's 1629 steam turbine-powered mill. (B) Dumbell's 1808 steam turbine.

endowed of a radial inlet. In 1875, Osborne Reynolds designed and later built a multistage steam turbine (Fig. 8), and between 1880 and 1890, the Briton Charles Parsons and the Swede Carl-Gustav de Laval introduced the first multistage reaction turbine (Fig. 9 [this type of arrangement is still today sometimes called "Parsons"]) and the impulse turbine (Fig. 10), respectively. Between 1890 and 1897, de Laval installed some of his turbines on steam-powered ships. During the same years, the French Charles Rateau introduced the first multistage impulse turbines, and the American Charles Curtis introduced the first double-bladed impulse rotors. In 1891, Parsons introduced the condenser, a sealed tank bottoming the turbine where the steam condensed on banks of water tubes, effectively lowering the discharge pressure of the turbine and allowing for a remarkable increase of the specific work output. In 1910, the Swede Berger Ljüngstrøm presented his axial inlet centrifugal turbine. The modern development of steam turbines began after the second decade of the 20th century when large industrial groups such as General Electric, Allis–Chalmers, Westinghouse, and Brown–Boveri built turbine-powered electricity generation plants. Currently, the vast majority of fossil-fueled thermoelectrical conversion plants employ steam turbines as mechanical drivers.

1.3 Steam Conditions and Fundamental Classification

Modern turbines are designed for a variety of applications and use steam at different inlet conditions, as shown in Tables I and II. Figure 11 reproduces the so-called Mollier chart, where the thermodynamic properties of steam are plotted on an entropy/temperature diagram. Higher inlet steam pressures and temperatures would generally increase the efficiency of the cycle in which the turbine is inserted, but for technological and economical reasons, it is unlikely that during the next 10 to 15 years or so an increase of more than 50 K over the current top inlet temperatures of 550 to 600 K will occur. This article makes reference essentially to industrial and power generation applications. Typical values for admission steam conditions are shown in Table I together with approximate indications of the power range.

Steam turbines may be classified according to several criteria. All of these criteria have some practical or theoretical relevance, but none is universally accepted. Table II summarizes the seven most common classification criteria.

1.3.1 Supercritical Turbines

A turbine stage is said to be "supercritical" when the steam conditions at its inlet are above the critical point. Although the higher temperatures do not pose particular problems in the first stages, the high pressures increase the demand for sophisticated design solutions in the boiler, so that supercritical units are costly and used less frequently. Of course, the advantage of using a supercritical high-pressure section is a larger power output for the same mass flow rate, that is, a higher power density.

1.3.2 Condensing versus Noncondensing Turbines

A condensing steam turbine is provided with a vacuum device at its exit (the condenser) where the forced flow of an external coolant (water or air) maintains the outlet pressure at a level dependent only on the coolant inlet and outlet temperatures. In practice, the exhaust steam is condensed on a bank of "cold" tubes (Fig. 12) and the condensate is collected in the so-called cold well. Because the condenser is otherwise sealed, the pressure in the cold well (and in the whole condensing chamber) is the saturation pressure corresponding to the condensate temperature, which for current applications ($T_{coolant} = 25$–60°C) is lower than atmospheric ($p_{sat} = 0.01$–0.2 bar). The increased pressure differential across the turbine leads to a larger enthalpy drop of the steam and to a higher shaft power for the same mass flow rate. Most turbines in power generation plants are of the condensing (or C) type.

A noncondensing (or back-pressure) turbine has no condenser, and its exhaust steam is used directly for process purposes. Specific processes require different steam temperatures, but the range of exhaust steam pressures generally varies between 1.5 and 10.0 bars.

Most of the so-called cogeneration units in use by the industry are of the noncondensing (or NC) type.

For the same rated power output and inlet conditions, NC turbines are much more compact than C turbines because the steam at the former's outlet has a much lower specific volume. For large class 5 turbines, the size of the exhaust end limits the acceptable steam volumetric flow through the final stages because at the usual rotational regimes (1500/1800 or 3000/3600 rpm) "long" blades (≥ 1 m) are subject to excessive centrifugal stresses. Therefore, the largest units (especially in nuclear plants) are built in a double-flow configuration where there are two low-pressure turbine bodies for each medium-pressure one (as shown in Fig. 1A).

TABLE I

Typical Values for Steam Admission Conditions in Modern Turbines

Type of application	Throttle steam pressure (bars)	Throttle steam temperature (°C)	Net power putput per unit (MW)
Geothermal	5–15	150–250	0.5–10
Nuclear	45–70	200–300	50–250
Industrial cogeneration	40–60	400–450	1–50
Electrical power generation	120–180	510–550	50–250
Supercritical	> 220	550–600	50–100

1.3.3 Extraction Turbines

For the overall economy of the steam turbine cycle, it is often convenient to extract a portion of the steam evolving in the turbine before it reaches the turbine exhaust. This involves an extraction turbine. The extraction can be automatic or controlled. In both cases, steam is extracted through openings properly located on the turbine casing between one stage and the other. However, in the automatic extraction case (Fig. 13A), there is no means of controlling the pressure of the extracted stream, whereas in the controlled extraction case (Fig. 13B), a system of throttling valves can modify the pressure drop

TABLE II

Some General Classification Criteria for Steam Turbines

Criterion	Classification	Application field in which the standard is most used
Inlet steam Conditions	*Subcritical*: $p_{in} < 220$ bars and T_{in} usually < 550°C	Design and Process Engineering
	Supercritical: $p_{in} > 220$ bars and T_{in} usually > 550°C	Industry
Exhaust pressure	"C", *condensing* if $p_{\text{exhaust}} < p_{\text{atmospheric}}$ and the exhaust steam is condensed	Design and Process Engineering
	"NC", *noncondensing* otherwise (also called *back-pressure*)	
Main steam flow path	*Axial* if the main steam flow path is parallel to the turbine axis	Design
	Radial otherwise	
Unit power	Class 1: 15–400 kW, noncondensing	Industry
	Class 2: 450–1500 kW	
	Class 3: 2000–15,000 kW	
	Class 4: 15,000–100,000 kW	
	Class 5: > 100,000 kW, reheat and condensing	
Steam extraction	*Extraction* if a portion of the steam is extracted between stages for process purposes other than power generation	Design and Process Engineering
	Non-extraction otherwise	Industry
Inlet steam pressure	*High pressure*, above 40 bars	Design
	Intermediate pressure, 5–40 bars	Industry
	Low pressure, < 5 bars	
Blade design	*Impulse* if the stage pressure drop takes place only in the nozzles	Research
	Reaction otherwise	Design

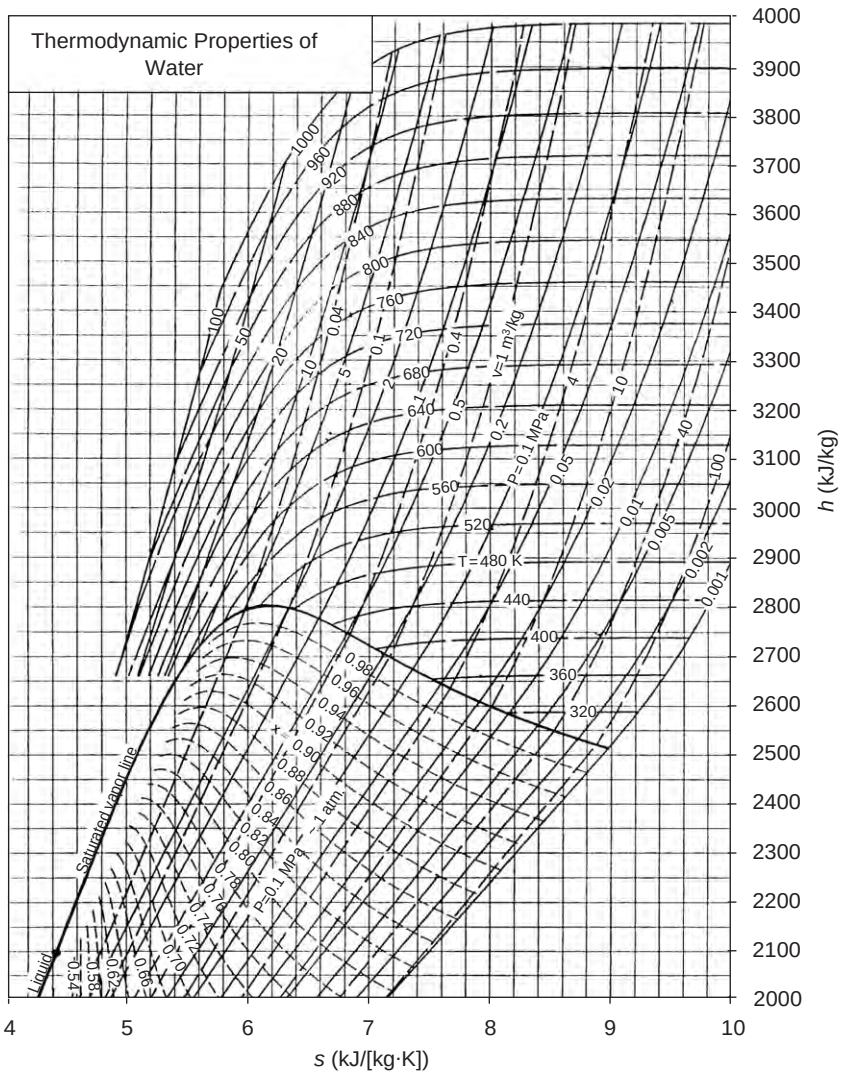

FIGURE 11 The Mollier steam chart. From Stanford University, Department of Mechanical Engineering.

between the extraction point and final use, thereby actively regulating the flow rate of the extracted steam. Extractions are commonly used to preheat the feed water in modern steam cycle-based power plants (class 5 C-type turbines) and to supply process steam in industrial plants (classes 3, 4, and 5, usually C-type turbines).

2. *ENERGY TRANSFER IN A TURBINE*

2.1 Expansion of a Fluid through a Turbine: Stage Efficiency

The flow through a turbine stage is usually modeled as an adiabatic expansion because the contact time of the fluid with the statoric and rotoric blades is very short (typically 0.1–1.0 ms), so that the amount of energy exchanged between the fluid and blade under the form of heat is entirely negligible with respect to that exchanged under the form of work. In the ideal case (no internal friction), the expansion is also isentropic (Fig. 14). At the inlet, the steam possesses a static enthalpy $h_0(p_0,T_0)$ and an absolute velocity V_0, so that its total (stagnation) enthalpy content is $h_{0,tot} = h_0 + 0.5V_0^2$. At stage exit, the static enthalpy has dropped to $h_{2i}(p_{2i},T_{2i})$ and the velocity is V_{2i}, so that the stagnation enthalpy is now $h_{2i,tot} = h_{2i} + 0.5\,V_{2i}^2$. The maximum specific energy that can be extracted from the fluid under these conditions is called the isentropic (or adiabatic) work:

$$w_{ad} = \Delta h_{ad} = h_{0,tot} - h_{2i,tot} \qquad (1)$$

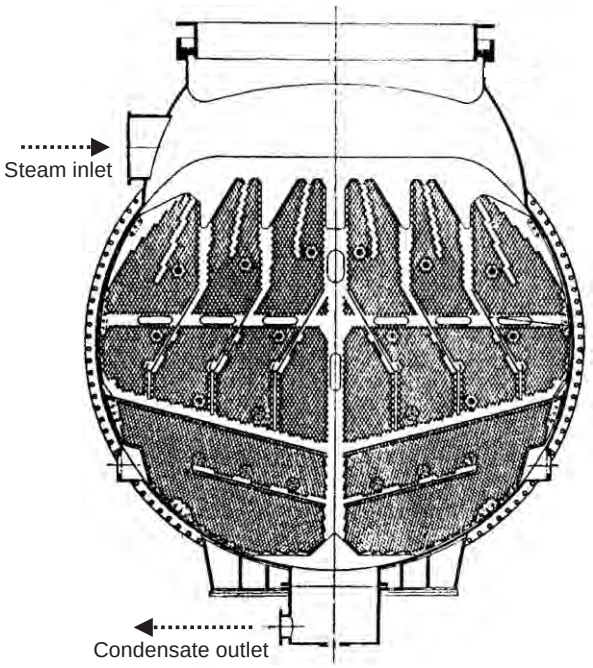

FIGURE 12 Meridional section of a steam condenser.

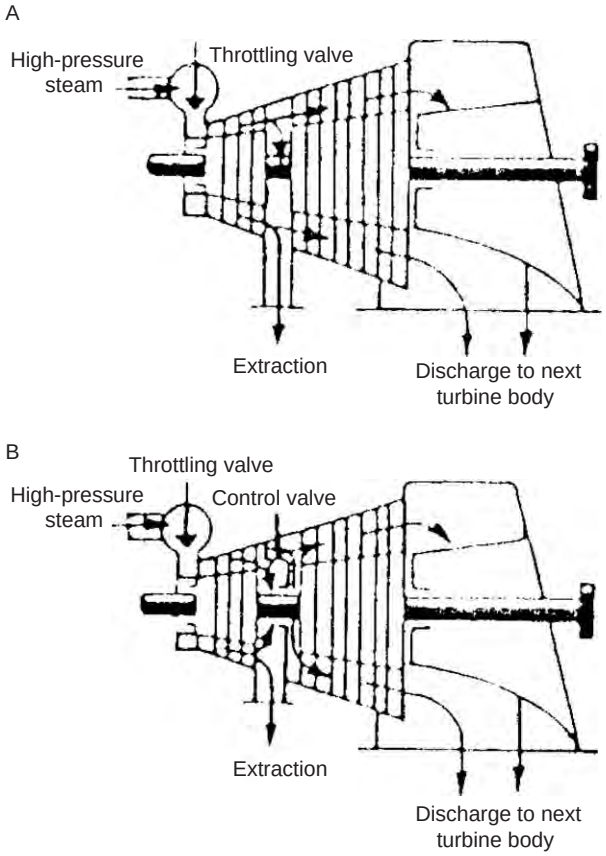

FIGURE 13 (A) Automatic extraction. (B) Controlled extraction.

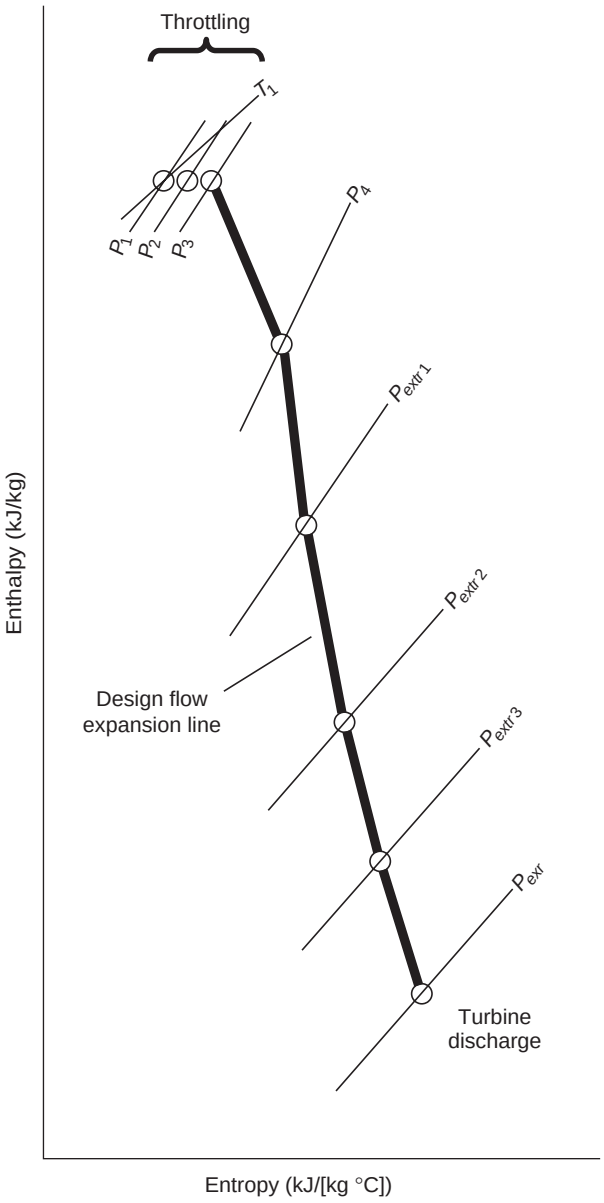

FIGURE 14 A real expansion line through a steam turbine.

The actual expansion is neither ideal nor adiabatic. Some heat flows from the hot fluid to the colder blades, creating a temperature gradient in the tangential and axial directions at each station. Boundary layers on the hub and casing walls originate velocity and temperature gradients in the radial direction. The flow is highly turbulent; neither the blade nor the disk and casing surfaces are perfectly smooth. A non-negligible amount of steam leaks through the unavoidable mechanical gaps and flows around the blades, originating "local recirculations" called secondary flows. All of these irreversible phenomena lead to the production of entropy,

degrading a portion of the steam energy and decreasing the overall amount of work provided to the blades by the fluid. Strictly speaking, a nonideal expansion cannot be represented on the Mollier chart because the "local" details of the entropy generation at each (p, T) point along the expansion line are unknown. But conventionally, the points representative of the inlet and outlet conditions can be connected with a line that has a concavity toward the right (Fig. 14) because the irreversible entropy generation increases with the stage expansion ratio. Because of the nonzero slope of the isobars, the actual total enthalpy drop is smaller than the isentropic one and the ratio of the two is referred to as the isentropic efficiency:

$$\eta_{is,tt} = \frac{h_{0,tot} - h_{2,tot}}{\Delta h_{ad}} = \frac{h_{0,tot} - h_{2,tot}}{h_{0,tot} - h_{2i,tot}}. \tag{2}$$

The quantity described by Eq. (2) is called the total-to-total efficiency as a reminder that the enthalpies appearing in its definition are stagnation values. It correctly accounts for the exit kinetic energy, which is a useful quantity because it contributes to the energy input in the next stage. Total-to-static and a static-to-static efficiencies are also used:

$$\eta_{is,ts} = \frac{h_{0,tot} - h_{2,tot}}{h_{0,tot} - h_{2i}} \tag{3}$$

$$\eta_{is,ss} = \frac{h_0 - h_2}{h_0 - h_{2i}}. \tag{4}$$

V_{2i} is always smaller than V_0 because in the absolute motion the fluid cannot accelerate; furthermore, the actual stage exit velocity V_2 is always somewhat smaller than its ideal counterpart because the same flow area must accommodate, *ceteris paribus*, a lower volumetric flow rate. It is possible to derive a relationship among the three efficiency expressions. Let

$$\begin{aligned}\Delta h_{tot} &= h_{0,tot} - h_{2,tot} \\ &= h_{0,tot} - h_{2i,tot} - T_0(s_2 - s_0) \\ &= \Delta h_{i,tot} - T_0 \Delta s\end{aligned}$$

and

$$V_2^2 = V_{2i}^2(1 - \alpha) \quad \text{where } \alpha < 1.$$

The following is obtained:

$$\eta_{is,tt} = 1 - \frac{T_0 \Delta s}{h_{0,tot} - h_{2i,tot}} \tag{5}$$

$$\eta_{is,ts} = \eta_{tt} \frac{1}{1 + \eta_{tt} \dfrac{V_{2i}^2(1 - \alpha)}{2\left(h_{0,tot} - h_{2i,tot}\right)}}. \tag{6}$$

$$\eta_{is,ss} = 1 - \frac{1 - \eta_{tt}}{1 - \dfrac{V_0^2 - V_{2i}^2}{h_{0,tot} - h_{2i,tot}}} + \frac{\alpha V_{2i}^2}{2\left(1 - \dfrac{V_0^2 - V_{2i}^2}{h_{0,tot} - h_{2i,tot}}\right)}. \tag{7}$$

The denominator in the right-hand side of Eq. (6) is greater than 1, so that $\eta_{is,ts} < \eta_{is,tt}$. With the usual values of $\Delta V_i (\cong 0.1 \Delta h_{i,tot})$ and of α ($\cong 0.05$), the values of $\eta_{is,ss}$ and $\eta_{is,tt}$ are indistinguishable for practical purposes. When in doubt, Eq. (5) is to be used.

2.2 The Steam Rate

It is still common in industrial publications to find mention of an alternate indicator of turbine performance, the so-called steam rate, defined as the mass of steam that must flow through the turbine to deliver a unit of power. Thus, this quantity ought to be expressed in kilograms per kilojoule but is commonly reported as "x kilograms per kilowatt-hour." The theoretical steam rate (TSR) is simply equal to the reciprocal of the ideal enthalpy drop,

$$TSR = \frac{1}{\Delta h_{ad}}, \tag{8}$$

whereas the actual steam rate (ASR) is the reciprocal of the actual work output,

$$ASR = \frac{m_{throttle}}{P_{out}}, \tag{9}$$

and the ratio ASR/TSR is equal to the net turbine efficiency. The steam rate is a redundant (and therefore useless) indicator that is cumbersome to use due to the necessary conversion between different systems of units, and its generality is limited by its explicit dependence on the initial and final expansion conditions. Its use ought to be discouraged.

2.3 From Zeroth-Order Approximation to Three-Dimensional Design

The thermodynamic stage efficiency constitutes a useful global description of the expansion process. However, the design of a turbine must be based on a detailed knowledge of the actual coupling between the working fluid and the machine channels. The "real" flow is fully three-dimensional, turbulent, and unsteady, and this makes a complete description

extremely difficult. As in many engineering tasks, we proceed by successive approximations:

1. First, we consider the so-called zero-dimensional problem in which the flow is steady and the fluid–machine interaction is expressed by global parameters such as mass (or volume) flow rate, expansion ratio, average values for the value and direction of velocity at the inlet and outlet of the blades, angular velocity of the rotor, and average physical properties of the fluid. We derive, via dimensional analysis, a set of general relations that constitute a basic design tool.
2. We then turn our attention to the ideal, steady, quasi-one-dimensional flow, devoid of boundary layers on either moving or fixed boundaries, and derive first-order expressions for the most important characteristic quantities. The flow rate and the specific work are expressed in terms of average velocities, and the stage performance is linked explicitly to the average flow field parameters.
3. The effects of boundary layers and other viscous and compressibility phenomena are then taken into account, and the results previously obtained are corrected to include the effects of losses, secondary flows, flow nonuniformities, sonic phenomena, and so on.
4. The fully unsteady, three-dimensional flow is studied. As of today, this is possible only under stringent simplifying assumptions and at the expense of substantial computational resources. Usually, cascade or stage simulations are performed to investigate particular characteristics of the flow field and are validated by comparing their results with experimental investigations.

2.3.1 Zeroth-Order Approximation: Dimensional Analysis

Dimensional analysis is a branch of applied mathematics that investigates the relationship between global characteristics of a physical phenomenon and a possibly small set of likewise global parameters that uniquely define it. This article adopts here a simple (but theoretically sound) approach. In turbomachinery design, dimensional analysis is essentially linked to the concept of similarity. Two machines, A and B, are said to be geometrically similar if the ratios between homologous dimensions all are equal (i.e., if $D_{2,A}/D_{2,B} = c_{tip,A}/c_{tip,B}$). The same two machines are also said to be kinematically similar if the ratios between corresponding velocities are the same (i.e., if $U_{2,tip,A}/U_{2,tip,B} = V_{1,A}/V_{1,B}$). Finally, two machines are said to be dynamically similar if the ratios between corresponding forces (or force-related quantities) are the same (i.e., if $\Delta p_{stator,A}/\Delta p_{stator,B} = \sigma_{centrifugal,tip,A}/\sigma_{centrifugal,tip,B}$). Notice that similarity considers ideal flow concepts only. Strictly speaking, two geometrically and kinematically similar machines are dynamically similar only if the dissipative features of the flow (leakages, boundary layers, and viscous and inviscid losses) are the same.

With specific reference to a turbine stage, let us consider the following question: can the global design parameters of the stage be reduced to a small set of fundamental dimensional variables that can be used to construct an even smaller set of dimensionless indexes that describe stage performance? A brief reflection indicates that a stage is described by the mass flow rate it elaborates, the work it extracts, the conditions of the fluid and the flow passage area at inlet and outlet, a proper measure of its size, and the angular velocity of its rotor. A possible set of relevant design parameters is listed in Table III. A fundamental set of dimensionless parameters that can be constructed with these quantities is reported in Table IV.

Turbines with equal Reynolds numbers, specific speeds, and specific diameters are dynamically similar (because the losses scale, albeit only approximately, with Reynolds numbers). This result, which can be derived theoretically and justified on the basis of first- and second-order considerations, has been confirmed by an extraordinarily large and comprehensive series of experimental results. It has several important consequences. First, the efficiencies of the two machines are also equal. Second, if we know the performance ($Q_{2,A}$, ω_A, and $\Delta h_{ad,A}$) and the scale ($D_{2,A}$) of the first machine, we can derive the corresponding quantities for the second machine once we fix either its dimensions ($D_{2,B}$) or one of its design specifications ($Q_{2,B}$ or $\Delta h_{ad,B}$, or ω_B). The

TABLE III

A Fundamental Set of Design Parameters for a Turbine

Parameter	Physical phenomena to which it relates
Fluid enthalpy drop (Δh_{tot})	Specific work
Fluid flow rate (m_o)	Machine size, power
Fluid density ($\rho(\rho,T)$)	Machine size, losses
Rotor and stator dimensions	Machine size, mechanical stresses, flow kinematics
Stage efficiency (η_{is})	Irreversible dissipation in blade rows
Rotor angular velocity (ω)	Mechanical stresses, flow kinematics

TABLE IV

A Possible Fundamental Set of Dimensionless Parameters for a Turbine

Parameter	Definition
Average flow Reynolds number	$Re = \frac{\rho U_{tip} D_{tip}}{\mu}$
Average flow Mach number	$Ma = \frac{C}{\sqrt{kRT}}$ (C is a local representative velocity)
Specific speed	$n_s = \frac{\omega\sqrt{Q_2}}{(\Delta h_{ad})^{3/4}}$
Specific diameter	$d_s = \frac{D_{tip}(\Delta h_{ad})^{1/4}}{\sqrt{Q_2}}$
Head coefficient	$\Delta\psi = \frac{\Delta h_{ad}}{U_{tip}^2}$
Flow coefficient	$\varphi = \frac{Q}{U_{tip}A}$ (A is local flow passage area)
Stage efficiency	$\eta_{is} = \frac{w_{real}}{w_{ad}}$
Degree of reaction	$R_\rho = \frac{h_1 - h_2}{h_{0,tot} - h_{2,tot}}$
Tip clearance/blade height ratio	$s = \frac{h_{gap}}{h_{blade}}$ (h is average height or clearance)
Rotor blade aspect ratio	$a = \frac{h_{blade}}{c_{blade}}$ (h and c are average representative values)

following relations hold:

$$\frac{\omega_A D_{2,A}}{\Delta h_{ad,A}^{1/2}} = \frac{\omega_B D_{2,B}}{\Delta h_{ad,B}^{1/2}} \tag{10}$$

$$\frac{\omega_A Q_{2,A}}{D_A \Delta h_A} = \frac{\omega_B Q_{2,B}}{D_B \Delta h_B} \tag{11}$$

$$\omega_A D_{2,A}^2 = \omega_B D_{2,B}^2, \tag{12}$$

where Eq. (10) derives from the Reynolds numbers equality, assuming that the steam viscosity at the exit of the two machines is the same (see Fig. 15 for the dependence of μ on temperature).

As can be seen in the following, the flow and head coefficient are also fundamental design parameters. They are related to n_s and d_s by

$$\Delta\psi = \frac{1}{(n_s d_s)^2} \tag{13}$$

$$\varphi = K_{shape} \frac{n_s \Delta\psi}{d_s}, \tag{14}$$

where K_{shape} is equal to $\frac{\pi\delta_b(1-\chi^2)}{2}$ and $2\pi\delta_b\left(\frac{b}{D}\right)$ for axial and radial turbines, respectively. The Reynolds number definition is clearly conventional. In most real cases, nowhere in the real flow field does the Reynolds number assume the value given by the formula in Table IV. Nevertheless, if used consistently, it allows a direct relative estimate of global

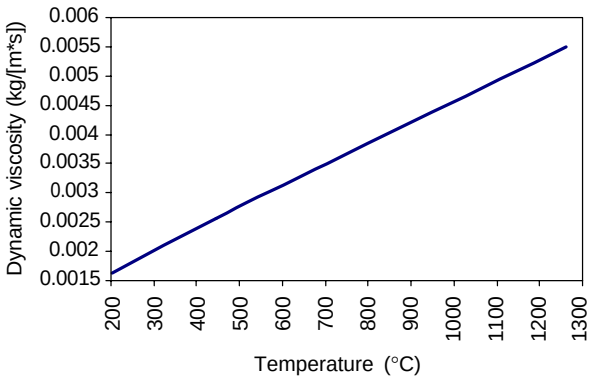

FIGURE 15 Steam viscosity versus temperature.

losses. For two turbines with the same n_s and d_s (or $\Delta\psi$ and φ, which is the same), a widely used formula, originally from Staufer in 1925, states that

$$\frac{1-\eta_{is,tt,A}}{1-\eta_{is,tt,B}} = C_1 + C_2\left(\frac{\mathrm{Re}_B}{\mathrm{Re}_A}\right)^n, \tag{15}$$

where $C_1 \approx 0.3-0.4$, $C_2 \approx 0.7-0.6$, and $n \approx 0.2-0.25$. Equation (15) implies that not all losses are of viscous origin (C_1 is the percentage of inviscid losses on the total).

On the basis of similarity analysis, universal performance charts can be compiled. If we have one verified performance map of a given turbine stage, similarity theory states (and experimental results confirm) that such a map applies to all stages with the same pair (n_s,d_s)—or (ψ,φ), which is the same—so long as their operation implies Reynolds numbers on the order of the one in the test. The admissible range is somewhat application dependent, but for turbines of commercial standard, a variation between $Re = 10^5$ and $Re = 10^7$ leads to a total-to-total efficiency change of approximately 0.05 (from 0.87 to 0.92). Two widely used performance maps, known as the Balje and Smith charts, are shown in Figs. 16 and 17, respectively.

In spite of the formal identity, there is a substantial practical difference in taking the sets (Re, n_s, d_s) or (Re, $\Delta\psi$, φ) to represent the variation of the stage efficiency at different design conditions. By definition, n_s/d_s maps are dependent on the stage outlet temperature and pressure and, therefore, do not apply strictly to similar machines working under different operating conditions. To eliminate this inconvenience, "corrected" quantities are sometime used, especially in industrial references. If for a turbine stage m_r is defined as the reference mass flow rate evolving in the stage when the inlet steam is at T_r and p_r and the rotor is rotating at a reference angular

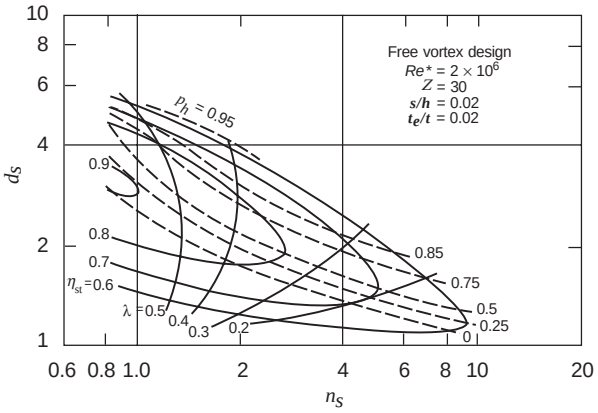

FIGURE 16 A typical Balje chart for steam turbines.

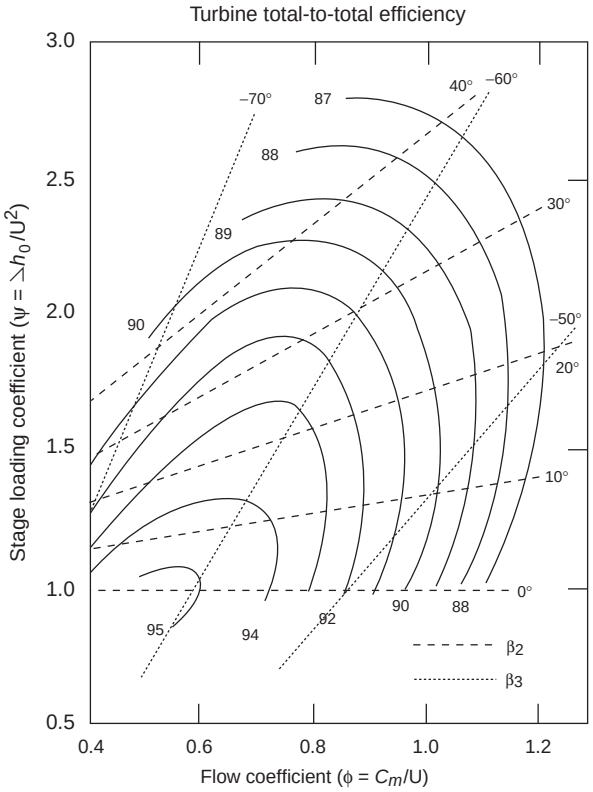

FIGURE 17 A typical Smith chart for a steam turbine with $R_\rho = 0.5$.

velocity ω_r, the following relations hold:

$$m_r = m\frac{\sqrt{T/T_r}}{p/p_r} \tag{16}$$

$$\omega_r = \frac{\omega}{\sqrt{T/T_r}}\,.$$

Of course, reference conditions are still included in the preceding definitions, but this reduces to a matter of convention. For geometrically and kinematically similar machines, corrected stage performance maps are displayed in Fig. 18.

2.3.2 First-Order Approximation: The Euler Equation and the Velocity Triangles

Consider the flow in a generalized turbine rotor (Fig. 19). The fluid enters the upstream side of the rotor with absolute velocity V_1 and exits from the downstream side with velocity V_2. Notice that suffixes 1 and 2 refer to the (virtual) geometric center of the inlet and outlet sections, so that V_1 and V_2 are proper average velocities, and that the rotor is rotating with a steady angular velocity ω. Newton's second law states that the module of the tangential force acting on the rotor is equal to the rate of change of angular momentum in the fluid, $|F_t| = \frac{d(mV_t)}{dt}$, which for steady V_t and m reduces to $F_t = F_{t1} - F_{t2} = m(V_{t1} - V_{t2})$. Therefore, the torque on the rotor shaft is

$$M = r_1F_{t1} - r_2F_{t2} = m(r_1V_{t1} - r_2V_{t2}). \tag{18}$$

The specific work (power per unit mass) is then

$$w_{ad} = P/m = M\omega/m = \omega(r_1V_{t1} - r_2V_{t2}). \tag{19}$$

Defining $U = \omega r$ as the rotational velocity, and recalling that $w_{ad} = \Delta h_{ad}$, we obtain the so-called Euler equation:

$$\Delta h_{ad} = \omega\,(r_1V_{t1} - r_2V_{t2}) = U_1V_{t1} - U_2V_{t2}. \tag{20}$$

This equation is fundamental in turbomachinery design because it relates the thermodynamic work (computed via steam charts or thermodynamic formulas) to the mechanical work expressed in terms of geometric and (average) kinematic quantities. Notice that the velocities appearing in Eq. (18) are ideal velocities (no losses included) averaged over the passage area.

The flow kinematics is conveniently represented by means of the so-called velocity triangles, which are simply a graphical display of the basic velocity vector relationship:

Absolute Velocity Vector
= System Velocity Vector
+ Relative Velocity Vector

or

$$V = U + W. \tag{21}$$

These diagrams (Figs. 1 and 19) are drawn on a single plane, tangent to the pseudo-cone that represents the machine at radius r. Three values are usually provided: at the hub (r_h), midspan (r_m), and tip (r_t). For radial stages, there is only one value at

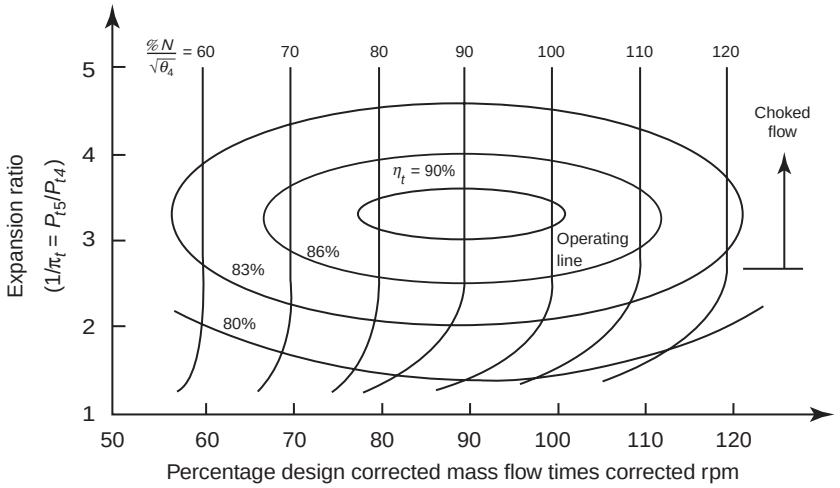

FIGURE 18 Corrected turbine performance map.

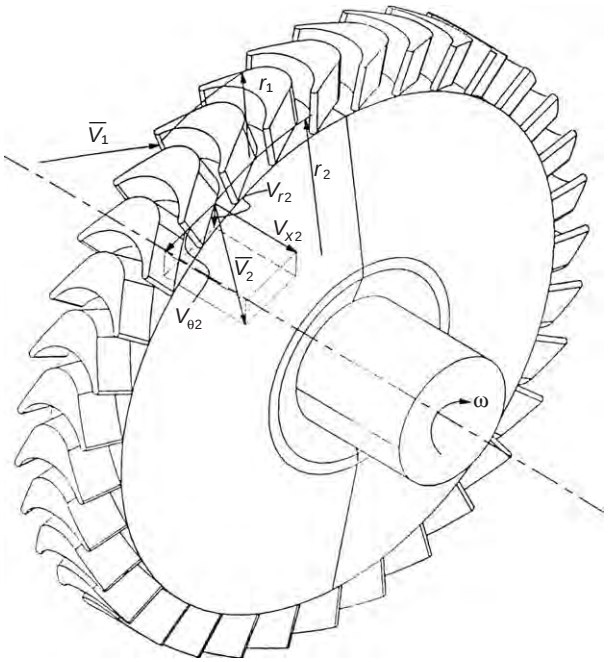

FIGURE 19 Schematics of the flow in an axial turbine rotor.

the inlet (r_1). These triangles can also be defined in terms of one velocity and two angles: the relative flow angle β and the absolute flow angle α. The cascade nomenclature provided in Fig. 1 is not universally adopted, and sometimes (especially in English monographs) the values $\beta-90^\circ$ and $90^\circ-\alpha$ are used instead. The following relations hold between the modules of the velocity vectors ("j" is a running index denoting the station to which the triangle refers):

$$V_{j,x} = V_j \sin\alpha = \varphi_j U_j \tag{22}$$

$$V_{j,t} = V_j \cos\alpha = \psi_j U_j \tag{23}$$

$$V_j^2 = V_{j,x}^2 + V_{j,t}^2 = U_j^2\left(\varphi_j^2 + \psi_j^2\right) \tag{24}$$

$$\begin{aligned} W_j^2 &= W_{j,x}^2 + W_{j,t}^2 \\ &= U_j^2\left[\varphi_j^2 + \left(1-\psi_j\right)^2\right] \end{aligned} \tag{25}$$

$$W_{j,t} = V_{j,t} - U_j \tag{26}$$

$$V_{j,x} = W_{j,x} \tag{27}$$

$$U_j V_{j,t} = \frac{\left(U_j^2 + V_j^2 - W_j^2\right)}{2}. \tag{28}$$

Relative total temperatures (T_{rel}) are defined as well:

$$\begin{aligned} T_{j,tot,rel} &= T_j + \frac{W_j^2}{2\overline{c_p}} \\ &= T_{j,tot} + \frac{\left(W_j^2 - V_j^2\right)}{2\overline{c_p}} \\ &= T_{j,tot} + \frac{U_j^2(1-2\psi)}{2\overline{c_p}}. \end{aligned} \tag{29}$$

$T_{tot,rel}$ is the stagnation temperature in the rotating frame of reference and, therefore, is the temperature to which the rotor material is subjected.

It is customary to classify turbine stages on the basis of four characteristic indexes identifying their velocity triangles: the degree of reaction R_ρ, the exit swirl ω_2, the stage loading coefficient $\Delta\psi = \psi_1 - \varepsilon^2\psi_2$, and the flow coefficient φ. The respective values must be labeled with the radius at which the index is computed (in the absence of another indication, blade midspan is to be assumed). The degree of

reaction is defined as the ratio of the static enthalpy drop across the rotor to the decrease of the total enthalpy across the stage:

$$R_\rho = \frac{h_1 - h_2}{h_{0,tot} - h_{2,tot}} = \frac{(U_1^2 - U_2^2) - (W_1^2 - W_2^2)}{(U_1^2 - U_2^2) + (V_1^2 - V_2^2) - (W_1^2 - W_2^2)}. \quad (30)$$

A stage in which $R_\rho = 0$ is said to be an impulse stage. For axial turbines, Eq. (30) implies that in such a stage there is no pressure drop across the rotor ($W_1 = W_2$); that is, the entire stage pressure drop is attained in the inlet nozzle (the stator), and the rotor absorbs only the fluid's kinetic energy. All stages for which $R_\rho > 0$ on a portion of the blade are said to be reaction stages. The value of R_ρ is, whenever possible, limited to approximately 0.5 to limit the absolute kinetic energy at stage outlet.

A zero exit swirl corresponds to the minimum absolute kinetic energy at stage exit. For a single stage and for the end stages of all machines, this is a desirable condition. For an intermediate stage, where the exit kinetic energy can be recovered by the next (bottoming) stage, work maximization often leads to a negative ψ_2.

The loading coefficient is chosen as large as possible, compatible with the desired value of the efficiency (Fig. 20). Common values for axial stages range from 1 to nearly 3. For radial stages, $\Delta\psi \cong 1$.

2.3.2.1 Impulse versus Reaction Stages: Blade Twist It is useful to provide a more detailed discussion of impulse and reaction stages. In an impulse stage, the steam experiences the entire stage pressure drop in the statoric channels and is ejected from the stator as a jet (or, better, as a number of jets—one for each statoric passage). In the rotor, these jets flow through a blade with a (nearly) constant relative velocity along the rotoric passage. Therefore, the pressure drop in the rotor is zero (Eq. 30). The stage work is produced in the rotor at the expense of the absolute velocity of the steam. Assuming zero losses in the stator,

$$h_{0,tot} - h_{2,tot} = \frac{(U_1^2 - U_2^2) + (V_1^2 - V_2^2)}{2}, \quad (31)$$

we see the following:

1. The stage work increases with the expansion ratio p_0/p_2 until V_1 becomes sonic and the stage is "choked."
2. With the stage work being maximum for $V_{2,t} = 0$, it can be easily shown that the optimal U/V_1 ratio for axial turbines is approximately 0.5. In centripetal turbines, experience shows that $(U/V_1)_{optimal} \sim 0.7/0.8$.
3. In centripetal turbines, the flow configuration is such that even if $V_2 = V_1$ (which is never realized in practice because it would lead to high rotoric losses), the stage would deliver a positive work $(U_1^2 - U_2^2)/2$.
4. Radial centrifugal turbines deliver, for the same steam conditions and peripheral velocity, a lower stage work. In fact, they have been abandoned except for the Ljüngstrøm turbine (described in the first section of the article).

Therefore, in an impulse stage, the rotor is likely to be unshrouded and devoid of the leakage seals that abound in the stator. A "typical" axial impulse stage is depicted in Fig. 21. Notice that for today's higher throttle conditions (400–560°C and 30–220 bars), the sonic velocity in the first nozzle is so high that the ratio U/V_1 would be much lower than 0.5, leading to a substantial efficiency penalty. An ingenious solution (first suggested by Curtis) is that of absorbing the absolute kinetic energy drop in two separate rotors "fed" by a single stator. The intermediate fixed blading is simply a deflector (Fig. 21B). This configuration is often adopted in the first stage(s) of large steam turbines because, for the same peripheral velocity U, the velocity V_1 is higher than $2U$ (its optimum is at $\sim 4U$); therefore, the enthalpy (and pressure) drop per stage is increased. This means not only a lower overall number of stages but also a smaller high-pressure casing, and this results in a lessening of the installation costs. The price is a somewhat lower stage efficiency.

Because the ratio of the blade height to the external diameter is small only for the very first high-pressure stages, and because the requirement of

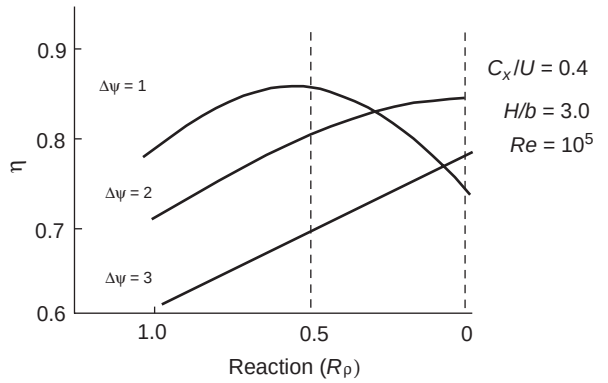

FIGURE 20 Loading coefficient versus degree of reaction and stage efficiency.

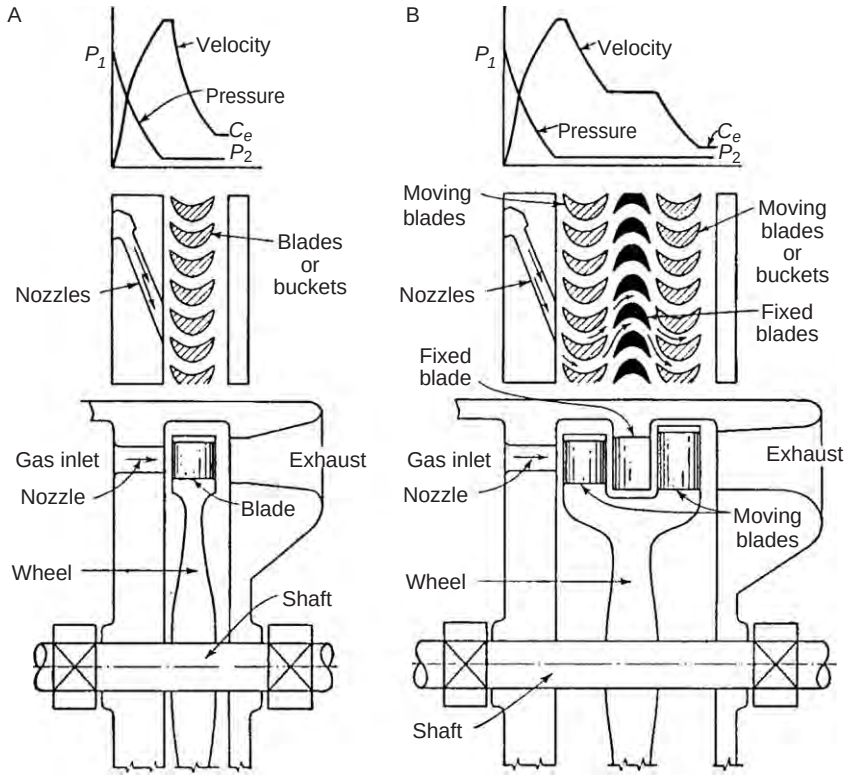

FIGURE 21 Impulse stages: (A) simple and (B) velocity compounded ("Curtis").

constant total enthalpy along the radius (to avoid excessive radial motion in the nonrotating channels) demands that the Euler work given by Eq. (20) be also constant along the radius, it follows that neither V_t nor R_ρ can be constant along the blade. Therefore, the term reaction stage implies that the degree of reaction at its midspan diameter is greater than zero. Actually, there are cases in which $R_\rho = 0$ at the hub and reaches values higher than 0.5 at the tip. For $h/D > 0.02$, the velocity triangles differ markedly at the hub, midspan, and tip, and the blade must accommodate to radially varying V_{1t} and V_{2t}. Several solutions are possible, with the one called free vortex ($V_t{}^*r = \text{constant}$) being used most frequently. The resulting rotation of the blade profile at various radii around its central radial axis is called "twisting." An example of a twisted blade is shown in Fig. 22.

2.3.3 Second-Order Approximation: Loss Correlations

The difference between the ideal turbine work Δw_{ad} and the actual shaft work is due to the losses in the turbine. It is common design practice to apportion these losses to each component and to write

$$\Delta w = \Delta w_{ad} - \Delta h_{tot,inlet} - \Delta h_{tot,stator} - \Delta h_{tot,rotor} - \Delta h_{tot,diffuser} - \Delta h_{tot,exit} - \lambda_{mechanical}. \quad (32)$$

Notice that fluid-related losses have been expressed in terms of total enthalpy drop. According to the Gouy–Stodola theorem, this may be also written

$$\Delta h_{tot,j} = T_0 \Delta s_j = \Delta e_j, \quad (33)$$

where $T_0 \Delta s_j$ is the irreversible entropy generation for the jth loss and Δe_j is the corresponding exergy destruction. In what follows, a concise and general description of how to include these losses in design calculations is provided.

- *Inlet losses*. These are due to frictional and flow turning effects (which cause flow separation and originate recirculation regions).
- *Partial admission losses*. In partial admission stages, there are two additional losses caused by the drag experienced by the blades in their inactive arc ("ventilation" losses) and by the fact that a portion of the energy of the statoric jet is perforce lost when the blade first enters its active arc and when it exits it ("sector" losses).
- *Statoric losses*. These are due to friction within the blade row, to secondary flows caused by turning effects (which cause flow separation and originate

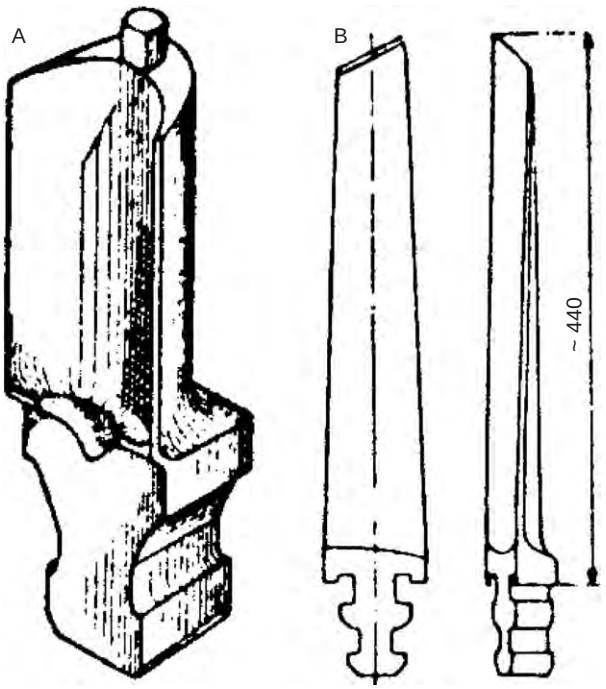

FIGURE 22 Untwisted (A) and twisted (B) steam turbine blades.

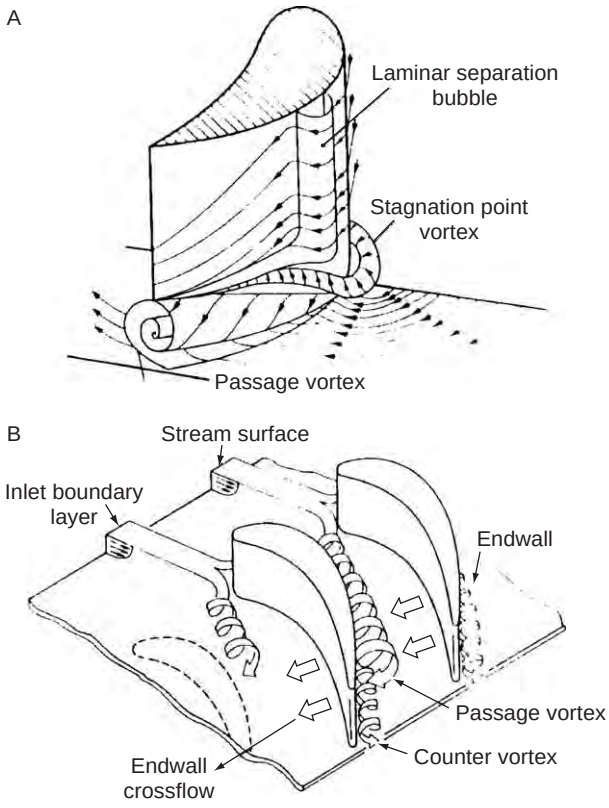

FIGURE 23 Vortical structures along the blade channel.

recirculation regions), to boundary layer growth along the blade ("blockage"), and to flow compressibility effects. These losses are usually split into their individual contributions, which are usually considered separately during design. Profile losses are originated by a complex system of vortical structures along the blade channels that strongly interact with each other and cannot be conveniently treated separately (Fig. 23). These losses are usually evaluated by computing or measuring the so-called lift and drag coefficients, defined as the ratios of the lift and drag force, respectively, to the kinetic energy of the oncoming flow (Fig. 24A). A large database exists for several blade profiles, and designers make use of "cascade performance charts" like the one depicted in Fig. 24B. If the velocity triangles are known, so is the cascade efficiency. Sometimes an additional loss, the wake loss, is included in the profile loss. Secondary and blockage losses are similarly modeled in terms of the square of the average meridional velocity, whereas shock losses, originated by sonic and supersonic shocks interacting with the boundary layers and with the wake, are computed on the basis of semi-empirical charts. Leakage flows (usually negligible in stators) are due to the unavoidable leaks around seals and gaps. They depend on the blade aspect ratio (h/l, height over chord) and gap size (g/h).

• *Rotoric losses.* These are modeled in a manner similar to that of stators. However, here the relevant velocity is the relative inlet velocity W_1:

$$\begin{aligned}\Delta h_{tot,rotor} &= \Delta h_{tot,profile} + \Delta h_{tot,secondary} + \Delta h_{tot,blockage} \\ &\quad + \Delta h_{tot,shock} + \Delta h_{tot,leakage} + \Delta h_{tot,windage} \\ &= 0.5\, K_{rotor} W_1^2, \end{aligned} \tag{34}$$

where K_{rotor} is a weight-averaged loss coefficient.

• *Diffuser losses.* These are also due to frictional and recirculation effects. The diffuser is a component in which the fluid flows against a pressure gradient (velocity is recovered into pressure); therefore, it is intrinsically affected by the highest losses (in percentage). In steam turbines, the importance of diffusers is normally negligible.

• *Mechanical losses.* These are due to frictional dissipation in bearings and seals. Customarily, they are accounted for introducing an organic efficiency:

$$\lambda_{mechanical} = \left(1 - \eta_{organic}\right)\Delta w_{ad}, \tag{35}$$

with $\eta_{organic}$ ranging from 0.95 to 0.98 for the entire shaft line (if a shaft supports N stages, the loss apportioned to each stage is $1 - \eta_{organic}/N$).

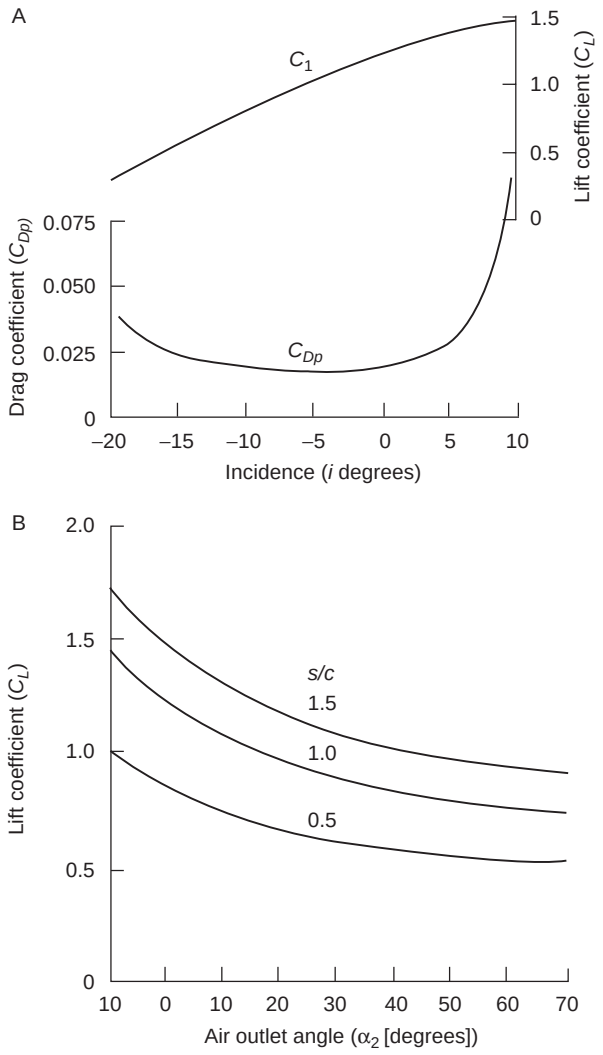

FIGURE 24 (A) Lift and drag coefficient for a cascade of fixed geothermal form. (B) Design lift coefficients.

Once the total stage losses have been computed, they are used to

1. Correct the ideal Euler work (Eq. 20). and derive the actual work delivered by each stage (Eq. 31).
2. Recompute the fluid thermodynamic conditions at the exit of each stage and draw the actual expansion line of Fig. 14.

2.3.4 Three-Dimensional Calculation of the Real Flow in a Complete Turbine Stage

The real flow in a turbine stage is highly turbulent, fully three-dimensional, and intrinsically unsteady. Although its general features are well understood (Fig. 23), it is the local features and their complex interactions that may make the difference in the stage efficiency. It is difficult to capture the individual flow phenomena through test bench experiments, and a large (and increasing) portion of turbine studies are performed by means of numerical simulations. Such simulations are complex, resource-consuming, and often not univocal (in the sense that some of the detected phenomena may be purely numerical features and not necessarily reflective of physical phenomena). Therefore, they must be carefully planned and performed, and their results are always calibrated against available experimental evidence. Basically, the flow domain (the portion of space in which the phenomena are studied) includes a portion of the interblade passage and also covers a limited portion of the channel upstream and downstream of the blade passage. Periodic tangential conditions are usually assumed (i.e., the basic features of the flow are considered to be the same in adjacent blade passages), and only recently has the coupling between statoric and rotoric blade rows been simulated in full. All of these studies strongly depend on the turbulence modeling adopted ("full" calculations, or the so-called DNSs [direct numerical simulations], are still impossible on the complex geometries of a turbine stage and in their operational high Reynolds numbers), and some of the effects can be assessed only under the simplifying assumption of inviscid flow. Nevertheless, reliable work has been performed to study both inviscid (i.e., purely kinematical) and viscous (i.e., including boundary layers and wake interactions) flow features, and the results compare well with global and local experimental measurements. A situation is now being approached where blade design can be performed on the basis of successive approximations, by iterative adjustment of several design parameters, to determine the best blade profile for a specified performance. However, at the industrial level, most of the design activity is still based on proprietary loss correlations, and fully three-dimensional simulations are still considered a helpful tool but not a completely reliable design procedure. With the advance of computer hardware (which leads to higher computational speeds and reduced simulation time), computational fluid dynamic research (which provides a better understanding of local flow features), and available software (which improves the quality of the commercially available flow models), it is clear that in the near future, inverse design problems will be solved by means of standard, well-understood, and relatively easy-to-use procedures.

3. OUTLINE OF A GENERAL PROCEDURE FOR PRELIMINARY STEAM TURBINE DESIGN

The actual design of a steam turbine is a complex task, usually carried out by a multidisciplinary design team whose members constantly interact with wind tunnel and test bench specialists. The technology is mature and extremely resource intensive, so that production is concentrated in very few locations worldwide. The independent steam turbine producers of commercial and industrial relevance (i.e., those that develop their own products, do not produce under license, and generate a significant number of units per year) amount to no more than perhaps 15 worldwide. Each has its own design procedure, formalized in detailed design manuals, usually meant for internal use only. However, it is highly likely that all of these proprietary design procedures follow the very same general logical flowchart and that the differences lie either in the formulas used for case-specific calculations (e.g., loss coefficients, blade angle corrections, material selection) or in the selection of a particular turbine shape (due to patent history and/or the company's technological background). Therefore, steam turbine design can in principle be said to follow nine general steps:

1. Calculation of the thermodynamic expansion process
2. Selection of the type of turbine (single stage vs multistage, radial vs axial)
3. Selection of the maximum tip speed
4. Calculation of n_s and selection of the proper similarity parameters
5. Tracing of the velocity triangles
6. Loss accounting and possible iteration (go back to step 3)
7. Preliminary blade design and costing
8. Numerical simulations under realistic operating conditions
9. Final design and costing

Because of space limitations, a detailed description of each of these phases cannot be provided here. The discussion is limited to a brief explanation of the most important features of each design step.

3.1 Calculation of the Thermodynamic Expansion Process

The expansion process is customarily calculated manually on *s/h* graphs such as the Mollier diagram. More recently, property packages have been developed that allow the calculation of a full expansion line on a personal computer. Notice that to trace the real expansion line, a turbine efficiency must be assumed here (Fig. 14). Clearly, this initial assumption requires an iterative verification.

3.2 Selection of the Type of Turbine

For small applications, where the design specifications require a low power output (less than a few megawatts) in conjunction with a low mass flow rate, single-stage radial steam turbines are probably most convenient. In all other cases, single- and multistage axial turbines dominate the field. The selection can be made either on the basis of specific experience on the part of the designer or of the company (there are companies that produce only a certain type of machinery) or with the help of "operating charts" (Fig. 25) that condensate decades of experience and are updated periodically. The semi-empirical Balje's charts (Fig. 16) are also a great help because they indicate the ranges in which a certain type of machine has performed well at the current stage of technology.

3.3 Selection of the Maximum Tip Speed

There are two major limitations in turbine design: excessive mechanical stresses on the blade and disk and choking of the flow in the blade passages. Both limitations constrain the maximum allowable tip velocity U_t. Very early in the design procedure, it is necessary to assign a value of U_t, and the choice is usually made on the basis of specific designers' experience, often explicitly tabulated in design manuals. Because this choice has a significant influence on the remaining design parameters, an iterative procedure must be used.

3.4 Calculation of n_s and Selection of the Proper Similarity Parameters

The specific speed is conventionally computed on the outlet section of the stage (i.e., the volumetric flow rate is computed on the basis of the exit steam density):

$$n_s = \omega \frac{\sqrt{\frac{\dot{m}_{out}}{\rho_{out}}}}{\Delta h_{tot,stage}^{3/4}}.$$

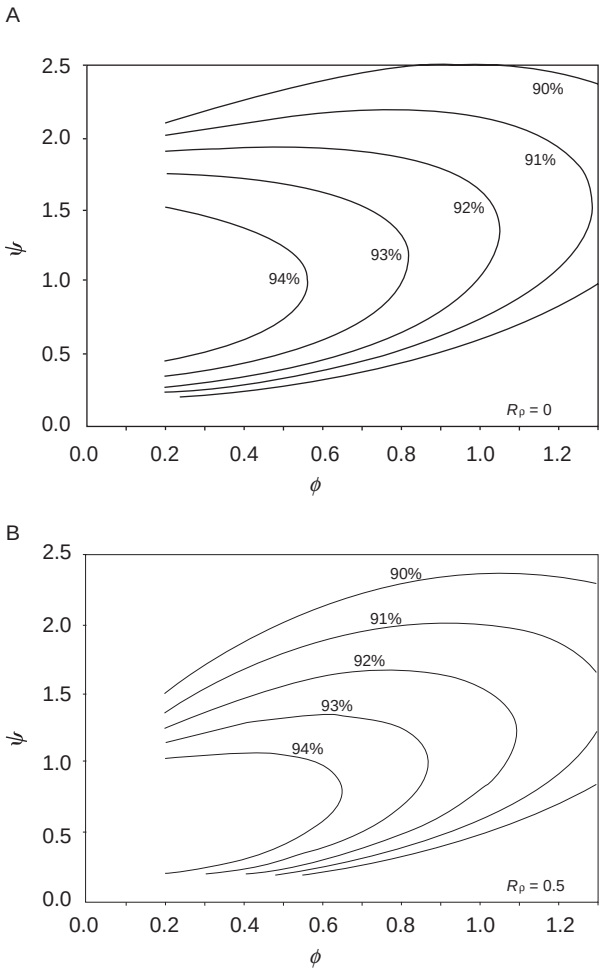

FIGURE 25 (A) Predicted total-to-total efficiencies for axial turbines with 0% reaction (impulse stages) and blade aspect ratio ($h/b = 10$). (B) Predicted total-to-total efficiencies for axial turbines with 50% reaction and blade aspect ratio ($h/b = 10$).

Confirmed experience has shown that the n^s for steam turbines varies between 0.1 and 4. If values smaller than 0.1 are obtained, a multistage configuration ought to be chosen and a new n_s should be computed using the stage enthalpy drop $\Delta h_i = \Delta h_{tot}/N_{stages}$. If, on the other extreme, n_s exceeds 4 or 5, to maintain high stage efficiency, it is mandatory to split the steam flow among M turbine bodies (parallel operation). M is determined by the condition that Q_{tot}/M is such that the n_s based on it falls within the range of 0.1 to 4. Once the specific speed is known, the remaining similarity parameters (most importantly the head coefficient ψ and the flow coefficient φ) can be determined on the basis of semi-empirical diagrams such as the Smith (for axial stages [Figs. 17 and 25]) and Chen–Baines (for radial stages [Fig. 26]) charts.

3.5 Tracing of the Velocity Triangles

The choice of the number of stages, of the n_s, and of the flow and head coefficients for each stage is far from being unique. For example, there are several reasons that suggest an uneven allocation of the Δh_{tot} among the stages (e.g., the need to maintain an optimal value of n_s, a convenient construction of the turbine bodies with each containing N_b stages). Whatever the choice is, at this point one possesses all of the information needed to draw the preliminary blade profile and can proceed as follows:

1. Introducing the chosen value of φ into the continuity equation applied at the rotor inlet section, we derive the blade height h (or the hub-to-tip ratio γ).
2. From U_t, ψ, and φ, we derive V_t, V_m, α, and β in each section of interest. For a radial stage, the inlet diameter at blade midspan is used together with both the tip (shroud) and hub exit values. For axial stages, it is customary to draw at least three triangles at the hub, midspan, and tip diameter. The ψ and φ given by the charts are tip values, and the other values must be computed properly. Usually, the assumption is that the V_m is constant along the radius and that V_t follows the so-called free vortex law: $V_t{}^* r = \text{con-}$ constant. But other choices, especially where the V_t is concerned, are possible.
3. The Euler work is computed at each section, and its average value on the entire blade is assessed. The ideal values for the relative flow angles (β) are calculated. A proper blade profile may now be chosen (or designed anew).
4. From a momentum balance in the relative flow, the pressure drop in the rotor can be calculated. Hence, the statoric pressure drop is obtained.
5. Once α_1 is known along the blade height, the statoric profile is also determined because it is reasonable to assume an entirely axial incoming flow ($V_o = V_{m,o}$, or $\alpha_o = 90^\circ$).

3.6 Loss Accounting and Possible Iteration

Now, the losses expressed by the semi-empirical relations discussed previously can be computed, and their overall effects can be considered before modifying the velocity triangles. Some of these losses affect the flow rate, and some others affect the flow section. Therefore, it is necessary to iterate to attain a reasonable compromise between good overall efficiency and a feasible design. Of course, the design specifications are imposed as strong constraints.

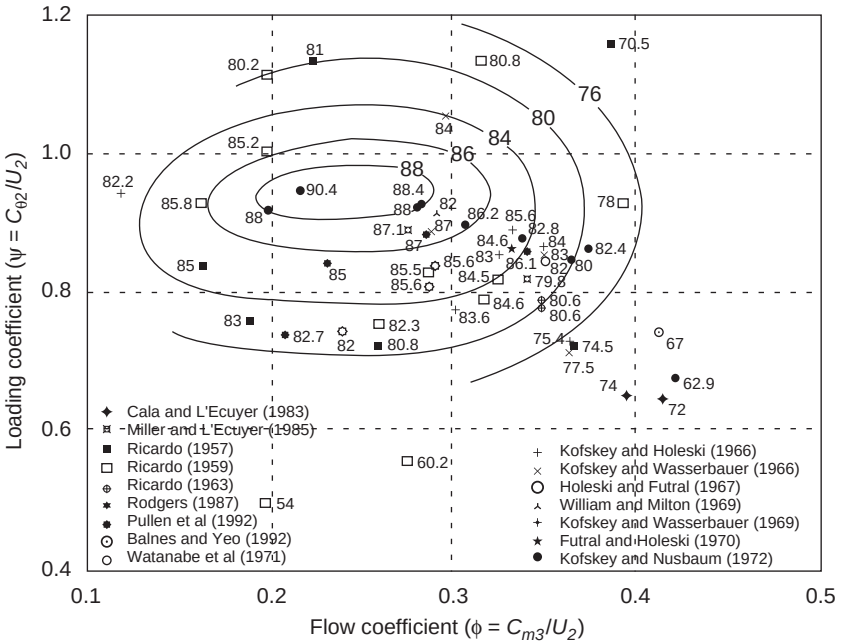

FIGURE 26 A Chen–Baines diagram for a radial turbine.

3.7 Preliminary Blade Design and Costing

Once all geometrical dimensions are known, the blades and all other components can be preliminarly sized. The choice of materials is imposed in practice by the environment within which the design activity takes place (with industrial and commercial strategies usually conflicting with purely technical considerations). A preliminary costing assessment of the machine is developed.

3.8 Numerical Simulations under Realistic Operating Conditions

As mentioned previously, the relatively simple and essentially two-dimensional procedure based on the velocity triangles can capture only the average and large-scale details of the flow in the turbine channels. Nevertheless, machines have been designed successfully with this method or similar methods for decades, attaining overall efficiencies of more than 90%. However, the progressive increase of the steam turbine unit power led to a situation where even minor efficiency improvements became attractive. Because an essentially two-dimensional design can be improved only by extensive testing, an impressive amount of experimental work was performed on models and full-scale stages alike. The advancement of computer technology made it possible to substitute physical testing with its numerical counterpart. Numerical experiments, which now constitute a substantial part of research and development (R&D) programs in the field, are attractive because, if properly conceived and performed, they share most of the properties of physical experiments but can be carried out at a fraction of the cost and possess an intrinsic degree of flexibility that makes their repetition under slightly different conditions relatively easy. To be useful for design purposes, numerical simulations must have the following requisites:

- *Physical relevance*. They must simulate phenomena that are relevant to design engineers. For instance, they must reproduce ranges of Reynolds numbers and Mach numbers that are found in commercial turbines.
- *Completeness*. They must include a realistically extended portion of the flow domain, so that the information that designers gather from the results may be immediately applicable to global design procedures. For instance, they must include at least one complete blade passage and possibly a complete stage.
- *Reliability*. Their results must not contradict known physical evidence (i.e., they must be calibrated against it). In addition, new phenomenological predictions that emerge from their results must be in accord with the established knowledge in the field.
- *Robustness*. Their results must be reproducible under slightly varied operational conditions within a

reasonable variation of the operating parameters. For instance, the limit behavior in time for all stable unsteady simulations must tend to the steady solution.

• *Physical consistency.* The models (numerical as well as physical) embedded in a numerical simulation must be in agreement with the general physics of all relevant phenomena. For instance, a turbulent model that assumes a certain relationship between the fluctuating velocity components and the local turbulent kinetic energy cannot violate any of the known energy balances established by global considerations.

The first numerical simulations (during the 1970s) were based on inviscid models of the Navier–Stokes equations and could be applied only to very simple geometries. Nevertheless, they demonstrated the capability of capturing some of the known physics. For instance, they correctly predicted the variation of the curvature of streamlines at different radii due to a Coriolis-like effect. During recent years, completely three-dimensional simulations of complex geometries have been presented where the entire stage is simulated (although a correct accounting of the relative motion of the rotoric and statoric blades is still problematic). At the current state of the art, a complete stage can be simulated only under some simplifying assumptions with regard to its geometry and the actual flow conditions. It is likely that in the short to medium run (3–5 years), fully three-dimensional simulations of realistic geometries can be carried out using complex turbulent models such as the LES (large eddy simulation) protocol or the time-dependent "RSM" (Reynolds stress model). Such extensive calculations require well over 10^6 grid points, solve 11 discretized differential equations per grid point on average, and can be performed today only on large, massively parallel computers.

3.9 Final Design and Costing

The two-dimensional design can be updated with the help of numerical simulations and generally results in minor modifications to the blade geometry (mostly, the tip region of the blade and the shape of the casing at the hub are affected). After some necessary testing, the design is finalized, is fully engineered, and goes into production. In this phase, detailed engineering cost accounting procedures are employed to provide an appropriately accurate calculation of the turbine production costs.

4. OFF-DESIGN CONSIDERATIONS

Steam turbines are ill suited to follow large ($>30\%$) load variations. A change in the thermodynamic parameters (pressure and temperature) causes a change in density and affects the fluid dynamics of the fluid–blade coupling. Inlet, profile, blockage, and secondary losses invariably increase if the operating point deviates from the design one. A mass flow rate reduction (or increase) at the entrance of any stage is reflected in a variation of pressures and densities at stage exit and results in an efficiency penalty as well. An exception is partial admission stages, where a rather large mass flow rate adjustment can be made by increasing or decreasing the number of active sectors.

Reaction stages can be regulated in a limited way by adjusting the interstage extractions. But this is not always possible, with extraction conditions often being dictated by process requirements. Thus, the load is usually controlled by throttling the steam upstream of the first stage. This practice is thermodynamically wasteful and in effect limits the load-following capabilities of these machines.

Part-load performance charts are easily drawn. The power delivered by a turbine is $P = m^* \Delta h^* \eta_t$, and it is experimentally verified that, for a fixed condenser pressure, throttling makes the Δh nearly proportional to the Δp. Because the stage pressure drop is linked to the stage mass flow rate by the turbine characteristic line, the partial load curve can be traced point by point. It can also be shown that a multistage turbine behaves as a subsonic nozzle near to its choking point, with its mass flow rate being nearly linearly proportional to the total expansion ratio (and therefore to the degree of throttling). Thus, the delivered power will be proportional to the mass flow rate. In the P/m plane, the line representing part-load performance is straight (in this approximation) and is called the Willans line. It will intersect the m axis at a nonzero point called the no-load flow rate, and it is completely defined by two experimental measurements that are easily performed on an installed machine. If extractions are present, the Willans line is shifted toward higher mass flow rates and the complete part-load performance map takes the appearance shown in Fig. 27. Notice that this "fan" of Willans lines can still be derived experimentally on the basis of two measurements for each extraction flow rate.

The Willans line represents a first-order approximation of the real behavior of a multistage turbine. At its lowest and upmost range, the power

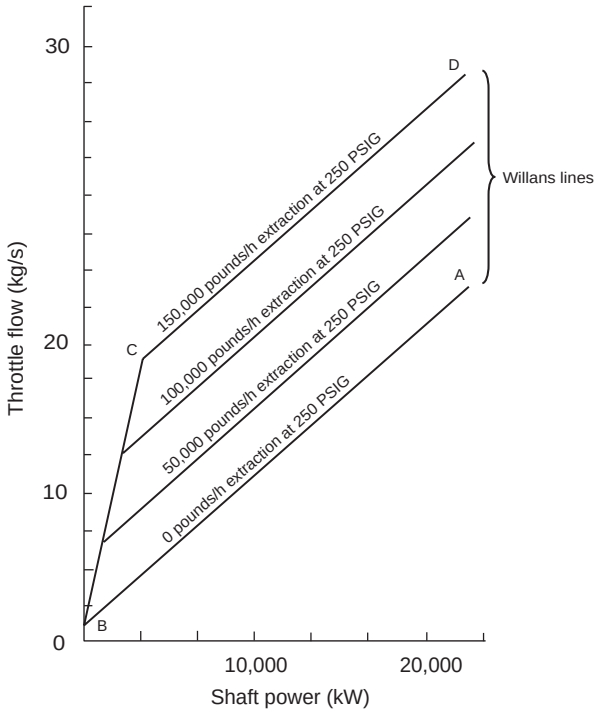

FIGURE 27 A typical extraction turbine performance map showing the Willans lines.

output/mass flow rate dependence is no longer linear.

5. CONCLUSIONS

Steam turbines are the most important machines in the energy conversion field. Their cumulative mechanical and electrical installed power exceeds that of any other type of unit by far. Their design and operational procedures are very advanced, and they can be regarded as mature technological components. They are characterized by the highest stage efficiency among all "prime movers" (with η_{stage} ranging from 0.80 to 0.95), by the highest power output per unit (up to 300 MW for a single body), by one of the highest power densities (up to 700 kW/cm^2 of active flow area), and by one of the highest mean times between failure ($>100{,}000$ h between major overhauls) and also cover an extremely wide range of applications (from a few kilowatts as auxiliary power units to more than 1000 MW in major nuclear plants). Their installed cost is relatively modest in comparison with those of their competitors in a very broad band of their operational field. They do not easily adapt to excessive load variations and, therefore, are better suited for base load plants. Steam turbine-based cogeneration plants have reached guaranteed exergetic efficiencies of more than 45%, and combined cycle units (with the steam turbine bottoming a gas turbine) nowadays exceed 50%. Although only marginal further increases in their performance can be expected to come from design improvements, a more substantial gain may be obtained by increasing the temperature and pressure of the feed steam. Steam turbines for motive applications (marine and terrestrial) are rapidly becoming obsolete because in this field they are being replaced by the lighter and more flexible diesel engines and (especially for the higher power outputs) gas turbines.

Turbine design is also a very mature engineering field. Current procedures are quite well defined and make extensive use of the automated optimal design methods. In this respect, a quantitative leap is necessary in computer speed and numerical methods (especially turbulent modeling) to attain an appreciable advantage over the current state of the art.

Glossary

consist An individual unit or multiple vehicles traveling in a linked set.
grade The slope, or inclination, of the guideway.
guideway The rail, support structure, power delivery conductors, and control sensors that make up the path on which ultralight vehicles move.
headway The time period between trains or individual vehicles passing a particular point on the guideway.
kilowatt-hour (kWh) Base energy unit equaling 1 kW of power used for 1 h.
passengers per hour per direction (pphpd) The measure of capacity of a rail transit system, in terms of the maximum number of passengers the system can move in one direction.

To best describe the relationship between ultralight rail and energy, it is necessary to establish a basis of understanding. This basis is best defined in terms of the energy requirements of known and familiar modes of transportation, since there are so few examples of ultralight rail in operation. This article establishes this basis in terms of conventional rail systems and, where applicable, bus, automobile, and truck systems. The basic characteristics of both conventional and ultralight rail systems are described, followed by a comparison of the two systems, with an emphasis on the energy aspects of their direct operation. The energy aspects of ultralight rail in the overall transportation system of the United States are analyzed and discussed.

1. DEFINITION OF ULTRALIGHT RAIL

Ultralight rail (ULR) is at the low end of the spectrum of weights of rail vehicles and is generally considered any vehicle with a loaded weight of less than 10,000 lbs and with a more personal type of operation. This compares with light rail transit (LRT) (www.travelportland.com/visitors/transportation.html) vehicles that can weigh over 100,000 lbs loaded and the locomotives that pull freight, commuter trains, and Amtrak trains and weigh over 300,000 lbs. The weight of a passenger vehicle on what is classified as a heavy metro rail, such as Bay Area Rapid Transit (BART) in the San Francisco Bay area (www.bart.gov) and the New York City (NYC) subway, can actually weigh less (approximately 60,000 lbs) than an LRT vehicle due to its construction and propulsion system (light refers more to total passenger capacity than individual vehicle weight).

In the ultralight range of steel-wheeled rail vehicles, there are several technologies in development but none in operation. CyberTran (www.cybertran.com), shown in Fig. 1, is an example at the top of the range (10,000 lbs, loaded). CyberTran was developed at the Idaho National Engineering and Environmental Laboratory (www.inel.gov), a Research and Development Laboratory of the United States Department of Energy, and transferred out of the government for commercialization. An Australian technology, Austrans (www.Austrans.com), is somewhat lighter, at approximately 6600 lbs, loaded. Futrex (www.futrexinc.com) is between the ultralight range and the LRT, or full-size rail vehicles, weighing approximately 20,000 lbs loaded.

FIGURE 1 CyberTran vehicle.

There are several systems with vehicles in the ultralight category that utilize rubber-tired vehicles and channel-type guideways, such as Taxi 2000 (www.taxi2000.com) and the ULTra system (www.atsltd.co.uk) at the University of Bristol in Cardiff, England. The Morgantown People Mover (www.wvu.edu/~facserv/prt.htm), at the University of West Virginia, Morgantown, is just over the 10,000 lb loaded weight (9000 lbs empty with a passenger capacity of 21), but represents the best operating example of ultralight-type systems. Although these rubber-tired systems share many of the energy-saving aspects of ultralight rail, they have a larger rolling friction than steel wheel on steel rail. The reader should keep these systems in mind regarding energy discussions that are functions of size, passenger load, small infrastructure costs due to vehicle size, and vehicle movement options generated by small vehicles. An excellent coverage of ultralight systems and innovative transportation concepts under development can be reviewed at the Web site of Professor Jerry Schneider, University of Washington (http://faculty.washington.edu/jbs/itrans).

2. A BRIEF DISCUSSION OF CONVENTIONAL RAIL

Regardless of the weight of the vehicle—ultralight to heavy metro—a steel wheel on a steel rail is the most energy-efficient way to move a load over land. This efficient process was initiated by placing an iron-rimmed wagon wheel on an iron-plated beam, allowing draft animals to pull much heavier wagon loads. With the advent of steam engines to pull the wagons and flanges to keep the wagon wheels from slipping off the steel rails, the essence of the modern railway was born in the early 1800s in the coal mines of England and quickly spread throughout the rest of the world. The energy efficiency of the basic steel wheel on steel rail system was further enhanced with the advent of roller bearings on the axles and propulsion systems with electric and diesel–electric power plants.

2.1 Energy Efficiency of Steel Wheel on Steel Rail

The primary reason for the energy efficiency of steel wheel on steel rail vehicles is the extremely low rolling resistance of the wheel, even under very high loads and/or stresses. A typical loaded freight car can weigh as much as 280,000 lbs, being supported by eight wheels, with each wheel supporting over 35,000 lbs. This wheel load is supported through a contact patch approximately the size of a dime, resulting in a contact stress between the wheel and the rail of approximately 100,000 psi. Although this stress actually deforms the steel wheel and the steel rail, the energy lost in this process is small compared to the energy it takes to deform and roll a rubber tire under a heavy load. The force required to roll a standard railroad vehicle on level ground is approximately 2–4 lbs per ton of vehicle weight.

2.2 Conventional Systems: Vehicle Weights and Capacities

Conventional transit vehicles typically weigh much less than loaded freight cars, but still represent a heavy load to place on wheels and rails. A BART car weighing 80,000 lbs loaded, and supported by eight wheels, has a per wheel load of 10,000 lbs. Articulated LRT vehicles generally have three sets of four-wheeled trucks and, with loaded weights up to 120,000 lbs, this results in a load of 10,000 lbs per wheel. These vehicles roll even more efficiently than heavily loaded freight cars, but still represent a sizable load, with energy-absorbing deformation of the wheel/rail contact area. Rolling friction of typical transit vehicles is on the order of 3 lbs per ton. Figure 2 shows a typical LRT vehicle, operating at ground level in Portland, Oregon. Figure 3 shows an example of a heavy metro rail system, BART, operating on an elevated track in the San Francisco Bay area. LRT vehicles can transport over 100 passengers per vehicle and a 10-car BART train can carry over 1000 passengers.

FIGURE 2 LRT vehicle in Portland, Oregon.

FIGURE 3 BART train.

2.3 Operation of Conventional Rail Transit Systems

The operational process of picking up passengers and moving vehicles around the system is an area where ultralight systems differ significantly from conventional rail transit systems, resulting in opportunities for energy and operational cost savings.

Conventional rail transit systems generally operate as a linear system; i.e., vehicles or trains proceed down the track in sequence, with each train stopping at each station and loading/unloading passengers. The NYC subway system is a rare exception to this process, having express trains that bypass certain stations in favor of decreasing the travel time to just a few stations. The NYC system requires an additional set of tracks in order to operate in this fashion. For most conventional systems in the world, however, the trains run in single file along the system, with the average speed of the system governed by the rate at which the trains can be cycled through each station. For an average station, it takes approximately 30 s for a train to approach a station and come to a complete stop, another 30–45 s to open the doors, unload/load passengers, and close the doors, and another 30 s or so to clear the station with enough margin for the next train to come in. The smallest delay in any of these functions slows the entire line of traffic, with subsequent negative impact on the average speed of the system. Minimum headways of 1.5–3 min are the norm when safety margins are included. Ultralight systems use a different operational process that minimizes the effect of local delays, resulting in a positive effect on average system speed.

2.4 Passenger Flow Rates of Conventional Rail Systems

Capacities of conventional rail systems vary substantially, depending on the capacity of each vehicle or train, the headway between trains, and the speed of the trains. The LRT system in Portland, Oregon is made up of 2-car consists with a total capacity of approximately 320 passengers (seated and standing). At their average headway of 5 min during peak flows, or 12 vehicles per hour, this constitutes a maximum flow rate of 3840 passengers per hour per direction (pphpd). BART, utilizing 10-car consists capable of carrying over 1000 passengers and operating at less than 3 min headways, has a capacity approaching 26,000 pphpd. The Paris Metro, using 5-car consists capable of carrying 1000 people and operating at 90 s headways, has a capacity approaching 40,000 pphpd.

3. CAPACITY AND ENERGY CONSUMPTION OF HIGHWAYS

Highways can also be rated with respect to their maximum capacity and energy consumption, thus making it easier to compare them with rail as a related transportation mode, relative to cost and energy usage. A great deal of research and observation has resulted in the understanding that a multilane highway has a maximum capacity on the order of 2400 vehicles per hour per lane. Considering the fact that approximately 95% of freeway traffic consists of single-occupancy vehicles, a highway lane has a passenger capacity of approximately 2500 pphpd. One can see instances, especially on Los Angeles freeways, of groups of vehicles moving at densities of 50% or more in excess of this number, but not on a sustained basis or over an extended distance.

Considering only those vehicles that meet the CAFE (Corporate Average Fuel Economy) standards of 27.5 miles per gallon, an average vehicle capacity of four seats, and an energy equivalent of 40 kilowatt-hour (kWh) per gallon, the energy efficiency of an automobile is approximately 0.37 kWh per seat-mile. New technology vehicles such as the hybrid-powered automobiles by Honda and Nissan have decreased fuel consumption by a factor of 2 or more, for an energy efficiency of approximately 0.18 kWh per seat-mile. The ultracar technology by Dr. Amory Lovins of the Rocky Mountain Institute (www.rmi.org) promises to increase this efficiency by another 50%, or 0.1 kWh per seat-mile, by achieving a fuel efficiency of approximately 80 mpg.

4. ULTRALIGHT RAIL—OPERATIONAL CHARACTERISTICS

The most dramatic and obvious characteristic of ultralight systems is the size of the individual vehicles relative to conventional rail vehicles. Figure 1 shows the CyberTran No. 2 Test Vehicle, a 38 ft long vehicle, weighing 10,000 lbs loaded, and designed to carry 15–20 passengers. Figure 4 shows the Taxi 2000 vehicle, designed to carry 3 passengers at a loaded weight estimated to be less than 1 ton.

4.1 Computer-Controlled Systems

An important characteristic of ultralight rail system vehicles is that they are computer-controlled.

FIGURE 4 Taxi 2000 vehicle.

Although this characteristic is not unique to ultralight systems (the Vancouver, British Columbia, SkyTrain Metro system and the Paris Metro Meteor line are driverless), in the ultralight systems it is almost a necessity for any reasonable operating economics. If a driver was required in each small vehicle, the overhead costs would be intolerable, requiring trip costs typical of taxicabs without the route flexibility of taxis. It is this characteristic, however, that offers the opportunity for significant energy and cost savings due to the different operating modes possible.

4.2 Ultralight Rail Station Configuration

Two important characteristics of ultralight rail systems are the rapidity with which passengers can be dispatched toward their destination and the speed with which the passengers arrive at their destination. Both of these characteristics are due to a passenger loading/unloading process known as off-line loading and direct-to-destination routing. Off-line loading means that the loading and unloading process takes place off the main line, in a station that is reached by going through a rail switch and proceeding to a loading platform well away from the high-speed traffic of the main line. This accomplishes two important functions: (1) delays in the loading/unloading process at one station do not slow vehicles on the main line and (2) by being able to maintain a high speed between origin and destination, a vehicle has a high average speed over its route. Direct-to-destination routing means that the vehicles do not stop at intermediate stations between their origin and their destination. The ability of a system to send vehicles directly between origin and destination requires that all passengers in that vehicle are going to the same destination, a situation that can be realized only by using small vehicles in conjunction with high speed and computer-controlled direction of passengers to their proper vehicles. Computer control over the operation of each vehicle, and between individual vehicles, results in headways between vehicles of 15 s or less. Managers of the Morgantown People Mover are suggesting going to 7.5 s between vehicles on the main line, and Dr. Edward Anderson, with Taxi 2000, is proposing running at even smaller time increments (www.taxi2000.com). The effect of these short headways is to get more people to their destination quicker, with fewer energy-consuming starts and stops along the way.

4.3 Ultralight Rail Structures

An important characteristic of ultralight rail is that the structures carrying the vehicles are much smaller than the bridges, columns, foundations, etc., normally associated with conventional rail transit systems or even highway bridges. This characteristic is the one having the most impact on relative costs between conventional and ultralight rail systems. The size of structures required to support a 100,000 lb vehicle 15 ft in the air versus elevating a 10,000 lb vehicle not only has a dramatic cost effect on the construction effort, but also in the amount of system energy it takes to produce the extra material and hardware.

4.4 Power Requirements of Ultralight Systems

A hidden, yet important characteristic of ultralight systems is the low power of the electric propulsion motors required to move the vehicles around. Though rolling friction is low for all rail vehicles, the energy required to accelerate or elevate a vehicle is in direct proportion to its weight. This characteristic of having low-power propulsion motors is of most importance relative to the movement of empty or low-ridership vehicles. Conventional, large, high-capacity rail systems must move 10 s of 1000 s of pounds of hardware around the system even if they are empty or lightly loaded. Ultralight rail systems move much smaller vehicles around and then only the number of vehicles that are required to meet the passenger load demands. The advantages of this aspect of ultralight rail systems are discussed further below.

4.5 Passenger Flow Rates

Capacities of ultralight systems cannot approach the capacities of heavy metro rail such as BART, the NYC subway system, or the Paris Metro, but can provide the carrying capacity normally provided by the various LRT systems around the United States. The capacity of a system like the Morgantown People Mover or CyberTran, both having a capacity of approximately 20 passengers and operating at 15 s headways, would be 240 vehicles per hour, for a capacity of 4800 pphpd. Morgantown operators are suggesting that the next upgrade to their system will provide for operation using 7.5 s headways, a headway also evaluated for use with CyberTran. Should these headways be implemented, these two systems would provide a line capacity of 9600 pphpd.

These headways are based on the requirement to allow enough time and distance between adjacent vehicles so that should the leading vehicle come to a sudden stop, the trailing vehicle has the time and distance to stop before hitting the leading vehicle. With this requirement in mind, during high-passenger-flow conditions, it is possible to slow vehicles down and operate under headways even shorter than the proposed 7.5 s. If one reduces the headway to 5 s, a speed of 40 miles per hour (mph) represents a separation the length of a football field and the safe emergency stopping distance is less than one-half of that distance. An operational scenario like this results in a passenger flow rate of 14,400 pphpd, which rivals the advertised capacity of almost any LRT system and is far greater than any actual flow being carried by an existing LRT system. The Taxi 2000 system is proposed to operate three-passenger vehicles at a headway of 0.5–1 s for a passenger flow rate of 7200 pphpd.

5. ENERGY REQUIREMENTS OF ULTRALIGHT RAIL AND CONVENTIONAL RAIL

This section examines the major factors affecting the energy requirements of ultralight and conventional rail systems and the factors that differentiate the energy requirements of the two systems.

5.1 Basic Energy Requirements of Rail Systems

There are four primary energy requirements in the operation of both ultralight rail and conventional rail. These are acceleration, rolling friction, elevation in grade, and aerodynamic drag. Energy requirements for acceleration, rolling, and grade changes are all a direct function of the weight of the vehicle and its occupants. Aerodynamic drag is a function of size, shape, length, etc., and although it is a small force relative to conventional system acceleration and grade-climbing forces, it can be a significant energy consumer in ultralight systems where vehicle weight is one-tenth that of conventional rail vehicles.

A major expenditure of energy is required for elevation change (upward) of conventional rail vehicles and their loads and it is in this area that one of the major differences in system energy consumption can be seen between conventional systems and ultralight rail systems. It is also the

reason that conventional rail systems, especially locomotive-powered systems, are limited to rather flat grades throughout their routing. A conventional, 100,000 lb LRT traveling up a 2% grade at 60 mph requires 240 kW of power just for energy associated with the grade change, plus the energy required to overcome the rolling friction and aerodynamic drag at this speed. An ultralight vehicle loaded to 10,000 lbs would require only 24 kW to handle the same grade. In transit systems where a series of "trailer" cars are pulled by a locomotive, such as with Amtrak, all of the "grade" drag must be supplied by the traction of the locomotive. In the case of a train of 10 cars, each weighing 100,000 lbs, the locomotive pulling this train must exert a pulling force of 10,000 lbs for each degree of slope of the roadbed (0.01grade $\times$ 10 cars $\times$ 100,000 lbs), plus the adhesion required to move the locomotive (2500 lbs for a typical 250,000 lb locomotive). BART has four 110 kW electric motors per car, for a total of 4400 kW for a 10-car train. LRT vehicles typically have electric motors in the range of 400 kW per vehicle. Ultralight vehicles require motors of less than 50 kW to meet rolling, acceleration, grade, and aerodynamic energy needs.

5.2 Vehicle Weight per Passenger

For rail vehicles not pulled by a locomotive (BART, NYC subway, Paris Metro, LRT, ultralight systems), the vehicle weight per passenger is remarkably similar. LRT vehicles have an advertised capacity in the neighborhood of 160 passengers and an empty weight of approximately 80,000–90,000 lbs (depending on manufacturer and configuration), for a per passenger capacity weight of approximately 500–560 lbs. BART has a vehicle weight of approximately 60,000 lbs and a capacity of approximately 120 passengers per vehicle, or 500 lbs per passenger. CyberTran has an empty weight of approximately 7500 lbs and a seated capacity of 15–20, or a maximum per passenger weight of 375–500 lbs per passenger. The Morgantown People Mover vehicle is approximately 9000 lbs with a 21-passenger capacity, or 428 lbs per passenger.

5.3 Vehicle Weight per Passenger versus Load Factor

In addition to the similarity of weights per passenger, all of the rail systems described use very efficient electric motors in their propulsion systems, albeit of greatly different power between the heavy and the ultralight systems. Therefore, on a per passenger basis, one should not expect much difference in the energy efficiency of a heavy system and a light system when both systems are operating at or near their capacity. It is when the systems are required to operate at less than their maximum loads (which is the case for most systems having a morning and evening rush hour) that significant differences can be seen between the operation of conventional rail systems and ultralight systems.

To illustrate the effects of weight, passenger capacity, and operating process on the energy consumption of a rail transit system, assume an LRT with an empty weight of 75,000 lbs and a passenger capacity of 150 (at 166 lbs per passenger), comparing its operation with an ultralight system of 7500 lb vehicles and a capacity of 15 (to simplify the math). Table I shows the effective system weight and the weight per passenger of a conventional system and an ultralight system as the ridership drops (assuming constant frequency for the LRT and sufficient ultralight vehicles to carry the ridership).

Table I shows the dramatic effect of operating a system with small vehicles and one that allows the system control to use only the number of vehicles (capacity) required to carry the load at any one time. The LRT system is forced to provide an entire, high-capacity vehicle even when there are only a few riders, whereas the ultralight system merely provides enough vehicles to carry the riders. From Table I, it can be seen that the primary energy requirements of an ultralight system that are based on vehicle and passenger load weights range from equal at full load to only 10% as the passenger load approaches zero.

TABLE I

Effects of Load Factor on Vehicle Efficiency

Riders/ cycle	Effective system weight		Vehicle weight per passenger	
	LRT	ULR	LRT	ULR
150	100,000	100,000[a]	500	500
75	87,500	50,000[b]	1000	500
37	81,166	28,642[c]	2027	608
20	78,333	18,320	3750	750
10	76,666	9166	7500	750
1	75,166	7666	75,000	7500

[a] Assumes 10 fully loaded vehicles to carry load at 10,000 lbs per loaded vehicle.

[b] Five vehicles at 7500 pounds each plus 12,500 lbs of passengers.

[c] Requires three vehicles to carry 37 passengers.

5.4 Energy Efficiency of Off-Line Loading and Direct to Destination Routing

Another aspect of operational differences between conventional and ultralight systems that can have effects on energy consumption is the ability of ultralight systems to operate in a full-time express mode, i.e., direct to destination, as opposed to the linear operating mode of conventional rail, i.e., stopping at every station. The standard operating mode of ultralight systems is the use of off-line loading/unloading, as described in the previous section. With an appropriately designed station, an ultralight vehicle can leave any station and go directly to any other station, in either direction. A conventional linear system, however, must start at one end of the line with all of the capacity it will require to handle the heaviest traffic between any two stations on the line.

Table II illustrates the effect of this necessity for "carrying your capacity" through the entire line versus the option available with ultralight systems to place in service only the capacity needed to carry the load.

The operational efficiency of each system for this example, defined as the passenger segments required/passenger segments provided, is 46.2% for the conventional system and 93.2% for the ultralight system.

Each unit of capacity delivered carries a cost in energy as well as wear and tear on the system. With each system having a vehicle weight of approximately 500 lbs per unit of capacity, accelerating each of these extra units of capacity and carrying them through any change in elevation, plus the small amount of rolling energy, indicates that, for this example, the ultralight system is more than twice as energy efficient in carrying the required passenger load. This increased efficiency is due entirely to the operating options available with the ultralight system, since the basic weight per passenger capacity, motor efficiency, and effects that are a function of weight, such as acceleration, elevation change, and rolling, are essentially the same.

An additional effect that is not illustrated in Table II, but can be readily seen as a source of additional energy savings, is the savings associated with not having to stop at intermediate stations. When traffic becomes sufficiently large, the small vehicles can be filled at one station with passengers destined for a single other station, as opposed to conventional linear rail systems where all passengers to all stations are in the same vehicle and stop at all stops. This single-destination vehicle then proceeds directly from its originating station to its destination station, not having to expend the energy of stopping and starting at each intermediate station, and traveling between the stations at a much higher average speed. Computer simulations between direct to destination routing and linear system routing indicate an increase in average system speed of a factor of 3 (from 15.7 mph in the Portland MAX system to 51 mph in a simulated system with ultralight vehicles).

TABLE II

Conventional versus Capacity-Dictated Vehicle Dispatch

	Passenger flow				
Station	Entry	Exit	Net capacity required	LRT capacity	ULR[a] capacity
1	20	0		150	30 (2 vehicles)
2	50	10	60	150	60 (4 vehicles)
3	50	20	90	150	95 (7 vehicles)
4	70	10	150	150	150 (10 vehicles)
5	20	80	90	150	95 (7 vehicles)
6	10	50	50	150	60 (4 vehicles)
7	5	30	25	150	30 (2 vehicles)
8	0	25	0	150	
Total capacity required:			485 passenger segments[b]		
Total capacity delivered (passenger segments):				1050	520

[a] Assumes that vehicles carry multidestination passengers, stop only at stations to which passengers are going, and can reverse direction at any station.

[b] One passenger segment is one passenger transported between adjacent stations.

5.5 Energy Efficiency Potential from Intermodal Operations

As illustrated in Table I, high-capacity, heavy metro and LRT systems can be very efficient, energy-wise, when operated at high passenger loads, and conversely, can be extremely inefficient during periods of low passenger flow. Figure 5 illustrates the effect of load on energy efficiency as the

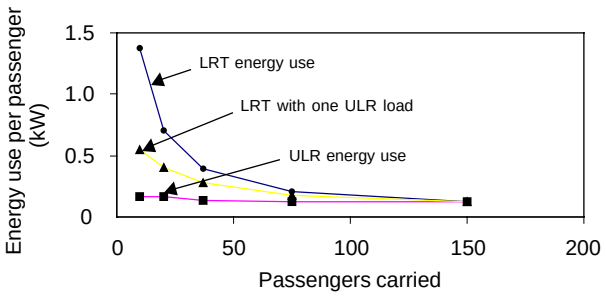

FIGURE 5 Energy use of LRT and ULR with intermodal effects.

passenger load decreases in (1) a 150-passenger LRT vehicle and (2) 10 ULR vehicles, with the ultralight vehicles being removed from service as the load decreases.

Ultralight rail systems have the potential to increase the energy efficiency of high-speed and heavy rail systems by feeding extra passengers into existing stations from outlying areas off the sides and ends of the high-capacity systems. Figure 5 provides an example of the increase in energy efficiency possible by the intermodal connection of conventional rail systems and ultralight rail, where a single ultralight passenger load is brought in from the side or end and added to the passenger load of a conventional LRT-size vehicle.

Additional passengers brought in from the side or ends of conventional systems by small ultralight vehicles not only increase the energy efficiency of the conventional systems, but reduce the need to provide additional parking in the immediate station area. Parking for the ultralight systems can be placed far from the conventional system stations in less expensive and more accessible real estate.

Conventional heavy metro and LRT systems are expensive ($50,000,000 to $100,000,000 per mile) and have a large ground footprint, two characteristics that detract from extending the systems into lower density sources of passengers. Additionally, it is not only expensive to provide parking around stations, where the land is at a premium, but 5 acres of expensive parking can hold only ~750 vehicles, approximately the passenger capacity of one heavy metro train. Therefore, the first train through the system can take all of the parking lot patrons, leaving the station isolated to many potential passengers and lowering the efficiency of the large transit system. Ultralight systems that cost $10,000,000 to $20,000,000 per mile and have a much smaller ground footprint can be extended far beyond the walking limits of conventional rail stations, bringing additional passengers to the conventional system in an energy-efficient process, making the operation of the conventional system even more efficient, since the marginal energy cost of additional passengers on a conventional system is extremely low.

5.6 Ultralight Rail and Cargo Transport

A final point in the spectrum of possibilities with ultralight rail is the transportation of cargo. Ultralight vehicles with a maximum gross vehicle weight of up to 10,000 lbs have a cargo-carrying potential of over 5000 lbs. With a rolling resistance and an aerodynamic drag of an ultralight vehicle having an average power requirement of approximately 12 kW, the energy consumption of an ultralight cargo vehicle can be on the order of 0.08 kWh per ton-mile. This value compares with a Class 8 truck that can carry 25 tons at an average diesel consumption of 6 miles per gallon, or for an energy equivalent of 40 kWh per diesel-gallon, an energy consumption of 0.266 kWh per ton-mile. Although the energy consumption of highway trucks is approximately a factor of 3 times that of an ultralight rail vehicle, the monetary economics of the process is not as disparate. For an electricity cost of $0.10 per kWh, the direct energy cost of an ultralight rail vehicle is $0.008 per ton-mile. For a diesel price of $1.50 per gallon, the direct energy cost of truck cargo is $0.01 per ton-mile, only 25% more that the ultralight vehicle cost. This cost comparison is more a reflection of the energy policy of the United States than of the energy consumption rates of the two modes of cargo transport. However, when one adds in the cost of the truck driver, approximately $0.02 per ton-mile, the monetary cost difference between the two modes of transport is comparable with the differences in energy consumption between ultralight rail and heavy trucks.

Obviously, ultralight rail systems would be best utilized in certain types of high-value cargo, such as the U.S. mail, electronics, or any item with a high time value.

6. COST OF ULTRALIGHT RAIL SYSTEMS

There are two primary areas of cost savings with ultralight systems, those being in the initial construction of the system and in the operation of the system. A further area of potential savings is in the process by which these systems are planned, designed, and constructed.

6.1 Construction Costs

The cost of any transit system is dominated by the structural infrastructure costs (~60%), followed by power systems (~20%), vehicles (~10%), and miscellaneous (~10%). Specific costs for planning, engineering, permits, etc. can be included in the individual unit costs or sometimes identified as separate unit costs.

The important item to note in the cost numbers is that the largest component by far is the structural aspect of the system, that being right-of-way real estate, support structures, bridges, rail and rail support systems, tunnels, etc. The size and cost of all of these subcomponents are driven by the size and weight of the vehicles that must be carried through the system. Not only are the size and cost of these components driven by the size and weight of the vehicles carried, but the components have a nonlinear relationship to the vehicle weight. As the weight of the vehicle to be carried increases, the size and weight of the bridge or guideway section increase due to the higher vehicle weight plus an increase in size and weight due to the increased weight of the structural section itself. This is a vicious circle that can result, in many cases, in the primary load on the structure being the structure itself. This effect can be particularly onerous in areas with high seismic activity where extra mass in elevated structures (elevated concrete guideways) can result in extremely large structures.

In addition to the nonlinearity in size caused by large structures having to support themselves, the cost of constructing these structures can have a nonlinear effect. It takes a disproportionate amount of time, labor, and construction machinery to put large structural systems in place relative to the lightweight components required for ultralight rail systems. Whereas very large components of heavy vehicle systems may have to be formed and poured in place (requiring a great deal of on-site labor and machinery), lightweight components can be mass produced off-site, trucked on-site, and lifted into place with readily available cranes and rigging.

As an example of relative weights, a 60 ft elevated steel guideway truss for CyberTran weighs approximately 3 tons, whereas the elevated concrete guideway sections typical of conventional people mover systems can weigh as much as 120 tons (prestressed section 3 ft deep and 9 ft wide). The guideway section for a Taxi 2000 vehicle would be expected to weigh even less than the CyberTran section. It is clear that a cost advantage exists in both the fabrication and erection processes between conventional systems and the ultralight systems, given that a 3-ton weight can be easily fabricated off-site, trucked to the site, and quickly lifted into place, as opposed to the same process associated with dealing with a 120-ton unit.

Structural components as low in the system as the rails also show a dramatic difference in size and costs. The Portland MAX system uses 115 lb rail (115 lbs per yard), whereas the CyberTran system is designed to use a rail weighing 12.5 lbs per yard. This approximate factor of 10:1 between the rail weights not only means a 10:1 factor in the basic material costs, but a 12 ft standard rail length weighs approximately 50 lbs and can be handled by one construction person, whereas a standard 39 ft rail section weighs approximately 4500 lbs and must be handled with machinery and at least two construction personnel.

Power delivery systems can show a similar ratio between size, and therefore cost, of conventional systems and ultralight systems. Two-car consists of conventional LRT vehicles (with 400 kW per vehicle) passing each other on a bidirectional right of way require a delivered capacity of 1600 kW at each point along the guideway. Two CyberTran vehicles (with 75 kW per vehicle) require a point capacity of 150 kW, or a factor of over 10:1 between the conventional system and the ultralight system. Lighter systems such as Taxi 2000 and Austrans would be expected to have even larger ratios.

The power ratios between ultralight systems can be even more dramatic when compared with high-speed trains, which some systems, such as CyberTran, are capable of competing with in the speed range of 125–150 mph. A French Train Grande Vitesse (TGV) has 8800 kW of motor capacity on board, which translates to the potential of 17.6 MW of power requirement at any point on the system where two trains might pass. Two high-speed versions of the CyberTran vehicles, using two 75 kW motors each, would require a point power delivery requirement of 300 kW, for a power system ratio of almost 60:1. A ratio like this results in a dramatic difference in the size and cost of power supply components such as transformers, rectifiers, cables, relays, and fuses.

Although the specific capital cost of any transit system is a function of the local conditions, it is apparent from the above comparisons that the cost of an ultralight system can be substantially less than the cost of a conventional technology system. Although a commercial ultralight system has not been placed in operating revenue service yet, a number of cost estimates have been made on these systems using conventional estimating techniques based on the use of conventional construction materials and techniques.

These estimates project a capital cost for ultralight systems in the range of $10 million to $20 million per bidirectional route mile. This compares with experience and estimates for conventional technology, LRT-type systems, in the range of $30 million to $60 million per route mile, and heavy rail systems like BART, on the order of $100 million per route mile.

6.2 Operating and Maintenance Costs

Ultralight systems have the opportunity to realize significant reductions in operating and maintenance costs due to the basic operating mode of the systems (automated system control and driverless computer-controlled vehicles) and the maintenance processes associated with small vehicles and small system components (rails, switches, etc.).

Maintenance facilities for ultralight systems can be substantially smaller and less costly than conventional technology maintenance facilities due to the much smaller size and weight of the vehicles to be handled. Buildings can be smaller and the associated lifting and handling machinery can be one-tenth the size of the machinery required to handle conventional rail equipment. The general practice in the ultralight rail concepts of keeping and storing vehicles at stations (for ready availability) results in smaller real estate needs for fleet storage, relative to the large marshaling yards typical of conventional rail technology.

6.3 Cost Effects of Construction Process

The construction procedure for conventional technology systems is a highly fractured process, even when one company takes on the responsibility for developing the complete system, such as a DBOM (design, build, operate, and maintain), because almost all of the major subcomponents (engineering, civil structure construction, vehicles, signaling, power systems, permanent way components, fare collection, etc.) are handled by different companies. This process results in excess costs for program management as well as the basic needs for profit and overhead costs by each of the subcomponent suppliers.

Significant savings in the supply of ultralight systems are possible if the developers of ultralight systems define a standardized system with standardized components available from efficient suppliers or produced internally. This process of standardizing the product and making the subcomponent supply line extremely efficient was started by Henry Ford in his automotive production process. Instead of buying many components from a variety of suppliers and using expensive custom manufacturing procedures, Ford generated many of his own components and put efficient mass production procedures in place. A very similar process was initiated by General Electric (GE) and General Motors (GM) in the production of rail locomotives. GE and GM produced a standard locomotive and the rail lines met their varied traction needs by using a varying number of locomotives, as opposed to the practice of many steam locomotive manufacturers that produced engines to the specific requirements of individual rail lines.

7. BARRIERS TO IMPLEMENTATION

There are significant barriers to implementation of any of these ultralight concepts, but none are technical in nature. The technologies associated with each of the concepts mentioned in this article are essentially off-the-shelf, with many of the subcomponents planned for use at a technical level much lower than already available and in use. The communication, computer control, and data transfer requirements of the ultralight rail systems are orders of magnitude less complex than similar functions performed continuously by the world's cell telephone operation or even a medium-sized office's computer network. The mechanics of ultralight systems are operationally similar to the systems that have been operating for 180 years and construction of the components of the system is a process within the capabilities of a broad spectrum of American and world industry.

The primary barriers to implementation are as follows:

1. The almost nonexistence of government research funds for the development and implementation of new technology
2. The reluctance (and sometimes legal barrier) to buy unproven technology or technology that is not yet in revenue service (a great Catch-22 that benefits in-place technologies)
3. The reluctance of existing industry members to take on a new technology with which they have no experience or expertise
4. The opposition by groups that view this concept as competition to their particular technology (automobiles, buses, taxis, airline, conventional rail) or profession (road construction, supplier to competing technologies, consultants for conventional technology)
5. Members of certain environmental groups who see any system that makes transportation more efficient as being a promoter of urban sprawl

Having identified all of the seemingly formidable barriers above, it is important to point out that these barriers are not new or unique to this particular technology. The diesel–electric locomotives faced similar concerns relative to the long history of steam locomotives and their technology support infrastructure. Automobiles faced opposition from those in the horse-drawn carriage trade and the manufacturers of the carriage components, as well as the legal structure concerned with public safety. Business leaders initially saw little need for telephones, considering the cost, convenience, and experience of message boys. American locomotive engineers have fought the automated control of locomotives in switching yards for years and have only just begun to accept a very efficient technology that has been used in Canada for years. One should also remember that it took George Westinghouse over 20 years—and took an act of Congress—to get air brakes on American trains, despite the obvious safety needs at the time for the system.

Dealing with these barriers to implementation is part of the development process for any new technology, and if history is any guide, an appropriate and timely technology will eventually win out.

8. ENERGY-SAVING OPPORTUNITIES WITH ULTRALIGHT RAIL

The above data and comparisons indicate that significant energy savings and cost savings are possible with the implementation of ultralight rail systems. The energy savings of ultralight rail systems relative to conventional rail systems is due primarily to the ability of ultralight systems to quickly adjust the number of vehicles, and thus capacity, to the ridership requirements. These savings are possible not only with stand-alone ultralight rail systems, but with their use as support and passenger-feed systems to high-passenger-volume conventional rail systems, such as BART, the NYC subway, and certain LRT systems.

The energy savings of ultralight rail relative to automobiles are due not only to the basic increased energy efficiency of a steel-wheeled vehicle over a rubber-tired vehicle, but also to the highly inefficient utilization of automobiles in congested commuting situations.

Table III illustrates the potential effect of ultralight rail on energy consumption in the human transportation sector of the United States economy. Table III shows the energy consumption of four transportation modes, in terms of their potential usage (kilowatt-hour per available place mile) and in terms of their actual (or best estimated) usage (kilowatt-hour per passenger mile).

TABLE III

Energy Usage of Various Transportation Modes

	LRT[a]	ULR	Bus[a]	Automobile[b]
Potential (k Wh per place mile)	0.04	0.04[c]	0.14	0.37
Actual(k Wh per place mile)	1.14	0.106[d]	4.06	1.4[e]

[a] Data from Portland MAX (1989) Special Report 221, Transportation Research Board, Washington, DC.

[b] Four passenger auto mobile getting 27 miles per gallon.

[c] Estimate based on weight and seats compared to LRT.

[d] Based on dispatching out at 60% occupancy and deadheading back empty.

[e] Based on 1.05 passenger average occupancy—units of kWhrper/passenger mile.

Table III shows that conventional rail and ultralight rail are essentially the same in terms of energy efficiency when operated at their maximum potential, but that the capability of ultralight rail to leave unneeded capacity at the station has a dramatic effect on energy efficiency at less than maximum loads. Table III indicates that in situations where ultralight rail can augment or be substituted for other transportation modes, significant energy savings can result, such as with LRT (91%), buses (97%), and personal automobiles (92%). Although there will always be a necessity for buses and automobiles, the energy consumption numbers indicate that rail in general, and ultralight rail in particular, should be implemented as widely as possible for the energy-saving potential the technology offers.

Significant energy savings are possible with the implementation of ultralight rail systems and, in addition, the energy source for these systems, electricity, can be generated from resources under domestic control (coal, hydroelectric, nuclear, natural gas) as opposed to the foreign oil base of the majority of the transportation infrastructure of the United States.

sustainable development Development that meets the needs of the present without compromising the ability of future generations to meet their own needs.

Type I agreements Agreements between governments to implement sustainable development.

Type II agreements Partnerships between a combination of governments, NGOs, and the private sector for the implementation of sustainable development.

World Summit on Sustainable Development (WSSD) Held in Johannesburg, South Africa, August 26 to September 4, 2002.

Sustainable development has been on the international environmental agenda since the 1980s. One of the most commonly cited definitions of sustainable development comes from the World Commission on Environment and Development (WCED), which states that "sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs." Developing the generation and usage of energy in a sustainable manner has been a primary focus of sustainable development initiatives. The involvement of private-sector energy companies has evolved during progressive global conferences, in the context of increasing globalization and a heightened focus on trade and development over pure environmental issues.

1. BACKGROUND TO TYPE II AGREEMENTS

During the United Nations Conference on the Human Environment, held in Stockholm in June 1972, sustainable development as an aim had not yet been identified, but the significant impact of business in environmental matters certainly had been. Thirty years ago, business was viewed as a problem to be solved by nation-states, certainly not as a stakeholder to be involved in any negotiation on international environmental treaties. The private sector was practically unanimously perceived as being on the side of development, encouraging increasing consumption of natural resources and therefore against the environment almost by definition.

Twenty years after UNCHE, the United Nations Conference on Environment and Development (UNCED) met in 1992 at Rio to produce fundamental principles and a program of action for achieving sustainable development, crystallized in the Rio principles and Agenda 21. In this forum, business as a driver of energy consumption was still viewed as the problem, but by this stage there existed a degree of grudging acknowledgement that to achieve the aims of sustainable development, there would have to be some level of dialogue between business and the nation-states. This acknowledgement was partially fueled by the increasing global power of large multinational corporations, some of whose individual economies were more significant than those of some states. In this context, any individual

 © 2004 Elsevier Inc. All rights reserved.

state had become unable to monitor and therefore control the activities of registered companies.

This push factor played a part in forcing nation-states to accept business to the table, albeit a table geographically removed from that of the 184 governments at Rio. This was documented in Agenda 21, which identified business and industry as one of nine major groups that can empower communities to mobilize for the environment. The North/South negotiating dynamic also increasingly played a part in involving business with sustainable development negotiations, as some countries from the South viewed their participation in potentially GDP-reducing environmental projects as contingent on support for development to alleviate poverty. Governments from the North possessed capacity to provide that support, but the private sector was vital to any implementation, which provided additional pressure to include business in the dialogue. The ecological interdependence of development and the natural environment became replicated in the negotiating dynamics of UNCED. Acknowledgement of this interdependence can be observed in the Rio Declaration on Environment and Development, which states in Principle 4 that "in order to achieve sustainable development, environmental protection shall constitute an integral part of the development process and cannot be considered in isolation from it."

After Rio, environmental issues became firmly established as global problems that require real solutions, and voices for business took the position that it is better be at the table and provide appropriate input rather than take an isolationist stance that may lead to the imposition of suboptimal legislation later down the line. With the formation of organizations such as the World Business Council for Sustainable Development (WBCSD) in 1995, the private sector began to develop a coherent voice on sustainable development issues, although the cooperation between those organizations and governments was limited. Toward the end of the 1990s, interest in business as a lever for promoting sustainable development began to increase, although environmental issues themselves fell down the list of government priorities in favor of global issues such as trade. Membership of the WBCSD grew to more than 170 and the organization began to develop sustainability reports on the energy sector, which were submitted to global conferences.

As the World Summit on Sustainable Development (WSSD) 2002 approached, the Preparatory Committee began to realize that a new type of agreement would be necessary at Johannesburg to enable implementation of sustainable development objectives. The low level of implementation since Rio was noted at the second session of the Preparatory Committee (Prepcom) for the WSSD (New York, January 2002), which also recognized that the WSSD would be unlikely to achieve specific commitments between governments in that global political climate. An outline of the nature of a second type of partnership was prepared, inviting governments, international governmental organizations (IGOs), and major nongovernmental organizations (NGOs) to put forward preliminary partnership proposals at the third (New York, March 2002) and fourth (Jakarta, May 2002) Prepcoms.

Proposals were required to be aimed at supporting practical implementation of Agenda 21 and sustainable development activities in developing countries. Additionally, proposals were to be international in scope, consist of more than one partner, and be specifically developed for the WSSD. This new type of agreement, labeled Type II, was intended as informal, voluntary commitments, generally between a combination of governments, business, NGOs, and IGOs. In contrast, Type I agreements are specific commitments between governments. The chairman's notes from the second Prepcom also stated that "partnerships and initiatives to implement Agenda 21 are expected to become one of the major outcomes of the World Summit on Sustainable Development." As these partnerships are a specified major outcome of a global summit attended by 189 governments, more than 700 NGOs, and hundreds of international corporations and quasi-governmental interests, the success of generating partnerships and whether those partnerships retain the characteristics intended by the WSSD both merit investigation.

Advantages of Type II agreements over Type I agreements cited during the later Prepcoms include the reduction of time taken to develop agreements, leverage of nongovernment resources and increased credibility, participation, and range of expertise. By the fourth Prepcom (May 2002), more than 400 stakeholders from 50 countries had collaborated to create 14 draft proposals, energy being one of the four broad issues addressed. At Johannesburg, more than 170 Type II proposals had been developed for presentation. Principle 27 of the Johannesburg Declaration on Sustainable Development stated, "We agree that in pursuit of their legitimate activities the private sector, both large and small companies, have a duty to contribute to the evolution of equitable and sustainable communities and societies." This position is more collaborative than in

either of the previous two declarations and may represent the balance point of business involvement in negotiated sustainable development. Since the WSSD, updates to both initial proposals and completely new proposals have been added to this set of agreements, and there is no submission deadline.

2. *ANALYSIS OF TYPE II ENERGY AGREEMENTS*

Some analysis of Type II agreements has been carried out by the Commission on Sustainable Development (CSD), which emerged from Agenda 21 after UNCED and is now designated to oversee progress on these agreements. As these partnerships were a last minute addition to the WSSD agenda, promoted as a significant outcome to the summit once it became clear that no new intergovernmental agreements could be achieved, it is important to establish to what extent they can add value to the quest for sustainable development. A detailed database analysis of Type II partnership agreements provides some level of insight into this question, using three CSD lists of Type II Agreements. The first was submitted as of August 16, 2002, for discussion during the conference, containing 172 agreements, and the second was published on April 24, 2003, containing 266 agreements. The CSD then reviewed this April list to ensure partnerships complied with guidelines laid out in their Implementation Track for Agenda 21 published in May and redrafted an approved partnership list of 232 agreements in June. This Implementation Track incorporated the Bali Guiding Principles and General Assembly resolution 56/76.

2.1 Partnership Aims

The majority of Type II agreements have multiple aims, and there are a number of ways to cluster the data set. The information can be assessed based on the target of the partnership (e.g., energy), the means of implementing the partnership (e.g., technology transfer and capacity building) or the geographic focus of the agreement. Africa and small island developing states (SIDS) were singled out by the CSD as geographic categories meriting primary aim status. For clarity, these aims have been hierarchically mapped into broad categories (Fig. 1). Tertiary aims of the agreements were then identified using information provided in the WSSD Type II Partnership lists and additional data provided by multiple online forms as submitted by individual partnerships.

Ninety-three agreements approved to date primarily characterize themselves as managing the natural resource base, with 88 implementation

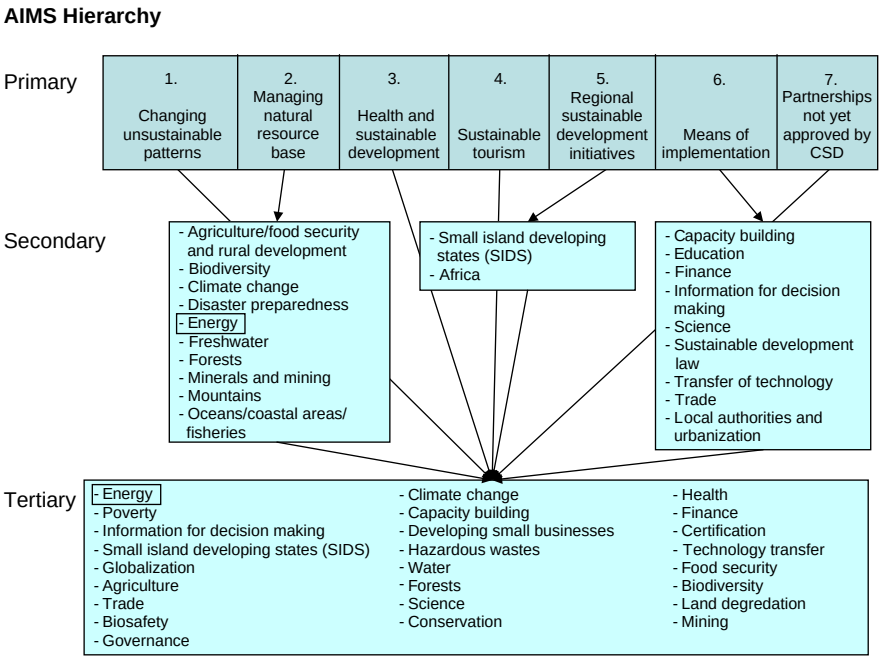

FIGURE 1 Flowchart illustrating the hierarchy of aims within which Type II agreements can be analyzed and the positioning of energy agreements within that hierarchy.

agreements as the second most frequent category (Fig. 2). Together, the categories of Managing Natural Resources and Implementation make up over 57% of the partnership proposals submitted to date and 70% of the 232 successful partnerships. Breaking these categories down into secondary aims demonstrates that energy is a major focus of natural resource management, and energy issues are explicitly addressed by 39 approved partnerships. Freshwater, agriculture, and oceans each comprise 15% of natural resource agreements. Biodiversity and climate change have 9 and 7 agreements, respectively, with disaster preparedness, forests, mountains, and mining each comprising of fewer than five agreements. The significance of African sustainable development initiatives in the third most frequent category of partnerships reflects the numerous sustainable development challenges faced by Africa. Successive United Nations Development Programme (UNDP) Human Development Reports document the challenges faced by sub-Saharan Africa, including low rates of access to electricity, low energy consumption per capita, declining income per capita, and information-poor schools and hospitals, the breadth and depth of which are unrivaled by any other continent.

Strengthening of local authorities (which includes urbanization and city planning partnerships) and provision of education are the methods by which more than half of the implementation agreements are to be enacted. Provision of information, science, trade, and capacity-building are also important implementation categories, with sustainable development law, finance, and technology transfer each comprising fewer than five agreements. The focus appears to be on implementation by empowerment, organization, and information (local authorities, education, capacity-building) rather than implementation by the application of explicit tools (finance, trade, law).

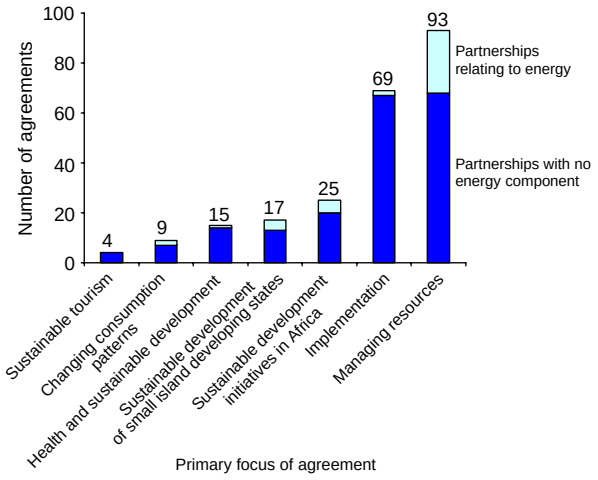

FIGURE 2 Bar chart displaying the primary focus of Type II agreements and highlighting the relative importance of energy as a sustainable development aim. Number of agreements (y axis) is plotted against primary aim of agreement (x axis).

The majority of tertiary aims appear to focus on implementation issues, the three most frequent tertiary aims being capacity building, technology transfer, and information for decision making, in that order. Poverty is a category not explicitly covered in primary or secondary aims and is the most frequent nonimplementation tertiary aim, stated by 48 (over a fifth of) Type II partnerships. Many sustainable development projects appear to have the underlying aim of poverty reduction while tackling primary natural resource management issues including energy, agriculture, freshwater, and biodiversity. Education partnerships have a large number of tertiary aims, reflecting the wide range of sustainable development topics that can be taught and the multiple benefits of education. The importance of both poverty eradication and education are reflected as two of the UN Millennium Development Goals: to reduce by half the proportion of people who live on less than a dollar a day and to ensure that all boys and girls complete a full course of primary schooling.

A number of the so-called small island developing states projects touched on similar concerns as those within the Oceans bracket, which enhances the importance of marine issues. It could be hypothesized that many of the challenges faced by SIDS stem from concerns on climate change, which is directly impacted by sustainable energy development initiatives. However, climate change does not feature highly on list of SIDS partnership tertiary aims. This may reflect the possibility that only a finite number of scientific partnerships on climate change are required, but that a host of development projects will be required to support the SIDS if climate change causes sea levels to rise significantly.

Although all partnership categories are weighted to target developing countries, local authority and climate change partnerships have the highest developed country target of approximately 28%. This does not reflect the WSSD aim that "only those partnerships/initiatives that … are aimed at sustainable development activities in developing countries … would be announced during the official partnership events." However, climate change and the interlinked energy consumption trends remain fundamentally global issues, even if initiatives to tackle the problem are based in developed countries.

2.2 Geographic Focus

Within this discussion, the North refers to developed countries and the South refers to developing countries and countries in transition. This differentiation is primarily but not solely economic, and there are more subtle geographic, linguistic, and cultural linkages that also define why the South (e.g., the G77 group of 77-plus countries) often negotiates as a caucus in the UN system.

More than half the agreements are targeted at enhancing the sustainable development of countries from the South (165 of the partnership proposals), with another third (98 of the partnership proposals) targeted globally. The global partnerships most commonly focus on health, education, and local authority development issues. Only 6% of the partnerships appear to be focused solely at countries in the North, which does not match the WSSD intentions of Type II agreements focusing on developing countries.

Over twice as many NGOs from the North submitted agreements as NGOs from the South (Fig. 3). Given the larger number of well-funded NGOs situated in the North, this is to be expected, although it may be of concern given the potentially remote nature of project management. However, all of these partnerships are open to approaches from other organizations, and they are continually evolving. Twenty partnerships already involve NGOs from the North and South working in partnership, and many North-based NGOs may have country offices in the South, staffed by people from the South.

Of the 39 approved agreements relating to energy, six have participants from the South, Indonesia being the only active lead government in an energy agreement from the South. Tanzania is working in partnership with Germany, and Mexico is working in partnership with Australia on sustainable energy projects. The Pacific Islands Energy for Sustainable Development agreement, run by the Pacific Islands Forum Secretariat, is based in Fiji, and from South Africa two energy projects have been submitted by a collective of African governments and the South African branch of the World Conservation Union (IUCN). When compared to the average level of intergovernment collaboration between North and South (4% of Type II partnerships), that for energy agreements is relatively high (8%), which is a positive indicator of cooperation within the sustainable energy sector.

2.3 Source of Partnerships

The high proportion of 1 partner only agreements (205 agreements) suggests they are in the process of evolving (Fig. 4). The number of statements

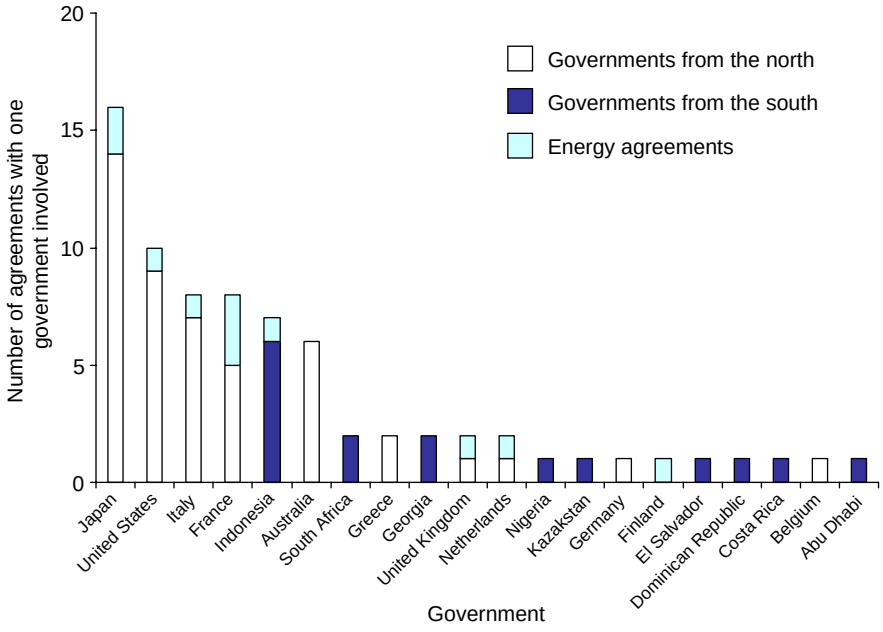

FIGURE 3 Bar chart illustrating the source of partners involved in Type II agreements, bisected into the categories North and South. A bar chart further illustrates the degree of government involvement in Type II agreements, plotting number of agreements (y axis) against government (x axis).

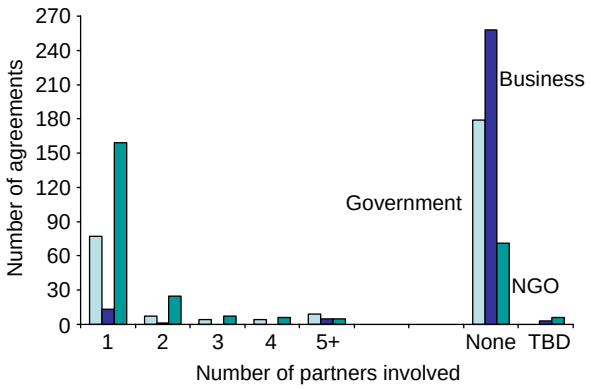

FIGURE 4 Bar chart illustrating the nature of partners involved in Type II agreements (government, business, and NGO) and highlighting the nature of partners involved in agreements relating to energy issues. Number of agreements (y axis) is plotted against number of partners involved (x axis).

suggesting that further partners are being sought (41 agreements are seeking business partners) further indicates this evolution. Nearly 70% of agreements involving NGOs do not involve other partners, and where governments are involved, 61% operate alone. Businesses are only explicitly involved in 10 agreements analyzed to date, 9 of which involve other partners. Energy enjoys the highest level of business involvement of any sector, present in 6 of the 39 approved energy partnerships. Types of business range from government energy utilities (e.g., Eskom and NamPower) to relatively small northern business interests (e.g., Velo Mondial).

At least one UN program is involved in approximately one-quarter of all agreements (66 agreements), suggesting that the IGO instigating Type II agreements is keen to provide a critical mass of initiatives. The agreements involving UN bodies are more likely to involve multiple partners (48% versus 26% overall) and appear to be more developed in other ways (target-setting, etc.). It is also evident that UN organizations provide funding for a number of NGO initiatives even when they are not explicitly involved in the Type II partnership. The number of parties involved in any agreement will also relate to the ability of the instigating parties to attract new participants.

Education initiatives have garnered the highest number of partners per agreement to date (see Fig. 5) and appear to be highly collaborative in nature. On average, Type II agreements each involve just under two partners, with agreements ranging from 1 partner only to 29 partners, as in the case of the Global Higher Education for Sustainability Partnership (GHESP). NGOs (including IGOs and other

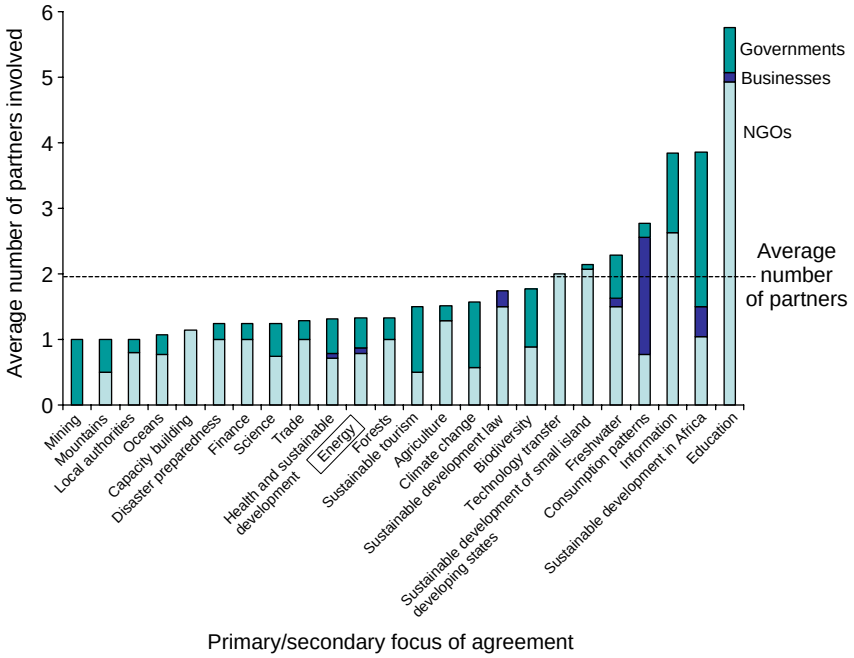

FIGURE 5 Stacked bar chart illustrating how the nature of partners involved in Type II agreements (government, business, and NGO) varies depending on the primary aim of the agreement. Number of partners involved (y axis) is plotted against primary aim of agreement (x axis).

international organizations) are more actively involved with Type II partnerships than governments, and they are far more actively involved than businesses. Capacity building and technology transfer partnerships solely involve NGOs. The majority of NGO/IGOs (153 of 181) are involved in just one agreement. The most active organizations with more than one agreement are fairly evenly divided between UN organizations, UN-influenced organizations, and organizations relatively independent from the UN. The United Nations Environment Programme (UNEP) and UNDP are the two most active organizations, and their agreements span a wide variety of sectors (>6 sectors each) and geographies. Both UNEP and UNDP have a significant amount of sectoral overlap, and they both focus on energy issues, in addition to biodiversity, freshwater, and ocean projects.

Although the three most active NGO/IGOs are UN-run or related, three other active organizations are not directly affiliated to the UN. IUCN′s 7 agreements concentrate on biodiversity and sustainable development issues in Africa, particularly regarding sustainable development law and information provision for decision making. The Caribbean Committee (CARICOM) and the Pacific Islands Secretariat each put forward seven partnerships, all of which relate to issues affecting the SIDS for their specific regions.

At a tertiary level, the aims of thse agreements address climate change and energy issues via capacity building. The Stakeholder Forum for Our Common Future has produced agreements across a wide range of sectors and is particularly active in inviting other organizations to participate.

In summary, NGO/IGOs appear to be most actively involved in forming Type II partnerships, particularly those with a UN affiliation. The international nature of these organizations makes it hard to differentiate a North/South bias, as many of these partnerships are initiated at a country office level. For example, IUCN′s South Africa office initiated the "Johannesburg Climate Legacy" partnership, although IUCN HQ is based in Switzerland, part of the North. Government involvement can be more clearly differentiated between North and South, and of the 200 cases of government partnership involvement, 91 are governments from the North and 109 from the South. Business has shown what could be considered a disappointing lack of involvement in Type II partnerships, with only 23 cases of direct business involvement. When launching the Commission on Private Sector and Development on July 25, 2003, Kofi Annan, secretary general of the UN, stated that "the birth of this Commission is yet another illustration of the rapidly growing partnership between the United Nations and the private sector … it also underscores the importance of that partnership in our work to reach the Millennium Development Goals … we cannot reach these goals without support from the private sector." In this light, it is notable that the private sector has thus far failed to support UN-instigated Type II partnerships.

2.4 Funding Arrangements

By August 16, 2002, only 5% of the Type II proposals made any mention of project funding issues, and less than 1% stated figures. Budget considerations would undoubtedly be a sensitive aspect of these proposals, and reasonable certainty would be required from potential funders before figures could be realized. Prior to the WSSD, the only two agreements containing specific funding instructions were the "Awareness Raising and Training on Sustainable Consumption and Productio partnership led by the UNDP and the Johannesburg Climate Legacy partnership led by the IUCN. These partnerships specified $2 million over 3 years and $5 million over $5\frac{1}{4}$ years, respectively, implying project burn rates of $670,000 p.a. and $950,000 p.a., respectively. These results should not be viewed as valuable or representative, given the small sample size. The funding for the first agreement came from the UNDP budget, and the second agreement planned to raise funds from WSSD participants to offset the environmental cost of Johannesburg, specifically referring to energy costs, although progress here is unclear in subsequent partnership documents. Within the partnership documents, the only specific funding information added after the WSSD date is for the United States. Water for the Poor Signature Initiative, which commits $970 million over 3 years (2003 to 2005), implies a burn rate of $323 million p.a. This is a funding level more than a factor of 100 greater than the previous two partnerships discussed. Partnership documents appear reluctant to specify exact funding terms and sources. This may be due to confidentiality issues or concern that publicizing a funding source may lead to unsolicited approaches to that source from many other partnerships.

The CSD researched the funding situation of the partnerships, and claimed that "nearly two thirds of the approved partnerships have funding, either to carry out initial phases or for the entire initiative." The analysis concedes that not all submissions

published figures of funds necessary to carry out projects, and the analysis appeared to utilize information that is not publicly available. Based on that information, the CSD estimated that $1,250 million had been committed by April 29, 2003, with a further $120 million in negotiation with potential donors. Of the $1.25 billion in secured funds, $977 million (78%) is accounted for in just three partnerships previously discussed, which implies that the majority of partnerships are yet to secure significant funds. Given the sums involved, it may be expected that this may take some time. Of the remaining funds, there is no specification as to which partnerships received what proportion of these secured funds, over what time period the funding is committed, or whether this is genuinely new funding or reallocated budget from existing organizations.

It is worth noting that during the WSSD, German Chancellor Schroeder promised €500 million over 5 years to promote renewable energy in developing countries. This new money was not classified within Type II agreement documentation.

2.5 Length of Agreements

Approximately 80% of the agreements analyzed state project length. Some agreements make qualitative statements suggesting the project may continue after a stated end date, although given the high level of uncertainty this element has not been included in the analysis. The average life span of a Type II agreement in this sample is 5.3 years, and 60 projects have no end date (Fig. 6). Of the 39 agreements concerning energy, 11 have no end dates and the average stated life span of the agreements is slightly longer than the overall figure at 5.7 years. The longest projects center on the SIDS and changes to sustainable development law. Agreements to address disaster preparedness and financing have the average shortest time span at 2.25 years.

2.6 Target Setting

Less than 10% of agreements contained quantifiable targets as of August 16, 2002. By June 2003, every partnership had stated targets, although few were easily quantifiable. This is one area which has certainly been the subject of updates within the agreements on the WSSD Web site, as project plans are gradually further developed. Targets involve the production of documents, the launch of new products, the establishment of financial funds and the training of personnel. Successful completion in many of these areas is hard to assess, although a qualitative target providing focus for a project may be preferable to no target at all. Agreements with targets may be expected to operate within a shorter and more focused time frame.

To what extent partnership targets can be quantified also appears to vary by the focus of the agreement. By examining partnership agreements, it becomes apparent that partnerships involving energy,

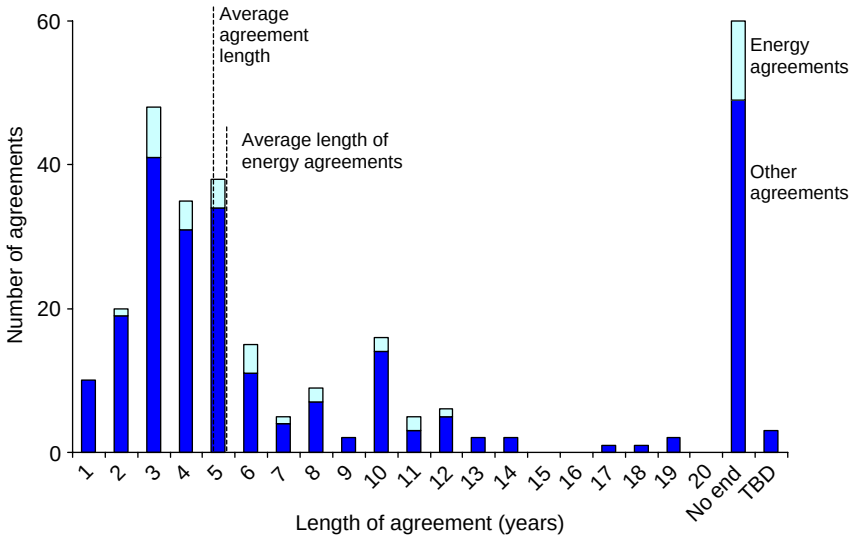

FIGURE 6 Bar chart illustrating the typical length of Type II agreements, highlighting the average length of those agreements relating to energy issues. Number of agreements (y axis) is plotted against length of agreement (x axis).

consumption patterns, and trade have more numerical targets than partnerships involving information for decision making and capacity building.

2.7 Originality

It is not possible to precisely identify recycled projects that have been rebranded as Type II agreements with no obvious additional investment. Projects run solely by government departments with similar names to the project and projects with start dates prior to 2002 provided indications that the project might be recycled. Research suggests that the large majority of Type II agreements are genuinely new partnerships, created in response to the WSSD. Approximately 217 (78%) of projects submitted are likely to be genuinely new agreements, and energy agreements appear to reflect this ratio. It is interesting to observe whether the new agreements possess any markedly different characteristics to the recycled agreements. The most striking indicator lies in project length. Also, 47% of recycled projects have no end date, whereas only 15% of new initiatives are so long term. Given that Type II agreements are a relatively new concept, statements regarding indefinite project length might seem optimistic had the project not been running prior to the commencement of Type II agreements. The sectors most prone to recycling of initiatives include mining, forests, sustainable development law, and technology transfer initiatives. Over half of the partnerships in each of these categories appear to be recycled; however, these categories do have lower than average sample sizes.

3. EVALUATION OF TYPE II ENERGY AGREEMENTS

3.1 Governments Must Continue to Pursue Type I Partnerships

Type II partnerships could only really be considered an abdication of responsibilities when their impact on the level (quality, number, etc.) of Type I agreements can be assessed, and it is too early to assess that impact. If governments are substituting effort from Type I to Type II agreements for sustainable development, then initial trends in Type II agreements may give cause for concern. As it stands, only 71 of the 189 governments attending the WSSD have any involvement in Type II agreements, and 38 of these governments are only involved in one partnership.

Only a handful of governments have shown significant leadership in creating cooperational Type II agreements. These include Japan, the United States, Italy, France, Indonesia, and Australia by order of partnership number. However, some governments appear to be using Type II to showcase a set of standalone initiatives that appear to be more prescriptive than cooperational in nature and thus do not serve to replace any type of collaborative agreement. Governments from the South appear to be participating in terms of collaborative effort, although individually they are not putting forward as many agreements as their counterparts in the North. Certain important governments (in terms of population) appear to be entirely absent from Type II agreements, including China and India. Type II agreements will gain strength from a critical mass of participants, and the noninvolvement of too many major players may serve to discredit these initiatives.

Smaller countries (in terms of economic and political clout) appear to be waiting for larger countries to take the initiative and then sign up to the outcome. This is particularly common in Africa, South America, and the states of the former Soviet Union. Countries from the South often experience resource constraint while negotiating Type I agreements, which may unfairly bias negotiation outcomes, and there may be a parallel within Type II agreements. If countries from the South wait to be offered participation in preprescribed Type II agreements, then they will lose another opportunity to lay down an agenda for sustainable development. Type II agreements may be just beginning a long process of evolution, and projects targets are far from clear. Given these concerns, work on Type I agreements should proceed as usual, until the success of Type II agreements can be assessed in the medium term.

3.2 Lack of Business Involvement

Prior to the WSSD, a number of articles were published by civil society organizations voicing concerns that the focus on Type II public-private partnerships could "leave the basic needs of billions of poor to the market forces." During the WSSD, articles in the mainstream press suggesting that Type II promises by business were unlikely to be met further discredited Type II agreements as a forum for business to contribute to sustainable development. Business is often criticized for not acting in a sustainable manner, but then accused of greenwash if it attempts to initiate sustainable development initiatives and publicize them. The bottom line for

business should be to maximize shareholder value; on some occasions this can be achieved in a sustainable manner, and on other occasions it cannot. Type II agreements could have provided a forum for business to learn about sustainable development approaches and how they can add to shareholder value, but the negative publicity associated with business involvement in Type II agreements appears to have discouraged business participation. A large number of businesses may have attended the WSSD, but very few followed this attendance through with concrete participation in sustainable development partnerships. This lack of business participation may be one of the most disappointing aspects of WSSD Type II agreements, although energy agreements provided the highest level of business involvement observed.

On July 25, 2003, Kofi Annan, Secretary General of the UN, stated that "the birth of this Commission on Private Sector and Development (CPSD) is yet another illustration of the rapidly growing partnership between the United Nations and the private sector … it also underscores the importance of that partnership in our work to reach the Millennium Development Goals … we cannot reach these goals without support from the private sector." The CPSD may help business undertake standalone sustainable development initiatives, but it does not hold the potential that Type II agreements once held for engendering collaboration and understanding between the state, corporations, NGOs, and IGOs. UN organization cannot aim to involve business in sustainable development initiatives if there is not a positive communications forum between business, government, and civil society.

This situation is in danger of becoming self-reinforcing. As business fails to find support from NGOs, it then pursues sustainable development initiatives within business-only organizations, such as the WBCSD and Business Action for Sustainable Development (BASD), which in turn are criticized for their insularity and business focus. Meaningful and mutually respectful communications and resulting collaborations between business and civil society are required. Type II agreements are missing the opportunity to achieve this and will require significant work by the CSD to recapture this opportunity. Credibility in Type II agreements must be regained to minimize the reputational risks faced by business in its involvement with collaborative sustainable development initiatives. This can be partially addressed by target setting and by tracking the progress of partnership projects.

3.3 Lack of Quantifiable Targets, Tracking and Accountability

Type II voluntary partnerships have not yet been in any way rigorous in setting out clear targets, timetables, and means to measure results consistent with sustainable development goals of economic efficiency, environmental integrity, and social equity. This could be anticipated as, early in the evolution of these agreements, it may be foolhardy to expect that project planning is sufficiently rigorous to allow for significant levels of accuracy in target assessment and therefore accountability. In this way, Type II agreements could be viewed in a similar light as conventions, which essentially act as empty shells within which greater levels of detail are gradually added. This may reduce the accountability of these agreements, but given their long-term nature (average 5.3 years), the retention of budget flexibility may be preferable to demanding specific goals at the outset. A logical compromise may be the introduction of short-term targets within these agreements (e.g., over 1 year rather than the full average 5.3 years), which can be used to demonstrate progress but would not set the direction of projects in stone. These targets could also help fundraising, as successful partnerships could showcase well-conceived and structured sustainable development projects, demonstrating progress against targets in order to pitch for additional investment from funding sources.

3.4 Transparency Is Required on Partnership Funding

Little quantitative information is available on the funding sources for Type II partnerships. In the small number of agreements that refer to funding mechanisms, the funding sources are the United States, UNDP, and IUCN offset fundraising from Johannesburg participants, totaling $977 million over 3 years. It is unclear whether the U.S. funds are restated from existing USAID budget or entirely additive. The UNDP source may take funding away from other projects, although the IUCN offset fundraising does appear to raise a separate, additive funding source. None of these sources appears likely to add to developing world debt, which was one concern cited by WSSD participants. However, the nature of these funds is not specified and information such as rates of interest, if any, is not addressed. Notably, €500 million over 5 years promised by German Chancellor Schroeder for promotion of renewable energy in

developing countries was not classified as a standalone Type II agreement.

To execute on these partnership agreements, funding will doubtless be required, and information on that funding should be made publicly available. The success of Type II partnerships will be assessed on their ability to raise additive funds, meaning funds that are not already dedicated to non-Type II sustainable development initiatives. Attention should also be paid to funds that are transferred between sustainable development-focused NGO/IGOs to fund partnerships, as this could lead to duplication when assessing the total amount of Type II funding generated. Fundraising cycles frequently take many months, if not years, to complete, therefore it is not particularly surprising that there is not a great deal of detailed information available to date. Partnerships should be encouraged to secure funds and report funding details for transparent analysis.

3.5 Were Type II Energy Agreements a Useful Outcome of the WSSD?

In terms of volume, approximately 280 partnerships have been submitted to date, involving 71 governments, 181 NGO/IGOs, and at least 23 businesses. Of these partnerships, 43 addressed energy issues and 39 of those partnerships have been approved by the CSD. Of initiatives addressing management of natural resources, energy agreements form the largest single body Type II agreements. The publication of these partnerships will, at the very least, raise awareness of sustainable development issues, which is a valuable outcome regardless of the final success of the partnerships. Additionally, the collaboration between partners will have led to the exchange of information and expertise on sustainable development issues, which should enhance the prospects for sustainable development.

After it became clear that Type I agreements were not a feasible outcome of the WSSD, the summit still had to go ahead due to the initial financial investment and the political embarrassment that could have resulted from a cancellation. In this scenario, Type II agreements were a relatively valuable fallback position, as they allowed the summit to focus media attention on the implementation of sustainable development initiatives while reducing the negative press that may have resulted from no agreements.

In addition, the shift toward Type II agreements has demonstrated that responsibility for sustainable development is collective and not limited solely to the state, civil society, or business alone. It therefore follows that implementation of sustainable development initiatives must be a collective activity, and partnerships are a valuable way in which information and understanding can be transferred between the state, civil society, and business. The promotion of these partnerships and the subsequent press attention appears to have created a sense of collective responsibility, which is beneficial regardless of the final results of partnership initiatives.

However, for these agreements to be worth the trouble as tangible sustainable development projects, rigorous target-setting and tracking of partnership performance against those targets is necessary. Credibility is vital to attract additional funding for Type II agreements, and this funding will be needed for the partnerships to implement their projects and demonstrate that Type II agreements were worthwhile. That credibility can only be built and sustained by openness, target setting, and tracking of Type II partnerships. Building the credibility of Type II agreements will maximize their potential value for sustainable development.

Glossary

cross section Probability of neutron interaction with a nucleus, expressed in terms of area, in units of barns, with 1 barn equal to 1.0×10^{-24} cm^2.

enrichment The fraction of an isotope, usually fissile ^{235}U, in a mass of uranium; enrichment is commonly quoted as the weight percentage of the particular isotope.

enrichment tails (or depleted uranium) The uranium remaining after the enrichment of natural uranium into fuel; today it is approximately 0.3% ^{235}U, whereas earlier it was 0.20 to 0.25% ^{235}U.

fractionation Crystallization from a magma in which the initial crystals are prevented from equilibrating from the parent liquid, resulting in a series of residual liquids of more extreme composition than would have resulted from continuous reaction.

highly enriched uranium (HEU) Uranium containing more that 20% ^{235}U.

J_{th} Joule (i.e., watt-second) thermal, with 1 British thermal unit (BTU) equal to 1055 J_{th}.

low enriched uranium (LEU) Uranium containing less that 20% ^{235}U.

mafic Composed chiefly of dark ferromagnesian minerals.

mega-separative work unit (MSWU) A million separative work units; a separative work unit is the separative work done to change the separation potential of 1 kg of a mixture of isotopes by 1. (See Benedict, 1981, p.6 for a more complete definition.)

mixed oxide fuel (MOX) Usually consists of a ceramic mixture of uranium dioxide and plutonium dioxide.

quad A quadrillion (i.e., 10^{15}) British thermal units, with 1 quad equal to 1.055×10^{18} J_{th}.

pegmatite An exceptionally coarse-grained igneous rock, with interlocking crystals, often found at the margins of batholiths.

placer A mineral deposit at the surface formed by a sedimentary concentration of heavy mineral particles from weathered debris.

unconformity A break or gap in the geological record such as an interruption in the normal sequence of deposition of sedimentary rocks or a break between eroded metamorphic rocks and younger sedimentary strata.

yellowcake A concentrate of uranium ore containing 80 to 90% U_3O_8.

This article discusses uranium resources in a global sense beyond relying on the official estimates of the International Atomic Energy Agency and the Organization for Economic Cooperation and Development. As an introduction to that discussion, the origins of the earth's current inventory of uranium, the geophysical and geochemical processes that serve to concentrate that uranium into economically viable deposits, and the technologies now being used for extraction and concentration of uranium ores are described. Finally, the potential impacts of technologies now under development and the overall impact of the cost of uranium on the cost of energy from nuclear fission are reviewed.

1. IMPORTANCE OF URANIUM AND THORIUM

Uranium is a widespread element that is essential, at least in the near term, to the use of nuclear fission as

 © 2004 Elsevier Inc. All rights reserved.

a source of energy. Uranium is ubiquitous in the earth due to the wide variety of minerals in which it can occur and due to the variety of geophysical and geochemical processes that have transported it since the primordial formation of the earth from stellar debris. Uranium is approximately as common in the earth's crust as is tin or beryllium, and it is a minor constituent in most rocks and in seawater. The average crustal abundance of uranium is 2.76 weight parts per million (wppm), higher than the average concentrations of economically important elements such as molybdenum (1.5 wppm), iodine (0.5 wppm), mercury (0.08 wppm), silver (0.07 wppm), and gold (0.004 wppm). Uranium occurs in ores as uraninite (UO_2, pitchblende), carnotite, autunite, uranophane, davidite, tobernite, and other minerals containing U_3O_8 (actually a stable complex oxide $U_2O_5 \cdot UO_3$).

Since the discovery of nuclear fission, uranium has been seen as a scarce resource. Uranium-235 (^{235}U) is the only naturally occurring isotope that can be made to fission with thermal neutrons. Consequently, the resources of uranium have been believed to inherently limit the sustainability of nuclear energy. There have been two periods of extensive exploration for uranium, during the 1950s and during the 1970s, and both were followed by long periods of severe contraction in the market and in exploration activity. Today, exploration activity is still at a low level for several reasons. First, deposits found during earlier exploration periods have proven to be larger than was initially estimated. Second, nuclear energy has not grown as rapidly as was forecast earlier. Third, improved nuclear fuel management techniques and materials have allowed higher burn-up and longer operating cycles. Finally, the conversion ("down-blending") of highly enriched uranium (HEU) of military origin to civilian purposes has postponed the need for large amounts of newly mined natural uranium.

Concern that uranium would soon be exhausted was one of the driving forces in the development of fast breeder reactors, in which the nonfissile isotope ^{238}U is converted into the fissile isotope ^{239}Pu. These concerns also led to the development of reactors capable of converting thorium into the fissile, but not naturally occurring, isotope ^{233}U. Thorium, consisting nearly entirely of the isotope ^{232}Th, is approximately three times more abundant than uranium and, thus, may represent a source of fissile material in the distant future.

The importance of the overall uranium and thorium resource is demonstrated by the attention given the estimates of international agencies such as the International Atomic Energy Agency (IAEA) and the Nuclear Energy Agency (NEA) of the Organization for Economic Cooperation and Development (OECD). The estimates of these organizations are backed by a great deal of research and are compiled regularly in the Red Book.

However, the estimates of uranium resources in the Red Book are based on the known reserves that can be economically extracted using current technology. Because of the wide range of uranium concentrations in various minerals, the cost of extraction serves as the independent variable against which resources are estimated. Furthermore, the sizes of reserves are categorized by the reliability of the estimates.

Despite the success of earlier exploration efforts and the continuing low prices of natural uranium, there is a persistent and widespread belief that global resources of uranium will limit the long-term sustainability of nuclear power. That belief is supported by a misinterpretation of the Red Book estimates. The World Nuclear Association (formerly the Uranium Institute) estimates the reserve based on current and prospective mining projects and concludes that there are now 1.32 million metric tons (t) of uranium of the best proven category recoverable worldwide at a marginal cost of $40 per kilogram or less. The current consumption of natural uranium by reactors worldwide is approximately 64,000 t per year; consequently, these best proven reserves could be expected to last only approximately 20 years. If this interpretation of the reserve and resource estimates were accurate, there would be no long-term resource base for even the current fleet of light water reactors (LWRs).

However, the preceding is a serious misinterpretation of the real uranium resource situation. The most recent estimates of the current resource base, which includes speculative and higher cost resources, are 14 million to 17 million t. Low market prices, the slow growth of nuclear power, and the ongoing down-blending of HEU have resulted in both a very low level of exploration and little effort in the development of advanced extraction technologies.

It is important to note at the outset that uranium today is used overwhelmingly in the LWR fuel cycle, where only approximately 1.1 to 1.5% of the ultimate energy of the mined uranium is extracted via fissioning of ^{235}U and the small amounts of ^{239}Pu bred *in situ*. The rest of the uranium remains either in the spent fuel or in the depleted uranium after enrichment. Of the 1.8 million t of uranium produced worldwide since 1945, the location of all but approximately 1500 t is known. Only that uranium used either in nuclear

weapons or in armor-piercing projectiles is not known. The inventory of spent fuel and of depleted uranium represents a very significant resource.

Although uranium is an essential input for the production of nuclear energy, the costs of natural uranium are a minor component of the overall cost. Today, at uranium prices of approximately $25 per kilogram, the uranium itself is responsible for only roughly 2% of generating costs. The fuel element cost is 15 to 20% of the generating costs, but those costs include conversion of the uranium ore to UF_6, enrichment of the natural uranium, production of the ceramic UO_2 fuel pellets, and fabrication of the fuel assemblies. A 10-fold increase in the cost of natural uranium would not be welcome but also would not fundamentally change the economics of nuclear power. A 10-fold increase in uranium prices would, at first estimate, be expected to increase the cost of nuclear electricity by 20%. However, a more detailed calculation, optimizing the ^{235}U content of the depleted uranium tails and adjusting fuel management for a higher priced resource, would result in an increase in the cost of electricity of significantly less than 20%.

1.1 Energy Content of Uranium and Thorium

Uranium has 18 known isotopes, none of which is stable and only 2 of which have half-lives longer than a million years: ^{235}U (704 million years) and ^{238}U (4.47 billion years). Only ^{235}U, which is approximately 0.720 weight percentage (wt%) of natural uranium, is fissile, that is, will fission using thermal (i.e., low-velocity) neutrons. ^{238}U, which is by far the dominant isotope at 99.2745 wt%, will fission if struck by high-energy neutrons. However, ^{235}U is the only naturally occurring isotope capable of sustaining a neutron chain reaction in a suitably designed reactor.

^{238}U can be transformed into ^{239}Pu through the absorption of a neutron and two subsequent beta decays, as shown in the following reaction:

$$^{238}\mathrm{U}(n,\gamma)^{239}\mathrm{U} \xrightarrow[\beta^- t_{1/2}=23.5\ \mathrm{min}]{}$$
$$^{239}\mathrm{Np} \xrightarrow[\beta^- t_{1/2}=2.35\ \mathrm{days}]{}$$
$$^{239}\mathrm{Pu} \xrightarrow[\sigma_{f\ thermal}=750b]{} \text{fission},$$

where β^- indicates a beta decay with electron emission and $\sigma_{f\ thermal}$ is the fission cross section in barns at a neutron energy of 0.025 eV.

Thorium has 25 isotopes, of which only the nonfissile isotope ^{232}Th is long-lived, with a half-life of 14 billion years. However, in the following reaction, ^{232}Th can be transformed into ^{233}U, a fissile isotope:

$$^{232}\mathrm{Th}(n,\gamma)^{233}\mathrm{Th} \xrightarrow[\beta^- t_{1/2}=22.3\ \mathrm{min}]{}$$
$$^{233}\mathrm{Pa} \xrightarrow[\beta^- t_{1/2}=27.0\ \mathrm{days}]{}$$
$$^{233}\mathrm{U} \xrightarrow[\sigma_{f\ thermal}=531b]{} \text{fission}.$$

The fission energy of ^{233}U is 190 MeV and that of ^{239}Pu is 200 MeV. If 1 kg of thorium is bred into ^{233}U, the fission energy available is 78.9 TJ_{th} (thermal), and the fission energy in 1 kg of uranium, bred to ^{239}Pu, is 80.4 TJ_{th}. Thus, thorium and uranium are quite similar in maximum energy content, but uranium is far more important in the near term due to the need for ^{235}U as a naturally occurring fissile isotope.

1.2 Thorium Resources

Thorium averages 7.2 parts per million (ppm) in the earth's crust and is the 39th most abundant of the 78 crustal elements. Soil commonly contains an average of 6 wppm of thorium. It is about three times more abundant than uranium. When bred to the fissile ^{233}U, thorium releases about the same energy per unit mass (79 TJ_{th}/kg) as does uranium when bred to ^{239}Pu (80.4 TJ_{th}/kg). When thorium is used as a nuclear fuel, much less plutonium and other minor transuranics (e.g., Np, Am, Cm) are produced than are produced in uranium fuel cycles. The reduced production of transuranics occurs for two reasons. First, the fissile product of ^{232}Th is ^{233}U, further in the actinide series from plutonium and the minor actinides. Second, the fission/capture ratio of ^{233}U is approximately 9, whereas that of ^{239}Pu is approximately 3, thereby resulting in lower production of the transuranics.

Thorium and its compounds have been produced primarily as a by-product of the recovery of titanium, zirconium, tin, and rare earths from monazite, which contains 6.0 to 8.5 wt% thorium oxide. Only a small portion of the thorium produced is consumed. Limited demand for thorium, relative to the demand for rare earths, has continued to create a worldwide oversupply of thorium compounds and mining residues. Most major rare earth processors have switched feed materials to thorium-free intermediate compounds to avoid the handling of radioactive

thorium. Excess thorium not designated for commercial use is either disposed of as a radioactive waste or stored for potential use as a nuclear fuel or other applications. Increased costs to comply with environmental regulations and potential legal liabilities and costs to purchase storage and waste disposal space were the principal deterrents to its commercial use. Health concerns associated with thorium's natural radioactivity have not been a significant factor in switching to alternative nonradioactive materials. According to the U.S. Geological Survey, U.S. consumption of thorium, all for nonenergy uses, has decreased from 11.4 to 5.27 t (thorium content) since 1997. In fact, 76 t of thorium was shipped to Nevada for disposal as low-level radioactive waste in 2000. The principal applications of thorium today make use of the very high melting point of ThO_2 (3300°C, the highest of all binary oxides) and the electron-emitting capability of thorium when alloyed with tungsten for use in filaments for high-powered magnetrons for radar.

In the short term, thorium is available for the cost of extraction from rare earth processing wastes. In the longer term, large resources of thorium are available in known monazite deposits in India, Brazil, China, Malaysia, and Sri Lanka.

Quoted prices for thorium dioxide in 2001 were $82.50 per kilogram for 99.9% purity and $107.25 per kilogram for 99.99% purity. Mantle-grade thorium nitrate was available for $56 per kilogram of contained thorium.

Thorium is present in seawater at only approximately 0.050 wppb, due primarily to the insoluble nature of its only oxide, ThO_2. Thus, the recovery of thorium from seawater is not a realistic option.

Because ^{232}Th is the only isotope of natural thorium, there are no enrichment plant tails from thorium nuclear fuel. Therefore, the cost of thorium in a mixed thorium–uranium LWR fuel or in a pure thorium–^{233}U fuel cycle is relatively minor. However, the cost of chemical processing of ThO_2-based fuel and the separation of ^{233}U is high.

2. *HISTORICAL CONTEXT OF URANIUM EXPLORATION*

Uranium has been fundamentally important during the past half-century, first as a military resource and later as a commercial resource now responsible for 8.1% of the primary energy in the United States and 6.7% worldwide. The perceptions of uranium resources and a growing understanding of geological processes have led to widely varying levels of exploration for uranium during that time.

2.1 Periods of Scarcity and Surplus

There have been two boom periods in uranium production; the first was driven by military demands for HEU in the wake of World War II and the onset of the cold war, and the second was to fuel rapidly growing commercial nuclear programs in the wake of the oil embargo of 1972. Driven by those concerns, there have been two periods of extensive exploration for uranium, during the 1950s and during the 1970s, and both were followed by long periods of severe contraction in the market and the near cessation of exploration activity. Overexpansion of the uranium supply infrastructure during the 1970s led to limited exploration and the closure of operating mines during the past 20 years or so. A second reason has been the much slower growth of commercial nuclear power than was originally anticipated.

2.2 Demilitarization of Highly Enriched Uranium

More recently, a third disincentive to uranium exploration has emerged: disarmament. As much as one-third of the natural uranium mined since 1945 was used for the production of HEU, primarily for weapons programs and to a lesser degree for naval propulsion and research reactors. The Strategic Arms Reduction Treaties (START-I and -II) and heightened concerns for the proliferation of nuclear weapons have led to ongoing programs for the downblending of weapons-derivative HEU. In the downblending programs, HEU is mixed with natural or depleted uranium to produce low enriched uranium (LEU) fuel for commercial LWRs. The civilian use of downblended HEU effectively eliminates the need for as much as 600,000 t of natural uranium, equivalent to 10 years of current worldwide production. Thus, the market prices for natural uranium have been further depressed, and incentives for further exploration have been very small.

Specifically, the Russian and U.S. governments agreed to a program to convert 500 t of HEU from weapons into LEU for civil reactors. These 500 t of HEU at 90% ^{235}U would be blended with 14,759 t of LEU at 1.5% ^{235}U to obtain a product of 15,259 t of LEU at 4.4% ^{235}U. This blending process would

take place over a period of 20 years. By using depleted uranium to obtain the LEU at 1.5% ^{235}U and the HEU, this agreement will replace 152,000 t of natural uranium, which could have been enriched instead to yield the 15,259 t of LEU at 4.4% (with tails at 0.3%). The fuel can be expected to generate approximately 600 GWe-years of electricity.

2.3 Higher Burn-up and Plutonium Recycle in Light Water Reactors

Recycling of uranium and plutonium adds a potential savings of 15 to 20% in natural uranium requirements for a mixed oxide fuel (MOX)-fueled reactor park. Although the worldwide impact of U/Pu recycling on uranium demand remains small today, these savings potentially could contribute to a more sustainable use of the available resources. In this context, Japan has an aggressive plan for using MOX fuel in LWRs due to the lack of uranium resources in that country. In addition to the fabrication of MOX fuel in Europe, Japan Nuclear Fuels Ltd. (JNFL) has started preparation of domestic fabrication of MOX fuel. However, in today's political and economic context, no major expansion of this recycling is envisaged for the coming years in OECD member countries.

3. GEOLOGY AND GEOCHEMISTRY OF URANIUM

Because uranium has become an economically significant element, and because decisions on future energy choices will be influenced by the accuracy of estimates and perceptions of the adequacy of uranium and thorium resources, it is incumbent on us to first recognize the origins of those elements.

3.1 Uranium Abundance in the Earth

The bulk amounts of uranium inherited by the earth during its accretion from primordial stellar debris can be predicted through the use of various astrophysics models of Alpher and Urey. In these astrophysical models, the formation of the elements is the result of a continuous building up of heavier elements through neutron absorption in a highly compressed neutron gas. The nuclear matter decayed into protons and electrons to form first protium and then deuterium, followed by the heavier elements in a rapid combination of absorption and decay. The process proceeded rapidly until arrested when the neutron gas pressure fell due to universal expansion.

Urey cited estimates by Goldschmidt of the primordial abundance of 41 weight parts per billion (wppb) for uranium and 106 wppb for thorium. Alpher's theoretical curves and Brown's observed astrophysical data show uranium approximately 6.5 orders of magnitude less abundant than silicon, resulting in a primordial abundances of 57 wppb. Deffeyes, accounting for the decay of uranium since the expansion of the primordial neutron gas, estimated global uranium abundance at 10.5 wppb. The half-lives of the isotopes of interest are ^{232}Th, 14.0×10^9 years; ^{235}U, 0.704×10^9 years; and ^{238}U, 4.47×10^9 years.

Therefore, based on these astrophysical models, it is fairly clear that the earth currently contains approximately 10 wppb uranium and 40 wppb thorium. Stated in other terms, the current global inventory is 63 Tt (63×10^{12} t) of uranium and approximately 400 Tt of thorium. Although this inventory is a vast amount of both elements, if uranium and thorium had a uniform radial distribution throughout the earth (as is assumed in the cold accretion model), concentrations of uranium and thorium would be far too small to be economically extracted.

Thermal models of the earth point to inevitable melting of the earth soon after its accretion due to gravitation energy and due to radioactive decay of uranium, thorium, and potassium. Because of its large ionic size and heating due to radioactive decay, uranium is transferred into low melting temperature fractions and out of the earth's core and mantle into the crust. These geochemical and geophysical models predict that two-thirds of the initial 63 Tt of uranium present in the earth is now concentrated in the crust, which constitutes only 0.4% of the earth's total mass. The low uranium and high iron concentrations predicted for the earth's mantle and core have been supported by concentrations in iron meteorites and in mantle issuing from oceanic spreading zones (0.1 ppm U), compared with uranium concentrations in magma and crust in subduction zones (2 ppm U).

3.2 Mechanisms for the Concentration of Uranium

Unlike other energy resources such as coal and petroleum, the resources of uranium are not fundamentally changed by geological processes. Whereas petroleum might be lost through evaporation or

combustion or a natural gas reservoir may vent into the atmosphere, uranium is lost only through radioactive decay or through the relatively rare formation of a natural reactor. Therefore, the primordial inventory of uranium, reduced by radioactive decay, is essentially entirely present somewhere in the earth. The crucial question is "where?"

The natural distribution of elements in the earth's crust is controlled by two major factors. The first is the set of ambient geological fractionating processes that leads to regions of depletion and concentration of the element. The second factor includes the overall geochemical characteristics of the element. Elements that are concentrated by a small number of fractionation processes can be expected to have a multimodal distribution, with a peak in the tonnage versus grade curve for each of the modes of geochemical concentration. For elements having a large number of applicable concentration processes, the peaks overlap and the resulting tonnage versus grade curve takes on a log–normal characteristic. For example, for the element chromium, whose distribution at high concentrations is solely governed by fractional crystallization in mafic magmas (i.e., high in magnesium and iron), one would expect a bimodal distribution of concentrations, with one peak at the average crustal abundance and the high-concentration peak at the mafic fractionation concentration. On the other hand, most elements, including uranium, can undergo a wide variety of fractionating processes, and deposits would be expected over a wide range of concentrations. In this latter case, the tonnage versus grade distribution would be expected to be log–normal. Bear in mind that geological conditions change over time and that, therefore, the distribution patterns have varied with time.

In considering uranium in particular, it is important to examine the tectonic and igneous processes that have redistributed the uranium within the crust. During the past 4 billion years, the most important processes are continental accretion and plate tectonics. During the accretion process, crust formed into masses of continental dimensions. During the second (continuing) process, the continental crust has become much richer in uranium while the oceanic crust, although larger in area, has relatively little uranium.

3.3 Igneous Processes

Igneous processes begin with the fusion of mantle rocks at depths of 60 to 200 km, followed by the migration of less dense liquids to the surface. The migration of these less dense minerals to the surface is a predominant process in the formation of the continental crust. The extruded liquid forms crust in two general locations: at mid-oceanic ridges, where the upwelling material forms new oceanic crust, and in subduction zones, where the oceanic crust plunges back into the mantle, usually passing under the edge of a continent.

The behavior of uranium in igneous processes is dominated by two characteristics of the element. In the $+4$ oxidation state, the condition expected in the earth's mantle, the U^{+4} ion has an ionic radius (97×10^{-12} m [picometers (pm)]) the same as the Na^{+1} ion (97 pm). Other ions common in the core and mantle are significantly smaller in radius: Fe^{+2}, 74 pm; Ni^{+2}, 69 pm, Mg^{+2}, 66 pm; and Al^{+3}, 51 pm. Thus, like sodium and the other large ions, uranium ions selectively enter partial melts within the mantle and are transported to the surface.

The second characteristic of uranium is its radioactivity, serving as a source of heat for melting the mantle and core. Like Th^{+4} (ionic radius 102 pm) and K^{+1} (133 pm), these heat-producing elements are readily fractionated out of the mantle and toward the surface. Deffeyes noted that the earth would be a radically different place if the heat-producing elements had small radii given that the geothermal energy source would then be located deep within the core and the convection currents driving plate tectonics would be much stronger.

The rocks forming the oceanic crust at mid-oceanic ridges are characterized by a uniform uranium concentration of approximately 0.1 wppm. Conversely, the crust formed above subduction zones is characterized by uranium concentrations of approximately 2 wppm. The wide difference in concentration is due to the differences in the source materials and to the different chemistries. The upwelling mantle at the oceanic ridge has a uranium concentration of approximately 0.005 wppm, whereas the subduction zones have as their source material oceanic crust and bits of continental crust, with an average uranium concentration of approximately 0.1 wppm. The continuous upwelling at the oceanic ridges serves as a mechanism for depleting the core and mantle of uranium and incorporating that uranium into the oceanic crust. That relatively low concentration of uranium in the oceanic crust is augmented with uranium from continental runoff that subsequently precipitates in the ocean basins. At the subduction zones, the oceanic crust is again subjected to partial melting and the uranium is again fractionated in the melt and transported to the surface.

As a result of the various igneous processes, the average concentration of uranium is highest at the surface of the continental crust and decreases approximately exponentially with depth.

The anticipated variation of uranium concentration with depth is given by the equation $U(Z) = U(Z = 0)e^{(-Z/6300\ \mathrm{m})}$, where z is the depth in meters and $U(z)$ is the concentration at depth z in weight parts per million. $U(z = 0)$ is the average continental crustal abundance of uranium at the surface (2.76 wppm). Thus, 15% of the crustal uranium inventory would be expected to be within 1000 m of the surface, and 27% would be expected to be within 2000 m.

3.4 Geochemical Beneficiation Processes

The governing characteristic in the geochemical transport of uranium is the fact that the uranium is highly soluble in oxidizing environments and essentially insoluble in reducing environments. Thus, the change in the earth's atmosphere from a reducing condition to an oxidizing condition some 1.8 billion years ago is responsible for a fundamental change in the dominant processes in uranium transport. During the earlier age, igneous processes and fractionation of uranium in partial melts due to its large ionic size were dominant. During the past 1.8 billion years, the transport of uranium by means of groundwater oxygenated at the surface has been dominant.

Thus, during the period more than 1.8 billion years ago, uranium was primarily concentrated in placer deposits as a chemically inert and physically dense phase. Because of the low solubility of uranium in reducing environments, rivers, lakes, groundwater, and the sea contained very low uranium concentrations. The placer deposits at Elliott Lake, Canada, and at Witwatersrand, South Africa, are typical of the deposits formed during this period.

With the dominance of photosynthesis during the past 1.8 billion years, the atmospheric and groundwater conditions have been oxidizing and uranium minerals have been highly soluble in the sedimentary weathering cycle. Placer deposits no longer formed and, in fact, began to dissolve. The uranium content of rivers, lakes, and groundwater increased, and gradually the uranium concentration in the oceans also increased. Nevertheless, the uranium concentration remained well below saturation.

However, in a few isolated locations, oxidation of organic-rich beds by groundwater led to locally reducing conditions. In these locations, the uranium ions or their complexes would reach supersaturation and reprecipitate. An important example of this reprecipitation is in the Mesozoic sandstones of the Colorado plateau. The uranium ores are found in organic-rich zones where the oxygen in groundwater was removed by carbon-rich debris. Precipitation of uranium has also occurred where restricted circulation in the oceans and organic-rich sediments led to anoxic conditions. Good examples are the black shales of Chattanooga shale and the phosphorite shale of the Phosphoria formation.

3.5 Specific Deposits

Before the discovery of the McArthur River deposit, the highest grade ores were obtained from igneous sedimentary deposits such as Great Bear Lake in Canada, Joachimsthal in the Czech Republic, and Katanga in the Congo. The deposits at Oklo in the Gabon Republic in Africa were of high enough concentration, and the uranium 1.7 billion years ago contained 3% ^{235}U, rather than the current 0.72%, such that several critical natural reactors operated in the deposit. The reactor zones released approximately 15,000 MW-years of fission energy over the course of some 250,000 years. These deposits were formed by the movement of hot water through fractures in blocks of rocks heated by their own uranium and thorium content.

Precambrian sandstones overlie much older Precambrian granites and metamorphic rocks. At the interface, there is a discontinuity in the age of the rocks. This type of discontinuity is termed an unconformity. Unconformity deposits, such as those in Saskatchewan and northern Australia, occur where uranium from the sandstone has formed into veins in the open spaces of the interface and has been heated to temperatures of several hundred degrees Celsius.

3.6 Roll-Front Deposits

As mentioned earlier, uranium oxide precipitates when the solution enters a reducing environment. The uranium oxide can be redissolved *in situ* by oxygenated leach solutions. In sandstone deposits, the uranium minerals have been deposited in the interstices between the sand grains. The deposits are often moving (very slowly) through the sandstone due to the flow of groundwater, much like the movement of a front through a liquid chromatography column. Oxygenated water from the surface

TABLE I

Natural Uranium Distribution

Geological unit	Mass (whole earth, 10^{19}t)	Concentrated uranium (ppm)	Mass-Uranium (whole earth, billion t)	Mass-Uranium (continental United States, billion t)
Whole earth	597.6	0.0105	63,000

enters the sandstone, where reducing agents, such as sulfides and organic matter, are located in the interstitial spaces. The organic carbon in one pore volume of sandstone can remove all of the oxygen dissolved in 50,000 pore volumes of oxygenated groundwater.

Therefore, the front between the oxygenated groundwater and the oxygen-free groundwater moves slowly through the sandstone. Uranium dissolved at the surface and uranium dissolved from the sandstone by the oxygenated groundwater is swept along and precipitated at the front. Upstream of the front, the uranium is present in the groundwater as the soluble hexavalent uranyl carbonate complex. As the oxygen is removed from the groundwater at the front, the soluble hexavalent uranium is reduced to the insoluble quadrivalent state.

The quadrivalent uranium precipitates in the form of the mineral uraninite (UO_2). Thus, the location of ore bodies is often associated with deposits of carbonaceous materials where the carbon, in much larger quantities compared with the uranium, has removed the oxygen from the groundwater.

Based on the various modes for the formation of uranium ore bodies, reviewing the large body of prior research, Deffeyes and MacGregor estimated the uranium content of the various crustal regimes in a report for the U.S. Department of Energy (DOE) in 1978. That information is shown as Table I.

Because of the wide variety of uranium-containing minerals and given the known quantities of those minerals, Deffeyes and MacGregor argued that worldwide uranium deposits have a log–normal distribution of mass versus grade. Current mining

activities are recovering uranium at market prices of $25 per kilogram from ores containing 0.05 to 20% U_3O_8. Given the log–normal distribution and the known quantities of the various uranium mineralizations, they estimated that a 10-fold increase in the price of uranium (and thus a 10-fold decrease in economically viable ore grade) would result in a 300-fold increase in the amount of uranium available. Equivalently, the World Nuclear Association estimated that a doubling of uranium prices would result in a 10-fold increase in supply.

The distribution of mass versus grade for the various types of uranium deposits is shown in Fig. 1. The three bars on the left (grade >1000 ppm U) indicate deposits of the type now mined for uranium alone. The expected log–normal distribution is shown, and the mass and grade of two Canadian mines discovered since 1978 are also indicated: (1) the McArthur River deposit, 137,000 t of proven reserves averaging 18 wt%, and (2) the Cigar Lake deposit, 90,000 t at an average grade of 17 wt%. Other known larger but lower grade deposits have not been shown.

The slope of the log–normal curve at currently mined grades is also shown in Fig. 1. This slope, roughly $+3.5$, indicates that for a doubling of the cost of mining (i.e., mining ore at half the current concentration), the economically available resources of uranium would increase by more than an order of magnitude ($2^{3.5} \approx 11$). This estimate presumes a continuation of current mining techniques and does not consider the increased use of *in situ* leaching (ISL) and recovery of uranium as a by-product in gold, copper, and phosphate mining.

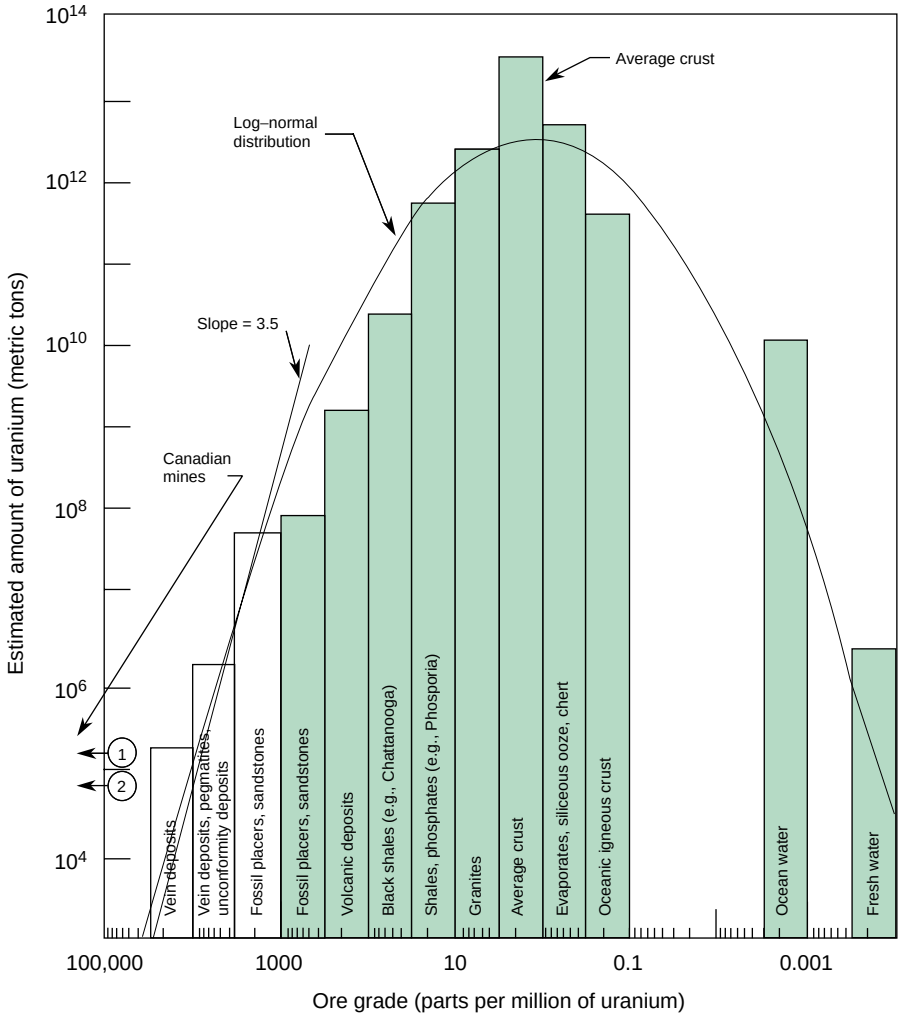

FIGURE 1 Distribution of uranium in the earth's crust. Adapted from Deffeyes and MacGregor (1978, 1980).

4. CURRENT URANIUM PRODUCTION

Canada produces the largest share of current world uranium production from mines (35%), followed by Australia (22%). Uranium production from mines in other countries is shown in Table II. Note that uranium production from mines has been depressed during the past 5 years due to the downblending of military HEU from the former Soviet Union. That demilitarization has effectively displaced the need for 10 years of natural uranium production (~600,000 t U).

4.1 Current Uranium Production Methods

As shown in Table III, the distribution of uranium production has been trending away from open pit mines and toward ISL and by-product production for the past 20 years or so. Those two methods are expected to grow in the future due to their relatively low cost and reduced tailings production.

5. CONVENTIONAL URANIUM RESOURCES

Today's uranium production comes from approximately 63 mining centers with concentrates produced at roughly 44 processing plants. Employment associated with this uranium production accounts for some 53,700 person-years annually, a reduction from some 64,000 person-years in 1994. Today, after more than 10 years of decreasing exploration expenditures, an increase of exploration expenditures has been noted, to $130 million annually worldwide.

5.1 Uranium Price History

The projected production capabilities (of existing and committed production centers) are expected to fall from approximately 45,800 t of uranium in 1997 to 33,000 t in 2015 due to the resorption of ex-military stocks and the closure of existing mines as a result of resource depletion or the lack of economics. Existing and committed capability at $40 per kilogram uranium or less is likely to meet only 40 to 60% of the requirements in 2015. However, the need for uranium will continue so long as nuclear electric generation continues and new mine production will be needed in large quantities sometime during the period to supply requirements once the excess supplies from past military efforts are exhausted. In the longer term, resources recoverable at higher costs and additional supplies would be necessary to fill the potential production shortfall indicated by some of the projections. Overall world reactor-related uranium requirements are expected to evolve from approximately 60,488 t of uranium in 1996 to levels ranging between 54,500 and 79,800 t per year by the year 2015.

As shown in Fig. 2, natural uranium prices, in the form of U_3O_8, have trended downward for the past 15 years after peaking in the wake of the oil shocks of the 1970s.

6. KNOWN URANIUM RESOURCES

For the reasons already noted, uranium is widely distributed in the earth's crust. Today's conventional uranium reserves are estimated at 4 million t (known conventional resources) at costs of less than $130 per

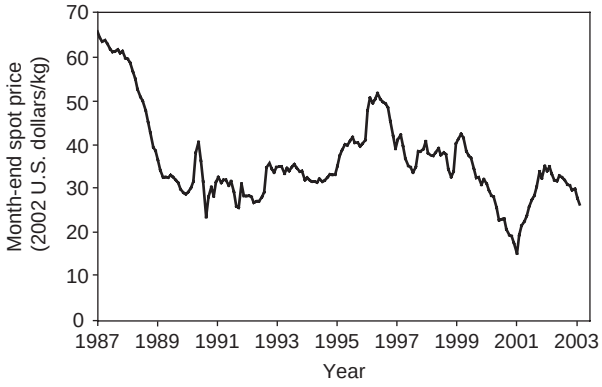

FIGURE 2 Historical uranium prices. (Compiled with data from the Ux Consulting Company, LLC and the U.S. Bureau of Labor Statistics.)

TABLE IV
Overview of Uranium Resources

Resources reported in 1999 (thousand t)			Number of years of current nuclear electricity production
Uranium stocks		200	4
HEU and Pu		600	12
Known conventional resources	< $40/kg	>1254	
	< $80/kg	3002	
	< $130/kg	3954	80
Undiscovered conventional resources	< $80/kg	1460	
	< $30/kg	5338	
	Total	11,459	230
Uranium in phosphates		22,000	440
Uranium in seawater		4,200,000	80,000

kilogram. Reasonably assured resources, recoverable at costs of less than $130 per kilogram, account for an additional 2.3 million t. Besides conventional resources, large resources of uranium exist. Phosphates are known to contain significant amounts of uranium, and industrial production has been performed in the United States and Belgium for the past 20 years or so. Another practically inexhaustible potential source of uranium is seawater (Table IV). The conventional resources alone could sustain the nuclear option for at least the next 100 years, based on today's nuclear reactors. In principle, they would last more than 60 times longer if uranium and plutonium present in the spent fuels were systematically recycled in fast reactors, subject to technical developments and economic considerations.

6.1 The Perspective for the Next 20 Years

However, despite these formidable resources, only highly localized deposits with a concentration of approximately 500 ppm or more can be mined economically in today's market conditions, that is, at prices of less than $40 per kilogram. Uranium is actually produced using both conventional mining (open pit and underground mining) and unconventional production techniques. Unconventional techniques include ISL technology, phosphate by-product recovery, and heap leaching. ISL technology has a very low environmental impact but can be used to extract uranium only from suitable sandstone-type deposits. The only three plants using phosphate by-product recovery (two in the United States and one in Belgium, with total production of 495 t U/year) suspended their uranium production in early 1999. The distribution of production for the four technology types or material sources is shown in Table III.

In the next 20 years or so, low-cost uranium production from new projects is expected to be primarily from high-grade unconformity-type deposits, multimineral deposits, and sandstone-type deposits amenable to ISL mining technology. It is expected that the use of conventional production technology will increase, with particular emphasis on underground mining, while ISL technology could maintain its relative share.

Today, primary production amounts to only 60% of the total world demand. Four additional (secondary) uranium resources make up the balance of supply and demand: uranium stockpiles, reenrichment of depleted uranium, recycling of uranium and plutonium, and the use of former weapons-grade material (HEU).

6.2 Locations of Known Uranium Resources

Australia, Kazakhstan, Canada, and South Africa dominate the known uranium resources of the world, with roughly 28, 15, 14, and 10% of the known resources recoverable, respectively, at a cost of less than $80 per kilogram (Table V).

The estimates of resources must be used with some caution. Often, the reasonably assured resources significantly underestimate resources that will be found with further exploration. For example, although the U.S. resources are listed as approximately 104,000 t uranium, 354,000 t were produced from domestic mines from 1949 through 2001. U.S. uranium mines have been closed, not for lack of resources but rather because current prices ($29.30/kg in June 2003 according to the Ux Consulting Company) no longer support profitable operation. The NEA and IAEA assess the current uranium resource base, including more speculative and higher cost resources, at 16.2 million t.

6.3 Canadian Reserves

The Canadian reserves are a good example of the potentially much larger size of the resource base. In

TABLE V

Known Recoverable Resources of Uranium

	Metric tons	Percentage of world
Australia	863,000	28
Kazakhstan	472,000	15
Canada	437,000	14
South Africa	298,000	10
Namibia	235,000	8
Brazil	197,000	6
Russian Federation	131,000	4
United States	104,000	3

World total	3,107,000	

Source. Organization for Economic Cooperation and Development, National Energy Agency, and International Atomic Energy Agency (2001).

the Red Book estimates, the Canadian resources are listed as 331,000 t uranium. These vast economic concentrations are unconformity-type deposits in Proterozoic sedimentary basins. However, the McArthur River deposit, 620 km north of Saskatoon, Saskatchewan, itself contains 161,000 t uranium in ore that average 23% U_3O_8.

6.3.1 McArthur River/Key Lake

McArthur River, which is the world's highest grade and largest uranium mine, was discovered in 1988 and, after regulatory approvals were obtained, began mining operations in 1999. Between 1988 and 1991, 60 exploratory holes were drilled from the surface, of which 37 intersected uranium mineralizations. Approximately 70% of the deposit is based on seven of those holes. One hole graded 43% U_3O_8 for a distance of 25 m. The proven reserves at McArthur River are 137,000 t of uranium from ore averaging 17.8 wt%, probable reserves of 15,000 t averaging 19.5 wt%, and indicated resources of 87,000 t averaging 9.1 wt%. Like the other large Saskatchewan deposits, the McArthur River deposit occurs close to the unconformity between the flat-lying unmetamorphosed Proterozoic sandstones of the Athabasca Group and the lower Proterozoic and Archean rocks beneath. At the McArthur River site, this unconformity is at a depth of 500 to 600 m.

Remote-controlled equipment and nonentry mining methods are used at McArthur River to minimize the direct and inhalation radiation exposure to workers extracting the high-grade uranium ore. Because the groundwater, at a normal hydrostatic pressure of 5.1 MPa, has radon concentrations as high as 8.9×10^9 Bq/m^3 (0.24 Ci/m^3), special provisions must be made for adequate ventilation of the radon and for freezing of the adjacent groundwater to prevent flow into the mine.

The ore is milled 80 km south of the McArthur River deposit at Key Lake. Uranium production from the combined McArthur River–Key Lake complex in 2001 was 7225 t. Although Key Lake reserves, estimated to total 70,400 t, will be depleted over the next 5 years or so, production from McArthur River is expected to continue for several decades, according to Jamieson and COGEMA Resources.

6.3.2 Cigar Lake

Cigar Lake, 660 km north of Saskatoon, is the world's second-largest uranium deposit. Discovered in 1981 and approved as a test mine in 1987, the mine received government approval in 1998 and could begin uranium production in 2005 or later depending on market conditions. During the first 15 years of operation, the mine is expected to produce approximately 232 million pounds of U_3O (90,000 t U) at an average grade of 21%. The mine is expected to have a life span of 30 to 40 years. The overall Cigar Lake reserve is estimated at 137,000 t of uranium.

The Jasper Lake deposit contains approximately 123,000 t of uranium in ore that is 13.6% U_3O_8. The two deposits cover less than 120 square miles and were first explored some 20 years ago. Cigar Lake (137,000 t U) and Key Lake (70,400 t U) are also within 20 miles of each other.

The richness of the Canadian deposits and the relatively small area that has been explored both suggest that additional demand and exploration will result in substantial further discoveries.

6.4 Australian Reserves

Australia has emerged as a major producer of uranium since 1960. An intensive exploration effort at that time led to the discovery of the Ranger, Jabiluka, and Olympic Dam deposits as well as several others. Today, Australia has 27% of the world's proven reserves and a similar share of worldwide production. Australian deposits are roll-front deposits in sandstone or caliche, unconformity deposits, and a few veins in pegmatites. In general, the Australia deposits are lower in grade than the currently operational Canadian deposits.

The Ranger deposit, located 230 km east of Darwin, originally contained approximately 93,000 t of uranium at an average grade of 0.16 to 0.25 wt%. The mine has been producing approximately 4300 t annually for the past two decades. Roughly half of the original deposit has been exhausted.

The Jabiluka deposit, 20 km north of the Ranger deposit, contains at least 60,000 t of uranium at an average grade of 0.43 wt%.

The Olympic Dam deposit, located 265 km north of Port Augusta in South Australia, is potentially one of the world's largest uranium deposits. Estimated reserves are 266,000 t with an ore grade of 0.04 wt% and an additional indicated resource of 388,000 t with an average grade of 0.03 wt%. In addition, the deposit contains approximately 12 million t of copper and significant amounts of gold and silver. Currently, the Olympic Dam deposit is not being operated as a primary uranium producer but instead recovers uranium as a by-product of copper and gold extraction. Production capacity is being increased to 4700 t per year from the current 4000 t.

6.5 Other Ore Deposits

The United States has extensive ore deposits in the West, where many production centers were built between 1947 and the 1970s. From 1960 to 1980, the United States produced an average of 10,850 t of uranium annually. From 1949 through 2000, U.S. production was 354,421 t annually.

However, because of slow demand growth and large discoveries in Canada and Australia, many of these facilities have been closed and dismantled or put on long-term standby. Current production of 1000 t of uranium per year from an aggregate capacity of 3060 t per year uses ISL at six locations. In addition, one by-product plant is operational with a capacity of 290 t per year. Four ISL, three by-product, and six conventional mills are on standby.

Reasonably assured resources, at up to $80 per kilogram of uranium, are estimated to be 104,000 t, whereas resources in the range of $80 to $130 per kilogram are estimated to be 244,000 t. Estimated additional resources are 839,000 t at up to $80 per kilogram and 434,000 t at $80 to $130 per kilogram. Speculative resources in the same cost brackets are 504,000 and 354,000 t, respectively. Additional speculative resources, with no cost range assigned, are estimated to be 482,000 t.

The only current source of Russian uranium production is the Streltsovsky region near Krasnokamensk in eastern Siberia. Output in 2001 was approximately 2000 t of uranium, of which an estimated 90% was derived from underground mining, with the balance being derived from low-grade ore by heap or in-place leaching. The Russian Federation has reasonably assured resources, at up to $80 per kilogram of uranium, of 140,900 t. The balance of the known conventional resources consists of 36,500 t recoverable at less than $80 per kilogram. Undiscovered resources are estimated to be exceedingly large—nearly 105,000 t of uranium at up to $130 per kilogram plus 1 million t of speculative resources, of which more than half are thought to be recoverable at less that $80 per kilogram.

7. UNCONVENTIONAL RESOURCES

Unconventional resources are those outside the mining industry or those in deposits not generally mined for the uranium or thorium alone.

7.1 Enrichment Tails

An unconventional source of uranium is the reenrichment of depleted uranium by using today's overcapacity of enrichment. Because of the low prices of natural uranium during recent years, many enrichment plants have been operating with tails assays of up to 0.3% ^{235}U. Therefore, the 1.18 million t of depleted uranium currently stored at enrichment plants could supplant a few hundred thousand metric tons of natural uranium if demand required. The inventory of depleted uranium is expected to increase by approximately 51,400 t per year through at least 2010. The enrichment capacity in 1999 was reported to be 55.6 million separative work units (MWSU) per year, compared with an annual demand of 35.4 MWSU per year. The current spare capacity in enrichment plants in the world, at roughly 15 to 20 MSWU per year, theoretically represents an equivalent of 7000 t of natural uranium per year if this spare capacity was used for enrichment of depleted uranium with an assay of 0.3% and a new tails assay of 0.1%.

However, the economics of reenrichment depend on the ^{235}U assay of the depleted uranium and the relationship between the price of uranium and the cost of enrichment services. A tails assay of more than 0.3% is preferable if reenrichment of depleted uranium is to be considered a possibility. Reenrichment of depleted uranium for the production of LEU and natural uranium in the Russian Federation has taken place for several years.

7.2 Gold and Phosphate Tailings

In addition to the discovery of new resources through increased exploration, improvements in mining technology are lowering the cost of previously high-cost deposits. In particular, ISL is of growing significance and could be applied to existing gold and phosphate tailings piles. The resource base of 16.2 million t does not include uranium in gold and phosphate tailings. The phosphate deposits are estimated at 22 million t.

7.3 Recovery of Uranium from Seawater

The recovery of uranium from seawater places an upper limit on the cost of uranium. Uranium is dissolved in seawater at 3 mg/m^3 (3 wppb) and represents a well-known resource of 4 billion t, more than 300 times the known land-based resource. Estimates of recovery costs have been in the neighborhood of $200 per kilogram, although these estimates are highly speculative. The uranium content of the oceans is relatively constant, and large-scale extraction can be done without local depletion of the resource. Because only approximately 3% of the global population live in landlocked countries, extraction of uranium from seawater is truly the bounding cost for uranium.

Uranium recovery from seawater has been studied in Japan for the very long term or to face a very strong development of fission energy. In a laboratory-scale experiment performed by the Japan Atomic Energy Research Institute (JAERI), uranium is trapped by an amidoxime adsorbent that has been prepared on nonwoven polyethylene material with the aid of radiation-induced cografting. This experiment, conducted 7 km offshore from Sekine-Hama in Aomori Prefecture, Japan, produced more than 1 kg of uranium on 350 kg of nonwoven fabric during a total submersion time of 240 days, as reported by Seko. Yet, at this stage of the study, it is difficult to predict the practical application of uranium recovery from seawater. An economic assessment has been reported indicating a possible cost for this uranium process in a 1000-t/year commercial plant of approximately $600 per kilogram. Ultimately, a goal of approximately $100 per kilogram was reported to be feasible in the longer term with an improved absorbent.

The recovery of uranium from seawater is highly speculative and may never prove to be economical. For example, 1 t of seawater contains 3 mg of natural uranium, which can deliver 244 MJ_{th} in a breeder or approximately 2.5 MJ_{th} in a present-day LWR. Simple calculations show that the pumping energy needed in an extraction plant could easily consume all of the energy available, particularly in the LWR case. Thus, seawater extraction conceptual designs relying on ion exchange or adsorption have used ocean currents or wave action to move the seawater past the uranium-collecting surfaces.

As discussed later, harvesting the remaining fissile material from enrichment tails or harvesting fissile isotopes from discharged fuel may prove to be more economical routes for uranium resource extension than is seawater extraction.

However, the magnitude of the seawater resource places an upper limit on the cost of uranium for several reasons. First, seawater is available to nearly all countries of the world at virtually the same uranium concentration and without local depletion due to the extraction of uranium. Second, because no group of countries can form a cartel over the uranium supply if seawater extraction is practiced, the price of uranium is unlikely to be driven artificially high through market manipulation. Furthermore, the only current limitation on the extraction of uranium from seawater is knowledge of the technology and resins. Thus, one would expect that if conventional sources of uranium become limiting, a healthy competition in research and development would drive the price toward the more optimistic $200 per kilogram.

Therefore, a successful technology for the extraction of uranium from seawater places a cap on the cost of uranium. However, for the foreseeable future, that cap will be well above the market prices of uranium from geological deposits.

The additional cost of uranium recovered from seawater, even under somewhat pessimistic costs of $1000 per kilogram, would not add more than 30% to the cost of electricity. Thus, although the availability of uranium from conventional mines is of some interest in the development of new reactor types, limited uranium resources should not be a determining factor in the choice of a reactor type. The increase in the overall cost of electricity would be less than that seen routinely in fossil fuels (e.g., the price fluctuation of natural gas since 1998).

8. NEW TECHNOLOGIES FOR URANIUM EXTRACTION

The current low prices of uranium provide little motivation for the development of new extraction technologies. However, regulations to minimize the

impact of mining on the environment and radiation exposure to workers have led to the use of technologies where uranium is extracted *in situ* or where ores previously mined for another element are processed for uranium extraction. In addition, the technologies described previously for the extraction of uranium from seawater could play a critical role in minimizing environmental impact and radiation exposure.

8.1 *In situ* Leaching

In conventional mining, the rock of the ore body is removed from the ground, transported to a mill, and treated to remove the minerals of economic value. The opening of the mine, the transport of the ore, the milling, and the disposal of remaining treated rock can create severe environmental impacts. ISL, sometimes known as solution mining, involves the use of liquids to dissolve the desired elements from the ore body without removing it from the ground. The liquid is pumped through the ore body and returned to the surface, where the desired elements are removed from the solution by precipitation, electrochemistry, or other means. The leaching liquid is then returned to the ore body and the process is repeated. ISL eliminates the need to remove large quantities of ore from the ground and to transport it to the mill, thereby minimizing surface disturbance. ISL also eliminates the need to dispose of the tailings or waste rock. However, for ISL to be effective, the ore body must be permeable to the flow of the leaching liquid. Furthermore, the ISL site must be located so as to not contaminate groundwater away from the ore body.

Today, because of its reduced surface impact and lower cost, ISL is used for 85% of U.S. uranium production. Most of the operations in Wyoming,

Nebraska, and Texas have been in existence for less than 10 years. Worldwide, approximately 16% of uranium production uses ISL, including all of the production in Uzbekistan and Kazakhstan.

ISL can be used to extract uranium from deposits below the water table in permeable sand or sandstone, provided that the deposits are confined above and below by impermeable strata. Suitable candidates are often roll-front deposits, as described earlier. The uranium minerals are usually uranium oxide or uranium silicate coatings on the individual sand grains. The ISL process replicates, in a few months, the conditions that led to the formation of the roll-front deposit in the sandstone initially.

There are two types of ISL, depending on the chemistry of the sandstone and groundwater. When the ore body is limestone or gypsum (i.e., containing significant amounts of calcium), an alkaline leaching agent, such as sodium bicarbonate and CO_2, must be used. Otherwise, an acid leaching agent, such as weak sulfuric acid plus oxygen at a pH of 2.5 to 2.8 (about the same as vinegar), is preferred. ISL in Australia is primarily acid, whereas ISL in the United States is primarily alkaline.

In general, the uranium is extracted by progressively drilling wells into the deposit on a rectangular grid with 30-m spacing. The leaching fluid is pumped into four wells surrounding a central extraction well, into which a submersible pump has been lowered. The wells are cased to ensure that the fluids do not enter strata above the deposit. In the United States, the production life of an individual alkaline ISL well is typically 6 to 10 months. The most successful operations have extracted 80% of the uranium from the ore. Production life is often limited when the sandstone is plugged by mobilized clay and silt. Sometimes the blockages can be dislodged by

reversing the flow through the field or by increasing the injection pressure.

The uranium is recovered from the pregnant solution in an ion exchange or solvent extraction process. Solvent extraction is preferred if the groundwater is saline, whereas ion exchanges is most effective if the chloride content is less than 3000 ppm. With alkaline leaching, ion exchange is effective until the total dissolved solids reach 3000 ppm. The uranium is then stripped from the resin or solution for further processing.

Before the process solution is reinjected, it is reoxygenated and recharged with sulfuric acid, if necessary, to maintain a pH of 2.5 to 2.8. Approximately 1% of the process solution is bled off to maintain a pressure gradient toward the wellfield. The pressure gradient ensures that groundwater from any surrounding aquifer flows into the wellfield and that ISL mining solutions do not enter the aquifer.

9. IMPACT OF URANIUM SCARCITY AND HIGHER EXTRACTION COSTS

Table VI shows the approximate impact of increases in the price of natural uranium on the cost of electricity from an LWR. In this set of calculations, the cost of natural uranium is set at $30.17 per kilogram (the approximate average price of domestic uranium to U.S. utilities in 2000), with $200 per kilogram representing an optimistic cost of extraction from seawater and $1000 per kilogram representing a more pessimistic (or perhaps more realistic) cost of extraction from seawater. Two burn-ups are shown for uranium price: 45 and 60 MW-day (thermal) per kilogram of initial uranium. The specific power of the fuel remains constant at 37.9 kW_{th} per kilogram of initial uranium, as does the interest charged on the fuel during the fuel cycle. In the cases with higher cost uranium, the tails assay ("tails ^{235}U content") to optimize the balance between raw materials and enrichment costs.

As shown in the final two lines of Table VI, an increase in the cost of natural uranium from $30.17 to $1000 per kilogram results in an increase in the cost of electricity of approximately 20 mills ($0.02) per kilowatt-hour. An increase in the price of natural gas of $3.00 per thousand cubic feet, as occurred in 2000, also results in an increase in the cost of electricity of $0.02 per kilowatt-hour.

9.1 Uranium and Thorium Resources Compared with Future Energy Needs

A simple calculation is needed to place the magnitude of current uranium mining in perspective. If we assume that the world population reaches a steady-state level of 10 billion and that each person consumes energy at the average rate of a U.S. resident in 2001, total world consumption of energy would be approximately 3.7×10^{21} J_{th}. Although that high rate of consumption would probably not be sustainable for a variety of other reasons, the required natural uranium input to a system of fast reactors to produce 3.7×10^{21} J_{th} would be approximately 45,000 t. Average worldwide uranium production, from both mines and the downblending of HEU, now exceeds 45,000 t per year. Expected requirements for the next 20 years or so are 60,000 to 80,000 t per year.

9.2 The Need for Fast Reactors

The early development of fast breeder reactors and of thermal breeder reactors using thorium was driven in part by the apparent scarcity of fissile isotopes to fuel a rapidly growing set of nuclear reactors. Slow growth in nuclear power and large discoveries of natural uranium have reduced the urgency for breeding more fissile material.

However, the use of a fast neutron spectrum or thorium offers unique capabilities for the consumption of the long-lived actinides, particularly plutonium, neptunium, americium, and curium.

In the long term, the capability of a fast reactor to make use of both ^{238}U and ^{235}U will be critical in meeting future energy needs. However, in the coming century, fast reactors will be crucial for the management of actinides and the reduction of the long-term radiotoxicity of the nuclear fuel cycle by at least two orders of magnitude.

9.3 Comparison of Fossil Fuel and Uranium Reserves

It is interesting to compare the cited uranium known reserves and the inventory of depleted uranium with the estimated reserves of coal, oil, and natural gas. In Table VII, the reserves of fossil fuels and uranium are compared on the basis of known economically recoverable reserves.

Fossil fuel reserves are those of the World Energy Council, the *Oil & Gas Journal,* and *World Oil,* as cited by the Energy Information

TABLE VII

Comparison with Fossil Reserves

Coal	1089 billion tons
	$= 2.41E + 22$ J_{th}
	= 22,869 quad
Petroleum	1028 billion barrels
	$= 6.29E + 21$ J_{th}
	= 5,962 quad
Natural gas	5450 trillion cubic feet
	$= 5.95E + 21$ J_{th}
	= 5,641 quad
Total fossil reserves	$3.64E + 22$ J_{th}
	= 34,472 quad
Uranium	3.1 million t natural Uranium
	+ 1.3 million t depleted Uranium
	$= 1.34E + 21$ J_{th} in LWRs
	= 1268 quad in LWRs
	$= 3.57E + 23$ J_{th} in fast reactors
	= 338,462 quad in fast reactors

Note. quad, quadrillion BTU.

Administration. In using Table VII, the caveat cited previously applies: resources of both fossil fuels and uranium are undoubtedly much larger than the reserves cited. Nevertheless, it is noteworthy that the uranium resources are energetically equivalent to approximately 20% of natural gas and oil resources, even with the use of LWRs only. The 1.3 million t of depleted uranium currently in storage itself represents an energy source larger the fossil reserves.

10. SUMMARY

Uranium is ubiquitous in the continental crust and is concentrated in economically recoverable deposits by several relatively well-understood processes. Today, we are mining uranium from the richest and most convenient of the deposits, although little exploration has taken place during the past 20 years. Uranium and thorium are often being extracted as by-products of mining for other elements. It is likely that other similarly rich deposits exist in relatively unexplored regions of Asia and Africa.

Prices in the current uranium market are dominated by large discoveries during the past 20 years and by the conversion of military HEU for civilian purposes. The continued use of nuclear energy and the end of downblending can be expected to raise uranium prices, encourage exploration, and return the uranium to a slightly higher priced equilibrium.

However, because of the wide range of igneous and geochemical processes that are responsible for the formation of uranium deposits, we can expect that uranium will be found in significant quantities with renewed exploration.

Emerging technologies for the extraction of uranium, particular ISL, will make resources in sandstone and shale economically recoverable and will minimize the surface disruption due to open pit mining and the occupational radiation exposures of underground mining.

In the more distant future, the extraction of uranium from seawater will make this fuel available to virtually every nation. Although extraction from seawater is likely to be 10 to 20 times more expensive than uranium is today, the overall increase in the cost of electricity and other energy products would be minimal.

Therefore, the need for fast reactors in the near term is driven not by a scarcity of uranium but rather by a need to effectively manage the long-lived actinides in spent fuel. A fast neutron spectrum is uniquely capable of fissioning the higher actinides and reducing the long-term radiotoxicity of the nuclear fuel cycle. Likewise, although thorium is more abundant than uranium, the primary use of thorium will probably not be for the breeding of ^{233}U; rather, it will be as a host material for the transmutation of the higher actinides.

There are many challenges in the development of safe, proliferation-resistant, and economical reactors and fuel cycles. Fortunately, the uranium and thorium resources do not appear to be a near-term limitation.

Glossary

alpha particle A particle consisting of two protons and two neutrons given off by the decay of many elements, including uranium, plutonium, and radon. Alpha particles cannot penetrate a sheet of paper; however, alpha-emitting isotopes in the body can be very damaging.

atom The basic component of all matter. The atom is the smallest particle of an element that has all of the chemical properties of that element. Atoms consist of a nucleus of protons and neutrons surrounded by electrons.

beryllium The fourth lightest element. Some nuclear weapon parts are made of beryllium.

beta particle A particle emitted in the radioactive decay of many radionuclides. A beta particle is identical to an electron. It has a short range in air and a low ability to penetrate other materials.

Cold War A conflict over ideological differences between the United States and the Soviet Union and their allies lasting from the late 1940s until the early 1990s.

Curie The amount of radioactivity in 1 g of the isotope radium-226. One curie is 37 billion radioactive disintegrations per second.

daughter products Radionuclides that are produced from other radionuclides when they decay.

dose A specific amount of ionizing radiation or a toxic substance absorbed by a living being.

gamma radiation High-energy, highly penetrating electromagnetic radiation emitted in the radioactive decay of many radionuclides. Gamma rays are similar to X-rays.

half-life The time it takes for one-half of any given number of unstable atoms to decay. Each isotope has its own characteristic half-life that ranges from small fractions of a second to billions of years.

heavy metals Metallic elements with high atomic weights (e.g., mercury, chromium, cadmium, arsenic, and lead) that can damage living organisms at low concentrations and tend to accumulate in the food chain. Uranium, thorium, and plutonium are heavy metals.

highly enriched uranium Uranium with more than 20% of the uranium-235 isotope used for making nuclear weapons and as fuel for some isotope production, research, and power reactors. Weapons-grade uranium is a subset of this group.

isotopes Forms of the same chemical element that differ only by the number of neutrons in their nucleus. Most elements have more than one naturally occurring isotope. Many more isotopes have been produced in nuclear reactors and accelerators.

mill tailings The sandlike materials left over from separating uranium from its ore. More than 99% of the ore becomes tailings. Mill tailings typically contain approximately 85% of the radioactivity present in unprocessed ore.

natural uranium Uranium that has not been through the enrichment process. It consists of 99.3% uranium-238 and 0.7% uranium-235.

plume A subsurface zone that contains predominantly dissolved and sorbed contaminants that originate from a contaminant source area. A plume can extend for some distance, depending on groundwater flow and chemistry.

plutonium (Pu) A man-made fissile element. Pure plutonium is a silvery metal heavier than lead. Material rich in the plutonium-239 isotope is preferred for

manufacturing nuclear weapons. The half-life of plutonium-239 is 24,000 years.

radiation Energy transferred through space or other media in the form of particles or waves. Certain radiation types are capable of breaking up atoms or molecules. The splitting, or decay, of unstable atoms emits ionizing radiation.

radioactivity The spontaneous emission of radiation from the nucleus of an atom. Radionuclides lose particles and energy through the process of radioactive decay.

radionuclide A radioactive species of an atom. For example, tritium and strontium-90 are radionuclides of elements of hydrogen and strontium, respectively.

radon A radioactive inert gas that is formed by the decay of radium. Radium, in turn, is a link in the decay chain of uranium-238. Radon, which occurs naturally in many minerals, is a main hazard of uranium mill tailings.

thorium A naturally occurring radioactive element.

uranium The basic material for nuclear technology. This element is naturally slightly radioactive and can be refined to a heavy metal more dense than lead.

uranium mill A processing plant in which uranium is separated from mined ore.

Uranium Mill Tailings Radiation Control Act (UMTRCA) of 1978 (U.S. Public Law 95-604) The act that directed the U.S. Department of Energy to provide for stabilization and control of the uranium mill tailings from inactive sites in a safe and environmentally sound manner to minimize radiation health hazards to the public. It authorized the department to undertake remedial actions at 24 designated inactive uranium ore-processing sites and at an estimated 5000 vicinity properties.

Uranium Mill Tailings Remedial Action (UMTRA) Project A program to reduce the hazards posed to the public by uranium mill tailings. The program was created by the U.S. Department of Energy in response to the Uranium Mill Tailings Radiation Control Act enacted in 1978. The U.S. Department of Energy's Office of Environmental Management is responsible for implementing the UMTRA Project.

uranium mining, milling, and refining Mining and milling involves extracting uranium ore from the earth's crust and chemically milling (processing) it to prepare uranium concentrate (U_3O_8), sometimes called uranium octaoxide or yellowcake. Uranium concentrate is refined, or chemically converted, to purify it into the form suitable as feed material for further use.

uranium-238 The heavier of the two main isotopes of uranium. Uranium-238 makes up more than 99% of the uranium ore that is mined. It has a half-life of 4.5 billion years and is not easily split by neutrons.

vicinity properties Locations away from inactive millsites where uranium mill tailings were used for construction or were transported by wind or water erosion.

yellowcake A common uranium compound, U_3O_8, named for its typical color. Uranium is sent from the uranium mill to the refinery in this form.

1. URANIUM AND ITS CHARACTERISTICS

Since the 1940s, uranium mining and milling have involved extracting ore from the earth's crust and chemically processing it to prepare uranium concentrate, sometimes called yellowcake. Processing of the uranium ore resulted in the generation of large volumes of slightly radioactive sandlike residues called mill tailings that typically contain radium, thorium, radon, and nonradioactive heavy metals in low concentrations. Usually, the tailings were deposited as slurry in unlined pondlike structures. Evaporation of the liquid content of the tailings left the fine-grained tailings materials exposed to wind and precipitation (Fig. 1).

To put the legacy waste problem into perspective, the largest residual piles of mill tailings in the United States and Canada may total 30 million tonnes of solid material. Near Nucla, Colorado, the Uravan pile contained more than 14 million tonnes of solids or mill tailings. The Helmsdorf pile near Zwickau in Saxony, Germany, consists of 50 million tonnes of tailings and the Culmitzsch pile near Seelingstädt in Thüringia, Germany, contains 86 million tonnes of solids.

Many tailings piles and ponds were left in a state of uncontrolled abandonment that harmed the environment. Windblown tailings contaminated soils, and radioactive and hazardous constituents migrated into surface waters and groundwaters. Significant efforts

FIGURE 1 In the early years of processing uranium ore in the United States, liquid waste was piped to ponds where the liquid component evaporated, leaving fine sandlike tailings.

have been implemented during the past 20 years to control and stabilize these piles and ponds and to mitigate the adverse environmental consequences. Today, more rigorous regulations and standards for mining and milling uranium ore help prevent negative effects to human health and the environment.

Uranium is a naturally occurring element and a metal that has been identified in approximately 50 minerals. Uranium minerals are not particularly rare. The main ores of uranium are uraninite (pitchblende) and secondary minerals formed from it by weathering. Another important source of uranium ore is carnotite. Carnotite is a complex uranium and vanadium mineral that occurs in sedimentary rocks, is visible as yellow streaks in sandstones, and is common in the southwestern United States. Uranium minerals are widespread in granites and pegmatites but generally not in large concentrations. The average crustal abundance of uranium varies from 2 to 4 parts per million, which is similar to the natural occurrences of arsenic, beryllium molybdenum, and tungsten.

A unique characteristic of uranium is its radioactive isotopes that are unstable and can change or "decay" to other forms. Some of uranium's descendants in its decay chain are more radioactive than uranium and emit a significant level of radiation.

Uranium is represented in the periodic table by the symbol U and the atomic number 92. It is an actinide and one of three naturally occurring isotopes that exist in nature: uranium-234, uranium-235, and uranium-238. The natural abundance (atom percent) of uranium-238 is greater than 99%. All three are long-lived radioactive isotopes with half-lives of 2.45×10^5 years for uranium-234, 7.04×10^8 years for uranium-235, and 4.46×10^9 years for uranium-238. A half-life is the time it takes for half of any sample or amount to decay.

Uranium-235, although occurring in natural uranium to the extent of only 0.71%, is so fissionable with slow neutrons that a self-sustaining fission chain reaction can be made in a reactor constructed from natural uranium and only a suitable moderator, such as heavy water or graphite. Because uranium-235 is the only uranium isotope with fissionable characteristics and because it is found in relatively low natural abundance compared to uranium-238, significant amounts of uranium ore need to be mined (extracted from the earth's crust) and milled (crushed and chemically processed) to produce uranium oxide (U_3O_8) or concentrate as the preparatory step in processing uranium for the nuclear fuel cycle. Yellowcake is the common term for uranium oxide.

Uranium oxide, the product of the milling process, needs further refinement and chemical conversion to purified forms that are suitable as feed materials. The product at this stage is uranium hexafluoride (UF_6), which requires enrichment as the succeeding step in the fuel cycle process. Enrichment is the isotope separation of the fissile material (uranium-235). The fuel cycle material (highly enriched uranium) is destined for fuel and target fabrication, reactor operations, chemical separations, component fabrication, and ultimately weapons operations. The depleted uranium (containing less than 0.711% uranium-235) is used in weapon components and in reactor targets to be irradiated for the production of plutonium-239.

2. RECOGNITION OF RISKS TO HUMAN HEALTH AND THE ENVIRONMENT

Uranium mill tailings are the sandy waste produced by the uranium ore milling process. Because only 1–5 pounds of usable uranium (depending on the ore grade) is extracted from each tonne of ore, large quantities of waste were produced during more than 40 years of processing ore for Cold War efforts, nuclear power plants, and medical uses. These tailings contain many naturally occurring hazardous substances, both radioactive and nonradioactive, and include approximately 85% of the radioactivity present in the unprocessed uranium ore. The greatest threat to public health and safety is the radioactive decay process of this material into radium and radon-222, an inert gas that may cause cancer or genetic mutations.

The dominant hazard from tailings is the radioactive decay products of uranium-238, particularly radium-226 and its short half-life decay products (Table I). Each gram of natural uranium ore contains approximately 500 pCi of uranium-238. In addition, natural uranium ore contains approximately 23 pCi of uranium-235 and 2 pCi of thorium-232. Because these isotopes occur in relatively small proportions and pose less risk to health, uranium-235 and thorium-232 and their radioactive decay products are usually ignored in evaluating the hazard of uranium mill tailings. However, thorium-230, with a half-life of 77,000 years, is a significant decay product because it is the radioactive parent of radium-226.

TABLE I

Decay Chain of Natural Radioactivity Starting with Uranium and Ending with Lead

Isotope	Name	Half-life	Main radiations emitted
U-238	Uranium	4.47×10^9 years	α
↓			
Th-234	Thorium	24.1 days	β, γ
↓

Pb-206	Lead	Stable	—

Uranium tailings emit three types of radiation: alpha (α) particles, beta (β) particles, and gamma (γ) rays. The type of radiation emitted by a nucleus depends on the nature of the imbalance in the nuclear forces, but all types are forms of ionizing radiation that breaks up molecules into electrically charged fragments called ions. Ions are created when an electron is removed from one of the orbital electron shells of an atom. This process is called ionization. In biological tissues, ionization can produce harmful cellular changes. At low radiation levels usually encountered in the environment, we expect the effects of such changes to be difficult to detect. Studies show, however, that individuals exposed to ionizing radiation have a greater chance of developing cancer.

The increased chance of cancer or genetic damage after exposure to radiation cannot be predicted with precision. Health experts have based risk estimates on studies of individuals exposed at doses higher than those associated with uranium mill tailings and on the assumption that the effects will be proportionally less at lower doses. The slope function of the proportionality is not well understood.

Alpha, beta, and gamma radiation from tailings can cause cancer or genetic damage. However, the major threat comes from breathing air containing radon decay products with short half-lives, such as polonium-218, with a half-life of 3.11 min. However, if alpha emitters have been inhaled, ingested (swallowed), or absorbed into the bloodstream, sensitive living tissue can be exposed to alpha radiation. The resulting biological damage increases the risk of cancer; in particular, alpha radiation is known to cause lung cancer in humans when alpha emitters are inhaled.

Human exposure to gamma rays from radioactive material in the tailing piles is possible under uncontrolled settings. Radium is also a source of gamma rays that can travel much farther than alpha or beta particles and have enough energy to pass through the entire human body, potentially exposing all organs. A large portion of gamma radiation passes through the body without interacting with tissue. The human body is mostly empty space at the atomic level and gamma rays are massless uncharged "packets" of electromagnetic energy. In contrast, alpha and beta particles inside the body lose all their energy by colliding with tissue and causing damage.

The body's internal organs would still be exposed to radiation from radionuclides even if all the uranium mill tailings piles suddenly disappeared because radon, radium, uranium, thorium, and other radioactive elements occur naturally in air, rocks, and soils. A typical background concentration of radium is 1 pCi of radium per gram of soil; outdoor air contains a few tenths of a picocurie of radon per liter. Normal eating and breathing introduces these and other radioactive materials into the body, increasing the potential for cancer and genetic changes. Understanding the occurrence of natural radiation and the potential for everyday exposure does not justify the risk of exposure to tailings but does provide a realistic context for comparison.

Tailings also contain toxic elements that could eventually be inhaled or ingested by man or animals or absorbed by plants. Often, hazardous elements leach from the uncontrolled tailings piles and contaminate shallow groundwater.

2.1 Radon and Radon Progeny

Because the milling and extraction processes removed most of the uranium from the ore, the remaining significant radioactive members of the uranium series (Table I) are determined by the presence of thorium-230 and its decay progeny. The thorium-230 decay product, radium-226, has a 1600-year half-life. Both thorium and radium are relatively insoluble and immobile in their usual chemical forms. However, the decay product of radium-226 is radon-222, an inert radioactive gas that readily diffuses through interstitial spaces to the surface of the uncontrolled tailings piles where it becomes airborne. The half-life of radon-222 is 3.8 days, so some radon atoms can travel a long distance through the atmosphere before decaying to nonradioactive lead-210.

The radon decay process involves seven principal decay products before ending with lead, a stable nuclide (Table I). The four short half-life radioactive-decay products immediately following radon in the decay chain are the most important sources of cancer risk. These decay, for the most part, within less than 1 h. Members of the decay chain with relatively long half-lives (beginning with lead-210, which has a 22.3-year half-life) are more likely to be ingested than inhaled and represent a much smaller risk.

The principal short half-life products of radon are polonium-218, lead-214, bismuth-214, and polonium-214. Polonium-218 has a half-life of 3.11 min, which is long enough for most of the electrically charged polonium atoms to attach to microscopic airborne dust particles that are typically less than 1 millionth of a meter across. When inhaled, these small particles have a good chance of sticking to the moist epithelial lining of the bronchial tubes in the lungs.

Most of the inhaled particles are eventually cleared from the bronchi by mucus but not quickly enough to keep the bronchial epithelium from being exposed to alpha radiation from polonium-214 and polonium-218. This highly ionizing radiation passes through and delivers radiation doses to several types of lung cells.

Since the 15th century, middle-aged miners who had worked underground in the European mining district of Schneeberg, Germany, for at least 10 years often died from a pulmonary disease that the miners called *Bergkranheit* or mountain disease. In 1879, doctors diagnosed the disease as lung cancer. By the mid-1930s, industrial health experts understood that radioactivity of the ore and the radon gas in the air were the leading causes of lung cancer among the European miners.

During the boom years of underground uranium mining, many miners were exposed to increased levels of radon by the very nature of their work (Figs 2 and 3). The ore zones were small and confined, and blasting in the stope (underground excavation

FIGURE 2 Burros pulled the ore carts in uranium mines on the Colorado Plateau during the 1950s. At that time, knowledge was limited about the dangers of radon in these mines. Photograph courtesy of the U.S. Bureau of Land Management.

FIGURE 3 A miner uses a jackhammer to drill a blast hole in a uranium mine (United States). Miners often worked without safety glasses and other personal protective equipment in the 1950s. Photograph courtesy of the U.S. Bureau of Land Management.

formed by the extraction of ore) created dusty conditions and suspended radon daughters in the confined air. The ionizing radon tended to attach to solid particles such as dust and cigarette smoke that were inhaled by the miners. The miners and millers often worked in unprotected conditions because of the desire to increase production. Radon exposure was not limited to the mines and mills. Often, unprotected workers carried radon home on their clothes and ingested it as they drank and ate.

2.2 Exposure Pathways

Uncontrolled use of uranium mill tailings may lead to radiation exposure in a number of ways (Fig. 4). Sandy tailings removed from piles and used for backfill and to improve drainage around foundations or for other construction purposes pose the largest hazard by increasing indoor concentrations of radon decay products. Tailings at an uncontrolled millsite emit radon gas into the atmosphere and are a source of radioactive windblown particles and direct gamma radiation.

Because of the chemicals used in uranium processing, the wet discarded tailings contain large volumes of toxic chemicals that leach out of the unlined piles and into the underlying soils and groundwater. The contaminated groundwater becomes a contaminant pathway if humans and animals drink the water. In some cases, the contaminated groundwater discharges to streams and lakes and contaminates surface water.

Movement of contaminants leaching out of uncontrolled piles into underlying soils depends on complex chemical and physical properties of the subsurface environment and on local climatic conditions, such as precipitation and evaporation. Chemical, physical, and biological processes in the subsoil remove a portion of some of the contaminants from soil–water interactions. However, some contaminants are relatively nonreactive and move though the soil at the velocity of water movement. For example, common tailings contaminants such as nitrate, sulfate, and natural uranium are more nonreactive than vanadium, selenium, and molybdenum.

The greatest hazard from uranium mill tailings that have been removed from waste piles and used in construction is their potential to increase levels of radon decay products in buildings. The concentration of radon decay products in a building depends on the amount of radium in the tailings and the location of the tailings in, under, or adjacent to the structure.

Many of the radioactive isotopes in tailings piles and abandoned mines emit gamma radiation. Unlike alpha radiation, which must originate within the body to become hazardous, gamma radiation can travel farther and penetrate both air and tissue. Near the edge of a pile, gamma radiation can be greater than the background level (unaffected) in uncontaminated areas. The gamma radiation from a pile, however, decreases rapidly because of shielding. Data show that at an approximate distance of a few tenths of a mile from a typical uncontrolled uranium ore tailings pile, the gamma ray measurement cannot be differentiated from the normal background, which is 80–100 millirems (mrem) per year.

Levels of radiation from an uncontrolled uranium tailings pile depend on the amount of radium in the

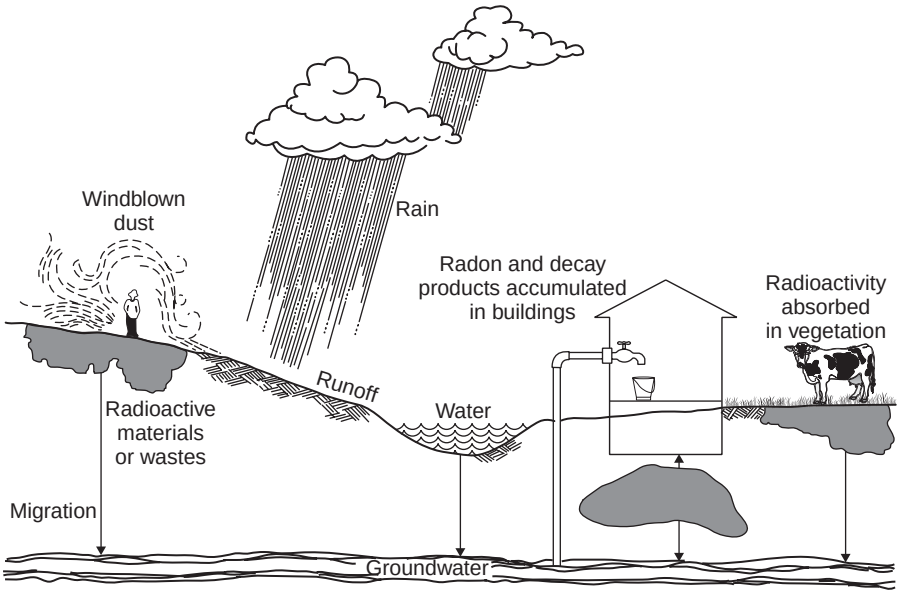

FIGURE 4 Some of the pathways by which environmentally dispersed radionuclides and wastes from uranium mill tailings can affect living organisms.

tailings. Field measurements of gamma radiation on top of tailings piles show levels up to 4000–8000 mrem per year.

3. HISTORICAL REVIEW OF URANIUM ORE MINING

Mining of uranium-bearing ores began in 16th-century mining centers such as the Erzgbirge Mountains (Ore Mountains) of Saxony and nearby Bohemia in Germany. Georgius Agricola (1494–1555), credited as the father of modern geology, artfully illustrated and scrupulously described uranium ore mining in "De Re Metallica." During this period of mining for silver, copper, and other base and precious metals, the uranium-bearing ores were discarded as waste because they had no known economic value.

At the beginning of the 20th century, there were no large-scale commercial uses for uranium. Marie Curie announced the discovery of the 88th element radium at the turn of the century. It was known that radium was associated with uranium ore, and European refiners needed radium for medical uses. Uranium ore was mined for radium, and the uranium was considered a by-product for the most part. At one time, it was thought that uranium was a viable alloy for hardening steel, but this industrial use never materialized. In the 1920s and 1930s, uranium was used in some brands of pottery (Fiesta Ware) to produce an attractive orange color. Prior to World War II, uranium production was not in high world demand because of limited commercial uses, and its scarcity kept the price of the metal too high to promote new industrial development.

Scientists' investigations to unlock the secrets of uranium evolved over 100 years. Martin Heinrich Klaproth isolated "a strange kind of half-metal" from its naturally occurring ore of pitchblende in 1789 in Germany and named it uranium after the planet Uranus. However, the uranium metal was first isolated in 1841 by Eugene-Melchoir Peligot, who reduced the anhydrous chloride uranium chloride (UCl_4) with potassium. The radioactive nature of uranium was not appreciated for another 55 years when Henri Becquerel detected its radioactivity in 1896.

Research by Ernest Rutherford led to publication of a paper in 1904 about the nature of radioactivity and the theory of radioactive decay. Physicists were aware of the potential military uses of nuclear energy by the 1930s, and Otto Hahn and Lise Meitner of Germany determined that uranium could release energy by nuclear fission in 1939. A chain reaction occurs during the nuclear fission process, starting with one nucleus that splits and releases neutrons that collide with other nuclei, causing those nuclei to split and release more neutrons, and the chain reaction continues.

Albert Einstein, a German-born scientist, sent a letter to U.S. President Franklin Roosevelt in 1939

alerting him to the importance of the nuclear research being conducted in Germany. Soon after the United States entered World War II, the U.S. government secretly established the Manhattan Project to develop an atomic bomb. Uranium for this new weapon was acquired from the Belgian Congo, Canada, and the Colorado Plateau in the United States. Deployment of two atomic bombs by the United States in 1945 ended World War II and heralded the arrival of the atomic age and the beginning of the Cold War.

4. THE COLD WAR ERA

Uranium ore mining increased dramatically following the end of World War II and during the Cold War era from 1946 to 1991. The Cold War was a result of growing tensions from the concluding resolutions of World War II. The Soviet Union and the United States were competing in an arms race to have the best, the largest, and the most nuclear weapons. Large quantities of uranium were necessary to produce those weapons.

Uranium was also needed to supply fuel for the nuclear reactors being constructed throughout the world to produce electricity and to replace diesel-powered units in submarines, aircraft carriers, and other naval vessels. Medical uses of uranium products include X-rays, radiation therapies, and radiation isotopes.

At the end of World War II, Germany was a divided country. The Allies controlled West Germany and the Soviet Union controlled East Germany. The Soviet Union knew of the large deposits of uranium ore in Saxony and Thüringia in East Germany. During the Cold War years, both East Germany and West Germany embarked on ambitious government-sponsored programs to explore, mine, mill, and refine uranium ore. The uranium would fuel the nuclear weapons programs. Most of the uranium fuel-cycle program was kept secret during the Cold War by both the Allies and the Soviet Union and its associates. Exploration for uranium ore spread from Eastern Europe and the United States to countries throughout the world. Table II presents production statistics for the top uranium producers during the 1946–1992 period.

Unfortunately, there were no international standards in the past, no best practices, and no environmental laws to protect workers, public health, and the environment and to ensure worker safety. Most of the uranium ore mining was accomplished with conventional mining methods, such as in open pits and underground excavations. In recent years, *in situ* mining methods with chemicals have been employed when the geologic conditions are appropriate. This method has the potential to reduce costs but adds complexity to the environmental consequences because of difficulties in controlling subsurface chemical excursions.

TABLE II
Uranium Production, 1946–1992

Country	Uranium (tonnes)
USA	339,290
Canada	257,692
East Germany	217,791
South Africa	143,302
Czechoslovakia	102,245
Kazakhstan	72,000
France	68,174
Namibia	56,682
Niger	54,143
Australia	25,600
Zaire	25,600
Gabon	22,226
Bulgaria	21,000
Rumania	16,850
Hungary	16,718
India	5920
Total	1,445,233

The principal known deposits of uranium ores in the United States are located in three major districts: the Wyoming Basins, the Colorado Plateau, and the Gulf Coast in Texas. The general area known as the Colorado Plateau covers more than 100,000 square miles in southeastern Utah, western Colorado, northeastern Arizona, and northwestern New Mexico.

Processing of tailings from dumps on the Colorado Plateau supplemented production of uranium from the Belgium Congo and Canada during the early 1940s to meet the military demand. Crude ore milling processes used during this period on the Colorado Plateau reflected little change from methods used 40 years earlier: Uranium was recovered in the milling process from leach solutions based on several stages of selective precipitation. Passage of the Atomic Energy Act of 1946 encouraged prospecting and mining through various forms of assistance. These incentives led directly to an increase in the known mineable uranium ore reserves in the western United States from

approximately 1 million tonnes in 1946 to 80 million tonnes in 1959.

During the peak production years from 1960 to 1962, the number of uranium ore mills in operation in the United States varied from 24 to 26, with the total annual production exceeding 13,000 tonnes of uranium per year from the treatment of 7.25 million-tonnes of ore per year. The number and production rates of the active uranium ore mills decreased from 1962 to 1976 with the cessation of government procurement contracts (Table III).

In the past, the five countries that produced the largest volumes of uranium had distinctively different mining profiles. The United States mined relatively low-grade uranium ores (average 0.03% uranium) by conventional underground methods, and the ore was transported to mills that were often located near waterways. Canada was, and still is, fortunate to possess the highest grade uranium ores in the world (Table IV). In fact, the unusually high grade of some Canadian ores requires special robotic procedures for extraction. Milling of this high-grade uranium ore produces less residual waste and, consequently, fewer adverse environmental impacts.

East Germany mined large quantities of uranium ore during the Cold War (Table II). Wismut, the German Democratic Republic/Soviet Company that mined the ore, produced more than 217,000 tonnes of uranium ore between 1946 and 1990. During peak times in following years, production exceeded 7000 tonnes per year with all uranium products delivered to the Soviet Union. Initially, the uranium was processed exclusively for nuclear weapons, but later it was also used for nuclear power plants. The ore grades were low, even less than those of the sandstone deposits of western United States. Toward the end of the Wismut mining era, the ore grades averaged 0.07%.

In South Africa, uranium ore is a secondary ore associated with gold mining. Large heaps of mill tailings from processing ore to recover gold remain visible in the Transvaal, often near residential areas. Although the tailings are regulated as radioactive, the mining and milling are primarily for other commodities and, therefore, the uranium is more a commodity credit than a stand-alone extraction and processing industry.

The Czech Republic (formerly Czechoslovakia) has mined uranium ore for many years. Diamo, a government-owned company, produced uranium primarily with *in situ* methods using acid. In the early years, Diamo mined uranium ore using conventional underground methods but later converted the mining operations to *in situ* leach methods. The *in situ* methods inflicted serious adverse effects to the environment, with challenging problems to solve. In this case, the environmental effects involve large volumes of low pH-contaminated groundwater requiring active engineered hydraulic controls to contain further migration of the contamination.

TABLE III

U.S. Uranium Production (Tonnes U in Concentrate)

Years	Conventional mining methods	Unconventional mining methods	Total
Pre-1983	281,000	10,000	291,800
1983–1989	23,800	14,250	38,050
1995–2001	Not available	Not available	13,050

TABLE IV

Canadian Uranium Ore Reserves, Grades, and Production Capacity

Mine	Proven reserves (tonnes U_3O_8)	Average ore grade (% U_3O_8)	Annual production (tonnes U_3O_8)
Key Lake	450	0.41	353
Rabbit Lake	10,150	1.30	2070
Cluff Lake	4100	2.7	1519
McClean Lake	19,500	2.40	2990
McArthur River	161,300	21.00	7830

Since the end of the Cold War, world uranium ore mining production has shifted (Table V). Now, Canada produces approximately one-third of the world's uranium. Germany is no longer one of the top 16 producing countries, and the United States has fallen to eighth place. Today, most countries mining and milling uranium ore follow international standards and best practices as provided by the International Atomic Energy Agency (IAEA), and many countries are actively engaged in the cleanup and disposal of the residual wastes.

5. ENVIRONMENTAL IMPACTS IN THE UNITED STATES

The early mills in the United States were built next to rivers within floodplains to harness the water for processing. Most of the tailings left the mill as a

FIGURE 5 This mill, located near Grand Junction, Colorado, processed uranium ore from 1951 until 1970 (three tailings ponds are visible in the foreground). Remediation of the land and buildings began in 1989 and was completed in 1994. The Uranium Mill Tailings Remedial Action Project removed contaminated material, backfilled remediated areas with uncontaminated soil, recontoured the land to promote surface drainage, and revegetated the site.

FIGURE 6 A portion of the remediated site of the former mill near Grand Junction, Colorado, located adjacent to the Colorado River, is now owned by the City of Grand Junction. Site restoration focused on compatibility with long-term plans for development of a riverfront park and trail system. Only one building (circle) remains on the site.

semiliquid waste or slime (fine-grain sandlike material) generated during the milling process. A common practice was to dispose of the radioactive liquid mill effluent directly into the rivers after it had been minimally diluted to reduce radiation and acidic or basic strength. Some tailings were discharged directly into river tributaries. More commonly, mills stored the wet tailings behind massive earthen dikes in structures called tailings ponds (Fig. 5). These containment structures were unlined, and most leaked pore fluids into the shallow groundwater systems beneath the ponds. As the moisture evaporated or seeped out of the ponds, the ponds became generally unstable piles of sand and slimes that were easily eroded by wind and rain.

As the price of uranium declined, many of the mills ceased operations. During the 1960s, going out of business for a uranium mill generally meant abandonment. No controls were in place at the abandoned mills to ensure that the tailings would not interact with the environment and would not be used for construction purposes. Environmental damage occurred for many years until the Uranium Mill Tailings Remedial Action Project, managed by the U.S. Department of Energy, began remedial action to remove, stabilize, and control the contamination (Fig. 6). In many cases, tailings had been taken from the millsites for use as foundation material under buildings and as an additive in concrete. Radium, which decays to radon gas, and radon progeny remained in the tailings. Risks to human health were identified by how the tailings were used in habitable structures, such as in mortar. More than 5000 of these contaminated properties, called vicinity properties, were identified and remediated in the United States.

In some cases, the tailings were left in place and the condition for nonremoval of the contamination

was designated as supplemental standards. An example is tailings used as cover material around underground utilities or under public streets. The U.S. Department of Energy and the state of Colorado cleaned up more than 4000 vicinity properties within the city boundaries of Grand Junction. An "engineered hole" was left in the disposal cell constructed near Grand Junction for future tailings disposal because additional tailings will be uncovered in the community during the next 25 years, primarily around utility lines.

The problem of radiological pollution from former uranium ore mill operations was first identified in the surface waters of the Colorado River Basin. Radium was the most hazardous of the elements in the tailings and was therefore of primary concern to public health officials. From a radiological standpoint, tailings were more dangerous than unprocessed uranium ore because tailings particles are extremely small. Water could more easily dissolve the radium component in the tailings than the radium component in its natural state in uranium ore.

During the 1950s, the U.S. Public Health Service identified radium concentrations that were more than 100 times the background level in samples from rivers in which raffinate liquids had been discharged by the uranium ore-processing mills. Aquatic insects collected during a 1955 survey revealed radium accumulation as high as 60 times normal background levels; algae samples showed radium concentrations as high as 100 times normal levels. By the 1970s, all the mills in the United States had stopped discharging raffinate liquids directly to river courses. As an alternative, the mills adopted the standard practice of discharging the contaminated liquids to unlined ponds. When contained in unlined ponds, contaminated liquid would partly seep into the underlying shallow groundwater and partly evaporate. Of the 24 sites specified in the Uranium Mill Tailings Radiation Control Act, 23 had associated contaminated groundwater.

6. ENVIRONMENTAL IMPACTS IN GERMANY

Disposal practices for wastes in other countries were similar to those in the United States. In Germany, some of the most egregious environmental impacts occurred in Saxony and Thüringia. Successful prospecting for uranium in the immediate postwar period induced the Soviet Union, the occupying power in East Germany, to launch Wismut, a state-run nonferrous metal stock company based in Aue (a small mining town in Saxony) in 1947. Managed by units of the Soviet Union military, the company's only aim was the rapid exploitation of East German uranium deposits for the Soviet Union's nuclear program.

To cover reparation claims of the war, Saxon mining companies were transferred to Soviet Union ownership; land was seized arbitrarily and became a "no go" area. An enormous workforce (peak of 130,000 employees) was employed, and uranium mining operations rapidly spread throughout the Ore Mountains and into eastern Thüringia. Poor working conditions and complete disregard for the environment characterized mining of uranium ore in these densely populated areas.

The binational Soviet–German company Wismut, founded in 1954, continued uranium mining, with the German Democratic Republic sharing equity capital. Intense exploration efforts increased Wismut's reserves as new deposits were discovered. Working conditions were gradually improved, and environmental protection legislation introduced during the 1960s enhanced awareness of radiation protection requirements.

Technology developments had an increasingly positive influence on production processes, reducing the workforce to a permanent staff of approximately 45,000 in later years. Market economy conditions after German reunification put a sudden end to uranium mining on December 31, 1990. Soviet Union personnel left the mines and mills, and Wismut and its environmental legacy became the sole possession of the Federal Republic of Germany.

Following the restructuring of Wismut, the company was legally changed at the end of 1991 to a company of German corporate law under the provisions of the Wismut Act. The corporate purpose of Wismut GmBH shifted from uranium production to decommissioning of the former mining holdings and remediation of the land that had been adversely affected by decades of unrestrained mining and milling of uranium ores. This remediation project will cost 6.6 billon euros, to be provided by federal funding, and it will take 15 years to complete the large-scale environmental restoration requirements (Table VI).

Exposure levels were measured at all the Wismut sites and vicinity properties. A total of 11,885 ha, including 8223 ha of vicinity properties associated with the nearby communities, has been investigated. Characterization data show that 85% of the radioactive dose rate representing all the Wismut GmBH sites is less than 200 nanoseiverts per hour.

TABLE VI

Summary of Wismut Remedial Operation Units at Beginning of Remedial Action

Site	Subsites	Unit area (ha)	Waste piles (ha)	Tailings ponds (ha)
Aue	Aue, Pohla	569.4	342.3	10.4
Koigsteinn	Konigstein, Dresden-Gittersee	144.8	40.0	4.6
Ronneburg	Ronneburg	1670.7	604.4	9.0
Seelingstadt	Seelingstadt, Crossen	1314.8	533.1	76.7
Total		3699.7	1519.8	730.7

7. REMEDIATION IN THE UNITED STATES

The demise of the United States uranium industry began quietly in 1958, when the U.S. Atomic Energy Commission withdrew its offer to purchase uranium from ore reserves developed thereafter. This action led either to the shutdown of mills after expiration of contracts or to continued mill production through so-called stretch-out contracts that were extended through 1970. Stretch-out contracts reduced government purchases and served to ease the uranium ore mining and milling industry through the transition period when nuclear power growth had not progressed sufficiently to create a significant commercial demand. United States production totaled approximately 17,000 tonnes of uranium oxide in 1980, but less than 1000 tonnes of uranium was mined and milled in 2002 (Table V).

When the industry realized that no more nuclear power plants were being constructed and that demand for uranium was greatly reduced, mining and milling of uranium ore again drastically declined. By the end of 1984, only eight conventional mills were still operating. Many of the unconventional uranium recovery plants were also inactive. Today, only a few mines in the United States are being worked, and these are mostly unconventional operations that employ *in situ* leach methods. Canada and Australia continue to produce more than half of the world's uranium (Table V).

The United States was the first country to implement a program to assess the risks of uranium mill tailings and begin cleanup of the adverse effects to the environment caused by past uranium ore milling practices. In the United States, the hazards posed by mill tailings were not completely recognized in the early years of production by the uranium industry. The Atomic Energy Act of 1954 instituted licensing of mill operations, but the tailings remained free of controls. Although numerous studies had assessed the hazards of uranium mill tailings and several federal agencies and states had acknowledged a need for controls, a comprehensive program to address the problem was not started until the late 1970s.

In 1974, the subcommittee on raw materials of the Joint Committee on Atomic Energy conducted a hearing to discuss two congressional bills. These bills proposed that the U.S. Atomic Energy Commission (later designated the Energy Research and Development Administration and now called the U.S. Department of Energy) and the state of Utah jointly assess and act to limit public exposure to radiation from a uranium mill tailings site located in South Salt Lake City, UT.

The U.S. Environmental Protection Agency endorsed the objectives of the bill but, with the U.S. Atomic Energy Commission, recommended instead that the two agencies, in cooperation with the affected states, assemble comprehensive studies of all inactive uranium mill tailings sites. The studies would be divided into two phases. Phase I studies would establish the condition of the sites, ownership, surrounding areas, and the need, if any, for more detailed studies. Phase II studies would, as needed, evaluate the hazards and analyze disposal alternatives and their costs. The U.S. Congress accepted this proposal. Phase I studies began in 1974, followed by phase II studies in 1975. Both studies were completed by 1978.

On the basis of these studies, the Congress enacted the Uranium Mill Tailings Radiation Control Act of 1978 (Public Law 95-604, 42 United States Code 7901). Congress found the following:

> *Uranium mill tailings located at active and inactive mill operations may pose a potential and significant radiation health hazard to the public.*
>
> *Every reasonable effort should be made to provide for the stabilization, disposal, and control in a safe and environmentally sound manner of such tailings in order to prevent or minimize radon diffusion into the environment and to prevent or minimize other environmental hazards.*

The act established a 7-year completion deadline for the project and outlined the funding formula for the cleanup. Participating states were responsible for 10% of the cost of remedial action, and the federal government would pay the remaining 90%. For those sites on Native American lands, the federal government was responsible for 100% of the cost. The Department of Energy would manage cleanup of the sites and the contaminated groundwater under the Uranium Mill Tailings Remedial Action Project. The Uranium Mill Tailings Radiation Control Act originally specified 24 former uranium ore processing sites for cleanup, but one state (North Dakota) withdrew 2 sites. The act requires the Department of Energy to keep community leaders informed of plans and activities involved in the remedial actions.

Remedial actions at the sites designated in the act began in the early 1980s (Figs. 5 and 6). By 1998, 22 disposal cells had been constructed for permanent entombment of the wastes. Ten of the disposal cells were constructed on former uranium processing sites, and 12 disposal cells were sited at locations that were more advantageous. Nearly all these former uranium ore processing sites are located in the arid west. Two commonalities associated with the arid west are low annual precipitation and vast open areas with few inhabitants. This scenario contrasts with that of the German Wismut program because the mining and processing sites are subjected to high annual volumes of precipitation and few uninhabited areas are available within the country. Therefore, relocation of tailings and other contaminated material has limited potential.

Most older uranium ore processing sites have a component of relic-contaminated groundwater related to chemicals used in the recovery processes. The contaminated groundwater is generally limited to shallow unconfined aquifers. Contaminants of concern are identified by potential risk based on toxicities and pathways to receptors. Ammonia, arsenic, cadmium, gross alpha, molybdenum, nitrate, radium, selenium, sulfate, and uranium are the most common groundwater contaminants associated with older uranium processing sites. Of these, nitrate, sulfate, and uranium are the most mobile and tend to move with the average velocity of groundwater. At many of the former processing sites, the groundwater contaminant of most concern is not a radionuclide but a stable inorganic, such as nitrate or sulfate.

Contaminated groundwater is a concern at most sites, especially those sites in arid regions where groundwater is a precious and valuable resource. At some sites, such as the Tuba City, Arizona, site located on the Navajo Indian Reservation, the contaminated groundwater occurs in a sole-source aquifer (the Navajo aquifer). This aquifer provides drinking water and irrigation water for northeastern Arizona and is noted as a high-quality water resource. A pump-and-treat groundwater remedial action was required at the Tuba City site to reduce the contaminant concentrations to acceptable levels. Active engineered treatment of the contaminants in the groundwater is expected to take at least 20 years employing extraction wells and an ion exchange system, coupled with a distillation unit and reinjection into the subsurface of the treated groundwater.

Contaminated groundwater sites near rivers are good candidates for natural flushing when modeling with computer software predicts that the contaminants will decrease to acceptable levels through natural attenuation processes and dilution within 100 years. Institutional controls and verification monitoring will be required at these sites. Institutional controls are "checks and balances" that effectively protect public health and the environment by reducing exposure to or reducing health risks by preventing inappropriate intrusion into contaminated groundwater or by restricting access to or use of contaminated groundwater for unacceptable purposes (e.g., domestic household use). One form of an institution control is a deed restriction on the property.

The global experience of using active engineered methods and technologies to reduce the contaminant levels to premilling water quality demonstrates that it is extremely difficult, if not impossible, to achieve complete restoration to pristine conditions. This fact is one more reason why today the emphasis is placed on prevention rather than intervention in protecting the environment.

8. OTHER REMEDIATION PROGRAMS

Wismut has become a global leader in uranium mill tailings cleanup, along with the United States, Canada, and other countries (Fig. 7). In recent years, Germany and the United States have emphasized integrating technical and nontechnical factors into remediation decisions. One example of integration is tailings cover designs. Environmental remediation factors for cover design extend beyond geotechnical and erosion criteria and include considerations such as esthetics. Will the cover material blend into the

FIGURE 7 The worked-out open pit at the Ronneburg Wismut uranium mine at Thηrgen, Germany, was backfilled with waste rock from mining operations.

FIGURE 8 Former waste rock piles near Schlema, Germany, generated from processing of uranium ore were recontoured and covered with uncontaminated soil.

surrounding environment? Will the cover be attractive to the public and nearby residents?

One of the Wismut remediation projects in Schlema, Saxony, has been advertised as "toxic town to health spa." Schelma is a small town southwest of Chemnitz in Saxony, a region in eastern Germany that has a southerly border with the Czech Republic. In the 1920s, individuals afflicted with rheumatism used a radioactive spring near the town. After World War II, the Soviet Union began mining uranium ore, and the town and former spa were sacrificed as a mining production zone. The mines were closed in 1990, and more than 45,000 jobs were lost.

The Wismut remediation program for Schelma considered a number of options: seal off the town and surrounding contaminated areas, continue operating the mine in a noncompetitive market, or convert the town into a world-class health spa featuring the radioactive springs. In 1992, Wismut began to decommission the former mine workings and actively rehabilitate the land (Fig. 8). The Schelma radon-containing springs and spa gardens are an example of integrating the technical requirements with land use decisions and considering esthetically pleasing factors. This approach to environmental restoration is becoming the norm today rather than the exception.

In Canada, uranium mine and mill tailings constitute the largest inventory by volume of radioactive waste. Uranium has been mined since the early 1930s in Canada, and approximately 225 million tonnes of tailings has accumulated in Ontario province, Saskatchewan province, and the Northwest Territories. This volume of tailings constitutes a small fraction of all nonuranium mine and mill tailings in Canada. Uranium ore is still actively mined in Canada, but the volume of tailings is expected to increase only marginally in the future because the current higher grade of uranium ore will generate lower volumes of mine and mill tailings.

The uranium mine and mill tailings in Canada are currently managed by a few large mining companies, and the tailings are held in containment areas close to the mine sites. Because of their relatively large volumes, the tailings are generally disposed of where they are deposited during operations, typically in tailings ponds or in mined-out pits. The final decommissioning of these tailings and the associated costs are the responsibility of the uranium mining companies and will be regulated in accordance with Canadian Atomic Energy Control Board regulations.

9. PROTECTING THE ENVIRONMENT FOR THE LONG TERM

In the United States, tailings must have a disposal cover designed to control radiological hazards for a minimum of 200 years and for 1000 years to the greatest extent reasonably achievable. Disposal covers must also limit radon (radon-222) releases to 20 $pCi/m^2/s$ averaged over the disposal area. Radon-release limitation requirements apply to any portion of the tailings disposal site unless radium concentrations do not exceed 5 pCi/g in the first 15 cm below the surface and 15 pCi/g in layers more than 15 cm below the surface.

No law exists in Germany specific to the management of the uranium-mining legacy. The German

government favors the Canadian approach of site-specific decisions. The Wismut program rehabilitates the uranium tailings, heap piles, mines, and other contaminated media based on site-specific risk-based analyses that demonstrate protection of human health and the environment.

10. COMPARISON OF DECOMMISSIONING AND CLEANUP COSTS

Wismut and other remediation programs investigated remedial action costs associated with the cumulative uranium production of 14 major uranium-producing countries through 1992 (Table VII). Cumulative production resulted in approximately 1.14 million tonnes of uranium or nearly 3 billion pounds of uranium oxide (U_3O_8), corresponding to approximately 63% of the cumulative world production of uranium. This production is accompanied by approximately 1681 million tonnes of processing residues, of which 780 million tonnes is related to processing plants that produced or still produce uranium as a by-product. The accumulated and estimated costs for the decommissioning and rehabilitation of the uranium-producing facilities in this study total approximately $3.7 billion (all costs are based on 1993 U.S. dollars). The resulting specific rehabilitation costs are $1.25 per pound of U_3O_8 and $2.20 per tonne of tailings. Omitting plants that produce or produced uranium as a by-product of gold and copper production, the specific cost per tonne of milling doubles to approximately $4.00.

These values, however, are only indicative because the specific costs for different projects and countries vary widely, ranging from a minimum of $0.12 per pound of U_3O_8 (Canada) and $0.12 per tonne of tailings (South Africa) to a maximum of approximately $40.00 per pound of U_3O_8 (Sweden) and $68.00 per tonne of tailings (Uranium Mill Tailings

TABLE VII

Decommissioning and Cleanup Costs of Uranium-Producing Projects

Country	Production (tonnes of U, including 1992)	Tailings (million tonnes)	Total cost (million U.S. $, 1993)	Specific cost	
				U.S. $ per tonne of tailings	U.S. $ per pound of U_3O_8

USA (total)	310,000	222.9	2428.96	10.90	3.01
Uranium Mill Trailings Radiation Control Act (UMTRCA) Title I sites (federal government)	56,000	31.3	2140.00	68.37	14.70
UMTRCA Title II sites (private industry)	254,000	191.6	288.96	1.51	0.44

Radiation Control Act Title I Program in the United States). This large range substantiates that remediation costs depend on numerous factors, such as upfront environmental studies, types of contaminants, concentration levels of contaminants, on-site or relocation disposal options, and required level of protection.

11. MANAGING THE LONG-TERM RISK

Consequences of uranium mining and milling will remain for a long time. The half-lives of uranium, radium, and thorium are long lived. Disposal considerations cover millenniums, but managing uncertainty for millenniums becomes impossible to understand with precision and accuracy. Are today's best management practices adequate environmental protection for more than 1000 years or are some countries going overboard with conservatism? This question will take time to answer. Over time, verifying the performance of disposal cells, checking cultural and economic paradigms shifts, adjusting to climate change, and understanding how technologies will change the paradigm of future generations are factors that will form the scorecard on judging our decisions for addressing the uranium mining and milling environmental legacy during the 1980s, 1990s, and early 21st century.

The IAEA, with more than 130 member states, is an independent, intergovernmental science and technology-based organization in the United Nations family that serves as the global focal point for nuclear cooperation. One of the missions of the organization is to develop nuclear waste management standards and, based on those standards, promote the achievement and maintenance of high levels of safety in applications of nuclear energy as well as the protection of human health and the environment against ionizing radiation.

Within the IAEA, the Waste Technology Section is responsible for fostering technology transfer, promoting information exchange and cooperative research, and increasing the number of member states to manage radioactive wastes from both the nuclear fuel cycle and nuclear applications. The agency routinely meets with member states for discussions concerning radioactive waste issues while emphasizing that radioactive waste is an unavoidable remnant from the use of radioactive materials and nuclear technology. IAEA representatives review practices involving industrial activities with naturally occurring radioactive material, such as the mining and milling of naturally radioactive ores.

The IAEA stresses that all radiation sources, including radioactive waste, are potentially hazardous to health and, therefore, must be managed to protect human health and the environment. The organization approaches the problem by acknowledging that a relatively small fraction of radioactive waste is routinely released into the environment in the form of discharges that need to be properly controlled. Some amounts may remain in the environment as radioactive residues, particularly after the termination of past operations and the decommissioning of installations, and may require restoration of the affected environments. The bulk of radioactive waste must be disposed of in repositories isolated from human and animal intrusions.

Technical meetings sponsored by the IAEA in Vienna, Austria, and in countries with significant uranium ore mining and milling operations share member states' experiences, lessons learned, and technical information. Today's challenges are final disposition of uranium wastes, risk reduction, long-term performance of disposal facilities, cost efficiencies, and archiving of records. The lessons learned and the experiences gained during the past 25 years of studying the effects of uranium mining and milling operations and conducting remedial actions to remedy those effects can help prevent negative impacts in the future.

1. Uranium Mining, Milling, and Processing
2. Uranium Refining and Conversion
3. Uranium Enrichment

Glossary

enrichment The physical process of increasing the proportion of U-235 to U-238.
isotope An atomic form of an element having a particular number of neutrons. Different isotopes of an element have the same number of protons but different numbers of neutrons and hence different atomic mass (e.g., U-235, U-238).
mill Treatment plant producing concentrate from ore.
ore Rock containing economic concentrations of minerals.
radon An inert but radioactive gas which is a decay product of radium.
stope Cavity formed underground by drilling, blasting, and removing ore.
tailings Crushed and ground rock from which economic minerals have been recovered. Uranium tailings are radioactive due to decay products that remain.

There are many uranium mines operating around the world, in some 20 countries, though almost three-quarters of world production comes from just 10 mines. Most of the uranium ore deposits at present supporting these mines have average grades in excess of 0.10% of uranium. In the first phase of uranium mining to the 1960s, this would have been seen as a respectable grade, but today some Canadian mines have huge amounts of ore up to 20% U average grade. Some uranium is also recovered as a by-product with copper, as at Olympic Dam in Australia, or as by-product from the treatment of other ores, such as the gold-bearing ores of South Africa. In these cases, the concentration of uranium may be as low as a tenth of those in orebodies mined primarily for their uranium content. Olympic Dam quotes ore reserves down to 0.045% U.

1. URANIUM MINING, MILLING, AND PROCESSING

1.1 Overview

Generally speaking, uranium mining is no different to other kinds of mining unless the ore is of a very high grade. Where orebodies lie close to the surface, they are usually accessed by open cut mining, involving a large pit and the removal of much overburden as well as a lot of waste rock. Where orebodies are deeper, underground mining is employed, involving construction of access tunnels and shafts but with less waste rock removed and less environmental impact. In either case, the grade is usually controlled by measuring radioactivity as a surrogate for uranium concentration. (The radiometric device detects associated radioactive minerals, which are decay products of the uranium rather than the uranium itself.)

At Ranger in north Australia, Rossing in Namibia, and most of Canada's Northern Saskatchewan mines through to McClean Lake, the orebodies have been accessed by open cut mining. Other mines such as Olympic Dam in Australia, McArthur River, Rabbit Lake and Cigar Lake in Northern Saskatchewan, and Akouta in Niger are underground, up to 600 m deep. At McClean Lake, mining will be completed underground. Table I lists the largest-producing uranium mines in the West.

AngloGold	South Africa	Anglo American	By-product/underground	840	2.9
Top 10 total				25,942	72.5

Some orebodies lie in groundwater in porous material and may be accessed simply by oxygenating that groundwater and pumping it out—this is *in situ* leach (ISL) mining. ISL mining means that removal of the uranium minerals is accomplished without any major ground disturbance. Weakly acidified or alkaline groundwater with a lot of oxygen injected into it is circulated through an enclosed underground aquifer, which holds the uranium ore in loose sands. The leaching solution with dissolved uranium is then pumped to the surface treatment plant.

Over half of the world's uranium now comes from underground mines, about 30% from open cut mines and 16% from ISL. Conventional mines have a mill where the ore is crushed, ground, and then leached with sulfuric acid to dissolve the uranium oxides. Most of the ore, however, remains undissolved in the leaching process, and these solids or tailings are then separated from the uranium-rich solution, usually by allowing them to settle out. At the mill of a conventional mine, or the treatment plant of an ISL operation, the uranium is then separated by ion exchange before being dried and packed.

1.2 Hard Rock Mining

With open cut mining, the overburden needs to be removed to expose the orebody, the part of the rock that contains economic concentrations of the minerals being sought. This, and subsequent mining, is undertaken by drilling and blasting, followed by removal of the broken rock. At open cut uranium mines, the drill cuttings from mine development may be tested radiometrically so that ore and waste (below ore-grade material) are blasted separately. In addition, loads of mined material are often scanned radiometrically to ascertain average ore grade, and trucks are then directed to stockpiles, primary crusher, or waste dump accordingly.

At Canada's McClean Lake mine, waste is material with less than 0.025% U or less than 0.085% U if it has high acid-generating potential and requires special disposal. Anything over 0.085% U is unequivocally ore, but is stockpiled according to grade so that mill feed may be varied according to market conditions.

With underground mining, the objective is to move as little waste rock as possible in sinking shafts or declines and digging tunnels (drives and adits) accessing the orebody as fully as possible. Mining the actual orebody is then generally more selective. Various mining techniques are employed, but open stoping is common. This involves carefully drilling and then blasting a large mass of rock so that the broken material can be removed. When the void is empty, it is usually filled from above with waste rock and coarse tailings material, with some cement and flyash binder, to maintain structural support and enable extraction of adjacent ore.

At Olympic Dam, mining is by longhole open stoping, back-filled after ore extraction. This means that a block of ore is drilled from below and above, then blasted so that up to 80,000 tonnes is broken at once. Each stope will yield up to 500,000 tonnes. Ore is extracted from drawpoints at the bottom of the stope and taken to the underground primary crusher. Crushed ore is hoisted to the surface in skips.

At McArthur River in Canada, the orebody is so high-grade (up to 20% U) that remote methods need to be employed for mining it because the minerals

associated with the uranium are also so concentrated that they emit high levels of gamma radiation. It is also about 600 m deep and in wet, porous rock, so control of water under high pressure is another problem. Manned operations are confined to the barren rock surrounding the orebody, and water is controlled by freezing all around the orebody with some grouting. The orebody is than accessed remotely by raise boring, using a 3-m diameter reaming head. Remotely operated front-end loaders remove the ore cuttings that fall from this. Each load is radiometrically scanned, and waste rock or low-grade mineralized material is hoisted to the surface for disposal. While this whole exercise is high cost per tonne of ore removed, the ore is of such a grade that relatively little is involved, about 120 tonnes per day.

The low volume also means that the ore cuttings are fed straight to an underground grinding circuit, and the ground slurry is then pumped to the surface. It is then loaded into special transportation tanks and road-hauled 80 km to the mill for further treatment. Meanwhile, the void from the raise boring is filled with concrete to provide ground support for subsequent raise boring operations.

At the Cigar Lake underground mine in Canada, poor ground conditions mean that water jet boring will be employed instead of raise boring, with ground freezing. Below ore-grade material with significant mineralization from open cut mines has in the past been heaped up on an impervious pad and leached with sulfuric acid. This heap leaching produces pregnant liquor, which is fed to the mill for uranium extraction. However, the process can give rise to significant problems of rehabilitation, so it is apparently no longer used. At Australia's Nabarlek mine in the 1980s, about 50% of the uranium recovery was achieved from 150,000 tonnes of heap leach material.

1.3 *In Situ* Leach (ISL) Mining

In situ leaching (ISL), also known as solution mining, involves leaving the ore where it is in the ground and using liquids that are pumped through it to recover the minerals out of the ore by leaching. Consequently there is little surface disturbance and no tailings or waste rock generated. However, the orebody needs to be permeable to the liquids used and located so that they do not contaminate groundwater away from the orebody.

Some ISL mining in the past, notably in the eastern bloc, has occurred in broken rock with insecure containment of fluids, and this has resulted in considerable pollution. ISL mining was first tried on an experimental basis in Wyoming during the early 1960s. The first commercial mine began operating in 1974. About a dozen projects are licensed to operate in the United States (in Wyoming, Nebraska, and Texas), and most of the operating mines were less than 10 years old in the early 21st century. Most are small, but they supply some 85% of the U.S. uranium production. About 16% of world uranium production is by ISL (including all Kazakhstan and Uzbekistan output).

ISL can also be applied to other minerals such as copper and gold. Uranium deposits suitable for ISL occur in permeable sand or sandstones, confined above and below by impermeable strata and below the water table. They may either be flat, or roll front—in cross section, C-shaped deposits within a permeable sedimentary layer. Such deposits were formed by the lateral movement of groundwater bearing oxidized uranium minerals through the aquifer, with precipitation of the minerals occurring when the oxygen content decreased, along extensive oxidation-reduction interfaces. The uranium minerals are usually uraninite (oxide) or coffinite (silicate) coatings on individual sand grains. The ISL process essentially reverses this ore genesis in a much shorter time frame. There are two operating regimes for ISL, determined by the geology and groundwater. If there is significant calcium in the orebody (as limestone or gypsum), alkaline (carbonate) leaching must be used. Otherwise, acid (sulfate) leaching is generally better.

Techniques for ISL have evolved to the point where it is a controllable, safe, and environmentally benign method of mining, which can operate under strict environmental controls and which often has cost advantages. The mine consists of well fields, which are progressively established over the orebody as uranium is depleted from sections of the orebody after leaching. Well-field design is on a grid with alternating extraction and injection wells, each of identical design and typical of normal water bores. The spacing between injection wells is about 30 m with each pattern of four having a central extraction well with a submersible electric pump. A series of monitor wells are situated around each mineralized zone to detect any movement of mining fluids outside the mining area. The wells are cased to ensure that liquors only flow to and from the ore zone and do not affect any overlying aquifers. They are pressure-tested before use.

The submersible pumps initially extract native groundwater from the host aquifer prior to the addition of uranium complexing reagents (acid or alkaline) and an oxidant (hydrogen peroxide or

oxygen) before injection into the well field. The leach liquors pass through the ore to oxidize and dissolve the uranium minerals *in situ*.

While uranium production in Australia uses acid leaching of the crushed ore, ISL elsewhere normally uses alkaline leaching agents such as a combination of sodium bicarbonate and carbon dioxide. At Beverley and Honeymoon in South Australia the process is acid leaching, with weak sulfuric acid plus oxygen. The leach solution is at a pH of 2.0 to 3.0, about the same as vinegar.

The pregnant solution from the production wells is pumped to the treatment plant where the uranium is recovered (see Section 1.4). Before the process solution depleted of uranium (i.e., barren liquor) is reinjected, it is oxygenated and if necessary re-charged with sulfuric acid, or with sodium bicarbonate or carbon dioxide, to maintain its pH.

Most of the solution is returned to the injection wells, but a very small flow (about 0.5%) is bled off to maintain a pressure gradient in the well field and this, with some solutions from surface processing, is treated as waste. It contains various dissolved minerals such as radium, arsenic, and iron from the orebody and is reinjected into approved disposal wells in a depleted portion of the orebody. This bleed of process solution ensures that there is a steady flow into the well field from the surrounding aquifer and serves to restrict the flow of mining solutions away from the mining area.

In the United States, the production life of an individual ISL well pattern is usually less than 3 years, typically 6 to 10 months. Most of the uranium is recovered during the first 6 months of the operation of those wells. The most successful operations have achieved a total overall recovery of about 80% of the uranium from the ore. Over time, production flows decrease as clay and silt become trapped in the permeable sediments. These can be dislodged to some extent by using higher pressure injection or by reversing the flow between injection and production wells. At established operations in the United States, after ISL mining is completed, the quality of the remaining groundwater must be restored to a baseline standard determined before the start of the operation so that any prior uses may be resumed.

In contrast to the main U.S. operations, the water quality at the Australian sites is very low to start with, and it is quite unusable. At Beverley the groundwater in the orebody is fairly saline and orders of magnitude too high in radionuclides for any permitted use. At Honeymoon, the water is even more saline and high in sulfates and radium. When oxygen input and leaching are discontinued, the water quality soon reverts to its original condition. With ISL, no tailings are involved and very little waste is generated. ISL thus has clear environmental advantages in the places it can be applied.

1.4 Milling and Extraction Process

Milling refers to the extraction of uranium product from the mined ore. The following is a simplified account. At conventional hard rock mines, the ore must first be crushed. At Olympic Dam and some other underground mines, the first stage is done underground. Primary crushing breaks up the largest pieces followed by secondary crushing to reduce the material to small pieces of about 20 mm and less. At some mines, after primary crushing the broken ore is fed through a radiometric ore sorter so that individual pieces of low-grade material are rejected. The broken ore is then ground in water to produce a slurry of fine ore particles suspended in the water. At McArthur River, the grinding is done underground. Because that is such a high-grade ore, it has to be diluted down to 4% U_3O_8 at the mill before being treated in order to limit radiation doses to staff at the mill.

The U_3O_8 slurry, effectively a mixture of UO_3 and UO_2, is leached with sulfuric acid to dissolve the uranium oxides, this being the same process as in acid ISL:

$$UO_3 + 2\,H^+ ==> UO_2^{++} + H_2O$$
$$UO_2^{++} + 3\,SO_4^{--} ==> UO_2(SO_4)_3^{4-}.$$

With an oxidant such as hydrogen peroxide or ferric iron present, the UO_2 is oxidized to $UO_2^{+\,+}$.

With some ores, and notably with ISL in the United States, carbonate leaching is used to form a soluble uranyl tricarbonate ion: $UO_2(CO_3)_3^{4-}$. This can then be precipitated with an alkali (e.g., as sodium or magnesium diuranate). Alkaline leaching or treatment of ores is not undertaken in Australia or Canada.

The liquid containing the uranium is filtered and the uranium then separated by an ion exchange process. Two methods are used for concentration and purification of uranium: solid ion exchange (IX) with resin and liquid ion exchange, better known as solvent extraction (SX). Early operations in Australia used ammonium type resins in polystyrene beads for ion exchange, but solvent extraction with amines in kerosene is now predominant.

With pregnant solution from the ISL production wells, the choice is largely determined by the salinity of the groundwater. SX is better with high salinity, as at Honeymoon (17,000 to 20,000 ppm dissolved solids), while IX is most effective below 3000 ppm chloride, as presently at Beverley. With alkaline leaching, IX is effective to about 3000 ppm dissolved solids, but there are no commercially available resins that work at high chloride levels.

In solvent extraction, tertiary amines ("R" is an alkyl [hydrocarbon] grouping, with single covalent bond) are used in a kerosene diluent, and the phases move countercurrently:

$$2R_3N + H_2SO_4 =====> (R_3NH)_2SO_4$$
$$2(R_3NH)_2SO_4 + UO_2(SO_4)_3^{4-} =====> (R_3NH)_4UO_2(SO_4)_3 + 2SO_4^{2-}.$$

In the mill at Olympic Dam (which is primarily a copper mine; uranium is the major by-product), the ore is ground and treated in a copper sulphide flotation plant. About 80% of the uranium minerals remain in the tailings from the flotation cells, from which they are recovered by acid leaching. The copper concentrate is also processed through an acid leach to recover the other 20% of the uranium. The pregnant liquor is then separated from the barren tailings, and in the solvent extraction plant the uranium is removed using kerosene with an amine. The loaded solvents may then be treated to remove impurities. First, cations are removed at pH 1.5 using sulfuric acid, then anions are dealt with using injected gaseous ammonia.

The solvents are then stripped in a countercurrent process using ammonium sulfate solution:

$$(R_3NH)_4UO_2(SO_4)_3 + 2(NH_4)_2SO_4 ====> 4R_3N + (NH_4)_4UO_2(SO_4)_3 + 2H_2SO_4.$$

Yellow ammonium diuranate is then precipitated from the loaded strip solution by adding gaseous ammonia to raise the pH and neutralize the solution (though in earlier operations caustic soda and magnesia were used).

$$2NH_3 + 2UO_2(SO_4)_3^{4-} ===> (NH_4)_2U_2O_7 + 4SO_4^{2-}.$$

The diuranate is then dewatered in a thickener and then by filter or centrifuge before being roasted in a furnace to produce a uranium oxide concentrate, about 99% U_3O_8, which is the form in which uranium is marketed and exported. This is sometimes known as yellowcake, though it is khaki.

With IX, such as at Beverley, uranium is stripped from the ion exchange resin and precipitated chemically, usually with hydrogen peroxide. The uranium slurry is dewatered and dried to give hydrated uranium peroxide ($UO_4.2H_2O$) product. Either product is then packed into 200-liter steel drums, which are sealed for shipment. The U_3O_8 is only mildly radioactive and requires no special packaging on that account.

1.5 Wastes from Mining and Milling

In most respects, conventional mining of uranium is the same as mining any other metalliferous ore, and well-established environmental constraints apply to avoid any offsite pollution. From open cut mining, there are substantial volumes of barren rock and overburden waste. These are placed near the pit and either used in rehabilitation or shaped and revegetated where they are. At Ranger mine, the development of the first orebody involved a waste to ore ratio of 2.2:1. However, uranium minerals are always associated with more radioactive elements such as radium and radon in the ore. Therefore, although uranium itself is not very radioactive, the ore that is mined, especially if it is high-grade, is handled with some care for occupational health and safety reasons.

Mining methods, tailings and run-off management, and land rehabilitation are subject to government regulation and inspection. Mining operations are undertaken under relevant national health and radiation protection codes of practice. These set strict health standards for exposure to gamma radiation and radon gas. Standards apply to both workers and members of the public.

1.5.1 Tailings and Radon

Solid waste products from the milling operation are tailings. They constitute most of the original ore and they contain most of the radioactivity in it. In particular, they contain all the radium present in the original ore. At an underground mine, they may be first cycloned to separate the coarse fraction, which is used for underground fill. The balance is pumped as a slurry to a tailings dam, which may be a worked-out pit as at Ranger and McClean Lake.

When radium undergoes natural radioactive decay, one of the products is radon gas. Because radon and its decay products (daughters) are radioactive and because the tailings are now on the surface, measures are taken to minimize the emission of radon gas. During the operational life of a mine,

the material in the tailings dam is usually covered by water to reduce surface radioactivity and radon emission (though with lower-grade ores neither pose a hazard at these levels).

On completion of the mining operation, it is normal for the tailings dam to be covered with some 2 m of clay and topsoil to reduce radiation levels to near those normally experienced in the region of the orebody, and for a vegetation cover to be established. At Ranger and Jabiluka in North Australia, tailings will be returned underground, as was done at the now-rehabilitated Nabarlek mine. In Canada, ore treatment is often remote from the mine that the new ore comes from, and tailings are emplaced in mined out pits wherever possible and engineered dams otherwise.

The radon gas emanates from the rock and tailings as the radium or thorium decays. It then decays itself to (solid) radon daughters, which are significantly alpha radioactive. About 95% of the radioactivity in the ore is from the U-238 decay series, totaling about 450 kBq/kg in ore with 0.3% U_30_8 (e.g., from Ranger). The U-238 series has 14 radioactive isotopes in secular equilibrium, thus each represents about 32 kBq/kg (irrespective of the mass proportion). When the ore is processed, the U-238 and the very much smaller masses of U-234 and U-235 are removed. The balance becomes tailings and at this point has about 85% of its original intrinsic radioactivity. However, with the removal of most U-238, the following two short-lived decay products (Th-234 and Pa-234) soon disappear, leaving the tailings with a little over 70% of the radioactivity of the original ore after several months. The controlling long lived isotope then becomes Th-230, which decays with a half life of 77,000 years to radium-226 followed by radon-222. Radon occurs in most rocks, and traces of it are in the air we all breathe. However, at high concentrations it is a health hazard.

1.5.2 Water

Run-off from the mine stockpiles and waste liquors from the milling operation are collected in secure retention ponds for isolation and recovery of any heavy metals or other contaminants. The liquid portion is disposed of either by natural evaporation or recirculation to the milling operation. Most Australian mines adopt a zero-discharge policy for any pollutants.

Process water discharged from the mill contains traces of radium and some other metals that would be undesirable in biological systems downstream. This water is evaporated and the contained metals are retained in secure storage. During the operational phase, such water may be used to cover the tailings while they are accumulating.

With *in situ* leach (ISL) operations, the orebody stays in the ground and uranium is recovered by circulating oxygenated and acidified groundwater through it, using injection and recovery wells. The saline quality of this groundwater in Australian ISL mines makes it far from potable in the first place, and after the uranium is recovered, oxygen input and circulation are discontinued, leaving the groundwater much as it was. The main environmental consideration with ISL is avoiding pollution of any groundwater away from the orebody and leaving the immediate groundwater no less useful than it was initially.

1.5.3 Rehabilitation

At the conclusion of mining, tailings are covered permanently with enough clay and soil to reduce both gamma radiation levels and radon emanation rates to levels near those naturally occurring in the region, and enough rock to resist erosion. A vegetation cover is then established.

Mary Kathleen in Queensland was the site of Australia's first major rehabilitation project of a uranium mine. It involved the plant site, a 28-hectare tailings dam, and a 60-ha evaporation pond area. All this has now returned to being a cattle station, with unrestricted access. The rehabilitation project was completed at the end of 1985 at a cost of some $19 million and won an award for engineering excellence.

The Nabarlek uranium mine in the Northern Territory, c 270 km east of Darwin, was the first of the new generation of uranium mines to commence operations and the first to be rehabilitated. Environmental protection was stressed at Nabarlek since before mining commenced, and everything proceeded with eventual rehabilitation very much in mind. During the life of the mine, the company worked together with government agencies, the Northern Land Council (NLC), and Aboriginal landowners to ensure a high standard of environmental management, culminating in its decommissioning and successful rehabilitation.

Apart from groundwater considerations, rehabilitation of ISL mines is straightforward, making this a technique with remarkably low environmental impact. Upon decommissioning, wells are sealed or capped, process facilities removed, any evaporation pond revegetated, and the land can readily be returned to its previous uses. Experience at many mine sites is networked throughout the industry and available to present and future operators.

1.6 Health of Workers

In Australia, all uranium mining and milling operations are undertaken under the *Code of Practice on Radiation Protection in the Mining and Milling of Radioactive Ores*. This was drawn up by the Commonwealth in line with recommendations of the International Commission on Radiological Protection (ICRP), but it is administered by state health and mines departments. This Health Code, which was updated in 1995 and again in 2002–2003 (as part of a combined Health-Waste Code), sets strict health standards for radiation and radon gas exposure for both workers and members of the public.

In Canada, the Canadian Nuclear Safety Commission is responsible for regulating uranium mining as well as other aspects of the nuclear fuel cycle. In Saskatchewan, provincial regulations also apply concurrently and set strict health standards for both miners and local people. Similar standards are set in other countries.

While uranium itself is only slightly radioactive, radon, a radioactive inert gas, is released to the atmosphere in very small quantities when the ore is mined and crushed. Radon is one of the decay products of uranium and radium, and occurs naturally in most rocks—minute traces of it are present in the air which we all breathe.

Australian uranium mines have mostly been open cut and therefore naturally well ventilated. The Olympic Dam and Canadian underground mines are ventilated with powerful fans. Radon levels are kept at a low and certainly safe level in uranium mines. (Radon in non-uranium mines also may need control by ventilation.)

Gamma radiation may also be a hazard to those working close to high-grade ores. It comes principally from radium in the ore, so exposure to this is regulated as required. In particular, dust is suppressed, since this represents the main potential exposure to alpha radiation as well as a gamma radiation hazard.

At the concentrations associated with uranium (and some mineral sands) mining, radon is a potential health hazard, as is dust. Precautions taken during the mining and milling of uranium ores to protect the health of the workers include the following:

- Good forced ventilation systems in underground mines to ensure that exposure to radon gas and its radioactive daughter products is as low as possible and does not exceed established safety levels
- Efficient dust control, because the dust may contain radioactive constituents and emit radon gas
- Limiting the radiation exposure of workers in mine, mill, and tailings areas so that it is as low as possible and in any event does not exceed the allowable dose limits set by the authorities; in Canada this means that mining in very high-grade ore is undertaken solely by remote control techniques and by fully containing the high-grade ore where practicable
- The use of radiation detection equipment in all mines and plants
- Imposition of strict personal hygiene standards for workers handling uranium oxide concentrate

At any mine, designated employees (those likely to be exposed to radiation or radioactive materials) are monitored for alpha radiation contamination and personal dosimeters are worn to measure exposure to gamma radiation. Routine monitoring of air, dust, and surface contamination is undertaken. Canadian mine and mill facilities are designed to handle safely ore grades of up to 26% U.

If uranium oxide is ingested, it has a chemical toxicity similar to that of lead oxide. Similar hygiene precautions to those in a lead smelter are therefore taken when handling it in the drying and packing areas of the mill. The usual radiation safeguards are applied at an ISL mining operation, despite the fact that most of the orebody's radioactivity remains well underground and there is hence minimal increase in radon release and no ore dust.

2. URANIUM REFINING AND CONVERSION

Most nuclear reactors require uranium to be enriched from its natural isotopic composition of 0.7% U-235 (most of the rest being U-238) to 3.5 to 4% U-235. The uranium therefore needs to be in a gaseous form, and the most convenient way of achieving this is to convert the uranium oxides to uranium hexafluoride, commonly referred to as hex. Conversion plants are operating commercially in United States, Canada, France, the United Kingdom, and Russia (see Table II).

Uranium leaves the mine as the concentrate of a stable oxide known as U_3O_8 or as a peroxide. It still contains some impurities, and prior to enrichment it has to be further refined before being converted to uranium hexafluoride (UF_6). The uranium oxide

TABLE II
World Uranium Conversion Capacity in 2001

	Tonnes U/yr
Canada	10,950
France	14,000
UK	7200
USA	12,700
Russia	18,700

Source. OECD NEA (2002). Nuclear energy data. Nuclear Engineering International (2002). "World Nuclear Handbook."

concentrate received by the refinery is dissolved in nitric acid. The resulting solution of uranyl nitrate $UO_2(NO_3)_2.6H_2O$ is fed into a countercurrent solvent extraction process, using tributyl phosphate dissolved in kerosene or dodecane. The uranium is collected by the organic extractant, from which it can be washed out by dilute nitric acid solution and then concentrated by evaporation. The solution is then calcined (heated strongly) in a fluidized bed reactor to produce UO_3.

The purified uranium oxide UO_3 is then reduced in a kiln by hydrogen to UO_2:

$$UO_3 + H_2 ===> UO_2 + H_2O$$
$$\Delta H = -109\,\text{kJ/mole}.$$

This reduced oxide is then reacted in another kiln with gaseous hydrogen fluoride (HF) to form uranium tetrafluoride (UF_4), though in some places this is made with aqueous HF by a wet process:

$$UO_2 + 4HF ===> UF_4 + 2H_2O$$
$$\Delta H = -176\,\text{kJ/mole}.$$

The tetrafluoride is then fed into a fluidized bed reactor with gaseous fluorine to produce uranium hexafluoride, UF_6. Hexafluoride ("hex") is condensed and stored:

$$UF_4 + F_2 ===> UF_6.$$

Removal of impurities takes place at several of these steps.

The UF_6, particularly if moist, is highly corrosive. When warm it is a gas, suitable for use in the enrichment process. At lower temperature and under moderate pressure, the UF_6 may be liquefied and the liquid run into specially designed steel shipping cylinders, which are thick walled and weigh up to 15 tonnes when full. As it cools, the liquid UF_6 within the cylinder becomes a white crystalline solid and is shipped in this form. The siting and environmental management of a conversion plant requires no special arrangements beyond those for any chemical processing plant involving fluorine chemicals.

3. URANIUM ENRICHMENT

3.1 General

Uranium found in nature consists largely of two isotopes, U-235 and U-238. The production of energy in nuclear reactors is from the fission or splitting of the U-235 atoms, a process that releases energy in the form of heat. U-235 is the main fissile isotope of uranium.

Natural uranium contains 0.7% of the U-235 isotope. The remaining 99.3% is mostly the U-238 isotope, which does not contribute directly to the fission process (though it does so indirectly by the formation of fissile isotopes of plutonium).

Uranium-235 and U-238 are chemically identical but differ in their physical properties, particularly their mass. The nucleus of the U-235 atom contains 92 protons and 143 neutrons, giving an atomic mass of 235 units. The U-238 nucleus also has 92 protons but has 146 neutrons, three more than U-235, and therefore has a mass of 238 units. The difference in mass between U-235 and U-238 allows the isotopes to be separated and makes it possible to increase or enrich the percentage of U-235. All enrichment processes, directly or indirectly, make use of this small mass difference.

Some reactors—for example, the Canadian-designed Candu and the British Magnox reactors—use natural uranium as their fuel. Most present day reactors (Light Water Reactors or LWRs) use enriched uranium, where the proportion of the U-235 isotope has been increased from 0.7% to about 3 or up to 4%. (For comparison, uranium used for nuclear weapons would have to be enriched in plants specially designed to produce at least 90% U-235.)

A number of enrichment processes have been demonstrated in the laboratory and some on a larger scale, but only two, the gaseous diffusion process and the centrifuge process, are operating on a commercial scale. In both of these, UF_6 gas is used as the feed material. Molecules of UF_6 with U-235 atoms are about 1% lighter than the rest, and this difference in mass is the basis of both processes. Large commercial enrichment plants are in operation in the United States, the United Kingdom, France, Germany, the Netherlands, and Russia, with smaller plants elsewhere (see Table III).

TABLE III

World Uranium Enrichment Capacity in 2001

	Method	× 1000 kg SWU/year
France	Diffusion	10,800
Germany, Netherlands, United Kingdom	Centrifuge	5250
Japan	Centrifuge	1050
United States	Diffusion	18,700
Russia	Centrifuge	19,000
China	Mostly centrifuge	400–800
Pakistan	Centrifuge	5
Total		55,000 approx.

Source. OECD NEA (2002). Nuclear energy data. Nuclear Engineering International (2002). "World Nuclear Handbook."

The capacity of enrichment plants is measured in terms of separative work units, or SWU. The SWU is a complex unit that is a function of the amount of uranium processed and the degree to which it is enriched (i.e., the extent of increase in the concentration of the U-235 isotope relative to the remainder). The unit is strictly a Kilogram Separative Work Unit, and it measures the quantity of separative work performed to enrich a given amount of uranium a certain amount. It is thus indicative of energy used in enrichment when feed and product quantities are expressed in kilograms. The unit tonnes SWU is also used. For instance, to produce one kilogram of uranium enriched to 3% U-235 requires 3.8 SWU if the plant is operated at a tails assay 0.25%, or 5.0 SWU if the tails assay is 0.15% (thereby requiring only 5.1 kg instead of 6.0 kg of natural U feed).

About 100 to 120,000 SWU is required to enrich the annual fuel loading for a typical 1000 MWe light water reactor. Enrichment costs are related to electrical energy used. A gaseous diffusion plant typically demands 2500 kilowatt hours (9000 MJ) per SWU (kWh/SWU), while modern gas centrifuge plants require only about 50 kWh (180 MJ) per kg SWU. Enrichment accounts for almost half of the cost of nuclear fuel and about 5% of the total cost of the electricity generated. It can also account for the main greenhouse gas impact from the nuclear fuel cycle if the electricity used for enrichment is generated from coal. However, it still typically amounts to only 0.1% of the carbon dioxide from equivalent coal-fired electricity generation if gas centrifuge plants are used, or up to 3% in a worst case situation.

3.2 Early Processes

The electromagnetic isotope separation (EMIS) process was developed in the early 1940s in the Manhattan Project to make the highly enriched uranium used in the Hiroshima bomb, but was abandoned soon afterward. However, it reappeared as the main thrust of Iraq's clandestine uranium enrichment program for weapons discovered in 1992. EMIS uses the same principles as a mass spectrometer (albeit on a much larger scale). Ions of uranium-238 and uranium-235 are separated because they describe arcs of different radii when they move through a magnetic field.

Two aerodynamic processes were brought to demonstration stage. One is the jet nozzle process, with demonstration plant built in Brazil, and the other the Helikon vortex tube process developed in South Africa. Neither is in use now. They depend on a high-speed gas stream bearing the UF_6 being made to turn through a very small radius, causing a pressure gradient similar to that in a centrifuge. The light fraction can be extracted toward the center and the heavy fraction on the outside. Thousands of stages are required to produce enriched product for a reactor. Both processes are energy-intensive—more than 3000 kWh/SWU.

3.3 Gaseous Diffusion Process

Commercial uranium enrichment was first carried out by the diffusion process in the United States. It has since been used in Russia, the United Kingdom, France, China and Argentina as well. Only the United States and France use the process on any significant scale. The remaining large USEC plants in the United States was originally developed for weapons programs and have a capacity of some 19 million kg SWU per year. At Tricastin, in southern France, a more modern diffusion plant with a capacity of 10.8 million kg SWU per year has been operating since 1979. This plant can produce enough 3.7% enriched uranium a year to fuel some 90 1000-MWe nuclear reactors.

The gaseous diffusion process accounts for over 57% of world enrichment capacity. However, though they have proved durable and reliable, most gaseous diffusion plants are now nearing the end of their design life and the focus is on which enrichment technologies will replace them.

The process involves forcing uranium hexafluoride gas under pressure through a series of porous membranes or diaphragms. As U-235 molecules are

lighter than the U-238 molecules they move faster and have a slightly better chance of passing through the pores in the membrane. The UF_6 that diffuses through the membrane is thus slightly enriched, while the gas which did not pass through is depleted in U-235.

This process is repeated many times in a series of diffusion stages called a cascade. Each stage consists of a compressor, a diffuser, and a heat exchanger to remove the heat of compression. The enriched UF_6 product is withdrawn from one end of the cascade and the depleted UF_6 is removed at the other end. The gas must be processed through some 1400 stages to obtain a product with a concentration of 3% to 4% U-235.

3.4 Centrifuge Process

The gas centrifuge process was first demonstrated in the 1940s but was shelved in favor of the simpler diffusion process. It was then developed and brought on stream in the 1970s as the second-generation enrichment technology. It is economic on a smaller scale (e.g., less than 2 million kg SWU/year, which enables staged development of larger plants). It has been deployed at a commercial level in Russia and in Europe by Urenco, an industrial group formed by British, German and Dutch companies. Russia's three plants at Seversk, Zelenogorsk and Novouralsk account for some 30% of world capacity. Urenco operates enrichment plants in the United Kingdom, the Netherlands, and Germany and is participating in a proposal for one in the United States.

In Japan, JNC and JNFL operate small centrifuge plants, the capacity of JNFL's at Rokkasho planned to be 1.5 million SWU/year. China also has a small centrifuge plant imported from Russia at Lanzhou, which is expected to reach 0.5 million SWU/year about 2005. Another small plant at Hanzhong is operating and was to reach 0.5 million SWU/year by 2003. Brazil has a small plant that is being developed to 0.2 million SWU/year. Pakistan has developed centrifuge enrichment technology based on Urenco designs, and this appears to have been sold to North Korea. Iran has sophisticated centrifuge technology, which had not been commissioned as of early 2003.

Both France and the United States are now considering centrifuge technology to replace their aging diffusion plants, not least because they are more economical to operate. As noted, a centrifuge plant requires as little as 50 kWh/SWU power (Urenco at Capenhurst, United Kingdom, input 62.3 kWh/SWU for the whole plant in 2001–2002, including infrastructure and capital works).

Like the diffusion process, the centrifuge process uses UF_6 gas as its feed and makes use of the slight difference in mass between U-235 and U-238. The gas is fed into a series of vacuum tubes, each containing a rotor about 1 to 2 m long and 15 to 20 cm diameter. When the rotors are spun rapidly, at 50,000 to 70,000 rpm, the heavier molecules with U-238 increase in concentration toward the cylinder's outer edge. There is a corresponding increase in concentration of U-235 molecules near the center. These concentration changes are enhanced by inducing the gas to circulate axially within the cylinder. The enriched gas is drawn off and goes forward to further stages while the depleted UF_6 goes back to the previous stage.

To obtain efficient separation of the two isotopes, centrifuges rotate at very high speeds, with the outer wall of the spinning cylinder moving at between 400 and 500 m per second to give a million times the acceleration of gravity. Although the capacity of a single centrifuge is much smaller than that of a single diffusion stage, its capability to separate isotopes is much greater. Centrifuge stages normally consist of a large number of centrifuges in parallel. Such stages are then arranged in cascade similarly to those for diffusion. In the centrifuge process, however, the number of stages may only be 10 to 20 instead of a thousand or more for diffusion.

3.5 Laser Processes

Laser enrichment processes have been the focus of interest for some time. They are a possible third-generation technology promising lower energy inputs, lower capital costs, and lower tails assays, hence significant economic advantages. None of these processes is yet ready for commercial use, though one is well advanced.

Development of the Atomic Vapour Laser Isotope Separation (AVLIS and the French SILVA) began in the 1970s. In 1985, the U.S. government backed it as the new technology to replace its gaseous diffusion plants as they reached the end of their economic lives early in the 21st century. However, after some US$2 billion in R&D, it was abandoned in United States in favor of SILEX, a molecular process. French work on SILVA has now ceased.

Atomic vapor processes work on the principle of photo-ionization, whereby a powerful laser is used to ionize particular atoms present in a vapor of uranium metal. (An electron can be ejected from an atom by light of a certain frequency. The laser techniques for uranium use a frequency that is tuned to ionize a

U-235 atom but not a U-238 atom.) The positively charged U-235 ions are then attracted to a negatively charged plate and collected. Atomic laser techniques may also separate plutonium isotopes.

The main molecular processes that have been researched work on a principle of photo-dissociation of UF_6 to solid UF_5, using tuned laser radiation as noted earlier. Any process using UF_6 fits more readily within the conventional fuel cycle than the atomic process. The leading molecular laser process on the world stage is SILEX, an Australian development that also utilizes UF_6. In 1996, USEC secured the rights to evaluate and develop SILEX for uranium (it is also usable for silicon and other elements). The SILEX process is now at prototype stage in Sydney and applications to silicon and zirconium are being developed.

3.6 Enrichment of Reprocessed Uranium

In some countries, spent fuel is reprocessed to recover its uranium and plutonium and to reduce the final volume of high-level wastes. The plutonium is normally recycled promptly into mixed-oxide (MOX) fuel by mixing it with depleted uranium.

Where uranium recovered from reprocessing spent nuclear fuel is to be reused, it needs to be converted and re-enriched. This is complicated by the presence of impurities and two new isotopes in particular: U-232 and U-236, which are formed by neutron capture in the reactor. Both decay much more rapidly than U-235 and U-238, and one of the daughter products on U-232 emits very strong gamma radiation, which means that shielding is necessary in the plant. U-236 is a neutron poison, which impedes the chain reaction and means that a higher level of U-235 enrichment is required in the product to compensate. Both isotopes tend to report with the enriched (rather than depleted) output, so reprocessed uranium that is re-enriched for fuel must be segregated from enriched fresh uranium.

Both diffusion and centrifuge processes are used for re-enrichment, though contamination issues are more readily managed with the latter. A laser process would theoretically be ideal as it would ignore all but the desired U-235, but this remains to be demonstrated with reprocessed feed.

3.7 Environmental Aspects

With the minor exception of reprocessed uranium, enrichment involves only natural, long-lived radioactive materials; there is no formation of fission products or irradiation of materials, as in a reactor. Feed, product, and depleted material are all in the form of UF_6, though the depleted uranium may be stored long-term as the more stable U_3O_8.

Uranium is only weakly radioactive, and its chemical toxicity—especially as UF_6—is more significant than its radiological toxicity. The protective measures required for an enrichment plant are therefore similar to those taken by other chemical industries concerned with the production of fluorinated chemicals.

Uranium hexafluoride is a corrosive material, therefore any leakage is particularly undesirable. Hence,

- In most areas of a centrifuge plant the pressure of the UF_6 gas is maintained below atmospheric pressure and thus any leakage could only result in an inward flow.
- Double containment is provided for those few areas where higher pressures are required.
- Effluent and venting gases are collected and returned to the process.

3.8 After Enrichment

The enriched UF_6 is converted back to UO_2 and made into fuel pellets—ultimately a sintered ceramic—which are encased in metal tubes to form fuel rods, typically up to 4 m long. A number of fuel rods make up a fuel assembly, which is ready to be loaded into the nuclear reactor.

Glossary

elasticity A dimensionless measure of the responsiveness of a dependent variable to a causal variable, constructed as the percentage change in the responding variable to a 1% change in the causal variable; the range of magnitude of an elasticity is from $-\infty$ to $+\infty$.

embedded (embodied) energy Energy used to produce a good; for example, the energy embedded in an automobile is that required to mine the minerals and fuels used in its production.

modern energy Fossil fuels and electricity.

traditional energy Firewood, charcoal, animal dung, human and animal traction, and stationary (nonelectric) hydropower.

Urbanization is the process of transferring a country's population and labor force from rural areas and predominantly agricultural pursuits to cities and industrial and related service occupations. A country's urbanization is largely coincidental with its industrialization and is a major feature in its economic development. Economic development is a society's transformation from predominantly local orientations, based largely on animate- or renewables-powered production and using technologies that have changed little if any over several centuries, to a more nationally and internationally integrated, larger scale society that uses more powerful and specialized technologies, usually powered by more flexible energy sources. Cities collect the concentrated labor forces required to undertake more specialized industrial production for larger markets and to facilitate the coordination between city and country, as well as among various locations in the countryside, required to support an efficient agricultural sector.

1. URBANIZATION, DEVELOPMENT, INDUSTRIALIZATION, AND ENERGY USE

1.1 Development as Urbanization

The 18th, 19th, and 20th centuries witnessed the urbanization of Europe and North America, with its Australian and New Zealand outposts, and Japan joined the group two-thirds of the way through the 20th century. These countries transferred approximately two-thirds of their labor forces from rural agricultural settings to cities over 100 to 150 years, with the gross national product (GNP) shares of agriculture and nonagriculture (industry and services) changing similarly. The increases in GNP shares coming from industry, particularly metal-producing and -using manufacturing industries, both induced and were facilitated by substitutions of coal for wood and charcoal as fuels. For financial feasibility, larger scale manufacturing required more dependable fuel supplies and found greater flexibility in delivery of coal, and later oil, than could be achieved with either of the wood renewables or with stationary hydropower. These other energy sources also proved to be capable of providing power with different qualities, such as controllability, and their energy densities permitted delivery of larger quantities of effective power.

Urbanization in the Third World outstripped late 20th-century projections, rising from about 27% urban in 1975 to nearly 40% in 2000. The 1999 revision of the United Nations' *World Urbanization*

 © 2004 Elsevier Inc. All rights reserved.

Prospects projected that the world's less developed regions' urbanization will rise to 56% by 2030 while that of the more developed regions will reach 83%. The populations of both China and India, the world's two most populous countries, are currently less than 25% urbanized.

1.2 Changes in Agriculture

A large part of the urban population comes from agriculture during earlier phases of urbanization, so the increments to urban labor forces are matched *pari passu* by decreases in agricultural labor forces. Consequently, farmers who largely fed only themselves and their own families must devise ways in which to feed a larger number of people. Most (but certainly not all) countries cannot shift increases in economy-wide food consumption per farm producer entirely to the foreign trade sector. Agricultural production must change to permit a smaller farming population to feed a larger nonfarming population. The requisite productivity increases come primarily through technological and organizational change: use of new seed varieties and chemical fertilizers, mechanization, irrigation (particularly pumped irrigation), and improvements in infrastructure such as rural credit, agricultural extension, and marketing. The use of machinery reduces labor shortage problems at peak demand times such as harvesting.

Traditional agriculture uses virtually no fuels; its power sources are human and animal labor. As with traditional fuels in cities, food production considered as a fuel source is a more spatially diffuse activity. Land requirements of fodder production have represented major shares of cropland in pre-fossil fuel societies. Mechanization increases the ability of a farm labor force to feed more consumers per worker, but it requires fossil fuels. India devoted nearly 17% of its oil imports to agricultural tractors alone during the early 1970s, and its agriculture was not highly mechanized. Replacement of draft animals releases land used for fodder for use in food production, equivalent to roughly a 20% yield increase in South Asia. Introduction of modern heating, lighting, and cooking fuels concomitant with mechanization releases more animal dung for use as fertilizer instead of fuel; however, eventual decline in the number of draft animals requires chemical fertilizers to substitute for dung, and chemical fertilizers require petroleum feedstocks in their production. Chemical fertilizer use may require pumped irrigation, which also requires fossil fuels. In India during the late 1970s, fertilizer production was the third most energy-intensive manufacturing activity, behind cement and iron and steel. As more multiple cropping is undertaken, coordination of the timely arrival of agricultural inputs requires more attention, and non-farm-produced supplies are more likely to be delivered by fueled vehicles. The same holds for transport of harvested outputs.

Evidence from post-World War II Taiwan shows a shift from 67% human-supplied and 33% animal-supplied energy in agriculture to roughly 35% human-supplied, 5% animal-supplied, and 60% mechanically supplied energy within a quarter-century. Evidence from India suggests that shifting workers from traditional agriculture to the least energy-intensive manufacturing (textiles) can quadruple the per worker energy requirements of the transferred workers.

1.3 Industrial Composition Changes and Energy Use

As a country urbanizes and develops, the composition of its employment and production systematically changes from predominantly agriculture to a much larger prominence of industry and services. Industry, even traditional industry, uses considerably more energy per worker and per unit of output than does agriculture, and the mechanization of energy, with its attendant substitution of modern energy for traditional, exacerbates this effect. The changes in industrial structure accompanying urbanization and economic development increase fuel consumption, particularly consumption of fossil fuels, per worker and per unit of output. Not all industrialization occurs within urban areas, and the energy use increases from industrialization can be separated from those increases attributable to urbanization, although the two developments are related.

Within manufacturing, the share of metals increases, partly due to increases in the array of capital goods and consumer durables produced and partly due to substitution of metal parts for wooden and leather ones in existing products. Similar substitution occurs with plastics. Both metals and plastics are more energy intensive than wood and leather parts. Plastics production ordinarily uses fossil fuels, although some metal products, particularly steel, may get by with charcoal or combustible scrap materials, at least during the early stages of industrialization.

Development involves the acquisition of market discipline among both workers and firms. Unreliable producers either improve their performances or go out of business. Fossil fuels offer greater reliability in

heating performance and often are required to produce products of required quality standards.

1.4 Characteristics of the Empirical Evidence

The structural outlines of the changes in energy use involved in urbanization are clear, but much of the empirical evidence is scattered to the point of being anecdotal. National-level data on energy use are compiled by the United Nations and the Organization for Economic Cooperation and Development (OECD), and these can be supplemented by comparably national economic and demographic data from which aggregate relationships can be estimated. Beyond cross-national studies of long-term developmental and structural trends, a number of country-specific studies, and even city-specific studies, have focused on particular issues such as energy embodied in food delivery to cities, the composition of urban and rural residential energy use, and urban transportation choices. In general, these studies are time-specific snapshots, although an occasional study tracks changes over time. Similar topics are sometimes studied in different cities but cover different time periods, and these may imply different developmental phases in the history of the societies. Some legitimate generalizations may emerge from these studies, although with circumspection and qualification.

2. EFFECTS OF URBAN POPULATION CONCENTRATION ON ENERGY USE

2.1 Scale of Production

Higher concentrations of populations in cities allow larger labor forces to be assembled for employment in larger scale, more specialized facilities. Assembling these larger labor forces, despite their greater residential density, requires reaching labor markets over greater distances, and selling the outputs of these facilities requires selling over larger markets. Although the larger scale of production often lowers unit production costs, the transportation component of total costs rises to sustain the scale increase. Data on Turkish cement production show that expansion of a market area from 6 to 190 km reduces capital and labor costs by 60% and delivered output price by 47% while increasing transportation costs 16 times.

The large scale of production drives up urban land prices and induces urban producers to conserve on their use of land for low-value uses, such as storing low-energy traditional fuels (e.g., firewood), leading in turn to substitution of higher energy per volume fossil fuels. This fuel substitution also permits production at greater distances from the fuel source, and the transportation of the fossil fuel is likely to encourage further substitution of fossil fuel for animate traction.

2.2 Food Delivery

In traditional agriculture in Third World countries, farmers consume large proportions of what they produce and also produce most of what they consume, particularly in terms of food. The separation of food consumers from food producers is a major consequence of urbanization. In low-income countries, food processing, particularly for nonexported products, remains relatively simple. Urbanization permits larger scale and more efficient food processing, but urban food processing is more likely to use fuels instead of human or animal power sources. During the mid-1960s, the United States devoted more than 7% of its energy use to food processing and another 2% to transporting food. During the mid-1970s, with considerably lower levels of urbanization, India and Pakistan devoted 2.3 and 3.6% of their national energy consumptions to food processing, respectively, and each devoted another 1.3% to food transportation. Similar percentages of processing and transportation energy were estimated for food delivered to Mexico City during the mid-1970s.

2.3 Infrastructure

The large concentrations of people in cities require the construction and operation of both public and private infrastructures. The assembly phase of construction is not particularly energy intensive, but construction materials, particularly cement and structural steel, are quite intensive. Data from India during the late 1970s indicate that construction required 2087 kcal per rupee of output, compared with 15,344 for cement and 8757 for iron and steel. These compared with 4552 for nonferrous metals, 2708 for chemicals, 2378 for electrical goods, 2004 for transport vehicles and equipment, and 625 for food and agriculture. Data from The Philippines from 1981 show a similar pattern of relative energy intensities: 5724 kcal per peso for cement, 1431 for basic metals, 399 for machinery and equipment, and 95 for agriculture and livestock. Clearly, the building

of a city—streets, bridges, private and public nonresidential buildings, sanitation systems, and power generation facilities—requires considerable expenditure of energy. Traditionally constructed residential housing in Third World cities is not particularly energy intensive, although the use of cement will involve embedded energy.

However, once the infrastructure is built, it still must be operated and maintained. The provision of urban services, such as water treatment and supply, municipal lighting, and garbage collection, can consume approximately 5 to 6% of the total private fuel use of residents in cities, judging from evidence collected in Mexico City, Nairobi, and India from the mid-1970s. These services are not urban luxuries but rather important inputs to maintaining the productivity of a high-density urban labor force. The diseases accompanying polluted water supplies and rotting garbage are well known from the histories of Western cities, and the resources devoted to these services are repaid in higher productivity.

2.4 Changes in Domestic Activity

In cities, energy use changes in the home as well as in the market. Households use 40 to 90% of all energy in Third World countries, so small percentage changes in domestic energy use can be important in the aggregate. Urban households purchase many goods and services that rural households provide domestically, with an increase in the energy used in their production. Increased specialization and division of labor accompany urbanization, and many production activities performed at home in rural areas are transferred to the market in cities. Some of these activities require fuels in the home, typically traditional fuels, but can be performed with lower fuel inputs per unit of output by specialized market providers, albeit often using modern energy forms. Such activities include baking, food preparation, and water heating for clothes washing. Other activities, such as weaving and sewing, generally use only human energy when conducted at home but use fuel when conducted in the market.

Probably the most obvious energy-using change in individual activity occurs in personal transportation. Urban life requires transportation to and from work, often over greater distances than those separating farmers from fields in agriculture. Although farmers may spend a quarter to a third of their total labor time traveling to and from fields, they almost always walk or use an animate power source. In cities, use of fuel-consuming transportation is much more the rule, even among lower income workers. Urban transportation has a large, modern, fuel-using component that is absent in rural settings, that is, automobiles and buses. Despite widespread use of bicycles and feet (walking) among low-income groups, transportation can take up to 25 to 60% of total household energy use in Third World cities. There is not an equivalent fuel use in agriculture.

2.5 Urban Density and Fuel Use Patterns

Whereas rural dwellers will send women and children into forests to collect wood, urban dwellers in many Third World cities are served by extensive markets in fuelwood transported by fossil-fueled trucks. Nonetheless, the higher residential densities of cities place a premium on the compactness and portability of domestic fuels and encourage the substitution of more compact modern energy forms for traditional fuels. Statistical analysis of Hong Kong census data from the early 1970s indicate that population density depressed the share of firewood and charcoal in household fuel consumption, with an elasticity of -0.25. (An elasticity is the percentage change in one variable, in this case the firewood and charcoal share of domestic energy use, caused by a 1% change in another variable, in this case population density.) Population density in Hong Kong is also associated with a larger share of domestic energy derived from kerosene and with a larger share of energy devoted to commercial uses as opposed to domestic uses.

Higher urban residential densities also reduce per capita transmission and distribution costs of electricity, reducing supply costs for electricity in cities by reducing hook-up costs. Data on the magnitude of this effect, holding the effects of income constant, are not available.

3. EFFECTS OF INCREASES IN INDIVIDUAL INCOME ON ENERGY DEMANDS DURING DEVELOPMENT

Real income increases with economic development, and in developing countries substantial differences exist between rural and urban real incomes. Movement to a city can be expected to raise the income of the average migrating individual or family immediately or within an acceptable period of time. These real income changes propel a number of consumption changes affecting energy.

Income elasticities of household demand for energy have been estimated to be greater than 0.5, and sometimes greater than 1.0, for a number of developing countries in East and South Asia, Africa, and Latin America. Income elasticities are higher for modern energy forms than for traditional forms. The magnitude of these demand elasticities will ensure increased consumption of energy when rural residents migrate to cities, with a shift to modern energy sources. The Hong Kong data show a strong effect of higher income on the traditional fuel share, with an elasticity of −1.17. That is, a 1% increase in income will lower the share of traditional fuels by 1.17%.

Real income increases also encourage the purchase of energy-using appliances. The energy use by these purchases is included in the energy consumption on which the income elasticities just noted are estimated, but their full energy implications are wider. In countries with domestic markets large enough to support appliance production, the increased demand for appliances associated with urbanization feeds back into industrial demand for energy to produce goods made of metals and plastics.

These income-induced increases in end use energy may be mitigated somewhat by the use of more efficient fuels and combustion technologies by urban consumers. In addition, some potential fuel substitutions induced by higher incomes may be restricted by food preparation traditions. For example, kerosene and electricity are poor substitutes for wood and charcoal in grilling food.

4. AGGREGATE ENERGY IMPLICATIONS OF URBANIZATION

4.1 Studies and Data

As noted earlier, although many of the preceding insights have been quantified, and although some have even been subjected to statistical analysis, they defy combination into a comprehensive measure of how much urbanization can be expected to contribute to a nation's energy use. However, two studies have assembled aggregate data for groups of countries and conducted statistical analyses of the relationships among urbanization, various indexes of development, and energy use. In 1989, Donald Jones analyzed a cross section of 1980 data from 59 developing countries. In 1995, Jyoti Parikh and Vibhooti Shukla conducted a somewhat different statistical analysis on a series of 78 developing and industrialized countries over the period from 1967 to 1985. Both studies yielded elasticities of energy use with respect to urbanization, that is, the percentage change in national energy use for a 1% increase in the share of the national population living in cities.

The two studies' results differ in some details, but altogether they largely corroborate each other. Jones analyzed modern, traditional, and total energy separately, whereas Parikh and Shukla analyzed only total energy. Where their quantitative results do differ somewhat, these differences can be explained largely by the differences in their measurements of income and energy and the variables they use to control for outside influences.

Jones used gross domestic product (GDP) data that had been adjusted for purchasing power parity (PPP) corrections for the prices of the nontradable components of GDP, whereas Parikh and Shukla did not use such PPP corrections in their GNP data. (The goods that a developing country produces that are traded internationally, or that compete with internationally traded goods, are priced—even domestically—at close to the international prices. However, the prices of personal services and immobile or otherwise nontraded goods, such as housing, depend on the income levels of the populations. The PPP correction raises the prices attributed to those nontraded goods and services closer to their international valuations. An example might be a lawyer in Chicago who gets a haircut for $20 before leaving for India, where he spends 6 weeks and needs another haircut, which costs him, calculating through the exchange rate [ER], $2. It is the same haircut, but it is offered by a barber with sharply lower costs of living in India. PPP corrects for such discrepancies in prices of equivalent goods that cannot be brought into parity by international trade.) Parikh and Shukla controlled for the economic structure of countries by using the share of agriculture in GDP, whereas Jones accomplished that control function with the share of GDP in industry (although Jones used a simple ER conversion, without the PPP corrections, in the share calculation, and this will yield a smaller industrial share for poorer countries). Jones controlled for nationwide population density with arable land, whereas Parikh and Shukla used all land as their control for population density. Energy use can be expected to exhibit more sensitivity to the PPP measure of GDP than to the ER measure because the adjustments in the PPP measure tend to raise estimates of GDP at earlier dates in a given country and at any particular time to raise the GDPs of lower income countries. Consequently, a given variation in energy use responds to a larger change in ER-measured GDP, leaving the response

appearing smaller with ER–GDP elasticities than with PPP–GDP elasticities. Both measures are valid, but the differences in what they measure should be kept in mind when considering the responsiveness of other variables to them.

4.2 The Pure Urbanization Effect on Energy Use

Despite these data differences, similar stories emerge. The magnitude of the urbanization elasticity of energy use depends importantly on whether one refers to all energy or just modern energy. The changes in total energy include substitutions of modern energy for traditional, and this depresses the urbanization elasticity of total energy (0.35, meaning that a 1% increase in urbanization increases total energy use per unit of GDP by 0.35%) below that of modern energy (0.47). The urbanization elasticity of traditional energy, whether measured on a per capita basis or per dollar of GDP, is not statistically different from zero. Parikh and Shukla's urbanization elasticity for total energy per capita (0.47) is virtually the same magnitude as Jones's urbanization elasticity for modern energy per dollar of GDP (0.48) and is very close to the per capita version (0.45), but it is roughly half again the magnitude of Jones's urbanization elasticities for total energy (0.35 and 0.30).

Parikh and Shukla's alternative analysis took advantage of the cross-sectional component of their data set to estimate country-specific effects for each country estimated from the time series. This estimation cut the magnitude of the urbanization elasticity in half (to 0.25), but it also cut the estimates of all other influences by the same magnitude or more, transferring much of the explanatory power of the analysis to the country effects. Approximately 40% of the country-specific effects can be explained by the percentage of a country's urban population residing in cities with populations exceeding 500,000; the larger the share of the population living in those big cities, the more energy use that is accounted for by the country-specific effect. This extra explanatory power of population concentration in larger cities may capture additional energy use in transportation congestion. The fact that another dimension of urbanization accounts for so much of the variation in per capita energy use across countries suggests that the 0.25 urbanization elasticity from the analysis relying on country-specific effects is not entirely comparable to the urbanization elasticities from the other statistical approaches, that is, that the difference between that and 0.47 depends on how the urban transportation energy is accounted.

4.3 The Effect of Income Changes, Industrialization, and Population Density on Energy Use

These urbanization elasticities were estimated while controlling for GDP per capita, the level of industrialization, and (in some cases) population density. Jones's estimates of the GDP elasticity with the PPP-adjusted GDP yielded larger values than did Parikh and Shukla's ER-converted GDP value (0.47). The GDP elasticities of modern energy of 1.10 and 0.95 are larger than the corresponding elasticities of total energy (0.77 and 0.64). The GDP elasticities of traditional energy are effectively zero. Jones's industrialization elasticity is positive, as expected, but varies considerably among modern, traditional, and total energy as well as across per dollar of GDP and per capita measures of energy. The elasticity per dollar of GDP for industrialization is 1.08 for modern energy but is effectively zero for traditional energy, and this weakens the statistical estimation of the corresponding elasticity of total energy. For energy per capita, the industrialization elasticity for modern energy is smaller than on the per product basis (0.83), but the elasticity for traditional energy per capita is nearly as large but negative (-0.67); as a country industrializes, people move away from traditional energy. Parikh and Shukla's agricultural GDP share variable depresses energy use per capita, with an elasticity of -0.69 that becomes effectively zero when controlling for country-specific effects. Parikh and Shukla's variable and Jones's industrial share variable are roughly mirrors of one another.

The control for population density is useful only in the analysis of traditional energy per dollar of GDP and modern and traditional energy per capita. It is small and of marginal statistical significance in Parikh and Shukla's analyses, but their definition, using all land rather than arable land, is less precise than the definition using arable land. Higher arable population densities reduce traditional energy use per dollar of GDP and per capita fairly sharply, and they yield small positive elasticities of modern energy use per capita. The effect on traditional energy reflects the higher land cost of supporting animals for dung and forests for wood and charcoal at higher population densities as well as the greater convenience of more compact modern fuels and the lower

hook-up costs of electricity. The opposite effect on modern energy per capita simply mirrors the substitution of modern fuels for traditional fuels prompted by higher densities.

Increases in energy prices would moderate energy consumption. Parikh and Shukla found that an index of sensitivity to energy price changes depressed the magnitudes of the country fixed effects. Jones found that two fuel-specific prices, those for oil and gasoline, depressed modern energy consumption, both per capita and per dollar of GDP, with an elasticity of approximately −0.30.

4.4 Significance of the Aggregate Findings

The United Nations' projection of urbanization in the developing world between 2000 and 2030, or roughly one generation, is a 40% increase. If GDP per capita and industrialization remained unchanged over that period, the urbanization alone, using Parikh and Shukla's elasticity obtained without the country-specific effects, would cause a 19% increase in per capita consumption of modern and traditional energy. Jones's elasticity for energy per dollar of GDP predicts the same 19% increase in modern energy alone. Some developing countries had well below 40% urbanization levels in 2000, with China and India being the most prominent at 32 and 28%, respectively. It is not out of the realm of possibility that those two countries' urbanization levels could double in two or possibly three generations. Again, without any increase in income or industrialization, the doubling of urbanization levels alone could increase energy consumption per capita or per dollar of GDP by nearly 50%.

It is reasonable to believe that these parameters would change over a two- to three-generation period of time, probably decreasing somewhat in absolute magnitude. Nonetheless, the Parikh and Shukla elasticities were estimated with the world's full range of development, income, and urbanization, and their fixed-effects elasticity of 0.28 might be a reasonable long-run lower bound. A 28% increase in energy consumption would still be worth noticing. Technological change probably would tend to mitigate such increases, and price increases would further retard growth in energy consumption. Nonetheless, urbanization can be expected to be a major contributor to growth in energy consumption over the next century.

diminishing marginal utility The desire for one additional unit declines with successive units of the good.

embodied energy The direct and indirect energy required to produce a good or service.

evolution In natural systems it has three components: (i) generation of genetic variation by random mutations or sexual recombination, (ii) natural selection by relative reproductive success, and (iii) transmission via information stored in the genes.

valuation The process of assessing the contribution of a particular object or action to meeting a particular goal, whether or not that contribution is fully perceived by the individual.

value The contribution of an object or action to specific goals, objectives, or conditions.

value systems Intrapsychic constellations of norms and precepts that guide human judgment and action. They refer to the normative and moral frameworks people use to assign importance and necessity to their beliefs and actions.

The concepts of value system, value, and valuation have many meanings and interpretations and a long history in several disciplines. This article provides a survey of some of these meanings to set the stage for a discussion of the relationship between energy and value. There is clearly not one "correct" set of concepts or techniques to address this important issue. Rather, there is a need for conceptual pluralism and thinking "outside the box." After a long and interesting history, the issue of value is now going through another period of rapid development that should help us to make better, and more sustainable, decisions, not only as individuals but also as groups, communities, and stewards of the entire planet.

1. DEFINITIONS OF VALUE

The terms value system, value, and valuation have a range of meanings in different disciplines. The definitions provided here are used in this article in order to impose some consistency and to put the range of prior and current definitions in context.

Value systems refer to intrapsychic constellations of norms and precepts that guide human judgment and action. They refer to the normative and moral frameworks people use to assign importance and necessity to their beliefs and actions. Because value systems frame how people assign importance to things and activities, they also imply internal objectives. Value systems are thus internal to individuals but are the result of complex patterns of acculturation and may be externally manipulated through, for example, advertising.

Value refers to the contribution of an object or action to specific goals, objectives, or conditions. The value of an object or action may be tightly coupled with an individual's value system because the latter determines the relative importance to the individual of an action or object relative to other actions or objects within the perceived world. However, people's perceptions are limited, they do not have perfect information, and they have limited capacity to process the information they do possess. An object or activity may therefore contribute to meeting an individual's goals without the individual being fully (or even vaguely) aware of the connection. The value of an object or action therefore needs to be assessed both from the subjective standpoint of individuals and their internal value systems and from the

objective standpoint of what we may know from other sources about the connection.

Valuation is the process of assessing the contribution of a particular object or action to meeting a particular goal, whether or not that contribution is fully perceived by the individual. One can thus (and must if one hopes to be comprehensive and accurate) do valuation from multiple perspectives, using multiple methods (including both subjective and objective), against multiple goals.

Intrinsic value refers more to the goal or basis for valuation and the protection of the "rights" of these goals to exist. For example, if one says that nature has intrinsic value, one is really claiming that protecting nature is an important goal in itself. Values (as defined previously) are based on the contribution that something makes to achieving goals (directly or indirectly). One could thus talk about the value of an object or action in terms of its contribution to the goal of preserving nature but not about the intrinsic value of nature. Therefore, intrinsic value is a confusing and unnecessary term and will not be used further. One should more accurately refer to the intrinsic rights of nature to qualify as a goal against which to assess value, in addition to the more conventional economic goals.

2. HISTORY OF ECONOMIC CONCEPTS OF VALUE

The history of economic thought is replete with struggles to establish the meaning of value, both what is it and how is it measured. Aristotle first distinguished between value in use and value in exchange. The distinction between use and exchange value has been "resolved" several times, but it remains an important issue even today. For example, the diamond–water paradox observed that although water has infinite or indefinite value, being necessary for life, its exchange value is low, whereas unessential diamonds bear a high exchange value. Following this observation, there was widespread recognition of the distinction between exchange value and use value of goods. Galiani defined value to mean a relation of subjective equivalence between a quantity of one commodity and a quantity of another. He noted that this value depends on utility and scarcity (*utilita et rarita*). Two hundred years later, Adam Smith distinguished between exchange value and use value of goods by citing the diamond–water paradox but used it to dismiss use value as a basis for exchange value. Smith formulated a cost of production theory of value, whereby wages, profit, and rent are the three original sources of exchange value. In his famous beaver–deer example, he suggested a labor theory of exchange value: If it takes twice the labor to kill a beaver than to kill a deer, one beaver will sell for as much as two deer. He also suggested a labor-disutility theory of exchange value, noting that goods exchange based on the unpleasantness of the labor required to bring the goods to market. However, it is significant that Smith limited his labor theory to "that early and rude state of society which precedes both the accumulation of stock and the appropriation of land." In other words, when labor is the only scarce factor, goods will exchange based on the ratio of labor use.

In addition to formulating his hypothesis regarding the origins of exchange value, Smith sought to establish a unit of measure of value or what he termed the real measure or real price of a good. He proposed that "labor alone … never varying in its own value, is alone the ultimate and real standard" of the values of all commodities. Hence, labor could be a numeraire, and it had special properties of invariant value.

Ricardo also sought an invariant unit of measure for value. He believed that there was no commodity, including labor, whose exchange value could serve as an invariant standard to measure the variation in exchange values of other commodities. Also, it was not possible to add up commodities to measure national wealth or production with only exchange ratios. According to Ricardo, this measure must be invariant to changes in relative factor rewards (i.e., capital versus labor) and be a commodity whose capital and labor use did not vary over time (i.e., no technological change). He proposed that both wheat and gold possessed these properties. Although not creating value, they could measure value.

Although Ricardo had several followers, including J. S. Mill and Marx, labor theories of value and the pursuit of an invariant standard of value waned in the late 19th century. This was partially in response to the logic of the utilitarians, such as Menger, Gossen, Jevons, and Walras, who argued that exchange value was based on both utility and scarcity. Sraffa, a noted Ricardian scholar, sought to resurrect the classical pursuit of a theory of value independent of demand or value in use. In his 1960 book, "Production of Commodities by Means of Commodities: Prelude to a Critique of Economic Theory," Sraffa established conditions under which exchange ratios between commodities can be determined based on their use

in production (i.e., a set of commodity prices that would exhaust the total product). These exchange ratios were not based on any optimality or marginality conditions. Instead, Sraffa divided commodities into basic (goods that entered into all production processes) and nonbasic, and he showed that an invariant standard of value would be a combination of basic commodities reflecting average input proportions in production. This contrived "commodity" would then be usable as a measure of national wealth or income.

The "marginal" revolution in value theory originated with the confluence of several related streams of economic thought in the 20th century. Menger proposed there were different categories of wants or desires, such as food, shelter, and clothing, that could be ordered in terms of their subjective importance. Within each category, there is an ordered sequence of desires for successive increments of each good. He postulated that the intensity of desire for one additional unit declines with successive units of the good. Replacing the term "desire for one additional unit" with the term "marginal utility," we thus have the economic principle of diminishing marginal utility.

The idea that people have different, but ordered, categories of wants or desires raises the critical issue of whether trade-offs exist between categories. If individuals weight categories, it implies a trade-off. At one extreme, categories may be lexicographically ordered, like words in a dictionary. One level of want must be satisfied before a lower level becomes relevant in the process of valuation. There are no trade-offs between levels of wants. For example, the need for caloric intake is likely superior to that of recreational pleasure: No number of recreational opportunities will likely substitute for an insufficient diet. In the lexicographic case, individuals would use their monetary resources hierarchically, satisfying higher order wants and needs first. When a higher order want or need is at risk, the individual would take resources away from lower level ones until higher level needs were satisfied. Lexicographic preferences do not mean monetary valuation is impossible because individuals would still be able to state how much of their resources they would be willing to sacrifice for a good or service; however, this may be all their resources if a high-level need is at risk.

More problematic for valuation are instances in which basic needs cannot be satisfied by the resources at an individual's disposal (i.e., time or money). Similar to Menger, Ekins and Max-Neef suggested the universality of basic human needs, including subsistence, affection, protection, understanding, leisure, identity, and freedom. Although one can imagine needs such as affection being "purchasable" with money, or freedom being purchasable by migration, many of these needs may not be satisfied by money or time because individuals simply may not consider them to be purchasable by money or time. Thus, not only is it possible that trade-offs between needs will not be possible but also some needs may not be reducible to money or time.

Lancaster introduced the concept of consumption technology, whereby consumers consider characteristics of goods. For example, food may be evaluated on caloric, protein, or vitamin content. Different foods are substitutable depending on the composition of their characteristics. People allocate their budget across characteristics, purchasing goods that are efficient sources of desired characteristics. The technological inability to substitute characteristics may restrict the margins on which environmental goods and services can be valued. For example, although health may be valued, and individuals would be willing to pay for it, the proper mix of calories, protein, and vitamins may make marginal increases or decrements in one of these characteristics either very highly valued or of very low value.

Building on this insight, multiattribute utility theory formalizes the utility-generating technology by proposing that total utility is a function of the characteristics of goods or services. A simple example is the case in which utility, U, from food consumption is a linear function of the caloric, C, protein, P, and vitamin, V, content:

$$U = aC + bP + cV,$$

where the parameters a–c reflect the weighting of three factors in determining utility for food consumption. When utilities are measurable in monetary willingness to pay or willingness to accept compensation, these parameters represent the marginal monetary value of each characteristic. This logic forms the basis for hedonic pricing models of valuation (discussed later) whereby the value of market goods such as a house depends on the characteristics of the house and its location as well as surrounding environmental amenities or disamenities.

Gossen proposed that in order to maximize satisfaction from a good, such as labor or money, an individual must allocate that good across different uses to equate its marginal utility in each use. Hence, marginal utility would provide a basis for explaining exchange value. If we treat things such as iron, cement, fertilizer, natural agents, and labor as incomplete consumable goods, the marginal utility

of the goods they produce can be used to explain their exchange value. This logic established a theory of value. It also demonstrated that exchange values could be based on marginal use value.

While the classical theorists sought a standard physical commodity unit for measuring exchange value, neoclassical theorists substituted utility for such a commodity. Because value was assumed to be determined solely by consumption utility on the margin, and consumers were assumed to allocate money optimally across uses (in possession of perfect information, no externalities, fixed preferences, and no interpersonal effects), the marginal utility of money was the same for an individual in all its uses. Money thus became the standard unit of measure.

The general optimization model of labor/leisure and consumption/saving given time and wealth constraints would yield equivalencies of goods for money, goods for time, and time for money. Time or money can thus be used as a standard of measure of use value; how much time or money will a person willingly sacrifice to obtain commodity X?

The utility-based values of goods and services are reflected in people's willingness to pay (WTP) to attain them or their willingness to accept compensation to forego them (WTA). WTP and WTA become measures of these values. They may be based on small marginal changes in the availability of these goods and services or on larger changes, including their complete absence or presence. These valuations are reflected in Fig. 1. Let the curve D represent the WTP for each unit of the good or service, T, for an individual or group. This is a marginal WTP. The total WTP for T_0 units of T is the aggregated areas A + B. Area A may be very large for goods or services that have some utility threshold where the good becomes increasingly valuable as it becomes scarcer. This is true for many ecological goods and services, including life-support goods such as oxygen and water; the marginal value is finite but the total value is indeterminate. This is the distinction that lies behind the diamond–water paradox discussed previously.

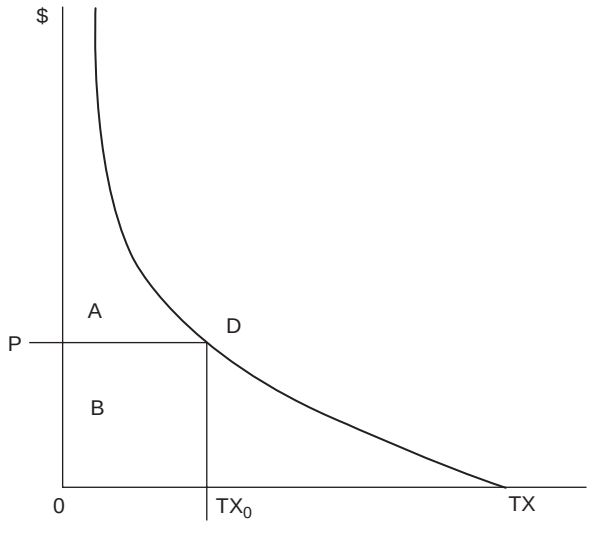

FIGURE 1 Utility- and exchange-based values of goods and services.

Exchange-based values are reflected in the prices, P, at which the goods or services are exchanged. When supply is T_0, and the item is sold competitively, a price P is determined that clears the market. These prices also reflect the marginal valuations placed on available quantities around T_0. Therefore, prices reflect marginal values when there are markets for the goods or services.The total exchange value of T_0 is $P \times T_0$. This is an observable market value when there are markets to observe. However, when there are no such markets, P must be determined indirectly, and $P \times T_0$ would represent a pseudo-market value. This would be the total exchange value of the good if there were a market with an available supply of T_0.

Measures of economic value are assumed to reflect the difference that something makes to satisfaction of human preferences. If something is attainable only at a cost, then the difference it makes to satisfy preferences is the difference between its utility and the cost of attaining it. Formal concepts of compensating and equivalent variations are used to reflect this difference. For example, suppose in Fig. 1 that T_0 is available at a cost of P. Under these terms of availability, the welfare difference made by T_0 is area A. The marginal value that alterations in availability make to welfare would be reflected by changes in area A. Using timber from trees as an example, suppose timber is harvested at a cost of P per unit of timber. The value of trees, per se, would be represented by area A, which is less than A + B.

Thus conceived, the basic notion of value that guides neoclassical economic thought is inherently anthropocentric or instrumental. Although value can generally mean the contribution to a goal, objective, desired condition, etc., the mental model used by neoclassical economists is that value is based on want satisfaction, pleasure, or utility goals. Things have value insofar as they propel individuals toward meeting pleasure and need objectives. Values of objects in the environment can be considered on the margin as well as on the whole (i.e., the value of one additional tree versus the value of all trees).

Although value relates to the utility of a thing, the actual measurement of value requires some objective measure of the degree to which the thing improves pleasure, well-being, and happiness.

In a finite world, the resources people have available to meet their personal objectives are limited. Economists have thus developed an extensive theory of how people behave in the presence of constraints on feasible activities. The working hypothesis is that people make decisions in order to optimize satisfaction, pleasure, or utility. This optimization always takes place in the presence of constraints, such as income, wealth, time, and resource supply. Optimization thus yields a set of possible decisions in most real-world situations—when constraints change, so do the decisions.

The essence of this perspective is that the economic world works largely deterministically, moving from one equilibrium to another in relatively stable fashion, and responds to changes in constraints in a predictable fashion. The determination of equilibrium is a resultant of conflicting forces, such as supply and demand, or unlimited wants and limited means. Although there are instances of instability, disequilibria, and indeterminism, these are treated as exceptions rather than the rule.

Since individuals can be observed making choices between objects in the marketplace while operating within the limits of income and time, economists have developed measures of value as imputations from these observed choices. Although monetary measures of value are not the only possible yardstick, they are convenient since many choices involve the use of money. Hence, if you are observed to pay $10 for a bottle of wine, the imputation is that you value wine to be at least $10 and are willing to make a trade-off of $10 worth of other things to obtain that bottle. The money has no intrinsic value but represents other things you could have purchased. Time is often considered another yardstick of value; if you spend 2 h golfing, the imputation is that you value the golf experience to be worth more than 2 h spent in other activities. Value is thus a resultant of the expressed tastes and preferences of persons and the limited means with which objects can be pursued. As a result, the scarcer the object of desire, the greater its value will be on the margin.

Importantly, the "technologies" of pleasure and production allow for some substitution between things. A variety of goods can induce pleasure and are thus treated conceptually as utility substitutes. A bear may substitute for an elk in consumption, hunting, and a wildlife viewing experience even though bears and elk are not substitutes in terms of ecosystem function. On the production side, inputs are also considered to be substitutable for one another. Machines and technology can substitute for people and natural inputs. Clearly, economists recognize that the relations between goods and services are often more complicated. For malnourished people, sugar is no technological substitute for protein, even though they both provide calories. As discussed previously, preferences may be lexicographic: Some things are more important than others and cannot be substituted for lower level wants or needs. On the production side, no number of lumbermen is a substitute for timber when there is no timber. Production may require certain inputs, but at the same time there may be substitutability between others. As Krutilla suggests, there may be close substitutes for conventional natural resources, such as timber and coal, but not for natural ecological systems.

The neoclassical perspective also assumes that tastes and preferences are fixed and given, and that the fundamental economic "problem" consists of optimally satisfying those preferences. Tastes and preferences usually do not change rapidly and, in the short term, this basic assumption is probably not too bad. In the longer term, however, it does not make sense to assume tastes and preferences are fixed. People's preferences do change over longer time frames, as the existence of a robust advertising industry attests. This observation is important because sustainability is an inherently long-term concept and ecosystem services are expected to continue far into the future. This fact is very disturbing for many economists because it takes away the easy definition of what is optimal. If tastes and preferences are fixed and given, then we can adopt a stance of "consumer sovereignty" and just give people what they want. We do not have to know or care why they want it; we just have to satisfy their preferences efficiently.

However, if preferences change over time and under the influence of education, advertising, changing cultural assumptions, variations in abundance and scarcity, etc., we need a different criterion for what is optimal. Moreover, we have to determine how preferences change, how they relate to this new criterion, and how they can or should be changed to satisfy the new criterion. One alternative for the new criterion is sustainability, or more completely a set of criteria: sustainable scale (size of the economic subsystem), fair distribution, and efficient allocation. This set of criteria implies a two-tiered decision

process of first coming to a social consensus on a sustainable scale and fair distribution and then using the marketplace and other social institutions, such as education and advertising, to implement these decisions. This might be called community sovereignty as opposed to consumer sovereignty. It makes most economists very uncomfortable to stray from consumer sovereignty because it raises the following question: If tastes and preferences can change, then who is going to decide how to change them? There is a real danger that a totalitarian government might be employed to manipulate preferences to conform to the desires of a select elite rather than the individuals in society.

Here, two points need to be kept in mind: Preferences are already being manipulated every day, and we can just as easily apply open democratic principles to the problem as hidden or totalitarian principles in deciding how to manipulate preferences. Viewed in this light, the aforementioned question is transformed: Do we want preferences to be manipulated unconsciously, either by a dictatorial government or by big business acting through advertising, or do we want to formulate preferences consciously based on social dialogue and consensus with a higher goal in mind? Either way, we believe that this issue that can no longer be avoided and is one that will best be handled using open democratic principles and innovative thinking. This leads us back to the role of individual preferences in determining value. If individual preferences change in response to education, advertising, and peer pressure, then value cannot solely originate with individual preferences. Values ultimately originate from within the constellation of shared goals to which a society aspires—value systems—as well as the availability of "production technologies" that transform things into satisfaction of human needs.

In addition to income and education, time places constraints on value creation. Constraints of time and intertemporal substitutabilities create temporal implications for value. Neoclassical economists presume that a present time preference exists due to limited time horizons and concerns for uncertainty in the future. This means individuals will discount values of things in the future in comparison to the same things in the present. If I have an equal endowment of apples now and a year from now, I would place a greater value on having an apple now than on having an apple 1 year from now. The ability to convert things to money in the presence of positive financial interest rates will therefore result in the "optimizing individual" discounting things in the future.

In contrast to economists' traditional assumptions of positive time preferences, or positive discount rates, psychologists suggest time preference is more complicated. For example, Lowenstein and Prelec find that in some circumstances people behave as if they have negative time preference, preferring more in the future to more now. The authors suggest this is due to dread, the anticipation of savoring better conditions in the future, and the aversion to loss. However, this negative time preference may not be operative when the time period is ambiguous. The implications of such experimental results for discounting in environmental policy settings are not clear, but they do raise serious questions about the standard practice of discounting future environmental benefits.

3. ECOLOGICAL CONCEPTS OF VALUE

Value is a term that most ecologists and other natural scientists would prefer not to use at all, except perhaps in its common usage as a reference to the magnitude of a number (e.g., "the value of parameter b is 9.32"). Using the definitions provided earlier, ecosystems and nonhuman species are presumed not to be pursuing any conscious goals, and therefore they do not have a value system. Likewise, one cannot talk about value as the degree to which an item contributes to achieving a goal in this context since there is no conscious goal being pursued. Nevertheless, some concepts of value are important in the natural sciences and are in fact quite commonly used.

If one limits the concept of value to the degree to which an item contributes to an objective or condition in a system, then we can see how natural scientists use the concept of value to talk about causal relationships between different parts of a system. For example, one could talk about the value of particular tree species in controlling soil erosion in a high slope area or the value of fires in recycling nutrients in a forest.

There are other ways in which the concept of value is used in the natural sciences. For example, a core organizing principle of biology is evolution by natural selection. Evolution in natural systems has three components: generation of genetic variation by random mutations or sexual recombination, natural selection by relative reproductive success, and transmission via information stored in the genes.

Although this process does not require conscious, goal-directed behavior on the part of any of its participants, one can still think of the overall process as being "goal-directed." The goal of survival is embedded in the objective function of natural selection. Although the process occurs without consciousness of this goal, individuals and species as a whole can be observed to behave as if they were pursuing the goal of survival. Thus, one often hears evolutionary biologists talk about the survival value of particular traits in organisms. Natural selection models, which maximize the fitness of individuals, are not only testable but also bear close similarities to economic utility maximization models.

In addition, the idea of coevolution among a whole group of interacting species raises the possibility that one species is valuable to the survival of another species. Extending this logic to the coevolution of humans and other species, we can talk of the value of natural ecosystems and their components in terms of their contribution to human survival.

Ecologists and physical scientists have also proposed an energy theory of value to either complement or replace the standard neoclassical theory of subjective utility-based value. It is based on thermodynamic principles in which solar energy is recognized to be the only primary input to the global ecosystem.

This theory of value represents a return to the classical ideas of Ricardo and Sraffa but with some important distinctions. The classical economists recognized that if they could identify a primary input to the production process then they could explain exchange values based on production relationships. The problem was that neither labor nor any other single commodity was really primary since they all require each other for their production. The traditional primary factors are really intermediate factors of production.

The classical economists were writing before the science of thermodynamics had been fully developed. Energy—or, more correctly, free or available energy defined as the ability to do work—has special characteristics that satisfy the criteria for a primary input described previously:

1. Energy is ubiquitous.
2. It is a property of all the commodities produced in economic and ecological systems.
3. It is an essential input to all production processes.
4. Although other commodities can provide alternative sources for the energy required to drive systems, the essential property of energy (the ability to do work) cannot be substituted.
5. At the global scale, the earth is essentially a closed system in thermodynamic terms (only energy crosses the boundary), so at this scale it is the only primary input.
6. Smith's three sources of exchange value (wages, profits, and rent) are intermediate inputs in this global scheme and interconvertable using the primary energy input.

Available energy is thus the only basic commodity and is ultimately the only scarce factor of production, thereby satisfying the criteria for a production-based theory that can explain exchange values.

Energy-based concepts of value must follow the basic principles of energy conversion. The first law of thermodynamics states that energy and matter are conserved. However, this law essentially refers to heat energy and mechanical work (raw energy or the bomb calorimeter energy). The ability to do work is related to the degree of organization or order of a thing relative to its environment, not its raw heat content. Heat must be organized as a temperature gradient between a high-temperature source and a low-temperature sink in order for useful work to be done. Similarly, complex manufactured goods such as cars have an ability to do work that is not related to their raw energy content but may be related to their degree of organization relative to their environment. The second law of thermodynamics states that useful energy (organization) always dissipates (entropy or disorder always increases) within an isolated system. In order to maintain organized structures (e.g., an economy) one must constantly add organized, low-entropy energy from outside the system. The earth as a whole is just such a system. In thermodynamic terms, it is essentially closed (i.e., energy, but not matter, crosses the boundaries). Of course, some matter does cross the boundaries (i.e., meteorites and spacecraft) so the earth system is at least slightly open, but these flows of matter are very small compared to the flow of solar energy in and heat energy out.

Estimating total energy consumption for an economy is not a straightforward matter because not all fuels are of the same quality; that is, they vary in their available energy, degree of organization, or ability to do work. Electricity, for example, is more versatile and cleaner in end use than petroleum, and it also requires more energy to produce. In a oil-fired power plant it takes 3–5 kcal of oil to produce 1 kcal of electricity. Thus, adding up the raw heat equivalents

of the various forms of fuel consumed by an economy without accounting for fuel quality can radically distort the picture, especially if the mix of fuel types is changing over time.

An energy theory of value thus posits that, at least at the global scale, free or available energy from the sun (plus past solar energy stored as fossil fuels and residual heat from the earth's core) are the only primary inputs to the system. Labor, manufactured capital, and natural capital are intermediate inputs. Thus, one could base a theory of value on the use in production of available energy that avoids the problems that the classical economists encountered when trying to explain exchange values in economic systems.

There have been a few attempts to empirically test this theory using both time series data and cross-sectional data. Studies that have tried to adjust for fuel quality have shown a very close relationship between available energy consumption and economic output. Cleveland *et al.* and Kaufmann have shown that almost all the changes in energy:gross national product (E:GNP) (or energy:gross domestic product) ratios in the United States and Organization for Economic Cooperation and Development countries can be explained by changes in fuel quality and the percentage of personal consumption expenditures (PCE) spent directly on fuel. The latter effect is due to the fact that PCE is a component of GNP and spending more on fuel directly will raise GNP without changing real economic output. Figure 2 is an example of the explanatory power of this relationship for the U.S. economy from 1932 to 1987. Much of the apparent gain in energy efficiency (decreasing E:GNP ratio) is due to shifts to higher quality fuels (e.g., natural gas and primary electricity) from lower quality ones (e.g., coal). Renewable energy sources are generally lower quality and shifts to them may cause significant increases in the E:GNP ratio.

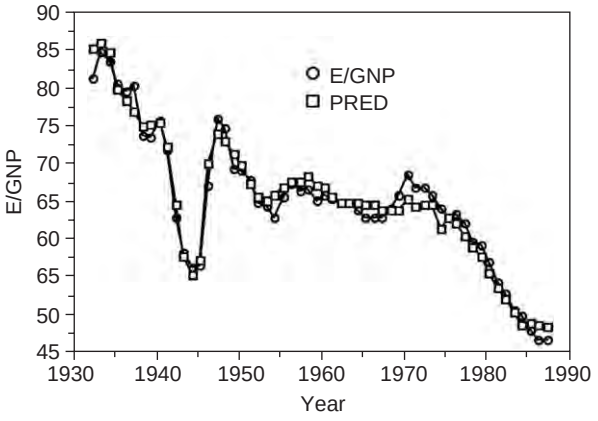

FIGURE 2 The energy:GNP ratio for the U.S. economy from 1932 to 1987. The predicted ratio (PRED) is based on a regression model with percentage of primary energy from petroleum and from electricity and percentage of personal consumption expenditures spent on fuel as independent variables ($R^2 = 0.96$). From Cleveland *et al.* (1984) and Kaufmann (1992).

Another way of looking at the relationship between available energy and economic output uses cross-sectional rather than time-series data. This avoids some of the problems associated with changes in fuel mix and distortions in GNP. For example, Costanza and Costanza and Herendeen used an 87-sector input–output model of the U.S. economy for 1963, 1967, and 1973, modified to include households and government as endogenous sectors (to include labor and government energy costs), to investigate the relationship between direct and indirect energy consumption (embodied energy) and dollar value of output. They found that dollar value of sector output was highly correlated ($R^2 = 0.85$–0.98) with embodied energy when this was calculated including the energy costs of labor, government, and environmental inputs (although not with direct energy consumption or embodied energy calculated excluding labor and government energy costs). Thus, if one makes some necessary adjustments to estimates of energy consumption in order to better assess available energy, it appears that the empirical link between available energy cost and economic value is rather strong.

Some neoclassical economists have criticized the energy theory of value as an attempt to define value independent of consumer preferences. This criticism is, on the one hand, axiomatic since a major purpose of an energy theory of value was to establish a theory of value not completely determined by individual preferences. On the other hand, techniques for calculating embodied energy utilize economic input–output tables. These tables summarize production interdependencies but they are not completely independent of consumer preferences, which helped to structure the production interdependencies over time.

In summary, the energy theory of value overcomes some of the problems of earlier production-based theories of value encountered by the classical economists and does a fairly good job of explaining exchange values empirically in the few cases in which it has been tested. Despite the controversy and ongoing debate about the validity of an energy theory of value, it seems to be the only reasonably successful attempt to operationalize a general biophysical theory of value.

4. COST AND PRICE

Energy (and earlier labor) theories of value are inherently based on relative production costs. Thus, it is more accurate to speak of energy cost or labor cost and not energy value or labor value. However, in economic systems it is well-known that cost and price will, in general, come to equilibrium. This is the essence of the basic ideas of supply and demand. If a commodity has a much higher value than its cost of production, profits will be high and more of the commodity will be produced (with increasing marginal cost) until cost just equals price and profits are 0 for the last unit of production. Likewise, if cost is much higher than price, less will be produced until they are again equal. Therefore, a method that estimates costs, although not technically estimating price or value, should in fact be a fairly good approximation to price and value in cases in which markets have reached an approximate equilibrium. Since markets are never really in equilibrium and there are many types of market failure to complicate things, we would expect there to be some divergence between cost and price in real systems. The question then becomes the following: Are the commodities overpriced or underpriced? Should the energy costs be taken as the standard and market exchange values be adjusted, or should the energy costs be ignored and the market prices taken as the standard? Given, on the one hand, the enormous data requirements to calculate energy costs accurately and, on the other hand, the pervasive market imperfections complicating market prices, there is no unambiguous correct answer. However, one can learn much by examining energy costs and market prices and comparing their degree of correspondence. Costanza did just that at the aggregate level of an 87-sector input–output model and found a fairly high degree of correspondence for those sectors in which markets were fairly functional and lacking severe externalities and a low correspondence for those sectors in which they were not (basically, the extractive sectors at this level of aggregation).

As discussed previously, embodied labor costs alone would give a much poorer approximation to exchange value than embodied energy costs since embodied labor is a less comprehensive measure of total cost than embodied energy, especially in industrial economies in which capital, direct energy, and government expenditures are significant components of total cost relative to labor.

5. CONCLUSION

A modern approach to value and valuation needs to be pluralistic, including a broad range of both subjective and objective methods. Embodied energy cost has proven to be an important element in this spectrum of approaches, and it makes the link with the classical economists' production-based theories of value. Embodied energy should more accurately be called a theory of cost rather than value, although the two are obviously related in well-functioning markets. The most productive approach is to keep these distinctions in mind while applying a range of subjective and objective methods in order to obtain a clearer picture of the complex nature of value and, ultimately, to do a better job of valuation against a much broader range of social goals.

Glossary

absolute pressure (**P**) Pressure measured relative to total vacuum—or zero pressure.
absolute temperature (**T**) Temperature measured in Kelvin or Rankine.
Carnot cycle An external combustion engine whose compression and expansion strokes are ideally accomplished without heat transfer and for which the heat addition and rejection processes occur at different but constant temperatures. The Carnot cycle engine achieves the maximum theoretical efficiency possible for an external combustion engine operating between the temperatures at which heat addition and heat rejection take place. Its thermal efficiency is given by $\eta = (T_{high} - T_{low})/T_{high}$. For a Carnot cycle, or any external combustion engine, to achieve an efficiency of 100% would require that either $T_{high} = \infty$ or $T_{low} = 0$ (absolute zero).
enthalpy (**H**) Defined as $H = U + PV$.
entropy (**S**) A measure of disorder.
external combustion engine An engine in which heat transfer from combustion occurring outside the engine is transferred across the boundary of the system to the working fluid of the engine (e.g., a steam engine).
Gibb's Free Energy (**G**) Defined as $G = H - TS$.
heat (**Q**) Energy transferred across the boundary of a system because of a temperature difference.
higher heating value (**HHV**) Heat transferred out of a constant pressure system in which complete combustion occurs and the products are brought back to the original temperature, with any resulting water being condensed to liquid.
internal combustion engine An engine in which the working fluid is initially an air-fuel mixture and, after combustion and until exhausted, the products of combustion. It is different from an external combustion engine. The maximum work obtainable from a given amount of fuel is the Gibbs free energy. High temperature is not required to achieve high thermal efficiency. The Carnot cycle limitation of thermal efficiency does not apply to an internal combustion engine. The ideal thermal efficiency for any internal combustion engines is 100%.
internal energy (**U**) Total energy in a defined closed system.
thermal efficiency (η) The ratio of the work out to the input fuel HHV.

Rapid transportation of persons and material is a critical component of modern society. Internal combustion engines, using petroleum as fuel, are the principle energy converter used in transportation. Consequently, transportation is a major consumer of petroleum. Because of increasing use and rapid growth of developing countries, petroleum will undoubtedly increase in cost and the supply is finite. The desirable results of rapid transportation are accompanied by undesirable air pollution, safety issues, and other problems. This article reviews the past trends of emissions, fuel economy, and safety together with customer preferences as well as techniques for minimizing the amount of petroleum needed to continue to meet society's desires for mobility.

1. HISTORY OF GROUND VEHICLE POWER PLANTS

Humans have always valued the capability of transporting themselves and possessions to desired

 © 2004 Elsevier Inc. All rights reserved.

locations. Although wind power was used extensively for water transportation, personal transportation was initially human powered. However, it was soon recognized that the augmented power available by using animals increased the distance that could be covered in a given time. During this period of development, horses became the most commonly used animal, hence the term horsepower. Fundamentally, the basic energy conversion process to develop this power was low-temperature, catalytic oxidation of combustible material (i.e., food).

As technological capability increased, it became increasingly feasible to use high-temperature oxidation (combustion) as the source of transportation energy. Suzuki shows a drawing, made by Huygens in 1673, of a primitive gunpowder internal combustion engine. Also shown is the Newcomen steam engine (1712), an external combustion engine. Each type of energy converter underwent successive development. The internal combustion engine, with its combination of high thermal efficiency and low weight per unit of power, has become the dominant choice for powering transportation vehicles. The manufacture of internal combustion engines for automobiles, boats, airplanes, trains, small power units, etc. is one of the largest industries in the world.

1.1 Thermodynamics

Thermodynamics, using ideal reversible processes, establishes the upper limit for the useful work that can be obtained from a given quantity of fuel and air. The upper limit of efficiency for an external combustion engine is temperature dependent, whereas the upper limit for an internal combustion engine is 100% (i.e., an internal combustion engine can theoretically convert all of the heating value of the fuel into work).

1.2 External and Internal Combustion Engines

The thermodynamic processes involved in external combustion engines and internal combustion engines are fundamentally different. The practical significance of this difference is not generally realized. For simplicity, most engineering thermodynamic texts do not make this distinction clear. For example, the internal combustion engine is often analyzed as if it were an air standard Otto cycle, which is an external combustion engine with heat added and rejected at constant volume. In some situations, this can aid in understanding, but it is a simplification that is fundamentally incorrect. It should also be clear that for both internal and external combustion engines, inevitable irreversible processes, such as friction (mechanical and fluid) and heat transfer to combustion chamber walls, will occur that decrease system thermal efficiency.

2. USE CLASSIFICATION OF GROUND VEHICLES

Transportation energy is responsible for 65% of all petroleum usage in the United States. Riley shows that personal transportation vehicles consume more than half of this petroleum (i.e., light-duty, personal transportation vehicles account for more than 35% of the nation's total consumption of petroleum and are the largest consumers of transportation fuel in the United States) (Fig. 1). Due to the current low price of gasoline, market forces provide little incentive to reduce fuel consumption of light-duty vehicles. However, competitive market forces provide strong incentives to minimize fuel consumption in the remaining sectors shown Fig. 1: freight trucks, air transport, marine, and rail. As discussed in the *Wall Street Journal* (May 14, 2002), definitions of a light-duty vehicle differ. Furthermore, it is not clear if small users of petroleum (i.e., agriculture, construction, lawn maintenance, recreation, etc.) are included in the data depicted in Fig. 1. This article focuses primarily on light-duty vehicles (i.e., cars and light-duty trucks).

3. CONSTRAINTS

Transportation vehicles are sold in a competitive market. However, for reasons of environmental impact, public health, and safety, government

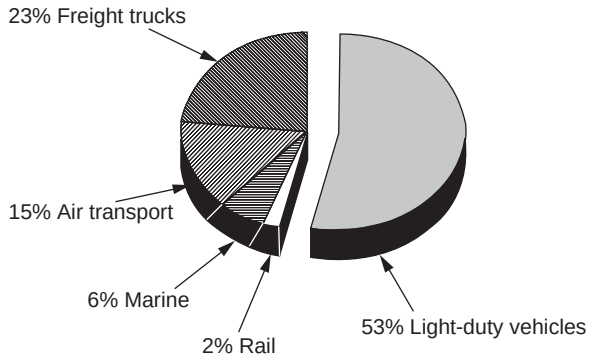

FIGURE 1 U.S. transportation energy consumption, 1990.

regulations, which must be met before vehicles can be sold, have been imposed. Often, these regulations result in attributes of the vehicle that are not part of the consumer's criteria for purchasing the vehicle.

3.1 Government Constraints

There are numerous government-imposed, regulatory constraints on the light-duty fleet. The most significant regulations embody interrelated aspects of a vehicle's operation: emissions, safety, and fuel economy.

3.1.1 Emissions

Four gaseous emissions from the engine are of primary concern for both gasoline and diesel engines: unburned or partially burned fuel, in both vapor and solid form; nitrogen–oxygen compounds, which are formed in the cylinder during high-temperature combustion; carbon monoxide (CO); and carbon dioxide (CO_2). These emissions enter the atmosphere via the vehicle exhaust. Reduction of pollutants in the engine exhaust, except for CO_2, is the primary control technique for reducing emissions. Carbon dioxide, which is directly related to the fuel consumed, is increasingly being viewed as a pollutant because of its impact as a greenhouse gas. Vehicle emissions are measured on a chassis dynamometer that is loaded, in steps, to represent different vehicle weights. The vehicle is operated over a specific driving cycle and emissions and fuel consumption are measured. Different countries have different driving cycles. For a given vehicle classification, regulations are typically expressed in mass of pollutant emitted per unit distance driven. The driving cycle requires engine operation over a variety of speeds and loads. This variation of operating conditions changes the engine's exhaust gas temperature and exhaust constituents. Confounding the situation, the variations in exhaust gas temperature and constituent composition during the driving cycle will be different for different types of engines (e.g., a compression ignition and a spark ignition engine).

3.1.2 Safety

There are many regulations on vehicle and occupant safety. Achieving vehicle occupant safety is difficult and is affected by many factors, including road characteristics; multiple- or single-vehicle collisions; vehicle weight, design, structure, and maneuverability; driver experience, mood, use of alcohol, distraction, use of safety constraints such as seat belts; solid objects within the vehicle; and occupant resiliency.

3.1.3 Fuel Economy

There are many interactive parameters that influence a vehicle's fuel economy. U.S. consumers are familiar with the term miles per gallon to express fuel economy. However, the inverse of miles per gallon, the volume of fuel consumed per unit distance, is the most useful for analysis purposes. Note that there is a nonlinear, inverse relationship between the two expressions. Europe's future vehicle fuel economy goal is 3 liters of fuel per 100 kilometers traveled.

The standard fuel consumption parameter used for engines, brake-specific fuel consumption, is the amount of fuel required to produce one brake horsepower-hour, or kilowatt-hour, of work. An analogous expression for vehicle fuel consumption of cars or light trucks would be gallons/vehicle ton/mile—that is, the gallons of fuel required to move a 1-ton vehicle 100 miles). Obviously, it will take twice as many gallons to move a 2-ton vehicle 100 miles than it will to move a 1-ton vehicle 100 miles. Figure 2 presents this data for 2000 and 2001 model year cars and light trucks. Vehicles of the same weight can have engines with major differences in power, performance, and fuel economy. Consequently, for vehicles of the same weight, significant differences in fuel consumption (i.e., vertical spread in Fig. 2) can be expected. The current system to regulate fuel consumption of light-duty transportation vehicles in the United States is the corporate average fuel economy (CAFE). Vehicles sold by a given manufacturer are divided into two groups—cars and light-duty trucks. Currently, the sales-weighted average fuel economy of all cars sold by a given manufacturer must be 27.5 miles per gallon or higher, whereas the sales-weighted average fuel economy of all light-duty trucks sold by a given manufacturer must be 20.7 miles per gallon or higher. Failure to meet these standards results in significant penalties.

3.2 Customer Preferences

To be saleable, cars and light trucks must meet customer desires. Customer preferences are obviously affected by the cost of desired amenities and by current trends. At current U.S. fuel prices, fuel economy is not a high-priority consumer item. In contrast, in Japan and Europe, where fuel prices are two to four times higher than those in the United States, fuel economy is much more important to the consumer. The trends in consumer choices of vehicles in these countries reflect this difference in priorities.

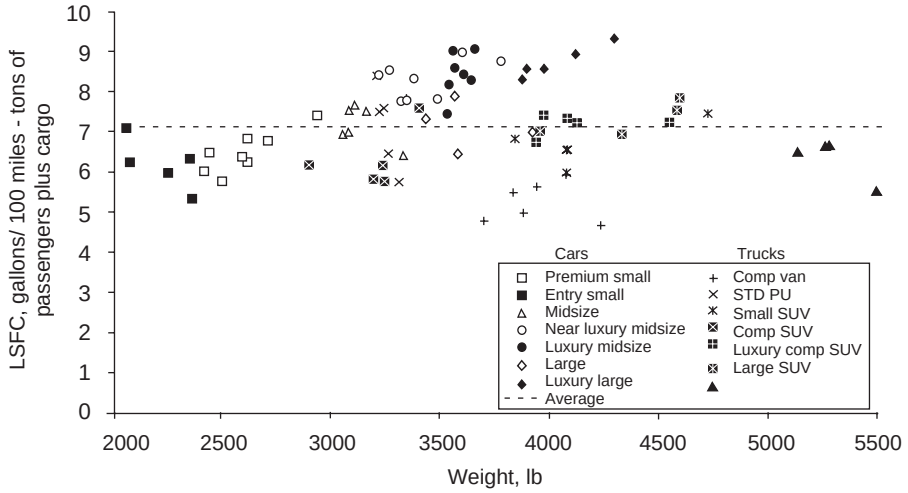

FIGURE 2 Weight-specific fuel consumption versus weight for all vehicles.

4. PAST TRENDS

4.1 Emissions

Vehicle emissions have been of concern since the early 1950s when a California researcher determined that traffic was to blame for the smoggy skies over Los Angeles. At that time, typical new cars were emitting nearly 13 g of hydrocarbons per mile, 3.6 g of nitrogen oxides per mile, and 87 g of CO per mile. Since then, the federal government has set increasingly more complex and restrictive standards to reduce these pollutants. Figure 3 shows the current standard for nitrogen oxides as well as the tier 2 standard. It is clear that dramatic reductions in emissions have been achieved from the vehicles of the early 1950s, but there is still work to be done to meet the tier 2 standards.

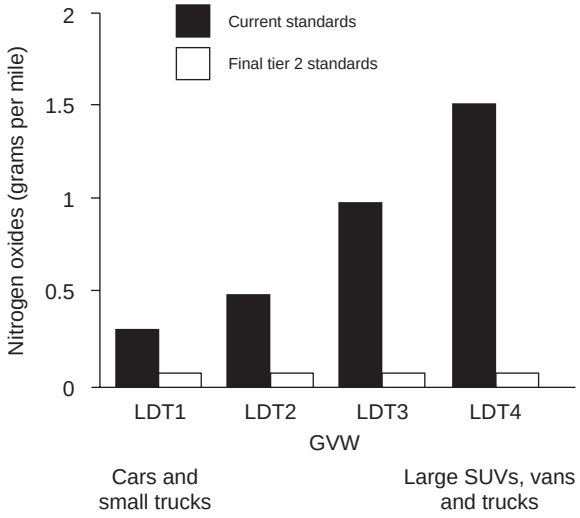

FIGURE 3 Comparison of current vehicle emission standards for nitrogen oxides and final tier 2 standards.

4.2 Safety

Numerous factors influence safety: vehicle design including mass, maneuverability, passenger restraints, driver age, driver sobriety, peripheral distractions, etc. Also significant are traffic design factors, such as traffic control lights, merging lanes, and speed limits. Figure 4 summarizes the history of death rates for vehicle crashes between 1950 and 1998 using three different normalizations. The lower curve (death rate per million population) initially exhibits a small increase followed by a continuing small decrease. The other two curves, the death rate per million vehicles and the death rate per 10 million miles traveled, show significant decreases over time. The complexity of and interaction between the factors causing traffic deaths (two-vehicle crashes, single-vehicle crashes, vehicle–pedestrian crashes, vehicle–fixed-object crashes, intoxication, speed, etc.) preclude simple conclusions and result in disagreement between authorities in the field.

4.3 Fuel Economy

From a national standpoint, fuel economy can be expressed in many different ways: per vehicle; per class of vehicle, car or light truck; a sales-weighted average for vehicles of a given classification from a given manufacturer; etc. For regulation purposes, the U.S. federal government uses the fuel consumption

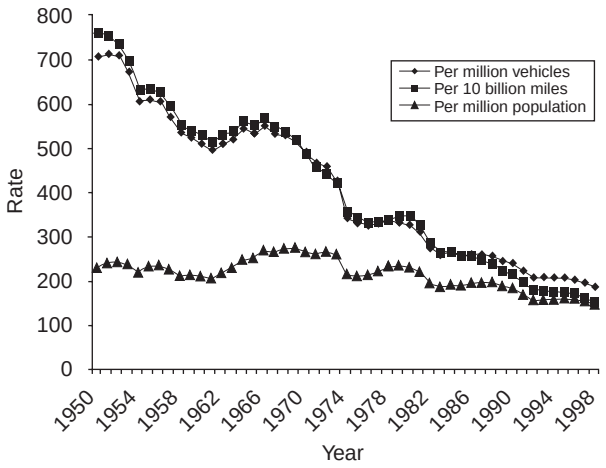

FIGURE 4 Motor vehicle crash death rate.

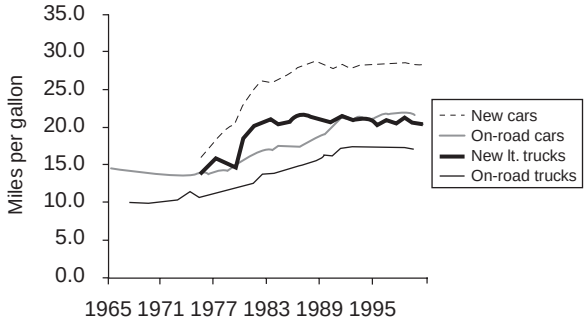

FIGURE 5 Fleet fuel economy of new and on-road passenger cars and light trucks.

results obtained from the emission-measurement test cycle. Figure 5 shows the history of fleet fuel economy for cars and light trucks as well as their on-road fuel economy. The difference between chassis-measured fuel economy and on-road fuel economy is significant. Figure 6 also shows trends in fuel economy-related characteristics of passenger cars, whereas Fig. 7 shows the fuel economy trends for light trucks. In both cases, miles per gallon has been relatively constant, probably reflecting the fact that the CAFE requirements have not changed. It is worth noting that horsepower/pound, or kilowatts/kilogram, has increased more rapidly for passenger cars than for light trucks, and weight has remained relatively constant for cars but increased slightly for light trucks. Figure 8 illustrates a different aspect of fuel economy, total fleet fuel economy. As shown in Fig. 8, the percentage of light trucks, which consume more gallons per mile (or liters per kilometer) than cars, has increased significantly in the past two decades. Consequently, the total fleet fuel economy

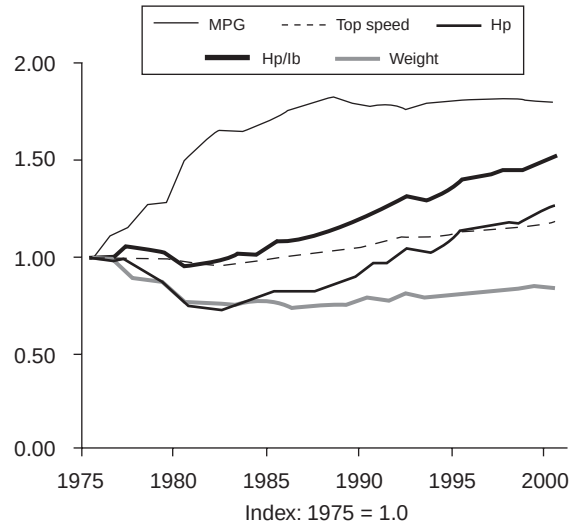

FIGURE 6 Trends in fuel economy-related characteristics of passenger cars, 1975–2000.

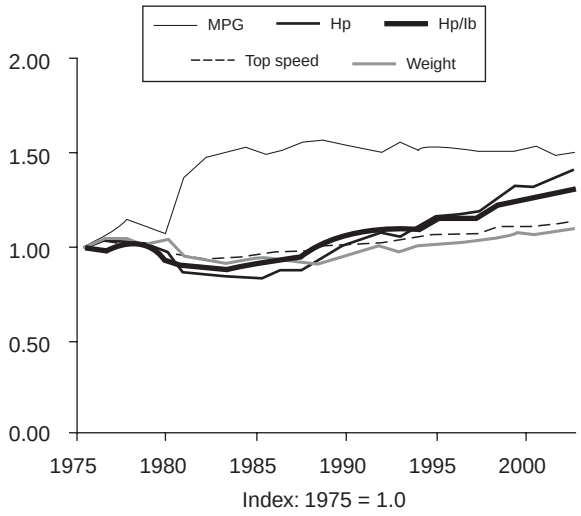

FIGURE 7 Trends in fuel economy-related characteristics of light trucks, 1975–2000.

(the "both" curve in Fig. 8) has decreased during the past decade.

4.4 Customer Preferences

Customer preferences, expressed at the time of purchase, depend on many factors and cover a range of costs. The time interval over which consumer preferences change varies from a few years to more than a decade. These preferences may be in contrast to general goals targeted by regulations. For example, consider vehicle volume. Figure 9 shows car interior volume for domestic (United States),

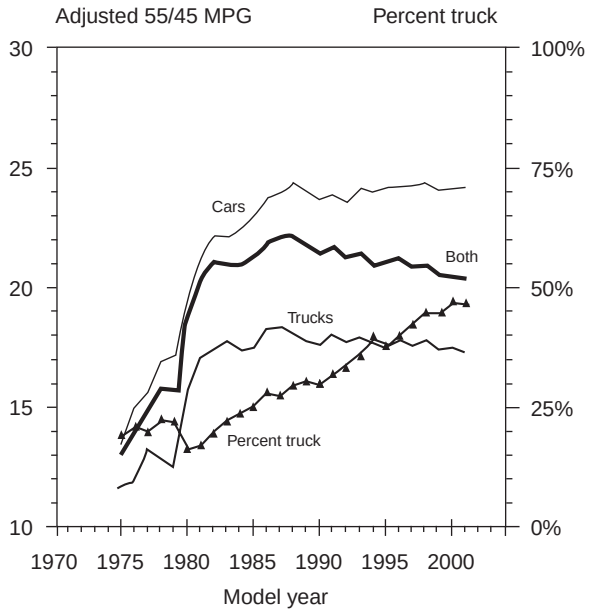

FIGURE 8 Miles per gallon versus model year of cars and light trucks and light truck percentage of sales.

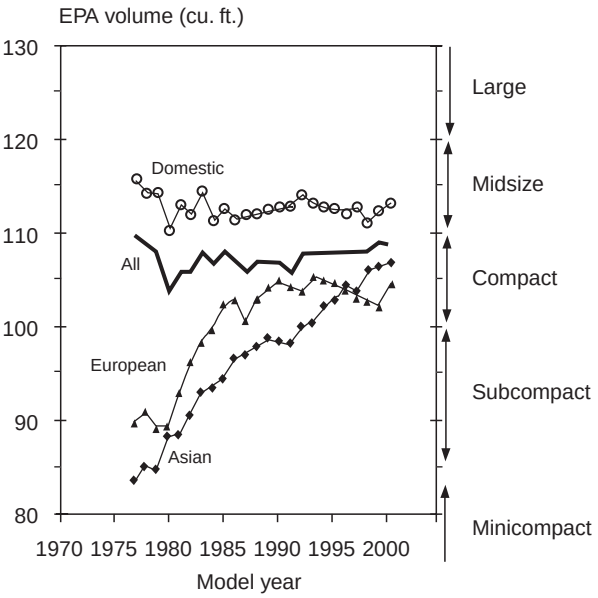

FIGURE 9 Car interior volume as a function of time.

European, Asian, and all as a function of model year. The volume of domestic cars remained essentially constant, whereas the volumes of European and Asian cars increased significantly. This increase reflects changes in vehicle sales. Initially, the foreign vehicles sold were compact or smaller vehicles; the progression in size simply reflects the strong U.S. market demand for high interior-volume vehicles. Another example is vehicle acceleration, typically

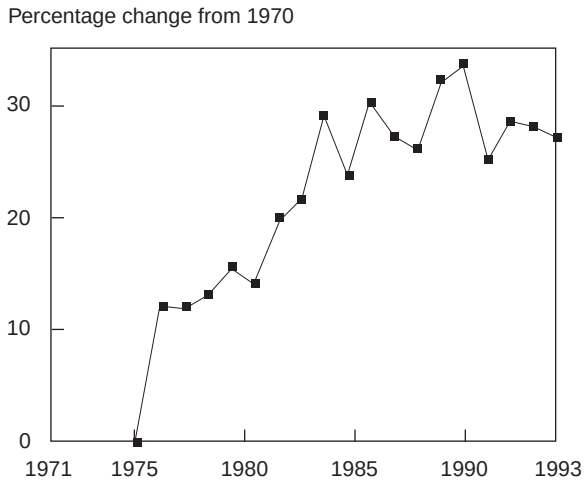

FIGURE 10 The increase in technical efficiency in new U.S. passenger cars, model years 1971–1993.

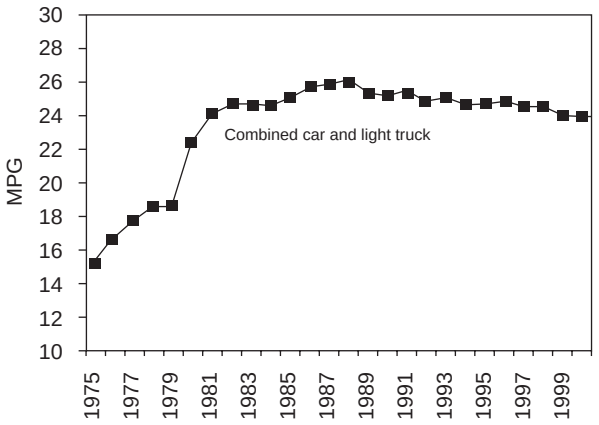

FIGURE 11 Fuel economy history of combined car and light truck.

expressed as the time, in seconds, to go from 0 to 60 miles per hour. High acceleration is of special interest when passing or merging. However, there is a trade-off between acceleration and fuel economy. There have been significant increases in technical fuel efficiency in new U.S. passenger cars (Fig. 10). However, this increase in technical efficiency has not necessarily translated into decreased fuel consumption.

To quote John German of Honda,

> *There is a misconception that vehicle manufacturers have not introduced fuel-efficient technology since the mid-1980s. This is understandable, as the car and light truck CAFE have remained constant for the past 15 years and the combined fleet has gone down due to increasing light truck market penetration as shown in Fig. 1 [Fig. 11]. However, there has been a substantial amount of fuel efficiency*

technology introduced in this time period. Some examples for the entire car and light truck fleet from EPA's 2000 "Fuel Economy Trends" are shown in Fig. 2 [Fig. 12]. However, this new technology has been employed more to respond to vehicle attributes demanded by the marketplace than to increase fuel economy. Over the past two decades consumers have insisted on such features as enhanced performance, luxury, utility, and safety, without decreasing fuel economy. Figure 3 [Fig. 13] shows the changes in vehicle weight, performance, and proportion of automatic transmissions since 1980 in the passenger car fleet. It is clear that technology has been used for vehicle attributes which consumers value more highly than fuel economy. Figure 4 [Fig. 14] compares the actual fuel economy for cars to what the fuel economy would have been if the technology were used solely for fuel economy instead of performance and other attributes.

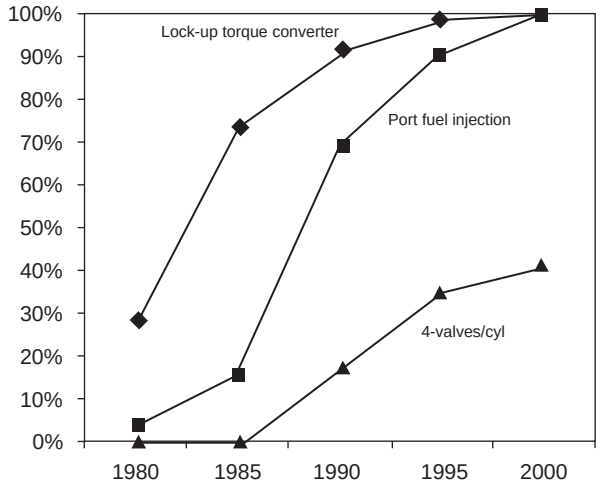

FIGURE 12 Examples of efficiency technology introduced since 1980.

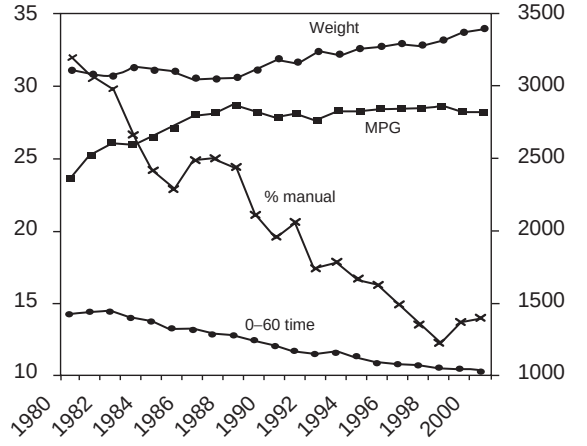

FIGURE 13 Changes in vehicle weight, fuel economy, proportion of automatic transmission, and acceleration time since 1980.

When considering vehicle trends, it is imperative to distinguish between individual and fleet trends. For example, Figs. 6 and 7 show vehicle weights remaining relatively constant with time. A different picture is obtained when the sales fraction of vehicles is included. Environmental Protection Agency data (Figs. 15 and 16) show a clear customer preference for cars and light trucks that are heavier. A similar picture is obtained when examining fuel economy; that is, a higher percentage of customers are purchasing new vehicles in the light truck category, resulting in a decrease in total fleet fuel economy even though the fuel economy standards for both cars and light trucks have remained constant.

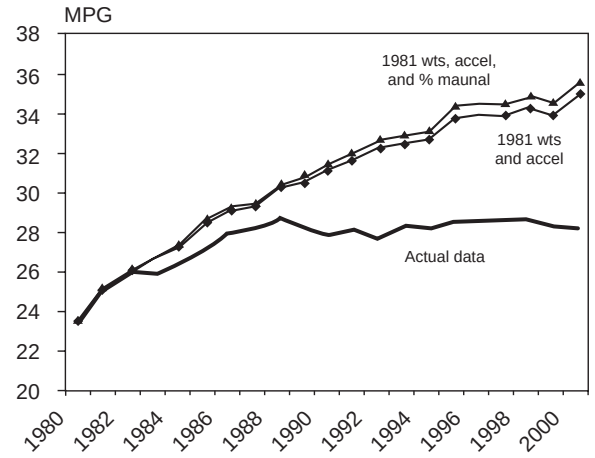

FIGURE 14 Fuel economy that could have been obtained if advanced technology had been used to increase fuel economy.

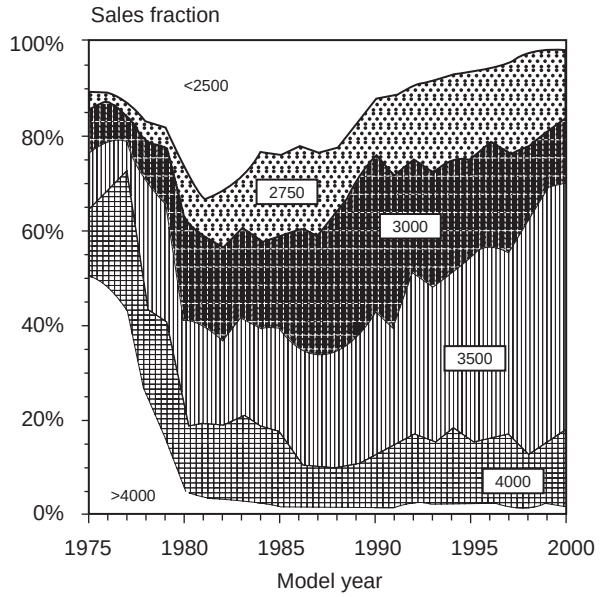

FIGURE 15 Changes in inertia weight class of cars with time.

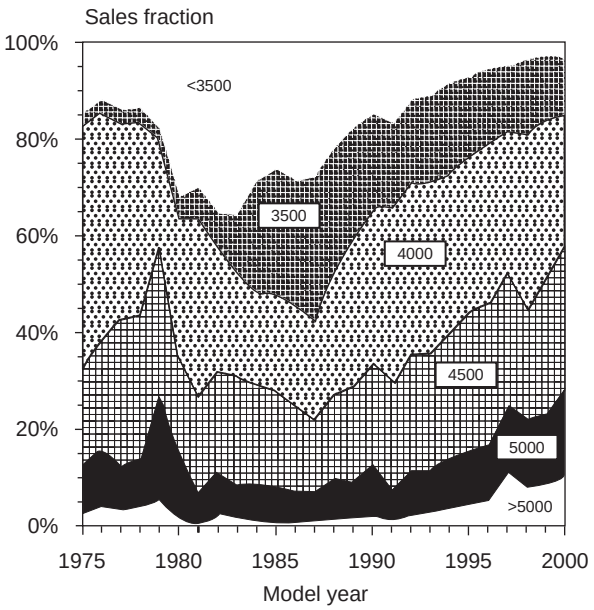

FIGURE 16 Changes in inertia weight class of light trucks with time.

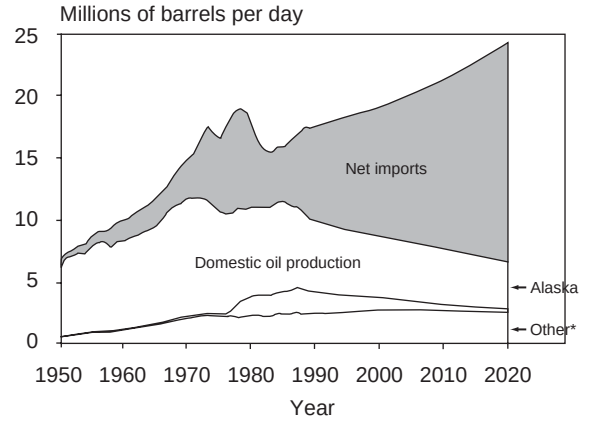

FIGURE 17 U.S. oil import trends. *Natural gas liquids and other.

4.5 Fuel Availability and Cost to Consumer

The United States has been the largest consumer of petroleum-based transportation. Prior to the past decade or two, the discovery of new petroleum resources in the United States kept pace with the increased usage. However, as shown in Fig. 17, an increasing amount of the petroleum used in the United States has been supplied by importation; it appears that this trend will increase with time. As shown in Fig. 18, the cost of gasoline to the consumer, expressed in constant dollars, has decreased with time. Note also that the average annual miles driven per car in the United States has increased slightly with time. Figure 19 suggests that there is a relationship between taxation rate and per capita consumption of petroleum.

5. ENERGY SOURCES FOR GROUND VEHICLES

Essentially all cars and light trucks have internal combustion engines using petroleum as their primary energy source. Optimum performance of a given type of internal combustion engine is achieved when fuel characteristics are optimized for that type of engine (e.g., diesel fuel, jet fuel, and gasoline).

All aspects of providing fuel to the vehicle must be considered. Because the fuel is necessarily combustible, fire and explosions during production, storage, distribution, and use are a common concern. Appropriate safeguards and distribution procedures must be followed. These are not without cost. In addition to the emissions from the vehicle, emissions during fuel procurement, modification, and use are also of concern. Consequently, to obtain a true picture of the global impact of using a particular fuel, engine, and vehicle combination, the "well-to-wheels" assessment, as described by Louis, should be used in all efficiency and emission analyses. For example, an electric vehicle is not truly a zero emission vehicle. Generating the electricity to charge the batteries is not without environmental impact.

A vehicle's range depends on both the overall operational efficiency of the vehicle and the amount of energy that can be stored onboard as fuel. To satisfy current consumer demands, energy density of the fuel used in the vehicle must be sufficiently high to yield a vehicle driving range in the hundreds of miles with an acceptable size and weight of the fuel storage tank. Figure 20 shows large differences in required tank volume and weight between different "energy carriers" (i.e., fuels). Although some progress has been made, Fig. 20 illustrates one of the reasons why vehicles using batteries for energy storage have had limited success in the marketplace. Hybrid vehicles, which accomplish battery recharging via engine and wheel generators, overcome this limitation and show significant improvement in fuel economy. They are in limited production. However, with today's gasoline prices in the United States, they are not cost-effective. As another example, solar energy falling on $1\,m^2$ is approximately equal to 1 horsepower (0.745 kW). Consequently, if solar energy is to be used extensively

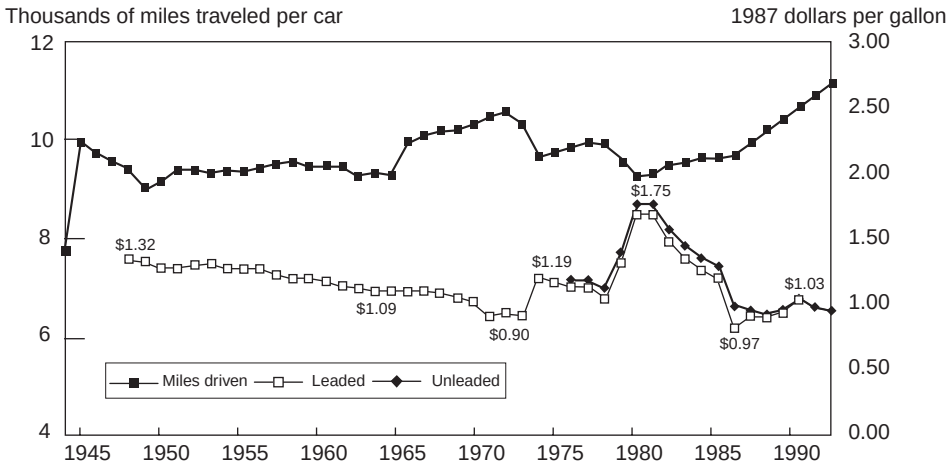

FIGURE 18 Real gasoline prices and annual miles driven per car, United States.

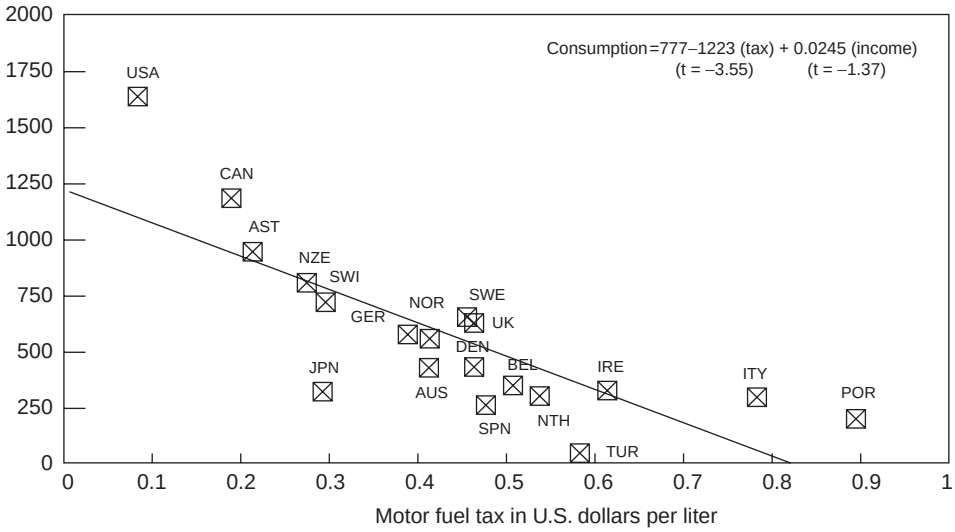

FIGURE 19 Relationship between motor fuel consumption and tax rates.

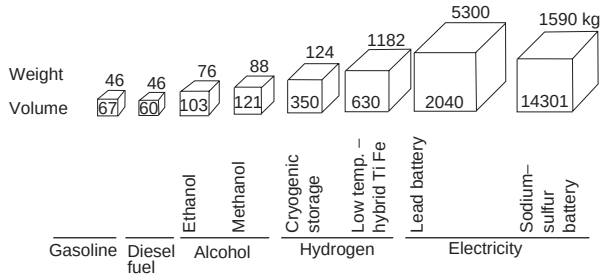

FIGURE 20 Tank volume and weight required for various energy carriers based on 55 liters of gasoline. Source: Sieffert and Walzer (1990).

for transportation, energy conversion and storage will be essential elements.

Increasing concern about greenhouse gas emissions may result in additional legislation affecting fuel economy. For example, California passed a law similar to other exhaust emission restrictions, limiting the permissible output of greenhouse gases per unit distance. Decreases in fuel consumption are the most obvious way to meet such a regulation. Whether the law will stand up in court is not known. However, the implication of the regulation in question is clear: Reduce CO_2 emissions via reduced fuel consumption.

6. PROGNOSIS FOR THE FUTURE

6.1 Maximum Fuel Energy Recoverable as Work

As indicated previously, when using an internal combustion engine the maximum fuel energy that

can be theoretically converted to work is the Gibbs free energy, which for hydrocarbon fuels is approximately equal to heating value of the fuel. In today's transportation market, the only engines used, or proposed for use, are internal combustion engines. Consequently, the thermodynamic efficiency of all transportation engines is computed as the ratio of the work obtained from the engine to the energy content of the fuel consumed to obtain that work, which is the heating value of the fuel: It has a maximum theoretical value of 100%. This is true for diesels, spark ignition engines, fuel cells, humans, animals, etc. Irreversibilities that naturally occur in all real processes decrease the thermodynamic efficiency actually obtained.

6.2 Where Fuel Energy Is Used, Reductions and Recovery

Figure 21 illustrates that fuel consumption is a result of the system efficiency and road load. The system efficiency is determined by the power plant and the driveline, which consists of the transmission and the final drive gear. Fuel is consumed and power is produced in an internal combustion engine (gasoline, diesel, fuel cell, etc.). A transmission (mechanical, electrical, hydraulic, etc.) and final drive are used, insofar as possible, to match the operation of the power plant to its optimum efficiency for each of the widely varying power requirements demanded during the driving cycle. In addition, power is also needed for consumer-demanded amenities. The road load of the vehicle includes aerodynamic drag, rolling resistance, and weight resulting in inertia. A vehicle must be moving to experience a road load. However, system power can be expended whether or not the vehicle is moving via the transmission, generator/alternator, water pump, amenities, etc. The magnitude of these expenditures is shown in Fig. 22.

Fuel consumption is determined by the integrated operation of the total system. It should be emphasized that the components of the system are interactive. How the functions of these components are achieved in future vehicles may be impacted by new technologies. The subsequent impact on fuel consumption will be dependent on how the interaction of the various components is integrated, the extent to which consumer desires continue along current trends, and how manufacturers choose to implement the capabilities of the new technology. To make projections of potential fuel economy gains requires assessing these trends and will be subject to significant engineering judgment. Comparisons of more detailed estimations are presented later.

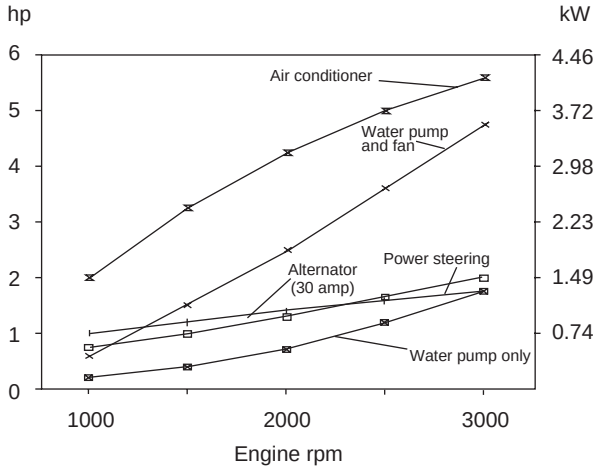

FIGURE 22 Accessory power requirements (full-size sedan).

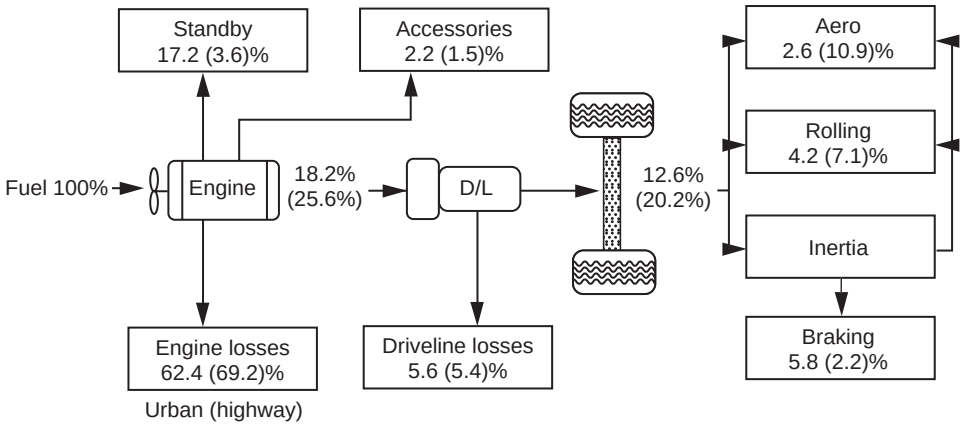

FIGURE 21 Energy flow diagram for a midsize car. Source: DOE (1994).

6.2.1 Power Plant

The power plant (engine) in Fig. 21 converts fuel energy into useful work to power the vehicle and customer-desired amenities. In a reciprocating engine, the work delivered to the top of the piston is called indicated work. The work ultimately delivered to drive the wheels is less than the indicated work because work is required to pump gases (air, fuel, and exhaust) into and out of the engine, overcome the friction of the engine, drive components, and drive amenities (Fig. 22). Figure 23 shows that for gasoline engines the maximum brake thermal efficiency achieved has increased with time. However, engines used in transportation vehicles necessarily work over a wide range of loads and speeds, with subsequent variations in brake thermal efficiency. This can be seen in an engine map as shown in Fig. 24. Diesel engines typically have higher maximum brake thermal efficiencies and different speed-torque maps than do spark ignition engines. Figure 25 shows the relationship between the equivalent of brake thermal efficiency and load for a fuel cell. Notice that the efficiency of the fuel cell declines significantly as the load increases. This is opposite the behavior of a typical spark ignition engine, whose efficiency increases with load.

During operation of the engine, fuel consumption can be decreased by increasing indicated efficiency or decreasing ancillary losses, such as rolling resistance, aerodynamic drag, or accessory power consumption. Fuel consumption can also be decreased at constant brake thermal efficiency. For example, essentially instantaneous engine starting is being introduced. This permits automatically turning off and restarting the engine during stops, coasting, etc. This does not change the efficiency of the engine when it is operating, but it does decrease fuel consumed during the driving cycle, and it also results in lower values of integrated emissions.

One of the reasons the indicated efficiency of the diesel engine is higher than that of the spark ignition engine is because its pumping losses are lower. Variable valve timing in spark ignition engines may be able to offset some of these pumping losses. Valve timing can be varied to increase indicated efficiency in a variety of ways. The engine can be run as a variable displacement engine (displacement on demand). All cylinders are active (large displacement) for high load operation, whereas some cylinders are deactivated (smaller displacement) for lighter load operation.

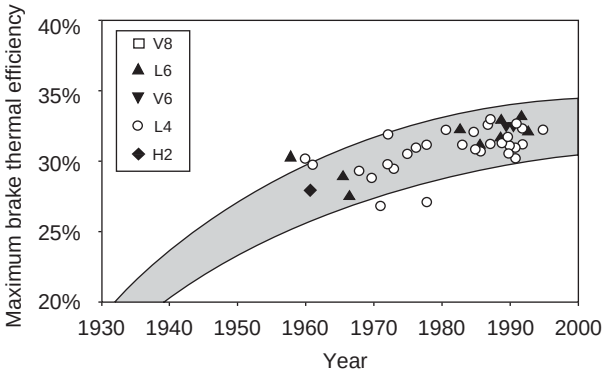

FIGURE 23 Brake thermal efficiency of gasoline engines.

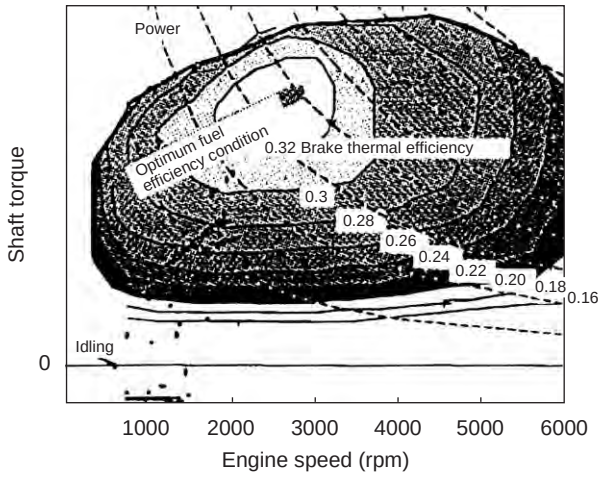

FIGURE 24 Engine brake thermal efficiency map for gasoline engines.

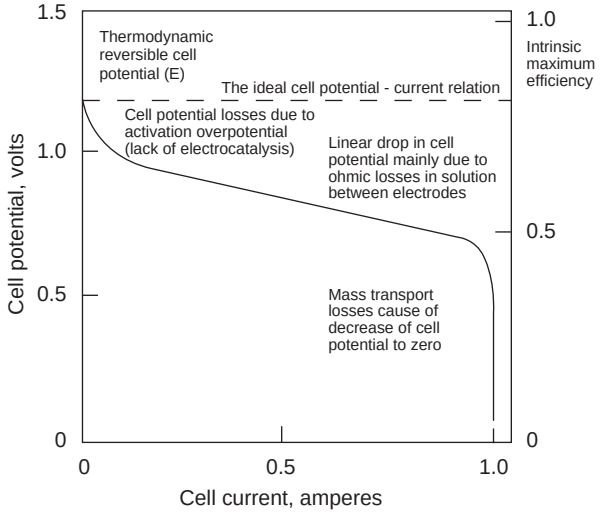

FIGURE 25 Typical plot of cell potential vs current for fuel cells.

Improved surface finishing of engine parts permits use of lower viscosity lubricants to reduce engine friction. Ringless carbon pistons are claimed to have lower weight, a lower coefficient of thermal expansion, and reduced friction. However, the introduction of new technologies can result in some detriments as well as benefits. For example, the more sophisticated valve mechanisms, which allow variable displacement operation, may result in higher frictional loads and more weight than the simpler valve trains they replace. This increased friction and weight would be a detriment and would have to be evaluated against the benefit achieved. As mentioned previously, trends in consumer demand also play a role. Accessory loads have continued to increase with time: We are demanding more amenities in our vehicles.

6.2.2 Transmission

The transmission (driveline) in Fig. 21 is intended to permit the engine to operate at a speed that will give minimum fuel consumption while still delivering the desired torque. This is accomplished by "stepping" through different ratios of engine speed to wheel speed (i.e., permitting the engine to operate as closely as possible to the minimum fuel consumption points on the engine map; Fig. 24). A large number of transmission steps provides the flexibility for a better match (i.e., lower fuel consumption) but may result in undesirable shifting patterns when the load is changed suddenly. Today's transmissions typically have three to five steps. The efficiency of manual shifting transmissions is quite high but requires active participation of the driver in determining shift points and therefore performance. The inclusion of a torque converter and automatic shifting improves consumer-demanded performance but may increase fuel consumption slightly. Continuously variable transmissions (CVTs) have, in concept, an infinite number of steps, but current designs tend to be power limited. Figure 26 illustrates how a CVT permits engine operation to minimize fuel consumption.

6.2.3 Aerodynamic Drag and Rolling Resistance

The road load is the power required to move the vehicle down the road. Figure 27 shows a representative proportioning of the road load between aerodynamic drag, rolling resistance, and inertia for both city and highway driving. The aerodynamic drag and rolling resistance portions of the road load increase with speed. Figure 28 shows the energy from the fuel needed to overcome aerodynamic drag and rolling resistance. This energy is dissipated and not

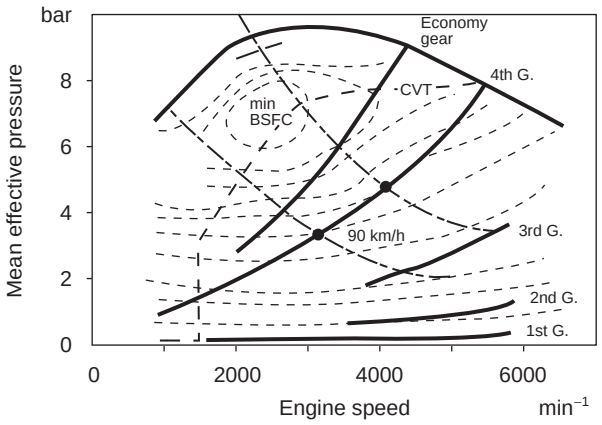

FIGURE 26 Engine map showing the line for a continuously variable transmission.

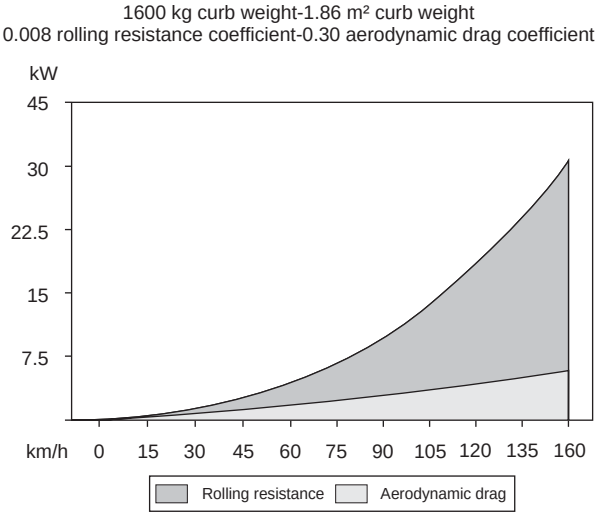

FIGURE 27 Steady-state road load of a full-size car.

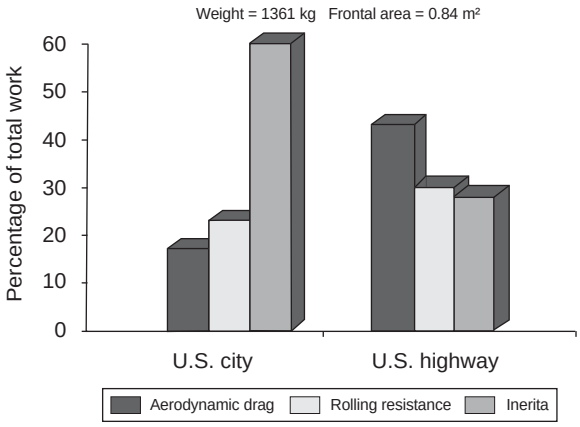

FIGURE 28 Driving cycle load comparisons.

recoverable as work. Consequently, efforts must be made to minimize aerodynamic drag and rolling resistance. Throughout the years, the rolling resistance of tires has been reduced, but there are tradeoffs: Wear, traction, ride, etc. may be compromised. Aerodynamic drag, which varies as the square of the speed, has been reduced over time in some vehicles (Fig. 29). However, in advanced vehicles aerodynamic drag seems to be close to minimum values. Considering the current price of gasoline, and that a significant fraction of public driving is at low to moderate speeds, the interaction between design characteristics of minimum drag vehicles and other desired consumer characteristics such as interior volume provides little incentive to reduce drag further.

6.2.4 Inertia Weight

Additional fuel is consumed when the kinetic or potential energy of the vehicle is increased. This occurs when accelerating or climbing a hill. Assuming reversible storage and recovery, this energy could theoretically be completely recovered and stored for future use. This would be accomplished by converting the vehicle's potential or kinetic energy into electrical energy and storing the electricity in a battery, for example. This is one of the ways in which fuel consumption is reduced in a hybrid car.

6.2.5 Onboard Energy Storage

Gasoline and diesel fuels have very high-energy storage densities (Fig. 20). For electric energy, the energy storage density is highest for advanced batteries but still not comparable with gasoline (Fig. 20). Electric hybrid vehicles try to overcome storage density limitation by retaining gasoline, or diesel fuel, as the primary energy storage media. Electricity generation, with temporary storage, occurs on the vehicle along with recapturing the vehicle's kinetic and potential energy through regenerative braking. However, the rate of charging required to capture the electricity that is being produced by regenerative braking often exceeds current battery capabilities. The noncaptured energy must be dissipated by the brakes and is lost. Exchange efficiencies are low for batteries (approximately 50%). Hydraulic storage exchange efficiencies are higher (85–90%), but energy storage densities are as much as an order of magnitude less than for batteries.

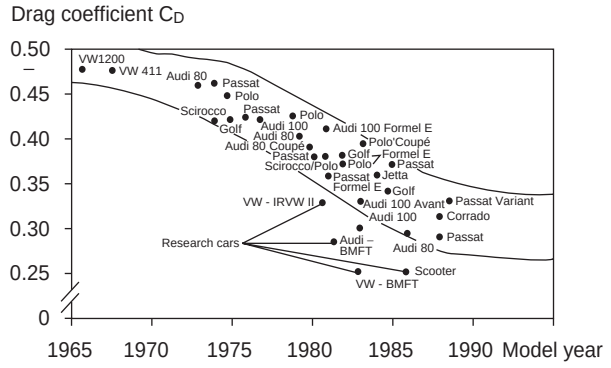

FIGURE 29 Drag coefficient improvements made over the years (VW–Audi models).

There is potential for a safety problem with hybrid vehicles, particularly if the power derived from the temporary energy storage is a large fraction of the total engine plus stored-energy power system. For example, performance in critical situations such as passing on a long hill, when the temporary energy storage is nearly depleted, could be a safety problem.

6.2.6 Estimates of the Costs of Reducing Fuel Consumption

Integrating new technologies into a vehicle to reduce fuel consumption must be cost-effective and acceptable to consumers. As seen in Fig. 21, the propulsion system is complex and must meet a number of constraints. It must operate over a driving cycle in which vehicle speed and load vary widely; meet mandated, increasingly restrictive emission and safety standards; and meet customer needs and desires (fads), etc. The ideal first step in choosing potential new technologies would be to mathematically estimate reductions in fuel consumption using these technologies when the vehicle is "driven" over the appropriate test cycle and then estimate the cost of the new or revised propulsion system. However, performance of new system components is almost inevitably not well defined, especially when projecting into the future. Production numbers and costs estimates for new systems are estimates. Consequently, it is not surprising that fuel economy and cost estimates for proposed future vehicles differ widely.

The ideal, but impractical, approach to predicting potential fuel economy gains would be to construct a complete, detailed mathematical model of the vehicle and its proposed propulsion system and drive the vehicle over the test cycle. A less precise method is to use a multiplicative technology menu approach. The literature reports many such approaches, and the results obtained span a range of predicted fuel consumption reductions. Most studies conclude that there is a clear technical potential to significantly reduce fuel consumption of light-duty cars and trucks.

TABLE I

Comparison of Performance Characteristics between the Aluminum Cow and a Stock Taurus

	Aluminum cow	Stock taurus
Fuel economy (mpg)	65	25
Weight (lbs)	2800	3400
1/8-mile acceleration event (s)	10.7	11.2

As further evidence of the technical potential to reduce fuel consumption, consider the results of a competition. In 1998 and 1999, the Society of Automotive Engineers sponsored a student competition to achieve low fuel consumption. A team of student engineers assembled the "aluminum cow" using a 1994 Ford Taurus aluminum body and a diesel–electric hybrid. Table I lists comparative performance characteristics between the aluminum cow and a stock Taurus.

However, as discussed previously, the manufacturer of a vehicle must take into account many other factors that were not part of the competition, such as incremental cost of the vehicle, environmental impact of its manufacture, sales appeal, and safety.

7. CONSIDERATIONS AND PROBLEMS IN REDUCING FUEL CONSUMPTION

The inherent advantages of current internal combustion engines (diesel, spark ignition, or fuel cell), make these engines preferable energy converters for personal mobility purposes. It is technically possible to achieve significant improvements in the fuel economy of cars and light trucks using internal combustion engines. However, there is no simple or definitive path to be followed to get more fuel-efficient vehicles into the fleet. Figure 30 illustrates the many considerations that vehicle manufacturers must take into account if for a vehicle to be marketable.

The diesel engine is a specific example of these complex considerations. A modern diesel engine is indistinguishable from a gasoline engine either by sound or exhaust color and visibility. It has significantly lower fuel consumption but higher initial cost than a comparable gasoline engine. Because of the inherent differences between the two engines, they have different exhaust emission characteristics, which present different challenges in meeting regulated emission standards. In Europe, where fuel prices are two or three times higher than

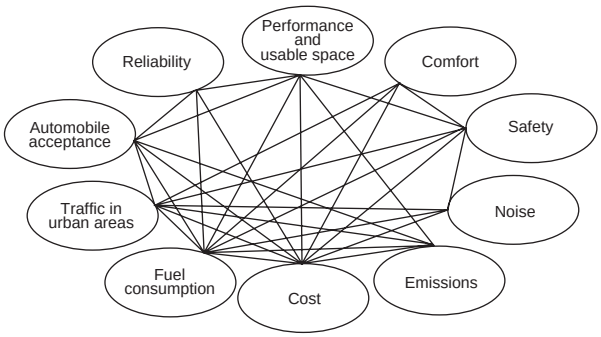

FIGURE 30 Interrelationships between requirements for an automobile.

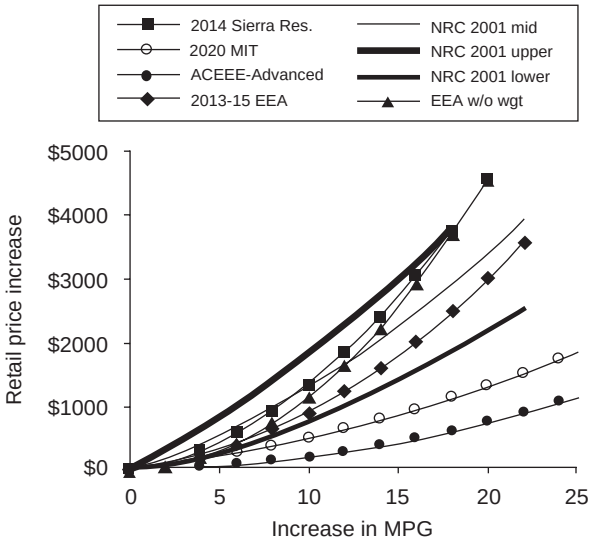

FIGURE 31 Passenger car fuel economy cost curves from selected studies.

the U.S. price, approximately half of new cars sold use diesel engines. Diesel sales in the United States are essentially zero. Proposed U.S. 2007 automotive particulate (smoke) regulations are significantly more restrictive than those for the same time period in Europe. This would mandate inclusion of even more advanced, and expensive, technology for diesel engines to be able to meet the emissions regulations. When fuel is inexpensive, the increased cost to the consumer of the more technologically advanced vehicle may exceed the savings from reduced fuel consumption. Figures 31 and 32 show the break-even price increase, obtained from different studies for passenger cars and light trucks, that would be acceptable through specific increases in miles per gallon. Finally, assuming the vehicle is marketable, it will still take a decade or two for the new technology to penetrate the fleet to the extent that it will influence fleet fuel economy (Fig. 33).

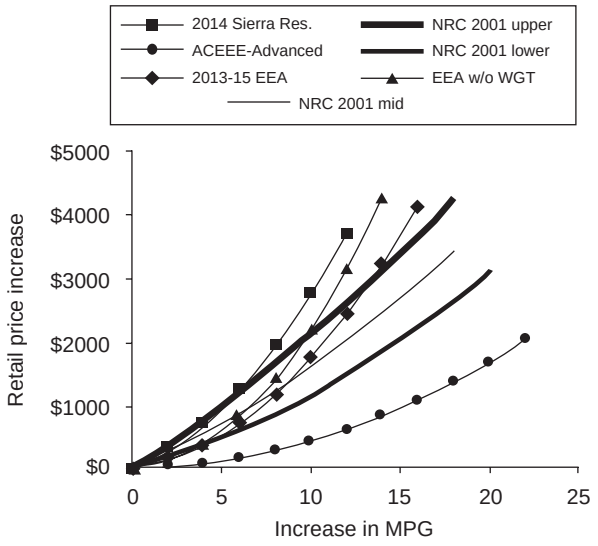

FIGURE 32 Light truck fuel economy cost curves from selected sources.

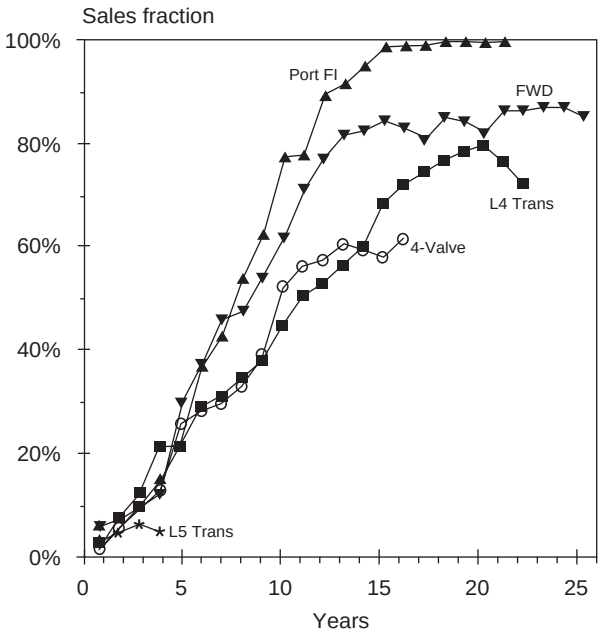

FIGURE 33 Car technology penetration: Years after first significant use.

There is no clear-cut and simple approach to achieving lower fuel consumption and more environmentally benign vehicles. However, there are many practical realities that cannot be dismissed. Because of their high energy density and ease of processing, transport, and storage, petroleum-based fuels, or more generally hydrocarbon fuels, are very well suited for mobility power plants. Potential alternative fuels or power plants all have significant shortcomings that need to be overcome. There are many pending issues. As shown in Fig. 17, the bulk of petroleum used in the United States is imported, and the percentage is increasing. Also, annual per capita travel is increasing with time. The current cost of petroleum in the United States does not explicitly include the costs of ensuring access to petroleum reserves outside of the United States or the impact of its use on health and the environment. Established petroleum reserves are typically discussed in terms of tens to hundreds of years, not thousands. The rapidly growing demand for petroleum by nations such as China and India will put additional strain on petroleum reserves. Increased use of petroleum because of an increased number of vehicles and increased demand for mobility will increase the emission of greenhouse gases into the atmosphere as well as the load on petroleum reserves.

When attempting to decrease the fuel consumption of the light-duty car and truck fleet, there are many problems to be solved. At the current price of gasoline in the United States, fuel economy is simply not a high priority for a prospective purchaser of a vehicle. Taxes on the fuel used by cars and light-duty trucks in the United States are relatively low in comparison to those of the rest of the industrial world (Fig. 19). The current U.S. fuel consumption control system, CAFE, is antiquated and works on the supply side. Consider that in the past decade U.S. fleet fuel economy has decreased significantly even though CAFE standards have remained constant. The European Union system for moderating consumption (increased taxation) works on the demand side and aligns consumer choice and use patterns with public policy objective, as evidenced by the increasing percentage of low fuel consumption vehicle technologies being introduced into the European market.

If major geopolitical catastrophes can be avoided, the increasing world population along with our increasing demand for personal mobility portend a necessary reduction in per capita fuel consumption. This will be necessary to preserve natural resources and to address the increased stress that our activities are placing on the ecosystem. This much is clear. The path by which we achieve this goal is not.

1. A Brief History of Weapons
2. Energy Costs and Consequences of War
3. Energy as the Cause of War

Glossary

explosives Compounds whose destructive effect results from virtually instantaneous release of kinetic energy that is generated either by internally oxidized chemical reactions that produce large and rapidly expanding volumes of gas (chemical explosives) or by fission of heavy nuclei or fusion of light nuclei (nuclear explosives).

intercontinental ballistic missiles (ICBMs) Missiles that can be launched from fortified silos or nuclear submarines and can carry a single warhead or multiple independently targeted reentry vehicles (MIRVs).

military spending A category of expenses whose definition varies widely among countries and is often greatly undervalued in official accounts; for example, official Soviet military spending included merely operation and maintenance costs, and the real total (including weapons research and development and production) was roughly an order of magnitude higher.

nuclear weapons Both strategic and tactical warheads, bombs, and munitions, carried by intercontinental ballistic and medium- and short-range missiles or delivered by bombers or field artillery, whose destructive power is released either through nuclear fission or, in thermonuclear weapons, through fusion.

Wars demand an extraordinary mobilization of energy resources, they represent the most concentrated and the most devastating release of destructive power, and their common consequence is a major disruption of energy supplies in regions or countries that were affected by combat or subjected to prolonged bombing. Given these obvious realities, it is inexplicable that wars have received very little attention as energy phenomena. At the same time, there is a fairly common perception—one that has been greatly reinforced by the American conquest of Iraq in 2003—that energy is often the main reason why nations go to war. This article addresses all of these concerns. Because the destructiveness of war depends largely on the weapons used, it first outlines their brief history. The energy cost of individual armed conflicts, as well as the peacetime energy cost of preparing for war, is difficult to assess, and the article presents some representative calculations and cites some recent statistics using the major 20th-century wars waged by the United States. Casualties are the most horrifying consequence of wars, and the greater destructive power led to their increase until the recent development of precision-guided munitions made it possible to minimize civilian deaths by careful targeting. Impacts of war on energy use during the conflict and in its aftermath, particularly in defeated countries that suffered a great deal of destruction, are clearly seen in consumption statistics. Finally, the article argues that the wish to be in actual physical control of energy resources has not been the sole reason, or even the primary reason, for any major modern armed conflict.

1. A BRIEF HISTORY OF WEAPONS

Weapons are the prime movers of war. They are designed to inflict damage through a sudden release of kinetic energy (all handheld weapons, projectiles, and explosives), heat, or a combination of both. Nuclear weapons kill nearly instantaneously by the combination of blast and thermal radiation, and they also cause delayed deaths and sickness due to the exposure to ionizing radiation. Classification of wars based on these destructive prime movers divides history into four distinct periods. All prehistoric, classical, and early medieval warfare was powered only by human and animal muscles. Invention of

 © 2004 Elsevier Inc. All rights reserved.

gunpowder led to a rapid diffusion of initially clumsy front- and breach-loading rifles and to much more powerful field and ship guns.

By the late 1860s Nobel's combination of nitroglycerine and diatomaceous earth produced the first practical high explosive, and other variants were soon made into munitions for newly invented machine guns as well as into large-caliber gun shells and airplane bombs. Wars of the 20th century were dominated by the use of these high explosives delivered in shells (from land and ship-borne artillery and tanks), torpedoes, bombs, and missiles. Finally, strategic thinking and the global balance of power changed after World War II with the development of nuclear weapons.

The period of muscle-powered warfare lasted nearly until the very end of the Middle Ages. The daily range of advancing armies was limited less by the stamina of walking or running troops than by the speed of their supply trains, made up of animals ranging from oxen and horses in Europe to camels and elephants in Asia. Men used axes, daggers, swords, and lances in close combat and used spears and bows and arrows for attacking unprotected enemies as far as 200 m away. Much more powerful crossbows were used since the fourth century BC in both Greece and China. Inaccurate targeting and relatively low kinetic energy of these assaults (Table I) limited the magnitude and frequency of injuries that could be inflicted by these weapons. Massed human power was also used to wind winches of catapults and to move assorted siege machines designed to overcome urban fortifications.

TABLE I

Kinetic Energy of Projectiles

Weapon	Projectile	Kinetic energy (J)
Bow and arrow	Arrow	20
Heavy crossbow	Arrow	100
Civil war musket	Bullet	1×10^3
Assault rifle (M16)	Bullet	2×10^3
Medieval cannon	Stone ball	50×10^3
18th-century cannon	Iron ball	300×10^3
World War I artillery gun	Shrapnell shell	1×10^6
World War II heavy AA gun	High–explosive shell	6×10^6
M1A1 Abrams tank	Depleted U shell	6×10^6
Unguided World War II rocket	Missile with payload	18×10^6
Boeing 767 (September 11, 2001)	Hijacked plane	4×10^9

Light horses were initially used to pull chariots, and only after the general adoption of stirrups (beginning in the third century AD) did mounted warriors become a particularly effective fighting force. Asian riders were unarmored, but they had small and extraordinarily hardy horses and could move with high speed and maneuverability. These abilities brought the Mongol invaders from the heart of Asia to the center of Europe between 1223 and 1241. In contrast, European knights relied on their heavy armor as they rode increasingly heavier animals. Their most spectacular series of long-distance forays brought them as Crusaders from many countries of Europe to the Eastern Mediterranean, where they established temporary rule (between 1096 and 1291) over fluctuating areas of the littoral. The only important nonanimate energies used in the pre-gunpowder era were various incendiary materials (sulfur, asphalt, petroleum, and quicklime were used in their preparation) that were either fastened to arrowheads or hurled across moats and walls from catapults.

Gunpowder's origins can be traced to the experiments of medieval Chinese alchemists and metallurgists. Clear directions for preparing gunpowder were published in 1040, and eventually the proportions for its mixing settled at approximately 75% saltpeter (KNO_3), 15% charcoal, and 10% sulfur. Whereas ordinary combustion must draw oxygen from the surrounding air, the ignited potassium nitrate provides it internally and gunpowder undergoes a rapid expansion equal to roughly 3000 times its volume in gas. The first true guns were cast in China before the end of the 13th century, and Europe was just a few decades behind. Gunpowder raised the destructiveness of weapons and radically changed the conduct of both land and maritime battles.

When confined and directed in barrels of rifles, gunpowder could impart to bullets kinetic energy an order of magnitude higher than that of a heavy arrow shot from a crossbow gun, and larger charges in field artillery and ship guns could propel even heavy projectiles (Table I). Increasingly accurate gunfire from far beyond the range of archers eliminated the defensive value of moats and walls and did away with lengthy sieges of cities and castles. As a new defense, the fortified structures were built as low spreading polygons with massive earthen embankments and huge water ditches. French military engineer Sebastien Vauban became the most famous designer of these fortifications that embodied large

amounts of energy. His largest project, at Longwy in northeastern France, required moving 640,000 m^3 of rock and earth (volume equivalent to about a quarter of Khufu's pyramid) and emplacing 120,000 m^3 of masonry.

The impact of guns was even greater in maritime engagements. Detailed historical accounts document how gunned ships (equipped with two other Chinese innovations, compass and good rudders, as well as with better sails) became the carriers of European technical superiority. By the beginning of the 16th century, they were the principal means of global empire building by the nations of the Atlantic Europe. By the late 17th century, the largest "men-of-war" carried up to 100 guns each. Dominance of these ships did not end until the introduction of naval steam engines during the 19th century.

The next weapons era began with the formulation of high explosives, which are prepared by the nitration of organic compounds such as cellulose, glycerine, phenol, and toluene. Ascanio Sobrero prepared nitroglycerin in 1846, but its practical use did not begin until Nobel mixed it with an inert porous substance (diatomaceous earth) to create dynamite and introduced a practical detonator (Nobel igniter) without which the new explosive would be nearly impossible to use. A single comparison conveys the explosive power of dynamite: its velocity of detonation is as much as 6800 m/s compared with less than 400 m/s for gunpowder (Table II). Slower acting, and preferably smokeless, propellants needed for weapons were produced during the 1880s: *poudre B* (gelatinized and extruded nitrocellulose) by Paul Vieille in 1884, Nobel's own ballistite (using nitroglycerine instead of ether and alcohol) in 1887, and cordite, patented in England by Frederick Abel and James Dewar in 1889.

Ammonium picrate was prepared in 1886. Trinitrotoluene (TNT), which was synthesized by Joseph Wilbrand in 1863 and which must be detonated by a high-velocity initiator, was used as an explosive by the end of the 19th century. The most powerful of all prenuclear explosives, cyclonite (cyclotrimethylenetrinitramine, commonly known as RDX [royal demolition explosive] and now a favorite of some terrorists), was first made by Hans Henning in 1899 by treating a formaldehyde derivative with nitric acid (Table II). Better propellants and inexpensive, high-quality steels increased the power and range of field of naval guns from less than 2 km during the 1860s to more than 30 km by 1900. The combination of long-range guns, heavy armor, and steam turbines (a superior new prime mover invented by Charles Parsons during the 1880s that made much faster speeds possible) resulted in new heavy battleships, with *Dreadnought,* launched in 1906, being their prototype.

TABLE II

Detonation Velocity of Common Explosives

Explosive	Density (g/cm^3)	Detonation velocity (m/s)
Gunpowder	1.0	1350
Dynamite	1.6	5000
TNT	1.6	6700
RDX	1.8	8800
ANFO	1.0	3200

Other new highly destructive weapons whose use contributed to the unprecedented casualties of World War I included machine guns, tanks, submarines, and the first military planes (e.g., light bombers). The two decades between the world wars brought rapid development of battle tanks, fighter planes, and long-range bombers and aircraft carriers, all of which were the decisive weapons of World War II. The German defeat of France in 1940 and advances of Wehrmacht in Russia in 1941 and 1942 were made possible by rapid tank-led penetrations. Japan's surprising assault on Pearl Harbor on December 7, 1941, would have been impossible without a large carrier force that launched fighter planes and dive bombers. The same types of weapons—Soviet T-42 tanks driving all the way to Berlin and American dive bombers deployed by the U.S. Navy in the Pacific—eventually led to the defeat of the Axis.

The closing months of World War II saw the deployment of two new prime movers and of an entirely new class of weapons. Gas turbines, independently invented during the 1930s by Frank Whittle and Hans Pabst von Ohain in the United Kingdom and Germany, respectively, were installed in the first jet fighters (the British Gloster Meteor and the German Messerschmitt 262) in 1944. During that same year, rocket engines were used in the German ballistic missile V-2 to terrorize England. And the first fission bomb was tested at Alamogordo, New Mexico, on July 11, 1945, with the second one destroying Hiroshima, Japan, on August 6, 1945, and the third one destroying Nagasaki, Japan, 4 days later.

Jet propulsion enabled the fastest fighter aircraft to surpass the speed of sound (in 1947) and eventually to reach maximum velocities in excess of mach 3. The postwar arms race between the United States and the Soviet Union began with the assembly of more

powerful fission bombs to be carried by strategic bombers. The first fusion bombs were tested in 1952 and 1953, and by the early 1960s the two antagonists were engaged in a spiraling accumulation of intercontinental ballistic missiles (ICBMs). But these are not technically weapons of war given that their real purpose was to deter their use by the other side. However, to achieve this objective, the superpowers did not have to amass more than 20,000 nuclear warheads. The sudden end of this expensive arms race did not usher in an era of extended peace; ironically, it initiated an era of even more acute security threats.

In a complete reversal of dominant concerns, the most common—and generally the most feared—weapons in the new war of terror are both inexpensive and easily available. A few kilograms of high explosives fastened to the bodies of suicide bombers (often spiked with metal bits) can cause dozens of deaths and gruesome injuries and can create mass psychosis among the attacked population. Simple "ANFO" car bombs are much more devastating (Table III). These devices, some of which weigh hundreds of kilograms and are able to destroy massive buildings and kill hundreds of people, are made from the mixture of two readily available materials: ammonium nitrate (a common solid fertilizer that can be purchased at, or stolen from, thousands of locations around the world) and fuel oil (which is even more widely available).

The most shocking weapons were fashioned on September 11, 2001, by 19 Islamic hijackers simply by commandeering rapidly moving massive objects, Boeings 757 and 767, and steering two of them into the World Trade Center in New York and one into the Pentagon in Washington, D.C. The World Trade Center towers were designed to absorb an impact of a slow-flying Boeing 707 lost in the fog and searching for a landing at the JFK or Newark airport. Gross weight and fuel capacity of that plane are just slightly smaller (15 and 5%, respectively) than the specifications for the Boeing 767-200, and the structures performed as intended even though the impact velocity of hijacked planes as they rammed into the buildings was more than three times higher (262 vs 80 m/s) than that of a slowly flying plane close to the landing.

As a result, the kinetic energy at impact was approximately 11 times greater than envisaged in the original design ($\sim$4.3 GJ vs 390 MJ). But because each tower had the mass of more than 2500 times that of the impacting aircraft, the enormous concentrated kinetic energy of the planes acted much like a bullet hitting a massive tree. That is, it penetrated instead of pushing; it was absorbed by bending, tearing, and distortion of structural steel and concrete; and the perimeter tube design redistributed lost loads to nearby columns. Consequently, it was not this instantaneous massive kinetic insult but rather a more gradual flux of the ignited fuel (each 767 carried more than 50 metric tons (t) of kerosene whose heat content was more than 2 TJ) that weakened the columns of structural steel.

TABLE III

Kinetic Energy of Explosives and Total Energy Released by Nuclear Weapons

Explosive device	Explosive	Kinetic energy (J)
Hand grenade	TNT	2×10^6
Suicide bomber	RDX	100×10^6
World War II gun shrapnell	TNT	600×10^6
Truck bomb (500 kg)	ANFO	2×10^9
Nuclear bomb	**Reaction**	**Total energy (J)**
Hiroshima bomb (1945)	Fission	52×10^{12}
U.S. ICBM	Fusion	1×10^{15}
Novaya Zemlya bomb (1961)	Fusion	240×10^{15}

Unfortunately, an eventuality of such a fire was not considered in the original World Trade Center design. Moreover, no fireproofing systems to control such fires were available at that time. Once the jet fuel spilled into the building, it ignited an even larger mass of combustible materials (mainly paper and plastics) inside the structures, and the fires burned with a diffuse flame with low-power densities of less than 10 W/cm^2. This left enough time for most people to leave the buildings before the thermally weakened structural steel (the fuel-rich, open-air fire could not reach the 1500°C needed to actually melt the metal), thermal gradients on outside columns, and nonuniform heating of long floor joists precipitated the staggered floor collapse that soon reached the free-fall speed as the towers fell in only approximately 10 s.

Although the preparation of the most feared viral and bacterial weapons of mass destruction requires a fair degree of scientific expertise and a high degree of technical expertise (particularly to prepare the cultured pathogens for widespread dispersal), the overall energy cost of their development is very low in comparison with their potential impact, be it measured in terms of actual casualties and ensuing population-wide fear or in terms of long-term economic losses. There is no doubt that even a largely failed large-scale smallpox or anthrax attack

on a major urban area would send property values falling and would lead to the flight of residents and businesses to less crowded locations.

2. ENERGY COSTS AND CONSEQUENCES OF WAR

Preindustrial land wars, fought largely by foot soldiers with simple weapons, did not require large amounts of energy embodied in arms and equipment, but even so, that investment was often a significant part of annual energy use in many poor subsistence societies. Large armies in transit, or during periods of prolonged sieges, almost always had a deep, and often quite ruinous, effect on regional supplies of food and fuelwood as they commandeered their provisions from the surrounding countryside. In contrast, maritime forays far from friendly shores always required careful planning of supplies that had to be carried by the ships during months of self-sufficient sailing.

Modern wars are waged with weaponry whose construction requires some of the most energy-intensive materials and whose deployment relies on incessant flows of secondary fossil fuels (e.g., gasoline, kerosene) and electricity to energize the machines that carry them and to equip and provision the troops who operate them. Production of special steels in heavy armored equipment typically needs 40 to 50 MJ/kg, and obviously, the use of depleted uranium (for armor-piercing shells and enhanced armor protection) is much more energy intensive. Aluminum, titanium, and composite fibers, the principal construction materials of modern aircraft, typically embody 170 to 250 MJ/kg, as much as 450 MJ/kg, and 100 to 150 MJ/kg, respectively.

The most powerful modern war machines are naturally designed for maximized performance and not for minimized energy consumption. For example, America's 60-t M1/A1 Abrams main battle tank, powered by a 1.1-MW AGT-1500 Honeywell gas turbine, needs (depending on mission, terrain, and weather) 400 to 800 L/100 km; in comparison, a large Mercedes S600 automobile consumes approximately 15 L/100 km, and a Honda Civic needs 8 L/100 km. Jet fuel requirements of highly maneuverable supersonic combat aircraft, such as the F-16 (Lockheed Falcon) and F-18 (McDonnell Douglas Hornet), are so high that no extended mission is possible without in-flight refueling from large tanker planes (the KC-10, KC-135, and Boeing 767).

Moreover, these highly energy-intensive weapons have been used in increasingly massive configurations; hence, the overall energy cost of a conflict can mount rapidly. The most concentrated tank attack during the final year of World War I involved nearly 600 machines, whereas nearly 8000 tanks, supported by 11,000 planes and by more than 50,000 guns and rocket launchers, took part in the final Soviet assault on Berlin in April 1945. During the Gulf War in 1991 ("Desert Storm," January–April 1991) and the months leading to it ("Desert Shield," August 1990–January 1991), some 1300 combat aircraft flew more than 116,000 sorties and the supporting transport and aerial refueling planes logged more than 18,000 deployment missions.

Another historically recurrent phenomenon is the necessity to expand the mass production of these energy-intensive machines in the shortest possible period of time. In August 1914, Britain had only 154 airplanes, but just 4 years later, the country's aircraft factories were sending out 30,000 planes per year. Similarly, when the United States declared war on Germany in April 1917, it had fewer than 300 second-rate planes, none of which could carry machine guns or bombs on a combat mission, but 3 months later Congress approved what was at that time an unprecedented appropriation ($640 million or ~$8 billion in 2000 dollars) to build 22,500 Liberty engines for new fighters. The situation was reprised during World War II. American industries delivered just 514 aircraft to the U.S. forces during the final quarter of 1940, but the total wartime production reached more than 250,000 planes, exceeding the combined output of Germany and Britain.

There are no detailed reasoned studies of energy cost of modern wars. This is not surprising given that even their financial costs cannot be accounted for with a fair degree of accuracy. This has to do primarily with deciding what to include in such accounts. When the very physical survival of a society is at stake, it becomes impossible to separate the output of such a wartime economy into easily identifiable civilian and military sectors and then to assign approximate energy costs to these activities. Available aggregates show the total U.S. expenditures on major 20th-century conflicts as approximately $250 billion for World War I, $2.75 trillion for World War II, and $450 billion for the Vietnam war (all in constant 2000 dollars). Expressing these costs in monies of the day and multiplying the totals by the adjusted averages of respective average energy intensities of the country's gross domestic product (GDP) during those periods sets the minimum energy costs of these conflicts.

Adjustments to average energy intensities are necessary because the war-related industrial production and transportation require considerably more energy per unit of output than does the rest of economic activity. Given the typical sectoral energy intensities of past GDPs, this article uses the conservative multiples of 1.5 for World War I, 2.0 for World War II, and 3.0 for the Vietnam war. Although this procedure cannot yield any accurate figures, it conveys well the most likely magnitude of the energy burden. This burden was approximately 15% of the total U.S. energy consumption during the 1917–1918 period (World War I), averaged roughly 40% during the 1941–1945 period (World War II), but was definitely less than 4% during the 1964–1972 period (main combat action of Vietnam war). Naturally, these shares could be significantly higher during the years of peak war endeavor. For example, the peak World War II spending, expressed as a share of national economic product, ranged from 54% in the United States (in 1944) to 76% in the Soviet Union (in 1942) and in Germany (in 1943).

Peacetime expenditures directly attributable to the preparation for armed conflicts can also be significant. For decades, the highly militarized Soviet economy was spending on the order of 15% of its GDP on the development, procurement, and maintenance of weapons and on its large standing army and border guard and paramilitary forces. In contrast, the U.S. defense spending reached nearly 10% of GDP during the peak year of the Vietnam war, fell to below 5% by 1978, rose to 6.5% during President Reagan's mid-1980s buildup, and has stayed below 5% since 1991. Given the enormous U.S. energy consumption (equivalent to $\sim$2.5 Gt of oil in 2000), the direct peacetime use of fuel and electricity by the U.S. military is a tiny fraction of the total. For example, the U.S. Department of Defense claimed less than 0.8% of the country's total primary energy supply in 2000.

But the comparison looks different in absolute terms. The average direct annual consumption of primary energy by the U.S. armed services was equivalent to approximately 25 Mt of oil during the 1990s. That is roughly the same amount of primary energy consumed annually by Switzerland or Austria; more remarkably, it is a total higher than the commercial energy consumption in nearly two-thirds of the world's countries. Naturally, operations such as the Gulf War, the war in Afghanistan, and the Iraq war boost the energy use by military not only due to the combat but also due to enormous long-distance logistic support. And of course, there are additional (and not easily quantifiable) expenditures of energy for the military research and development (R&D) and the procurement of weapons.

The link between energy use and success in modern war (or in preventing war) is far from being a simple matter of strong positive correlations. Of course, there is no doubt that the possession of nuclear weapons (the MAD [mutually assured destruction] concept) was the main reason why the two superpowers did not fight a thermonuclear war, but the nuclear stockpiles, and hence their energy cost, went far beyond any rational deterrent level. Development and deployment of these weapons, beginning with the separation of the fissile isotope of uranium and ending with the construction of nuclear submarines to carry them with nearly complete invulnerability during the extended submerged missions, has been highly energy intensive.

A conservative estimate might be that at least 5% of all U.S. and Soviet commercial energy that was consumed between 1950 and 1990 was claimed by developing and amassing these weapons and the means of their delivery. And the burden of these activities continues with expensive safeguarding and cleanup of contaminated production sites. Estimated costs of these operations in the United States have been steadily rising, and much greater investment would be needed to clean up the more severely contaminated nuclear weapons assembly and testing sites in Russia and Kazakhstan. Even so, given the potentially horrific toll of a thermonuclear exchange—even when limited to targeting strategic facilities rather than cities, the direct effects of blast, fire, and ionizing radiation would have caused 27 million to 59 million deaths during the late 1980s—one could argue that the overall cost/benefit ratio of the nuclear arms race has been acceptable.

Of course, there is no doubt that the rapid mobilization of America's economic might, which was energized by a 46% increase in the total use of fuels and primary electricity between 1939 and 1944, was instrumental in winning the war against Japan and Germany. In contrast, the Vietnam war was a perfect illustration of the fact that to win a war, it is not enough to use an enormous amount of explosives (the total was nearly three times as much as all bombs dropped by the U.S. Air Force on Germany and Japan during World War II) and to deploy sophisticated weapons (state-of-the-art jet fighters, bombers, helicopters, aircraft carriers, defoliants, etc.). The attacks of September 11, 2001, on the World Trade Center and the Pentagon illustrate the perils and penalties of the aptly named asymmetrical threats. In those attacks, 19 Muslim *jihadis*, at the

cost of their lives and an investment that might not have surpassed $100,000, caused approximately 3000 virtually instantaneous deaths (and the death toll could have easily surpassed 10,000 if the towers were not so structurally sound), created enormous direct and indirect economic dislocations, and led to costly deployments of military and covert power.

During the 2 years following the terrorist attacks, these costs (including the stock value declines and the lost economic output) could be estimated at nearly $2 trillion—and the count keeps rising. Airlines still operate well below their pre-September 11 capacity and are not expected to recover, even in the absence of further attacks, before the year 2007. At the time of this writing, the proposed U.S. 2004 budget envisions nearly $40 billion for the new Department of Homeland Security and approximately $100 billion in additional spending for Iraq and Afghanistan besides the increased baseline spending on defense. Unfortunately, there is no easy military solution for this predicament. Both the classical powerful weapons and the new "smart" machines are of very limited use in this new, highly asymmetric global war, as are most of the security checks and precautions that have been taken so far at the airports.

The two most important and unprecedented consequences of warfare waged by modern societies are the just noted extent of economic mobilization for major armed conflicts and the growing magnitude of destructive power. The latter trend has brought increased casualties, including larger numbers of noncombatants, and huge material losses. World War I was the unmistakable divide. Enormous resources had to be rapidly diverted to war production, and the death toll, in both absolute and relative terms, surpassed that of any previous experience. The increasing destructiveness of modern wars is best illustrated by comparing the overall conflict casualties. Battle deaths, expressed as fatalities per 1000 men of armed forces fielded at the beginning of a conflict, were less than 200 during the Crimean War of 1853–1856 and the Franco–Prussian War of 1870–1871. They surpassed 1500 during World War I and 2000 during World War II (when they were more than 4000 for Russia).

Civilian casualties of modern warfare grew even faster. During World War II, they reached approximately 40 million, more than 70% of the 55 million total. Roughly 100,000 people died during nighttime raids by B-29 bombers using incendiary bombs that leveled approximately 83 square kilometers of Japan's four principal cities between March 10 and March 20, 1945. Five months later, the explosion of two nuclear bombs, which killed at least 100,000 people, released energy of 52.5 and 92.4 TJ, respectively (Table III). At that time, only a few people envisioned how much more powerful these weapons would get. Expressed in common units of TNT equivalents (1 t TNT = 4.184 GJ), the two bombs dropped on Japan rated 12.5 and 22 kt, respectively. The most powerful thermonuclear bomb tested by the Soviet Union, over the Novaya Zemlya on October 30, 1961, rated 58 Mt, equal to 4600 Hiroshima bombs, and by 1990 the total power of U.S. and Soviet nuclear warheads surpassed 10 Gt, the equivalent of 800,000 Hiroshima bombs.

Effects of major wars on energy consumption, be it in defeated countries or in the aftermath of major civil conflicts, are usually quite pronounced. The Soviet Union after the civil war of 1918–1921 and Germany and Japan after their defeat during the late 1940s are the best documented examples. Japan's accurate historical statistics reveal the magnitude of this impact. In 1940, the country's primary energy supply was an equivalent of approximately 63 Mt of oil; by 1945, the total had fallen nearly exactly by half; and in 1946, the aggregate declined by another 10%. The 1940 level was not surpassed until 1955, 10 years after the surrender.

3. ENERGY AS THE CAUSE OF WAR

Finally, this article concludes with a few paragraphs on energy resources as the *cassus belli*. Many historians single out Japan's decision to attack the United States in December 1941 as a classic case of such causation. In January 1940, President Roosevelt's administration, determined to aid the United Kingdom that was under Nazi attack, abrogated the 1911 Treaty of Commerce and Navigation with Japan. In July 1940, Roosevelt terminated the licenses for exports of aviation gasoline and machine tools to Japan, and in September the ban was extended to scrap iron and steel. Already by July 1940, some of Japan's top military officers warned that the navy was running out of oil and that they wanted a quick decision to act. An attack on the United States was to clear the way for the assault on Southeast Asia with its Sumatran and Burmese oilfields.

Although it would be wrong to deny the proximate role that Japan's declining oil supplies might have played in launching the attack on Pearl Harbor, it is indefensible to see Japan's aggression as an energy-driven quest. The attack on Pearl Harbor was preceded by nearly a decade of expansive Japanese militarism (so clearly demonstrated by the 1933

conquest of Manchuria and by the attack on China in 1937), and Marius Jansen, one of the leading historians of modern Japan, wrote about a peculiarly self-inflicted nature of the entire confrontation with the United States. No convincing arguments can made to explain either Hitler's serial aggression—against Czechoslovakia (in 1938 and 1939), Poland (in 1939), Western Europe (beginning in 1939 and 1940), and the Soviet Union (in 1941)—or his genocidal war against Jews by concerns about energy supplies.

The same is true about the geneses of the Korean War (North Korea is the coal-rich part of the peninsula), the Vietnam war (waged by France until 1954 and by the United States after 1964), the Soviet occupation of Afghanistan (1979–1989), and the U.S. war against the Taliban (launched in October 2001) as well as about nearly all cross-border wars (e.g., Sino–Indian, Indo–Pakistani, Eritrean–Ethiopian) and civil wars (e.g., Sri Lanka, Uganda, Angola, Colombia) that have taken place (or are still unfolding) during the past two generations in Asia, Africa, and Latin America. And although it could be argued that Nigeria's war with the secessionist Biafra (1967–1970) and Sudan's endless civil war had clear oil components, both were undeniably precipitated by ethnic differences and the latter one began decades before any oil was discovered in the central Sudan.

On the other hand, there have been various indirect foreign interventions in the Middle Eastern countries—through arms sales, military training, and covert action—that aimed at either stabilizing or subverting governments in the oil-rich region. Their most obvious manifestation during the cold war was the sales (or simply transfers) of Soviet arms to Egypt, Syria, Libya, and Iraq and the concurrent American arms shipments to Iran (before 1979), Saudi Arabia, and the Gulf states. During the 1980s, these actions included strong and, as it turned out, highly regrettable Western support of Iraq during its long war with Iran (1980–1988). This brings us to the two wars where energy resources have been widely seen as the real cause of the conflicts.

By invading Kuwait in August 1990, Iraq not only doubled crude oil reserves under its control, raising them to approximately 20% of the world total, but it also directly threatened the nearby Saudi oilfields (including the four giants—Safania, Zuluf, Marjan, and Manifa—that are on- and offshore just south of Kuwait) and, hence, the very survival of the monarchy that controls 25% of the world's oil reserves. Yet even in this seemingly clear-cut case, there were other compelling reasons to roll back the Iraqi expansion. At that time, the United States was importing a much smaller share of its oil from the Middle East than were Western Europe and Japan (25% vs more than 40% and 67%, respectively, in 1990), but the Iraqi quest for nuclear and other nonconventional weapons with which the country could dominate and destabilize the entire region, implications of this shift for the security of U.S. allies, and risks of another Iraqi–Iranian or Arab–Israeli war (recall Saddam Hussein's missile attacks on Israel designed to provoke such a conflict) certainly mattered a great deal.

There is one very obvious question to ask: if the control of oil resources was the sole objective, or at least the primary objective, of the 1991 Gulf War, why was the victorious army ordered to stop its uncheckable progress as the routed Iraqi divisions were fleeing north, and why did it not occupy at least Iraq's southern oilfields? Similarly, more complex considerations were behind the decision to conquer Iraq in March 2003. Although the *ex post* perspectives may question a justification based on the Iraqi development of weapons of mass destruction, it could be argued that Hussein's past actions and the best available prewar evidence did not leave any responsible post-September 11 leadership in the United States with the luxury of waiting indefinitely for what might happen next. Such a wait-and-see attitude was already assumed once, with fatal consequences, after the World Trade Center bombing in February 1993.

Of course, a no less important reason for the Iraq war has been the grand strategic objective of toppling the Baathist regime and to eventually replace it with a representative government that might serve as a powerful and stabilizing political example in a very unsettled region. Once again, after the events of September 11, one could argue that no responsible U.S. leadership could have ignored such a risky but potentially immensely rewarding opportunity to redefine the prospects for a new Middle East. And so even this instance, which so many commentators portray so simplistically as a clear-cut case of energy-driven war, is anything but that—yet again confirming the conclusion that in modern wars, resource-related objectives have been generally determined by broader strategic aims and not vice versa.

Glossary

fluidized bed combustor The term used to describe a method of combustion in which a bed of sand is suspended in an upward-flowing airstream; the turbulence created by the "boiling" sand bed enhances combustion and promotes efficient heat transfer and uniform mixing.

gasification The process of partially oxidizing the fuel feedstock by introducing it into a furnace with insufficient air/oxygen to support complete combustion; the resulting exhaust gas contains hydrogen, methane, and other organic gases along with carbon monoxide, carbon dioxide, and nitrogen.

mass burn The term used to describe the practice of combusting municipal solid waste (MSW) in a furnace where the material is fed in with little or no prescreening or separation; within the furnace, the combustible content is burned away and the remaining ash, glass, and metal from the MSW is removed as a bottom ash.

municipal solid waste (MSW) A general characterization of the waste stream resulting from the accumulation of all residential, commercial, and light industrial waste normally handled by local municipalities and typically deposited in a landfill; this waste stream consists of metal, glass, dirt, vegetation, paper, plastic, and the like, whether recyclable or nonrecyclable in nature.

Rankine power cycle The process of converting heat energy from fuel into high-temperature, high-pressure steam that is then used to drive a steam turbine generator to create electricity.

refuse-derived fuel (RDF) The fraction of municipal solid waste (MSW) remaining after processing, separating, and sizing of the MSW to remove any recyclable components and noncombustible materials. This stream typically consists of paper, plastics, vegetation, and wood along with minimal glass and metal.

Every year, millions of tons of solid waste are disposed of by landfilling. At the same time, millions of therms of energy from oil, natural gas, and/or coal are burned to create electrical power. The energy content available from the solid waste residue represents a significant "alternative" energy supply to alleviate the use and dependency on fossil fuels. This article discusses the details regarding the energy content of municipal waste and the potential technology to convert and recover that energy as useful electricity in a waste-to-energy system.

1. WASTE TO ENERGY

The category of waste to energy broadly describes any of a number of processes in which a useful by-product (energy) is recovered from an otherwise unusable source. The sources of waste can vary nearly as much as the varieties of social and economic communities worldwide. By definition, the term "waste" implies a nonusable by-product of a process or production. However, the factors that make this a waste stream from one perspective do not necessarily make the material worthless or useless in some other form or fashion. In fact, in the global aspect of waste management and disposal, recycling and reuse of waste materials have become prominent means of reducing the quantities of discarded materials. Recovery of available energy from the waste is, in truth, simply another specific method of reuse. In general terms, "waste" could describe anything from liquid chemical effluent to used automobile tires or anything from municipal sewage treatment residue (sludge) to municipal solid waste (MSW), also known as garbage. With the

exception of certain private disposal locations, most of the waste generated from any single source will eventually end up as a contributing component to the overall MSW disposal composition for a specific community. Depending on population density, local industrial development, and numerous other socio-economic factors, the actual makeup of the MSW stream could be significantly weighted to consumer waste products or industrial wastes. In addition, MSW composition can have significant seasonal variations, with yard wastes and overall quantities increased during the nonwinter months. Such variations in the waste characterization can have a significant impact on the value of the material as an energy source.

The value of waste as an energy source is determined by its composition and fuel calorific heating value, typically measured in British thermal units (Btu) per pound. The heating value is determined specifically from the available hydrogen and carbon content in the fuel that provide heat from combustion and result in by-products of water and carbon dioxide. Conversely, the heating value is reduced by the level of noncombustible material remaining in the waste. Glass, metal, and dirt are the most significant factors to the noncombustible portion of the waste stream.

A quick review of the general composition of MSW (Table I) provides a reference for the sources of energy available within a waste stream and provides a relative comparison of which components are most and least valuable for energy. Interestingly, many of the components within the waste stream least valuable as an energy source are most valuable as recyclable materials. Aluminum, ferrous metals (iron), plastics, newsprint, cardboard (corrugated paper), and glass are typically among the sought after recyclable components of a waste stream. With the exception of the plastics and paper components, the other recyclable components contribute nothing to the energy content of the waste stream. The most recent developments in solid waste management efforts have taken advantage of this fact by endeavoring to remove these recyclable materials from the waste stream prior to converting into a fuel.

TABLE I

Sources of Energy Available within a Waste Stream

Component	Contribution (percentage)	Heat value (Btu/pound, dry)	Moisture (percentage)
Newspapers/Magazines	18.0	8900	30
Paper/Cardboard	20.0	8900	32
Plastic	4.5	12,000	0
Dense plastic	4.2	16,700	0
Textile, leather	3.3	9000	20
Glass	5.8	0	0
Vegetable waste	20.2	8200	55
Metal—iron	5.7	0	0
Metal—aluminum	1.0	0	0
Wood/Yard waste	7.3	8400	40
Grit, dirt, misc	10.0	0	55
Rubber tires	NA	15,000	0

2. HISTORY OF WASTE COMBUSTION

The earliest waste combustion systems were simple incinerators. With no energy recover capabilities and only basic wet scrubber gas cleanup technology, this practice was able to reduce the quantity of waste ultimately routed to the landfill by 75 to 85%. These early incinerators were typically small (only 50–100 tons/day capacity) and were considered simple, mass burn, starved air, multistaged incinerators. During operation, the waste was introduced into the furnace onto the first of a series of ram-activated cascading grates. In this primary zone, the fresh fuel would contact some combustion air and a stream of recycled gases from the exhaust header. As the waste began to burn, the ram feeders would push the pile off the grate onto the next step. In the process, the material would be stirred and agitated to present a fresh combustion surface to the airstream. Likewise, the material from this second step was ram fed inward until it "cascaded' onto the next grate. This process continued until the remaining noncombustible material plus some unburned carbon fell into a water-cooled ash trough and was removed from the furnace in an ash conveyor. The combustion and volatile gases driven off from the fuel pile were mixed with combustion air in the primary chamber directly above the grate. Further combustion and quench occurred in the secondary and tertiary chambers, where additional ambient air and recycled flue gases were mixed into the combustion exhaust stream. All of the gases from the tertiary chamber were conveyed into the wet scrubber, where particulate was removed.

During the early 1970s, the surge in energy costs, spurred by the oil embargo, created a demand for energy recovery in these waste disposal facilities. At that time, although waste-to-energy technology was

still in its infancy stage, it was poised to take one of two paths to implementation: mass burn or process fuel (typically known as refuse-derived fuel [RDF]). Like the earlier technologies, mass burn technology opted to burn the waste virtually as it was received, eliminating nearly all processing of the material prior to burning. The mass burn units were typically very large furnaces, most often field erected, where the waste was literally plucked from a receiving floor with a grappling hook and ram fed into the furnace onto a cascading grate design. Following the success of other European designs beginning in the 1950s, these systems were typically of the water wall furnace design as opposed to a more "conventional" refractory furnace design. One advantage of this was the direct removal of much of the heat from the furnace by the water walls, thereby minimizing the requirement for significant volumes of excess combustion air or recycled flue gas to maintain acceptable operating temperatures in the furnace. These plants have also evolved into much larger capacity facilities—they were already field erected, so upsizing the capacity did not represent any further economic disadvantage—and have been built to capacities as large as 2500 tons per day (TPD).

The extent of preprocessing of the waste stream, and the resultant potential for recovery and recycling of a majority of the waste materials, is also a significant factor in determining what type of energy recovery technology might be considered for the waste stream. Waste-to-energy technologies can be generally categorized into two types: mass burn and RDF. Mass burn technology derives its name from the fact that very little effort is spent in the fuel preparation area. Removal of oversized items and obvious noncombustible materials, such as white goods (appliances), engine blocks, and propane canisters, comprises the segregation efforts to the waste stream. The remaining waste is fed, en masse, into the furnace of the burner. RDF technology is perhaps not the most descriptive nomenclature to describe all non-mass burn technologies. RDF denotes the waste processing effort that typically involves sorting, separating, and sizing the incoming waste stream to generate various by-product streams. A portion of the wastes (typically up to 30%) can be separated and recovered for recycling. A portion (10–20%) can be separated and diverted on to the landfill for disposal. The final portion (50–75%) contains the greater portion of the energy contributors, with much of the non-energy contributors removed, and can then be shredded and sized to a much more homogenous fuel stream called RDF.

With much of the noncombustible material eliminated from the blend plus the shredding of the waste material to a more uniform size, the remaining material is much more suited as a fuel feedstock for a more conventional solid fuel boiler technology such as water-cooled grate or fluidized bed boilers. Among these classifications are various other categories that delineate even further various advantages and design features of each technology. Such distinctions are left to future discussions on the subject. Suffice it to say that RDF technology is more dependent on preprocessing of the waste stream to create a fuel feedstock with some level of homogeneity, both in composition and in particle sizing. The obvious advantages to this are the improved combustion control resulting from more stabile fuel characteristics and improved design criteria as well as smaller furnace volumes resulting from better fuel definition and less potential variability in the incoming feed stream. The environmental advantage gained from RDF processing is a greater opportunity to recycle primary components from the waste stream without imposing added effort on the consumer or waste collection agency.

Mass burn technology, on the other hand, has proven to be the favored technology historically due to the extreme simplicity associated with the fuel handling requirements. In many cases, the "front end" technology, the common term used to define the fuel processing requirements on the front end of a waste-to-energy facility, was nothing more than a receiving pit for mass dumping and storage of all the waste coming from the hauling trucks along with a grappling hook and oversized conveyor to deliver the waste into the furnace. The waste delivered to the furnace is typically ram fed through a penetration in the furnace wall onto a water-cooled, cascade grate furnace floor. Typically, a pile of fuel, often representing 15 to 40 min of inventory, is maintained on the floor of the furnace. Control of the combustion characteristics is largely achieved via combustion air control only, with the fuel pile being too significant to facilitate anything but the most crude combustion adjustments. Because the mass burn furnaces must operate under the many variations in fuel quality and size presented by the bulky fuel mix, the furnace must be extremely robust and conservative in design. In addition, the ash removal system must be capable of handling every bit of the size and capacity of material coming out the furnace as it is fed into the furnace on the front end. Although this universal acceptability has proven to be one of the most important features of the mass burn success, it

has also created certain liabilities in the performance of the furnace. Extreme variations in the fuel within the furnace can create significant temperature excursions, among other things, and these can cause damage to the grate and other areas of the boiler. Unpredictable fuel composition can create surges in ash quantities, resulting in slagging and fouling of the boiler surfaces and increased emissions levels of unburned hydrocarbons, acid gases, and dioxins/furans in the outlet gases. In spite of these obvious drawbacks, mass burn technology flourished during their first three decades of development in the United States and most worldwide markets.

This was not the initial direction of the technology during the late 1960s and early 1970s. At that time, the industry appeared to be heading down the path of waste processing to generate an RDF feedstock. Unfortunately, explosions and catastrophic failures in some of these first facilities, including some fatalities, squelched the interest in further processing efforts and opened the door wide open for mass burn development. Furthermore, at the onset of the waste-to-energy industrial development, there was little interest in the recovery and recycling markets; the waste was processed simply to create a more usable fuel feed. However, much has changed over the past three decades, and the recent vitalization of the recycling effort has fostered a resurgence of processing technology of waste streams, with the primary focus being on recovery and recycling. The fallout from the tail end of the process has become the fuel stream for many of the modern waste-to-energy systems and has enabled the RDF technologies to move to the forefront of the technical arena.

3. TYPICAL RDF WASTE-TO-ENERGY FACILITY DESIGN

To better describe the details of waste-to-energy technology, including specific items pertaining to energy conversion, environmental considerations, operating and maintenance features, and other specific aspects of the technology, this section presents a more detailed discussion of a specific design of a modern waste-to-energy facility that might be considered typical of the industry in general (Fig. 1). The energy recovery technology being presented is for a bubbling fluidized bed (BFB) boiler and has a number of technology-specific criteria that will be different with different boiler technologies. Where applicable, such differences are identified and clarified for the other approaches; however, for discussion purposes, the level of detail is focused on the BFB technology.

Perhaps the first criterion in defining a waste-to-energy facility is to establish the amount of waste requiring disposal. For purposes of this exercise, it is assumed the system will be designed for an application in the United States. The average person in the United States is reported to generate between 3 and 4 pounds of waste per day. Modern waste-to-energy facilities have been sized for anywhere from less than 500 tons per day (TPD) to more than 2500 TPD. For purposes of this design exercise, an incoming stream of 1000 TPD is considered, representing a municipal community of approximately 500,000 to 600,000.

The initial activity in the design effort is to establish the fuel quantity and quality resulting from the incoming waste stream supply. This is determined by the design of the waste processing facility and the extent to which noncombustible and/or nonrecyclable materials are removed from the waste stream prior to creating the RDF. In a very simplified process, magnetic separation is used to remove ferrous materials, and some form of density separation (e.g., air knives, flotation) or screening (e.g., trommel, disc screen) is used to further classify the lighter fraction (e.g., paper, plastics, textiles, wood wastes, sawdust) from the larger and heavier material (e.g., rocks, metals, wet material). The remaining lighter waste is then shredded and sized to create a fuel feed material. This shred–burn concept represents the simplest method for material separation but results in the least opportunity for recyclable recovery and usually loses a substantial amount of the potential fuel value with the rejected stream. In this case, a more rigorous material

FIGURE 1 Typical waste-to-energy facility in Ravenna, Italy.

recovery facility (MRF), which will maximize recoverable materials and produce a quality RDF for use in the fluidized bed boiler system, is considered.

In the MRF, waste material is received on an open area or tipping floor, where it can be grossly sorted to remove any significant items, such as white goods and furniture, from the remaining mixed waste. From the tipping floor, material is loaded onto a transport conveyor that delivers it into a rotary trommel screen. Prior to the trommel, the material passes along a "picking station" where bulky materials, especially cardboard and color-coded recyclable bags, may be removed and diverted to a separate processing line. Inside the trommel, the material passes through a section where wall-mounted knives tear open any sealed garbage bags and empty the contents into the main stream. The trommel is a rotating cylinder, laying on its side, with holes of progressively larger sizes cut into its outer shell. The first series of holes are typically 2 inches in diameter or smaller. These will separate out the finer fraction of dirt and grit, small rocks and gravel, bits of wire and metal, and broken glass as well as much of the fine combustible material, including wood waste (sawdust) and paper and plastic scrap. This separated stream can be further processed with magnets, air classification, and flotation to remove and recover the ferrous metal, light fraction combustible material, and heavy material and glass, respectively.

Within the trommel, the larger sized material remaining is further sized to approximately 6 inches with a second series of holes. Through this section, separation of most of the normal waste materials is accomplished, including plastic and glass containers, aluminum cans, organic and yard wastes, and a significant portion of the remaining wastepaper fraction. Again, further processing of this separated stream, including magnetic and eddy current separation, air curtains, and plastic sorting lines, can classify this stream into ferrous metals, aluminum, glass and plastic containers, and potential fuel.

The remaining fraction of waste passing completely through the trommel screen and having a size exceeding 6 inches can then be hand sorted, if desired, and shredded to nominal size of 4 inches or smaller. Once again, magnetic separation and air classification can separate this stream into ferrous metal, fuel feedstock, and heavy noncombustible residue.

Once through the separation processing, the incoming waste stream has been classified into a number of individual streams, including ferrous metals, aluminum, glass, dirt and grit, and fuel (i.e., RDF). The fuel analysis and characterization of a typical RDF is shown in Table II. Characterization of such widely divergent waste streams into a single "homogenous" blend, as is reported herein, is an extreme simplification of the overall fuel analyses and represents a "leap of faith" in believing such information to be absolute and all encompassing. Perhaps more important than the information provided in Table II is the knowledge that these fuel specifications can vary as widely as the sources of waste from which they are derived.

Of the total 1000 TPD of waste arriving at the facility, approximately 20 to 35% may be removed, recovered, and possibly recycled. Normally, the yield of fuel from incoming waste is predicted to be 75%, resulting in an average fuel generation capacity of 750 TPD. Taking into account daily, weekly, and seasonal variations in the waste generation and delivery schedules, it is practical to expect higher hourly averages during the morning hours and higher daily averages during the middle of the week. Consequently, design considerations may be necessary to accommodate a "weekly" capacity of 7000 tons that may actually be delivered to the processing facility in 4 to 5 days. Although storage of unprocessed waste is not condoned—in fact, most regulations require the waste to be received and processed within the same day—it is necessary that a fuel facility provide storage capability to enable the 4- to 5-day waste supply to be consumed in the power plant over the full 7-day period.

TABLE II

Refuse-Derived Fuel Analysis

Component	Percentage dry basis
Carbon (C)	45.3
Hydrogen (H_2)	6.0
Nitrogen (N_2)	0.7
Chlorine (Cl)	0.5
Sulfur (S)	0.3
Oxygen (O_2)	31.3
Ash	13.4
Glass	1.5
Iron (Fe)	1.0
Higher heat value, (Btu/pound, dry)	7800
Moisture (percentage wet)	25
Higher heat value (Btu/pound, as received)	5850

4. CONVERSION TO ENERGY

The preceding discussion has focused on the material processing requirements necessary to generate a fuel from the incoming municipal waste. Once this is achieved, the focus of the waste-to-energy facility turns to converting the energy in the waste into a beneficial use. This is accomplished through the use of a steam boiler and power turbine cycle, much the same as most solid fuel power plants throughout the world. In simple terms, the fuel is burned in a furnace to generate heat. The heat is used to generate steam in a power boiler, which in turn drives a power turbine to generate electricity. The exhaust gases from the steam generator, having been cooled to nearly ambient temperatures, are cleaned of most pollutants and exhausted into the air. The electricity is transferred into the utility transmission system and eventually back to the homes and industries that generated the waste.

The power cycle is simple and straightforward, and it dates back to the industrial revolution. It is based on proven technology and, for the most part, proven equipment. Unfortunately, the drawback of the steam turbine (Rankine) power cycle is the exorbitant losses experienced by the condensing of the low-temperature, low-pressure steam at the discharge of the turbine. This represents two-thirds to three-quarters of the energy content of the steam and limits the overall power cycle efficiency to 20 to 25%. Improvements in metallurgy and construction techniques over the past few decades have raised operating temperatures and pressures within the steam cycle to increase these turbine cycle efficiencies significantly; however, most of the resulting improvements are not practical for normal waste-to-energy facilities. First, the relative size of the waste-to-energy power plant is too small to absorb many of the operating and capital costs resulting from these critical pressure and temperature conditions. Furthermore, because of the contaminants in the waste stream, most notably chlorine and sulfur, the potential for high-temperature corrosion throughout the process is significant. To optimize plant costs with operating efficiencies, steam conditions have typically been limited to 650 psia and 750°F. Some recent facilities have increased this limit to 850 psia and 825°F with limited success.

With the power cycle established by the steam conditions of 650 psia and 750°F, the overall power generation capacity of the 750 TPD in incoming RDF can be determined. At 31.25 tons per hour and the referenced fuel heating value, an input energy level of 366 million Btu per hour is available. Operating at excess air levels in the furnace of at least 45% and normal gas exhaust temperatures of approximately 375°F, the overall boiler efficiency for this fuel is estimated at 77%. Given normal fluidized bed boiler design characteristics, this unit would generate approximately 250,000 pounds per hour (PPH) of steam. In a typical turbine power cycle, this steam quantity would deliver a gross generation capacity of 25,500 kW. Thus, we can reduce the waste-to-energy criteria for this summary to a simplified ratio of approximately 40 TPD per megawatt (TPD/MW) of incoming municipal waste to power generation capacity. In addition, this also reduces to approximately 30 TPD/MW of incoming RDF to output power.

5. EMISSIONS CONTROL TECHNOLOGY

Environmental compliance and controls are significant criteria to consider in waste-to-energy facilities. As guidelines and standards have become more stringent, abatement and control technologies have been developed to keep pace. In the earliest waste incineration systems, most of which did not even incorporate any energy recovery, the mass burn combustion technology was very crude, the fuel was extremely low quality, and the emissions control requirements were very simple (if present at all). Current requirements address emissions of products of combustion such as carbon monoxide (CO) and volatile organic hydrocarbons (VOCs) and nitrogen oxides (NO and NO_2). Acid gas emissions resulting from sulfur and chlorine are required to be reduced significantly. High-efficiency filters are mandated for reduction of particulate emissions as well as heavy metals.

Current furnace designs and combustion practices have achieved very high combustion efficiencies resulting in extremely low CO and VOC levels, commonly referred to as products of incomplete combustion (PICs). These can also include the category of dioxins and furans, which encompass a specific family of ploy aromatic hydrocarbons (PAHs). In the case of fluidized bed combustion, the technology describes the practice of burning a solid fuel in a combustion zone consisting of small particles of sand suspended in a stream of upward-flowing air. The buoyancy force of the air velocity lifts and suspends the individual sand particles within

the mixture. As more air is introduced into the sand, it appears to bubble in much the same way as a pot of boiling water, hence the term "fluid bed" and, more specifically, "bubbling fluid bed." In a modification to this concept, referred to as a circulating fluid bed, the air velocities are actually increased to the terminal velocity of the sand particles, thereby carrying the sand up and out of the furnace. At the outlet of the furnace, the sand is mechanically separated from the air/gas stream and is recirculated back into the bottom of furnace, hence the term "circulating fluid bed" or "recirculating fluid bed."

The advantages of fluid bed combustion over the more traditional technology arise from the increased turbulence provided by the bed particle action. This fluidization increases the interaction of the fuel particles with the combustion air and creates a very accelerated combustion environment for the incoming fuel. In addition, the sand, initially heated to an ignition temperature for the incoming fuel, provides a means of heating and drying the new fuel introduced into the furnace and eventually igniting it. The thermal stability provided by the hot sand in the bed plus the turbulence of the fluidization causes the fuel particles to be consumed in a very short period, typically a few minutes or less. Complete combustion is achieved by the uniform temperature zone within the furnace created by the bubbling sand medium plus the enhanced intermixing of fuel and combustion air. This technology is illustrated in Fig. 2. Historically, fluidized bed combustion systems have been able to achieve better operating flexibility, lower emissions levels, and improved combustion and boiler efficiencies. In the case of RDF combustion requirements, where the fuel characteristics are nonhomogenous and the overall fuel quality is relatively low compared with standard fuel such as coal, the fluid bed provides a method of stabilizing the combustion characteristics and creating very good emissions results. In some locations, especially the European Community, regulations specify a furnace temperature of at least 1550°F for a minimum of 2 s residence time and a minimum oxygen level of at least 6% in the furnace. This is not a universal requirement for design of the furnace; however, it does establish reasonable minimal levels for good combustion practices. Table III displays the current requirements for emission levels for new waste-to-energy power plants. Typical emissions levels from operating systems are included for comparison.

NO_x emissions are the result of combustion/furnace conditions that promote the "burning" of nitrogen. The source of nitrogen can be air (as is normally supplied for combustion) or fuel-bound nitrogen that is contained in the basic analysis of most solid fuels to some degree. To generate NO_x from air-bound nitrogen, very high temperatures (>2200°F) are required. Although not normal in most types of waste-to-energy technologies, these temperatures can be created in specific areas of the fuel piles in mass burn and conventional grate furnaces. Lack of mixing of the fuel with the air can result in channeling, a condition where air and fuel mixtures can become very rich, resulting in the high temperatures. With the mixing of the fuel and sand in the fluidized bed combustor (FBC) plus the reduced operating temperatures required to achieve good combustion, the creation of NO_x from air

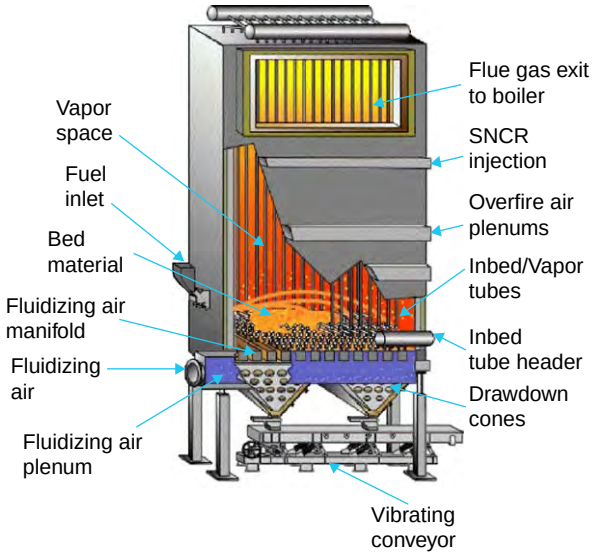

FIGURE 2 Bed combustor/boiler.

TABLE III

Typical Emissions Requirements (European Standards)

Temperature	850°C	1560°F
Oxygen (percentage dry)	6	6
Reference O_2 (percentage)	11	11
Particulate	10 mg/nm^3	0.006 g/sdcf
CO	50 mg/nm^3	44 ppm
VOC	10 mg/nm^3	6 ppm
SO_2	50 mg/nm^3	19 ppm
HCl	10 mg/nm^3	6 ppm
HF	1 mg/nm^3	
NO_X	200 mg/nm^3	105 ppm
NH_3	10 mg/nm^3	
Total heavy metals	1 mg/nm^3	0.0006 g/sdcf
Dioxins (total)	0.1 ng/nm^3	

fixation is essentially nonexistent. On the other hand, fuel-bound nitrogen accounts for most of the NO_x generation in FBC units and contributes even more NO_x in other types of furnaces. In all cases, the uncontrolled (or combustion-created) NO_x levels are likely to be well in excess of the allowable limits established by current regulations. Controlling combustion parameters, such as total excess air levels, and introducing combustion air into the furnace in stages to avoid high levels of excess oxygen in any particular combustion zone both can contribute to reduced NO_x emissions. Postcombustion control using selective noncatalytic reduction (SNCR) technology in the high-temperature region or selective catalytic reduction (SCR) in the cooled exhaust gas zone can reduce NO_x levels to allowable limits under most circumstances. In either process, ammonia is introduced into the flue gas. At the high temperatures ($>1500°F$), the ammonia can react with NO_x to produce nitrogen gas and water vapor. At the lower temperatures, the same reactions occur; however, the reactions require a special catalyst to increase the reactivity of the ammonia in the flue gas. Restrictions in temperature and flue gas characteristics have so far limited the application of SCR technology to these processes. To date, SNCR has been successfully incorporated into all of the different types of furnaces.

Acid gas emissions of sulfur and chlorine as SO_2 and HCl, respectively, are largely independent of the type of furnace used in the waste-to-energy technology. It is a fair assumption that all of the sulfur and all of the chlorine inbound with the fuel will be released during the combustion as SO_2 or HCl. The exception to this, at least partially, is the ability of the FBC to "capture" some of the SO_2 created. In the fluidized bed furnace, a portion of the sand media can be displaced with a calcium oxide material, or limestone, which has an affinity for SO_2. At normal temperatures within the furnace, the limestone can react with the SO_2 to create calcium sulfate ($CaSO_4$), also known as gypsum, which is a stable solid compound at temperatures below approximately 1700°F. Thus, the fluid bed can reduce the overall sulfur gas emissions significantly, in some cases by as much as 95%, by incorporating a continuous feed of limestone into the furnace. For any excess SO_2 plus all of the HCl emissions from the furnace, additional scrubbing is required at the exhaust end of the system before the gases are discharged into the environment. Various methods are available to effect this scrubbing, including wet or dry scrubbers or some combination thereof. In all cases, the flue gases from the boiler are injected with some reagent, either a calcium-based material (lime) or some other acid-neutralizing compound that reacts with the sulfur and chlorine gases to form a solidified compound, such as the gypsum, of sodium chloride (NaCl), commonly known as salt. With this add-on technology, the exhaust levels for most acid gases can be reduced by 95 to 99% of the inlet concentrations.

Once the acid gases have been converted to a solid material, they become a part of the particulate emissions from the system that also must be removed from the gases before they can be released into the air. High-efficiency bag filters (or baghouses) and electrically charged particle separators (known as electrostatic precipitators [ESPs]) are commonly used for this. Using state-of-the-art filter materials, dust removal efficiencies as high as 99.9% can be achieved in this system.

Once the combustion process is complete and the flue gases have been treated and exhausted into the air, the waste has been reduced to an ash stream that comprises about 5% of the original volume of the waste. This ash is made up of essentially all the noncombustible material in the fuel stream plus any additional materials such as limestone, or lime, that may have been added to the process for gaseous emissions controls as discussed previously. This ash stream becomes the concentrated repository of any of the metals and other such materials found in the waste stream that have not been removed by preliminary processing. Consequently, the ash has become a major focal point for "concerns" about environmental contamination resulting from disposal of this waste. The ash can be demonstrated as a nonhazardous waste through standard tests such as the toxic characteristic leaching procedure (TCLP), which measures the quantity of metals leached from a sample. Years of testing ash samples from numerous types of waste-to-energy facilities have consistently demonstrated the nonhazardous nature of the material. In fact, hundreds of thousands of tons of ash are currently being used in beneficial products such as landfill cover, road aggregate, asphalt mixture, concrete, and granular base material. In most instances, the characteristics of the ash are more benign than those of the metals and other ingredients as they exist in the original waste stream.

6. NOT IN MY BACKYARD

As a fuel, MSW does not compare too favorably with more traditional solid fuels such as coal. MSW averages in the neighborhood of 4500 Btu per pound

versus coal at 10,500 to 13,000 Btu per pound. However, given the current U.S. population of approximately 250 million and the annual generation of waste per person of roughly 1500 pounds, the potential energy content in the annual waste generated in the United States alone is comparable to nearly 70 million tons of coal annually and has the potential to generate more than 13,000 MW of electrical power. As of 1993, the capacity of waste consumed in these facilities was approximately 103,000 TPD, representing approximately 18% of the projected annual waste generation.

As of early 2000, waste-to-energy technology accounted for disposal of more than 30 million tons of waste annually in the United States alone. This corresponds to an electricity generating capacity of more than 2800 MW. Although these numbers might seem significant, this represents only approximately 14% of the total waste stream within the United States and accounts for only one-third of 1% of the electrical generating market in the United States. Waste-to-energy technology represents one of the most significant sources of renewable energy available today. It was reported during the mid-1990s that 128 facilities were actually in operation in the United States, with an additional 42 planned or under construction. Of the existing plants, 92 produced electricity to some degree. The remaining 36 produced only steam or hot water. The size of facilities ranged from 20 plants of less than 100 TPD to 20 plants of more than 2000 TPD. Roughly 40 plants were of 100 to 500 TPD, 25 plants were of 500 to 1000 TPD, and 25 plants were of 1000 to 2000 TPD capacity. Most of the smaller plants were installed during the early period of waste-to-energy development. Most of the recent facilities represent sizes from 500 to 1000 TPD.

Waste-to-energy technology not only provides a clean source of energy but also provides a clean and long-term disposal of the waste. Studies have compared the emissions from a waste-to-energy facility with those from a landfill handling similar quantities of waste. In cases where no methane recovery was included in the landfill, a ton of waste was shown to generate 25 times more greenhouse gas emissions than was a ton of waste combusted in a modern waste-to-energy facility. Furthermore, even with landfill gas recovery techniques currently available, waste-to-energy systems are still at least 10 times more beneficial than landfilling.

So, with all of the wonderful benefits to this technology, why has it not been more widely accepted and implemented? First, this technology is not specific to any one industry, utility, or municipality. The fuel source is generated by the community and possibly the local industry. Although they have the need to dispose of this waste material, they do not normally have a specific and unified energy demand other than the need for electrical power. Moreover, the municipality does not normally control the electrical power generation, distribution, or pricing other than by exercising a political influence over the local public service commission. Furthermore, the community does not normally have ready access to large sums of capital and operating funding without a serious legislative exercise.

The successful implementation of a waste-to-energy project requires a "sponsor" that will coordinate all efforts necessary to complete a project, including designing; environmental permitting; contracting with the municipality (or municipalities) for the waste; contracting with the utility for sale of the power; contracting with the waste haulers for material delivery, recyclable markets, and ash and waste disposal; and convincing a financial entity (or entities) of the viability of the overall plan and economical advantages enough to obtain sufficient investment to pursue the project. Logistically speaking, the development of a simple waste-to-energy project involves contractual negotiations with no less than five separate entities (municipality, utility, financial, contractor, environmental), none of which represents an easy task. The complexity is further exaggerated by the interdependence of one contract on another. As a result, the time involved before a project can even begin the construction effort could be as long as 5 years or more. During that period of time, municipal elections can drastically alter the receptiveness of one or more of the major partners to the project. In addition, the costs involved to develop these contracts, agreements, permits, and the like can mount into the millions of dollars. This represents an investment with no chance of recovery unless and until the project is built, operating, and paying back dividends to the investors.

A second basic obstacle to the success of waste-to-energy technology is the cost competitiveness with other options. On the one hand, the technology is a waste disposal option and, therefore, competes with basic waste disposal practices such as landfills. On the other hand, the waste-to-energy facility is an energy producer and must compete with selling electricity at a rate competitive with options such as high-efficiency combined cycle gas turbine stations, supersized coal-fired utility power stations, and perhaps hydroelectric generation. In most instances, the costs to generate new or existing

power are very low in comparison with the costs for a straight solid fuel-fired energy system, especially one sized for only 10 to 20 MW capacity. To be economically viable, the waste-to-energy system must provide a competitive tipping (or disposal) fee to the community to dispose of the waste and generate an electrical output for a cost that can compete with market rates for electricity. In many cases, geographical conditions may influence one or both of these conditions to the benefit, or detriment, of a potential waste-to-energy facility. Where land is plentiful relative to the municipal population base, the costs of landfilling and hauling may be very competitive. Where hydroelectric energy provides a large base to the utility supply or where low-priced natural gas or coal generation remains prevalent, the power rates may be too low to from a competitive standpoint.

The capital costs for waste-to-energy facilities have been reported to range from approximately $75,000 to more than $125,000 per daily ton of waste input. On that basis, the "typical" 1000-TPD facility described previously would cost approximately $75 million to $100 million. In some instances, costs exceeding $125 million have been reported for this size of facility. This is a fairly "expensive" cost for a power plant to generate only approximately 25 MW of electricity. A natural gas combined cycle power station in this size range would cost approximately $18 million to $20 million, and a biomass-fired power plant using similar technology would cost $50 million to $55 million.

Given the capital investment for such a facility, the required revenues from either waste disposal (tipping) fees or electric power sales are significant. As a bare minimum, tipping fees in the neighborhood of $40 per ton plus power rates approaching $40 per megawatt are necessary to present an economically viable project. In the event that one revenue stream is reduced due to competitive circumstances, the other revenue stream must be increased to compensate. As a very general rule of thumb, it can be estimated that roughly a $10/ton variance in the tipping fees is comparable to an $8/MW variation in the power rate. Thus, in the case where there was absolutely no value for the electrical power (a highly unlikely scenario), the required tipping fee would need to exceed $65 per ton. Conversely, in the case where the revenue for fuel disposal was nil, the power rates required for economic viability would need to exceed $80 per megawatt (or $0.08/kW).

Finally, the most significant reason why more waste-to-energy facilities have not been commissioned to date is the "NIMBY" (not in my backyard) sentiment that arises at the first sign of a proposed facility in a "new" community. The NIMBY syndrome is a very emotional reaction to the possibility of seeing a new "pollution source" spring up in one's own neighborhood. Fear of health risks, air and water contamination, traffic upheaval, noise and visual pollution, and hundreds of other disadvantages due to such a facility gives rise to an emotional reaction and spirited resistance to the development of any such project. In some cases, such emotional outcries are justified given historical experience where industry did not look out for the well-being of the local populations. Years of industrial pillaging of local communities and the consequential cynicism that has developed have created an environment where there is very little confidence in the "promises" of good neighbor practices and environmental compliance with these new systems. No matter what "facts" are represented to justify the environmental impact of a new facility, the information is viewed by the lay community as unbelievable and incorrect. Most people are more willing to embrace the worst-case scenario than to believe that they might reap any potential benefit from such a facility. With such a political uncertainty arising from these public hearings, many projects that could achieve technical and economic viability will end up being delayed or even cancelled due to the lack of community support for such projects. Unfortunately, there is no absolute black-and-white definition of the advantages and/or disadvantages of these waste-to-energy facilities. A willingness to accept the status quo (i.e., landfilling) can often become a major hurdle to siting a new facility. The irony is that the status quo may be as bad as, or worse than, the proposed facility, but because it already exists, it automatically becomes the favored solution. There are numerous studies that report the emissions and other environmental ramifications of landfills and even compare them with the new standards for waste-to-energy facilities. One such study, in fact, listed the greenhouse gas emissions from a landfill (CO_2 and methane as CO_2-equivalent) as 26 times greater than those from a modern waste-to-energy facility.

Glossary

fetch Distance over which wave-inducing wind–sea interaction takes place.
high tide Highest water level during a tidal period.
linear wave Theoretical wave form of sinusoidal shape; describes offshore wave conditions with satisfactory accuracy.
low tide Lowest water level during a tidal period.
lunar tide Ocean tide induced by the gravitational forces of the moon.
neap tide Lowest low tide during a lunar month.
solar tide Ocean tide induced by the gravitational forces of the sun.
spring tide Highest high tide during a lunar month; period of revolution of the moon around the earth (~29.5 days).
tidal range Difference in water level between consecutive high and low tides.

This article outlines the state of the art of exploitation of two renewable energy sources that are available in abundance in the world's oceans: ocean wave energy and tidal energy. It is evident that humanity could cover a significant part of its electricity demand from these energy sources. The potential global wave energy contribution to the electricity market is estimated to be on the order of 2000 TWh/year, approximately 10% of the world electricity consumption. The global tidal range energy potential is estimated to be on the order of 3000 GW, with approximately 1000 GW (~3800 TWh/year) being available at comparably shallow waters. Tidal current energy conversion technologies, which have started to be investigated during the recent past, are predicted to supply up to 48 TWh/year from sites around Europe. Furthermore, other large tidal current resources are still to be explored worldwide. Although research and development on ocean energy exploitation is under way in several countries around the world, ocean energy conversion technologies have not yet progressed to the point of massive power generation. This is due in part to the often rough and unpredictable conditions under which these technologies have to operate. However, considerable progress has been made during the past decade in various engineering fields associated with ocean energy conversion. Recent advances indicate that some technologies could meet the goal of power production at the commercial level by or before 2010. This article outlines the nature and worldwide resource of ocean wave and tidal energy, explains the basic conversion concepts, and points out the advantages and disadvantages of ocean energy conversion. The presentation of the ocean energy conversion development status is confined to brief descriptions of the most advanced technologies.

1. INTRODUCTION

Worldwide energy consumption is predicted to rise considerably over the coming decades. Many countries in the world, constantly reminded that traditional methods of energy production are contributing to serious environmental problems and in view of their commitment to the Kyoto Protocol, have seen the urgent need for pollution-free power generation. The energy sector has been forced into a renovating process that sees an opening toward renewable energy. In the dynamic evolution of the renewable

 © 2004 Elsevier Inc. All rights reserved.

energy industry, an ocean energy industry is emerging. Although the technology is relatively new and currently not economically competitive with more mature technologies (e.g., wind energy), the interest in ocean energy conversion from governments and industry is steadily increasing. An important feature of ocean energy sources is their high density, and density is highest among the renewables.

The oceans, occupying nearly three-quarters of the world's surface and the atmosphere above, intercept most of the energy from the sun—approximately 80,000 TW. This energy appears in the oceans in a variety of forms, for example, as waves generated by wind blowing over the ocean surface and as currents driven by the wind or caused by thermal gradients.

In addition, the oceans are influenced by the gravitational interactions in the planetary system of the sun, the earth, and the moon that represents an extremely large reservoir of kinetic energy. This reservoir is tapped slowly, but continuously and predictably, to provide the energy to maintain the tidal system in the oceans.

Various other sources of renewable energy are available in the oceans, for example, the vast thermal potential between the upper warm and the deep cold ocean water layers and the density gradients between water layers of different salinity.

Recent technological advances indicate that ocean wave energy and tidal energy conversion technologies could be developed on the level of commercial power production in the foreseeable future. This article describes the main features of these renewable energy sources and of the state of the art and the perspectives of their use.

2. *WAVE ENERGY CONVERSION*

2.1 Wave Energy: Physics and Resources

Among different types of ocean waves, wind-generated waves have the highest energy concentration. Wind waves are derived from the winds as they blow across the oceans (Fig. 1). This energy transfer provides natural storage of wind energy in the water near the free surface. Once created, wind waves can travel thousands of kilometers with little energy loss unless they encounter head winds. Nearer the coastline, the wave energy intensity decreases due to interaction with the seabed. Energy dissipation near shore can be compensated by natural phenomena such as refraction and reflection, leading to energy concentration ("hot spots").

Ocean waves contain two forms of energy: the kinetic energy of the water particles that generally follow circular paths (the radius of which decreases with depth) and the potential energy of elevated water particles (Fig. 2). On the average, the kinetic energy in a linear wave equals its potential energy. The energy flux in a wave, the wave power, is proportional to the square of the amplitude and to the period of the motion. The average power in long-period ($\sim$7–10 s), large-amplitude ($\sim$2 m) waves commonly exceeds 40 to 50 kW per meter width of oncoming waves.

Like most forms of renewables, wave energy is unevenly distributed over the globe. Increased wave activity is found between the latitudes of $\sim$30 and $\sim$60° in both hemispheres, induced by the prevailing western winds ("westerlies") blowing in these regions (Fig. 3). Particularly great resources are located along the western European coast, off the coasts of Canada and the United States, and along the southern coasts of Australia and South America.

Conservative estimates of the Commission of the European Communities predict a wave energy

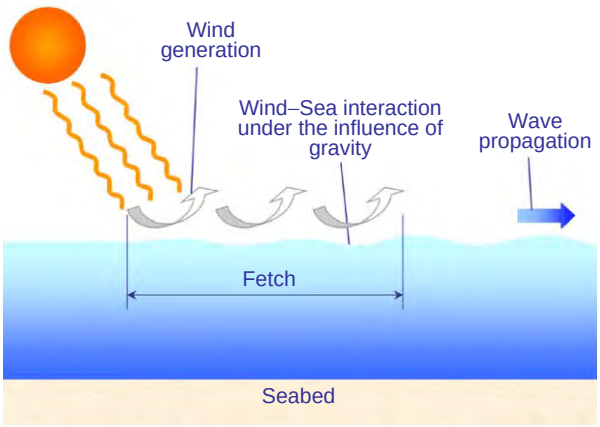

FIGURE 1 Wind-induced wave generation.

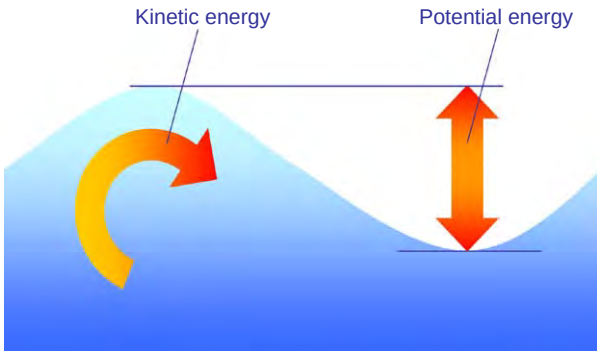

FIGURE 2 Wave energy components.

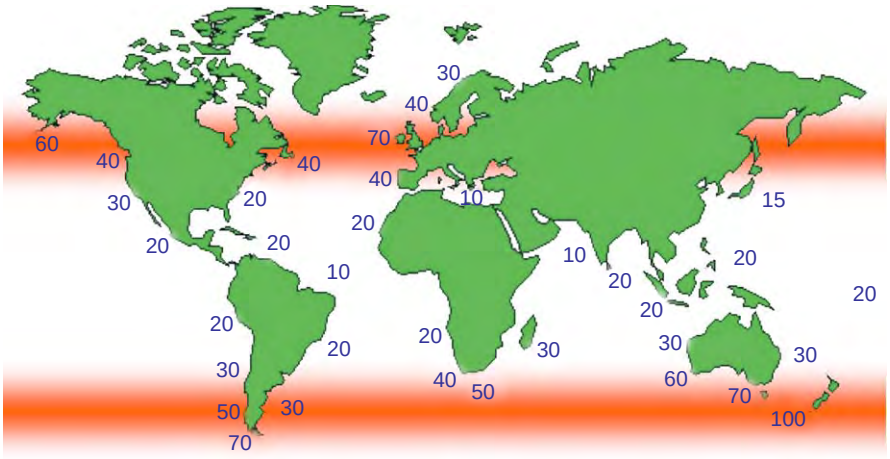

FIGURE 3 Global wave power distribution in kilowatts per meter of crest width.

market in the medium term (~2010) of approximately 5.5 TWh/year. However, the potential worldwide wave energy contribution is estimated to be on the order of 2000 TWh/year, approximately 10% of the world electricity consumption.

2.2 Wave Energy Conversion Techniques

In contrast to other renewable energy sources, the number of concepts for wave energy conversion is very large. Although more than 1000 wave energy conversion techniques are patented worldwide, the apparent large number of concepts for wave energy converters can be classified into a few basic types. The followings concepts are widely adopted:

- *The oscillating water column that consists of a partially submerged hollow structure open to the seabed below the water line* (Fig. 4). The heave motion of the sea surface alternatively pressurizes and depressurizes the air inside the structure, generating a reciprocating flow through a "Wells" turbine installed beneath the roof of the device. This type of turbine is capable of maintaining constant direction of revolution despite the direction of the airflow passing through it.
- *Overtopping devices that collect the water of incident waves to drive one or more low head turbines* (Fig. 5).
- *Heaving devices (floating or submerged) that provide a heave motion that is converted by mechanical and/or hydraulic systems in linear or rotational motion for driving electrical generators* (Fig. 6).
- *Pitching devices that consist of a number of floating bodies, hinged together across their beams* (Fig. 7). The relative motions between the floating

bodies are used to pump high-pressure oil through hydraulic motors that drive electrical generators.

• *Surging devices that exploit the horizontal particle velocity in a wave to drive a deflector or to generate a pumping effect of a flexible bag facing the wave front* (Fig. 8).

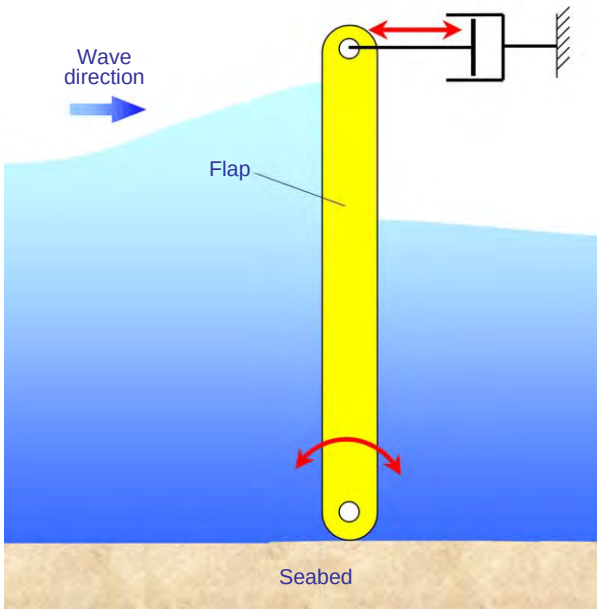

FIGURE 8 Operating concept of a surging device.

2.3 Advantages and Disadvantages of Wave Energy Conversion

It is important to appreciate the difficulties facing wave power developments, the most important of which are the following:

• Because of irregularity in wave amplitude, phase, and direction, it is difficult to obtain maximum efficiency of a device over the entire range of excitation frequencies.

- The structural loading in the event of extreme weather conditions, such as hurricanes, may be as high as 100 times the average loading.
- The coupling of the irregular slow motion (frequency ~ 0.1 Hz) of a wave to electrical generators typically requires ~ 500 times greater frequency.

Obviously, the design of a wave power converter has to be highly sophisticated to be operationally efficient and reliable, on the one hand, and economically feasible, on the other. As with all renewables, the available resource and variability at the installation site have to be determined first. The preceding constraints imply comparably high construction costs and possibly reduced survivability. These factors, together with misinformation and lack of understanding of wave energy by the industry, government, and public, have often slowed down wave energy development.

One of the important advantages of wave energy conversion is its environmental compatibility given that wave energy conversion technologies are generally considered to be free of polluting gas emissions. The abundant resource and the high-energy fluxes in the waves prescribe, at appropriate design of the devices, economically viable energy production. Other advantages of wave energy include its natural seasonal variability, which follows the electricity demand in temperate climates, and the introduction of synchronous generators for reactive power control. The negligible demand of land use is an important aspect, followed by the current trends of offshore wind energy exploitation. As for most renewables, the *in situ* exploitation of wave energy implies diversification of employment and security of energy supply in remote regions. Furthermore, the large-scale implementation of wave power technologies will stimulate declining industries (e.g., shipyards) and promote job creation in small and medium-size enterprises.

2.4 Wave Energy Conversion Development Status

Wave energy conversion is being investigated in a number of countries, particularly in the European Union member states, China, India, Japan, Russia, and the United States. Although the first patent certificate on wave energy conversion was issued in 1799, the intensive research and development (R&D) study of wave energy conversion began after the dramatic increase in oil prices in 1973.

During the past 5 years or so, there has been a resurgent interest in wave energy, especially in Europe. Nascent wave energy companies have been highly involved in the development of new wave energy schemes such as the Pelamis, the Archimedes Wave Swing, or the Limpet. Currently, the world-installed capacity is approximately 2 MW, mainly from pilot and demonstration projects.

The electricity generating costs from wave energy converters have shown significant improvement during the past 20 years or so and have reached an average price of approximately 0.08 €/kWh at a discount rate of 8%. Compared with the average electricity price in the European Union (~ 0.04 €/kWh), the electricity price produced from wave energy is still high, but it is forecasted to decrease further with the development of the technologies.

Although early programs for R&D on wave energy considered designs of several megawatts output power, more recent designs are rated at power levels ranging from a few kilowatts up to 2 to 4 MW. Massive power production can be achieved by interconnection of large numbers of devices.

The amount of ongoing development work on wave energy technologies is very large and cannot be described adequately in a single article such as this. In the framework of this article, the promising wave energy device developments are described briefly. More detailed reviews can be found in the extensive literature in this area.

The Archimedes Wave Swing, developed by Teamwork Technology BV in The Netherlands, consists of a hollow pressurized structure, the upper part of which is initiated to heave motions by the periodic changing of hydrostatic pressure beneath a wave. A 2-MW pilot plant has been constructed and was waiting to be deployed off the Portuguese coast during the spring of 2003.

The Energetech Oscillating Water Column was developed by Energetech Ltd. in Australia. The device uses a novel variable-pitch turbine and a parabolic wall to focus the wave energy on the device collector. This scheme has received a power purchase agreement with the local utility at Port Kembla, 80 km south of Sydney, for a 500-kW plant.

The European Pilot Plant on Pico Island in the Azores is a 400-kW oscillating water column developed by a European team coordinated by the Instituto Superior Técnico (Portugal), which consists of six Portuguese partners and two partners from the United Kingdom and Ireland. The plant was designed as full-scale testing facility. It is fully automated and supplies a sizable part of the island's energy demand.

The Floating Wave Power Vessel is a floating overtopping device for offshore operation developed by Sea Power International in Sweden. It consists of a floating basin supported by ballast tanks in four sections. A patented anchor system allows the orientation of the vessel to the most energetic wave direction. A pilot plant was developed and deployed during the 1980s near Stockholm, and the company has signed contracts in various countries for commercial deployment of the technology.

The LIMPET is a 500-kW oscillating water column developed by the Queen's University of Belfast and Wavegen Ltd. in the United Kingdom. A 75-kW prototype was constructed on the island of Islay in Scotland in 1991. The LIMPET is the successor of this prototype, intended to address many of the issues currently hindering the full-scale deployment of oscillating water column devices.

The McCabe Wave Pump consists of three rectangular steel pontoons that are hinged together across their beam. The bow of the fore pontoon is slack moored, and two more slack moorings are attached part of the way down the aft pontoon. This allows the system to vary its alignment so as to head into the oncoming seas. A 40-m long prototype was deployed in 1996 off the coast of Kilbaha in Ireland.

The Mighty Wale is an offshore device, based on the oscillating water column concept, that was developed by the Japan Marine Science & Technology Center. A 120-kW prototype with three oscillating water columns in a row has been operating 1.5 km off Nansei Town at 40 m depth since 1998. The mooring system is designed to withstand wind–wave conditions resulting from a "once in 50 years" storm.

The OPT Wave Energy Converter, developed by Ocean Power Technology in the United States, consists of a 2- to 5-m diameter buoy-type cylinder closed at the top and open to the sea at the bottom. A hydraulic ram is positioned between the top of the shell and a highly buoyant steel float contained within the shell. The relative motion of the shell to the buoyant float activates a hydraulic system to pump oil at high pressure to a generator. Extensive tests on a large scale in the eastern Atlantic have been concluded, and as of this writing, the first commercial schemes were about to be built in Australia and in the Pacific. The individual converters are rated at between 20 and 50 kW, intended to meet multimegawatt demands using arrays.

The Pelamis device is a semisubmerged articulated structure composed of cylindrical sections linked by hinged joints. The wave-induced motion of these joints is resisted by hydraulic rams that pump high-pressure oil through hydraulic motors via smoothing accumulators. A 130-m long and 3.5-m diameter device rated at 375 kW is being developed by Ocean Power Delivery Ltd.–OPD in Scotland.

The Pendulor is a surging-type converter consisting of a rectangular box that is open to the sea at one end. A pendulum flap is hinged over this opening, so that the actions of the waves cause it to swing back and forth. This motion is then used to power a hydraulic pump and generator. Several schemes (≥ 5 kW) have been built in Japan, and there are plans to develop a larger plant.

The Point Absorber Wave Energy Converter, developed by Rambøll in Denmark, consists of a float connected to a suction cup anchor by a polyester rope. The relative motion between the float on the sea surface and the seabed structure activates a piston pump (actuator) inserted between the rope and the float. A 1:10 scale model was tested at sea at the Danish test site "Nissum Bredning" over a period of 3 months, and a 1:4 scale model with a 2.5-m diameter is currently being developed for open sea testing.

The concept of the Salter Duck was introduced in 1974 by S. Salter. An important feature of this device is the capability of converting both the kinetic and potential energies of the wave, thereby achieving very high absorption efficiencies (theoretically $>90\%$). The system has undergone considerable development since 1983 and was redesigned in 1993. The current design is characterized by high availability and overall efficiency and low energy production costs.

The Wave Dragon is an offshore wave energy converter of the overtopping type developed by a group of companies coordinated by Wave Dragon ApS in Denmark. It uses a patented wave reflector design to focus the wave toward a ramp and to fill a higher level reservoir. Electricity is produced by a set of low-head Kaplan turbines. The scheme has been tested in the laboratory on a 1:50 scale and on a 1:3.5 scale model turbine. A 57-m wide prototype weighing 261 tons on a 1:4.5 scale rated in full scale to 4 MW is being deployed in Nissum Bredning in Denmark.

3. TIDAL ENERGY CONVERSION

3.1 Tidal Energy: Physics and Resources

Tidal energy conversion techniques exploit the natural rise and fall of the level of the oceans caused

principally by the interaction of the gravitational fields in the planetary system of the earth, the sun, and the moon. The main periods of these tides are diurnal at approximately 24 h and semidiurnal at 12 h 25 min. This motion is influenced by the positions of the three planets with respect to each other, and these positions vary during the year. Spring tides occur when the tide-generating forces of the sun and moon are acting in the same directions. In this situation, the lunar tide is superimposed to the solar tide (Fig. 9). Some coastlines, particularly estuaries, accentuate this effect, creating tidal ranges of up to approximately 17 m. Neap tides occur when the tide-generating forces of the sun and moon are acting at right angles to each other.

The vertical water movements associated with the rise and fall of the tides are accompanied by roughly horizontal water motions termed "tidal currents." Therefore, a distinction should be made between tidal range energy (the potential energy of the water at high tide) and tidal current energy (the kinetic energy of the water particles in horizontal direction in a tide).

Tidal currents have the same periodicities as do the vertical oscillations and so are predictable, but they tend to follow an elliptical path and do not normally involve a simple to-and-fro motion. Where tidal currents are channeled through constraining topography, such as in straits between islands, in shallows between open seas, and around the ends of headlands, very high water particle velocities can occur. These relatively rapid tidal currents typically have peak velocities during spring tides in the neighborhood of 2 to 3 ms^{-1} or more.

Currents are also generated by the winds as well as temperature and salinity differences. The term "marine currents," often found in literature, encompasses several types of ocean currents. Wind-driven currents affect the water at the top of the oceans, from the surface down to approximately 600 to 800 m. Currents caused by thermal gradients and salinity differences are normally slow deep water currents that begin in the icy waters around the north polar ice. Wind-driven currents appear to be less suitable for power generation than do tidal currents because the former are generally slower. Moreover, tidal currents usually exhibit their maximum speed in comparably shallow waters accessible for large engineering works.

The global tidal range energy potential is estimated to be 3000 GW, with approximately 1000 GW being available in comparably shallow waters. However, the tidal energy resource that could realistically be developed (tidal ranges of 4.5–5.0 m or higher) is confined to a few regions with exceptional tidal ranges (Fig. 10). Within the European Union, France and the United Kingdom have sufficiently high tidal ranges of up to approximately 10 m. Beyond the European Union, Canada, the Commonwealth of Independent States (CIS), Argentina, Western Australia, and Korea have potentially interesting sites that have been investigated periodically.

Recent studies indicate that marine currents have the potential to supply a significant fraction of future electricity needs. Tecnomare SpA and IT Power Ltd. studied 106 locations in European waters that were predicted to be suitable for current energy exploitation. The potential of these sites resulted in an

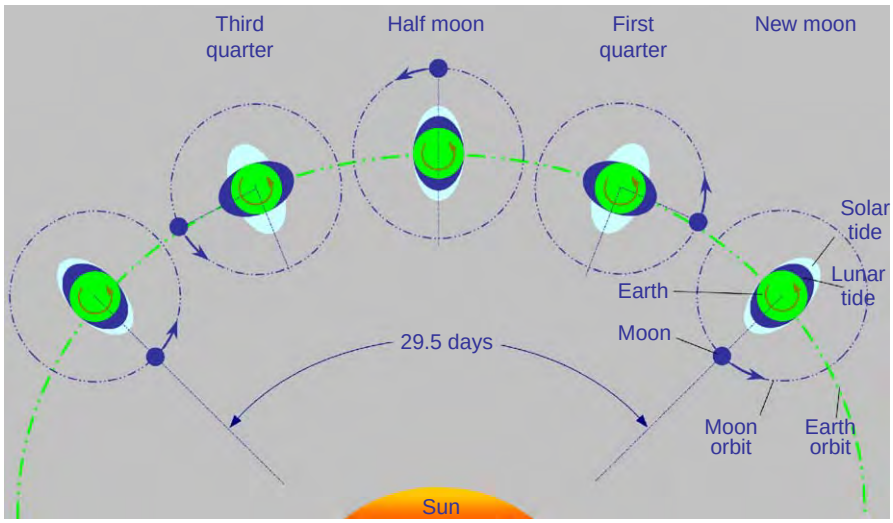

FIGURE 9 Interaction of lunar and solar tides during a lunar month.

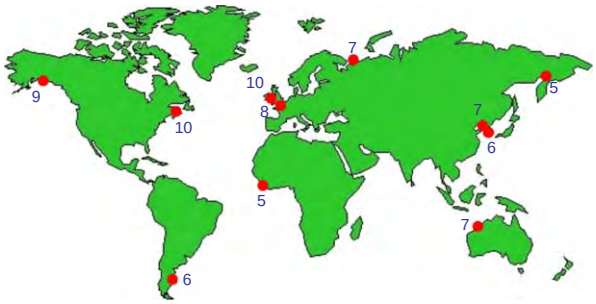

FIGURE 10 Regions of exceptional average tidal range.

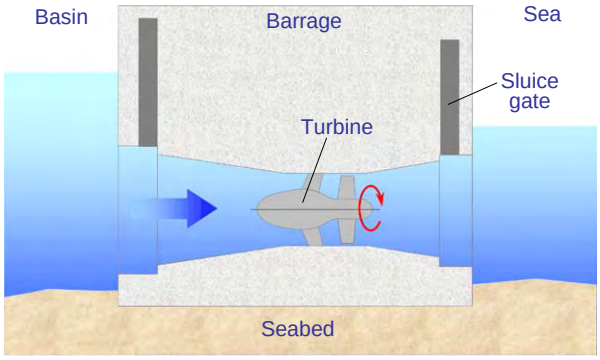

FIGURE 11 Operating concept of a tidal barrage.

installed capacity of marine current turbines of more than 12,000 MW. Locations with particularly intense currents are found around the British Isles and Ireland, between the Channel Islands and France, in the Straits of Messina between Italy and Sicily, and in various channels between the Greek islands in the Aegean. Other large marine current resources can be found in regions such as Southeast Asia, both the east and west coasts of Canada, and many other places around the globe that require further investigation.

3.2 Tidal Energy Conversion Techniques

3.2.1 Tidal Range Energy

The technology required to convert tidal range energy into electricity is very similar to the technology used in traditional hydroelectric power plants. The first requirement is a dam or "barrage" across a tidal bay or an estuary. Building dams is an expensive process. Therefore, the best tidal sites are those where a bay has a narrow opening, thereby reducing the necessary dam length. At certain points along the dam, gates and turbines are installed. When there is an adequate difference in the elevation of the water on the different sides of the barrage, the gates are opened. This "hydrostatic head" that is created causes water to flow through the turbines, turning an electric generator to produce electricity (Fig. 11).

Electricity can be generated by water flowing both into and out of a basin. Because there are two high tides and two low tides each day, electrical generation from tidal power plants is characterized by periods of maximum generation every 12 h, with no electricity generation at the 6-h mark in between. Alternatively, the turbines can be used as pumps to pump extra water into the basin behind the barrage during periods of low electricity demand. This water can then be released during the day periods with the greatest electricity demand, thereby allowing the tidal plant to function with some of the characteristics of a "pumped storage" hydroelectric facility.

A recently proposed technology to exploit tidal range energy, termed "offshore tidal conversion," relies on the use of impoundment structures placed offshore on shallow flats with large tidal ranges. Rather than blocking an estuary, impoundment structures would be completely independent of the shoreline. Such structures, which could be built of economical rubble mound construction materials, would resolve many of the environmental and economic problems of shoreline tidal barrages.

3.2.2 Tidal Current Energy

Tidal currents can be harnessed using technologies similar to those used for wind energy conversion, that is, turbines of horizontal (Fig. 12) or vertical (Fig. 13) axis ("cross-flow" turbines). Because the density of water is some 850 times higher than that of air, the power intensity in water currents is significantly higher than that in airflows. Consequently, a water current turbine can be built considerably smaller than an equivalent-powered wind turbine.

A novel technique recently developed by Engineering Business Ltd. in the United Kingdom uses a hydrofoil, which has its attack angle relative to the onset water flow varied by a simple mechanism (Fig. 14). This causes the supporting arm to oscillate, which in turn forces hydraulic cylinders to extend and retract. This produces high-pressure oil, which is used to drive a generator. A more detailed description of the technique is provided in the next section.

Other techniques for tidal current energy conversion have been proposed in the past, for example, the generation of vortices by submerged delta wings to drive horizontal axis turbines.

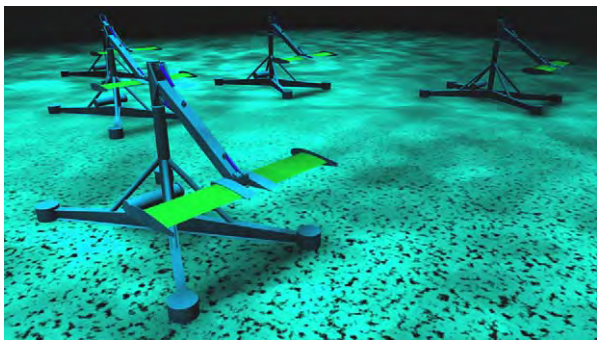

FIGURE 14 Stingray generator. Reprinted with the permission of Engineering Business Ltd.

3.3 Advantages and Disadvantages of Tidal Energy Conversion

3.3.1 Tidal Range Energy

Tidal barrage technology is considered mature, but as with all large civil engineering projects, there would be a series of technical and environmental risks to address. The main environmental risks are associated with the changes in water levels that would modify currents and sediment transport and deposit. However, there are regional development benefits as well. For example, the La Rance plant in France, the only commercial tidal range conversion scheme so far, includes a road crossing linking two previously isolated communities and has allowed further development of the distribution network for raw materials and developed products.

Tidal barrage projects normally require high capital investment at the outset and so have relatively long construction periods and low load factors, leading to long payback periods. As a consequence, the electricity cost is highly sensitive to the discount rate used. Therefore, access to suitable funding is a serious problem and is unlikely to be achieved without public intervention.

Offshore tidal technology is expected to be associated with less environmental damage than are traditional shoreline barrages. Furthermore, offshore tidal schemes are predicted to be more economical than tidal barrages. The structures would be built in a similar way to rubble mound breakwaters using conventional inexpensive materials such as sand, loose rock, and gravel. Their load factors would be higher than those of barrages. In contrast to barrages, which must generate primarily in one direction (on the ebb tide) to minimize progressive disruption of the intertidal zone, offshore tidal converters would be free to use both the ebb and flood tides for generation.

3.3.2 Tidal Current Energy

Several types of tidal current conversion devices, particularly fully submerged devices, are subject to the corrosive effects of seawater. This leads to high construction costs because it becomes necessary to use corrosion-resistant materials. In addition, maintenance becomes difficult because divers are needed to access submerged machinery. Although placing the generator above water can minimize the need for divers, maintenance costs would still be higher than, for example, in wind turbines. The installation of large schemes could also be confronted with major technical problems, safe and economical methods of deployment, and recovery requiring further investigation.

One specific advantage of tidal current conversion technologies is their limited environmental impact. This is considered negligible because their operation is not associated with polluting gas emissions. Their installation requires only minimal land use, and fully submerged devices will not affect their surroundings optically or acoustically. Their effects on flora and fauna have not been studied extensively, but it is unlikely that they would be of significance. In contrast to atmospheric airflows, the availability of tidal currents can be predicted very accurately because their motion will be tuned with the local tidal conditions. The power density from flowing water is much higher than that from most other forms of renewable energy. Thus, marine current converters could be built considerably smaller than equivalent machines, for example, those for wind energy conversion. Finally, submerged marine current converters are considered to operate in a safe environment. It is evident that disturbances caused by extreme weather conditions are significantly attenuated to the depths of approximately 20 to 30 m where the devices will normally operate.

3.4 Tidal Energy Conversion Development Status

3.4.1 Tidal Range Energy

The first large-scale, commercial tidal range energy plant was built on the La Rance estuary in France during the 1960s and has now operated successfully for more than 30 years. The La Rance station is still the only industrial-sized tidal power station in the world. Its 240-MW power is roughly one-fifth that of an EDF (Electricité de France) nuclear reactor and is more than 10 times that of the largest other tidal stations in the world. The barrage was designed for two-way operation. Today, it is operated nearly exclusively in ebb generation mode. The net annual energy yield of the 10 horizontal Kaplan turbines averages 544 GWh.

The good performance of La Rance has resulted in examination of several other projects in France, particularly in La Somme and Saint-Brieux bays, in Brest roadstead, along the Cotentin peninsula west coast, and a 200-square-kilometer area between Grandville, Chausey islands, and Coutainville. These projects were finally abandoned due to their very high investment costs and concerns over ecological impact. The Russians built a small 400-kW device near Murmansk that was later followed by a 17.4-MW experimental device built by the Canadians at Annapolis. A series of small plants have been installed in China. In the United Kingdom, a series of industrial consortia in collaboration with the government have investigated the prospects for tidal energy on the Severn, Mersey, and a number of smaller estuaries. None of these schemes has progressed to full-scale development.

The comparably high generation costs and long payback periods of tidal range schemes imply that within deregulated electricity markets, which are based on private investment, tidal energy is unlikely to be commercially developed if the kilowatt-hour price does not become competitive with cost-effective renewable energies.

The generation costs of offshore tidal energy are expected to be lower than those of tidal barrage schemes. Offshore tidal energy is currently being investigated in the United Kingdom. Three projects are in development, with two of them having a capacity of 30 MW and one having a capacity of 432 MW.

3.4.2 Tidal Current Energy

Tidal current technology is in its infancy. However, recent developments in this area open up prospects for commercial deployment of some schemes in the near future. The economical viability of these schemes has not yet been proven, with the estimated production costs typically ranging from approximately 0.08 to 0.35 €/kWh. However, it is anticipated that the production costs will decrease as the technologies advance.

Currently, different pilot plants are in operation or about to be installed, mainly in Europe. The devices rely on the horizontal or vertical axis turbine concepts and on the previously outlined oscillating hydrofoil technique. The most promising schemes are described in what follows.

The SEAFLOW device (Fig. 12), developed by Marine Current Turbines Ltd. in the United Kingdom, consists of an axial flow rotor of approximately

15 m in diameter, rated at approximately 300 kW in a current velocity of roughly 2.0 to 2.5 ms^{-1}. The system will be installed on a mono-pile, socketed to the seabed at a depth of approximately 30 m. This project is expected to lead directly to a second phase involving the development of 5 to 10 larger turbines, approximately 1 MW each. The SEAFLOW device is the successor of a 15-kW prototype with a 3.5-m rotor diameter that was tested successfully in 1994.

A similar device developed by SINTEF Energy Research in Norway is aimed to be the first tidal current converter that produces power for the grid. The turbine has a 25-m high tower with a 20-m diameter rotor, although the tower is capable of supporting a 30-m rotor. The turbine design allows the pitch of the blades to be changed to optimize power transfer from the tidal currents. When the tide turns, the blades are turned 180° and the direction of rotation is reversed so that both current directions can be used. The prototype was expected to undergo further development until 2004. If the pilot project produces the results that its owners are seeking, they owners will proceed with the installation of a 20-turbine plant in the Kvalsund Strait.

The ENERMAR device (Fig. 13), developed by Ponte di Archimede nello Stretto di Messina SpA in Italy, employs a patented vertical axis rotor termed "Kobold" connected to a synchronous generator. The rotor has an outer diameter of 6 m and consists of three blades with a span of 5 m each and a chord length of 0.4 m. An important feature of the device is that the direction of rotation of the rotor is independent of the current direction. The system is mounted on a floating platform 10 m in diameter. In 2002, a prototype was deployed in the Strait of Messina 150 m offshore at a depth of 20 m. Tests performed on the prototype indicate that the turbine produces approximately 20 kW of power at a current speed of 1.8 m/s, indicating a global system efficiency of 23%. In a current of 3.2 m/s, 150 kW is expected.

The Stingray Generator (Fig. 14), developed at Engineering Business Ltd. in the United Kingdom, uses a novel technique patented by the company during the late 1990s. The device produces electricity using the oscillatory movement of hydroplanes driven by flowing water. The hydroplanes rise and fall as the angle of each hydroplane is altered at the end of each stroke. A hydraulic cylinder is connected to the hydroplane arm, and the up-and-down movement generates high-pressure oil that is used to drive a hydraulic motor, which in turn drives an electric generator. A full-scale prototype rated at 150 kW was deployed in September 2002 at Yell Sound at a depth of 36 m and has since been in operation. A simultaneous program, aiming to start installation of a 5-MW demonstration farm with connection to the local distribution network, was expected to commence in the summer of 2004.

4. CONCLUSIONS

The sea is a colossal reservoir of energy of particularly high density—the highest among the renewables. The use of this energy resource could cover a significant part of the electricity demand worldwide. Currently, the exploitation of two forms of ocean energy, namely ocean wave energy and tidal energy, is considered prospective for massive power generation in the near future.

Although R&D on ocean energy conversion is under way in several countries around the world, ocean energy technologies have not yet been developed on an industrial level. However, considerable progress has been made in this sector over the past decade or so in Asia, Australia, Europe, and North America. For some technologies, this has resulted in approaching commercialization, whereas other technologies require further R&D.

Wave energy conversion is characterized by a large number of techniques. The environmental impact of most of them is considered negligible. Different schemes, mainly oscillating water columns and heaving, pitching, and overtopping devices, could meet the goal of electricity production on a commercial scale by 2010.

The concepts for tidal energy conversion can be classified into techniques converting the potential energy of the tides and techniques exploiting the kinetic energy of tidal currents. The traditional technique of exploiting the tidal head by using dams built across bays or estuaries still remains costly, having a major environmental impact. However, offshore impoundment structures could resolve many of the problems of shoreline tidal range energy conversion. The progress in tidal current conversion over the past years has been considerable. Recently, developed techniques are being considered environmentally compatible and are predicted to become economically viable in the medium term.

The potential for improvement of the technoeconomical performance of ocean power conversion technologies is large. After their integration and their penetration into the world electricity market, ocean energy conversion technologies are expected to make

substantial contributions to the achievement of a wide range of objectives of environmental, social, and economic policies in many countries around the world, providing superior services to their populations.

Glossary

accretion The upward growth of a sedimentary deposit due to settling of suspended sediments or *in situ* organic soil formation (due to root growth).

benthos Aquatic bottom-dwelling organisms; benthic is the adjective form (e.g., benthic animals).

bioremediation The addition of materials to a contaminated environment to cause an acceleration of the natural biodegradation processes.

estuary Any semi-enclosed coastal body of water that has a connection with the open sea and within which fresh water and salt water mix.

impoundment An enclosed wetland that is hydrologically isolated, either completely or partially, from the surrounding ecosystem; impoundment can be due to a combination of natural (e.g., beach ridge, natural levee ridge) and anthropogenic (e.g., road embankment, spoil bank) features.

levee A linear dike or embankment built along the bank of a channel, often to prevent inundation of lowlands by flooding.

primary production Total amount of organic matter newly formed during photosynthesis.

produced water By-product of the oil production process that is brought to the surface along with petroleum; produced water often contains high levels of salt, heavy metals, and hydrocarbons.

relative sea level rise A rise in sea level relative to that of the land due to a combination of eustatic sea level rise (i.e., worldwide sea level rise due to global warming) and sinking of the land as a result of subsidence.

subsidence Sinking or settling of the land surface due to natural (compaction and consolidation of sediments) or artificial causes.

The Mississippi Delta encompasses the largest area of coastal wetlands in the United States and supports one of the most extensive developments of petroleum extraction of any coastal area in the world. This area has experienced ecological impacts from energy development related human activities since the early 1900s. The Louisiana coastal zone encompasses approximately 3.8 million ha (9.5 million acres). The zone includes water bodies, marsh (fresh, intermediate, brackish, and salt), forested wetlands, submerged aquatic vegetation, mudflats, beaches, and upland habitats on natural levees with forests, agriculture, and urban development. Marshes make up approximately 63% of the land area in the coastal zone, and coastal Louisiana contains approximately 60% of the estuaries and marshes in the Gulf of Mexico. Coastal wetlands are vital for protecting developed areas from storm surges, providing wildlife and fish habitat, and improving water quality. The coastal zone has experienced multiple ecological impacts due to human activities, including leveeing of the Mississippi River, large-scale wetland reclamation, water quality deterioration, pollution, and widespread disruption of hydrology. Oil and gas development has contributed significantly to these impacts.

1. INTRODUCTION

Historically, Louisiana has been the second most important oil- and gas-producing state behind only Alaska. Crude petroleum is a complex mixture of mainly hydrocarbons and organic compounds of sulfur, nitrogen, and oxygen. Geologically, organic matter that accumulated in sandstones, siltstones, and shales during the Cenozoic era was transformed into petroleum by heat and pressure. The northern coast of the Gulf of Mexico had a thermal regime favorable to optimal maturation of organic matter into hydrocarbons and formed stratigraphic traps through faulting and salt movements. In Louisiana, oil and gas are produced from formations of the Paleocene through Pleistocene eras in the subsurface coastal and offshore areas. Oil production in Louisiana began in 1902, and the first oil production in the coastal zone occurred in 1926. The coastal zone produced more than 50% of oil production in the state during the 1950s and reached a peak in 1970 with 513 million barrels. From the 1920s to the 1980s, 58% of the state's total oil production and 47% of the state's natural gas production were in the Louisiana coastal zone. Gas production in the coastal zone peaked in 1969 at 7.8 trillion cubic feet. By 1990, there were more than 500 oil and gas fields in the Louisiana coastal zone. By 1987, more than 13,000 state leases for oil and gas development had been issued, and more than half of the leases were located in the coastal zone. Approximately 25% of domestic crude oil and 33% of domestic natural gas of the nation flow through Louisiana's coastal marshes. More than $12 billion in revenues from leases and production in the coastal zone was collected from 1926 to 1983. In 2000, the revenue was $354 million for mineral royalties only, and approximately 1.8 million jobs in Louisiana were related to the oil industry. Fully 40% of the U.S. refining capacity is located within the coastal zone in the Gulf of Mexico region. Therefore, the risk of ecological damages in the Mississippi Delta from energy development has been high (Fig. 1).

Oil and gas development activities have had multiple ecological impacts on wetlands and coastal ecosystems through the various stages of oil and gas development, including oil exploration, drilling site access, site preparation, drilling, production, pipeline installation, spills and cleanup, and site closure (Table I). Wetland ecosystems are susceptible to oil- and gas-related activities for a number of reasons. First, the high productivity of wetland vegetation is dependent on natural hydrological flows and inputs of nutrients and sediments to the Mississippi Delta. Second, levees, canals, and impoundment disrupt the natural hydrological regime in the Mississippi Delta and, in turn, affect plant health and sediment dynamics. Third, subsidence due to depressurization from oil and gas production enhances subsidence. Fourth, pipelines for transporting oil and gas

TABLE I

Multiple Impacts of Energy Development inside Wetlands

Stage	Short-term impacts	Long-term impacts
Exploration	Changes in marsh surface elevation	Changes in surface hydrology and drainage
	Breaks in natural hydrological barriers	Saltwater intrusion
	Noise and commotion during exploration	Changes in plant growth, organic matter accumulation, and sediment distribution
	Immediate loss of marsh vegetation	
	Destruction of biota	
	Changed habitat	
	New migration pattern of aquatic organisms inside marsh	
Access to site	Direct conversion to open water	Increased wave action
	Direct conversion to spoil bank habitat	Changed water circulation and turnover; stagnant water
	Return of nutrients and toxins to marsh	Dredged canal deeper than natural channel
	Noise and commotion during construction	Intercepted freshwater flow
	Immediate loss of marsh/shallow water habitat	Saltwater intrusion
	Changes in soil/water chemistry	Increased drainage of marsh
	Destruction of biota	Changes in surface hydrology and drainage
	Potential for interrupting fish spawning and feeding	Changes in sediment distribution
	Potential negative impact on plant growth	Changes in interaction of surface/subsurface hydrology and sediment distribution
	Potential for disturbing avifauna nesting by noise	
Drilling	Reduction in water quality	Alteration of surface hydrology and drainage
	Return of nutrients and toxins to surroundings	Changes in subsurface hydrology and drainage
	Inhibition of rainfall penetration	Changes in sediment distribution
	Noise and commotion during construction	Saltwater intrusion
	Increase in suspended solids	
	Changes in soil/water chemistry	Increased sediment release from discharges
	Changes in plant growth	Anoxia
	Destruction of biota	Loss of marsh habitat
	Potential for interrupting fish spawning and feeding	Altered soil/water chemistry
	Potential for disturbing avifauna nesting by noise	Possible negative influence on aquatic/benthic organisms
		Changes in mineral accretion and soil nutrition
Production	Noise and commotion during construction	Noise of processing facilities
	Flowlines in the marsh	Changes in surface hydrology and drainage
	Pit construction; toxins to surroundings	Changes in subsurface hydrology and drainage
	Changes in marsh elevation	Saltwater intrusion
	Reduction in water quality	More saltwater species
	Saltwater disposal	Anoxia
	Oil spills	Increased localized subsidence
	Destruction of biota	Loss of marsh habitat
	Potential for interrupting fish spawning and feeding	Altered soil/water chemistry
	Potential for disturbing avifauna nesting by noise	Possible negative influence on aquatic/benthic organisms
Pipeline building	Direct conversion to open water	Changes in surface hydrology
	Increased turbidity	Bank erosion
	Loss of forested wetlands	Compacted marsh surface
	Noise and commotion during construction	Direct habitat conversion
	Increased susceptibility to storm damage	Indirect wetland loss

continues

Table I continued

Stage	Short-term impacts	Long-term impacts
	Formation of open water ponds	Changes in forest succession
	Disruption of natural surface drainage	Changes in plant species, composition, diversity, and percentage cover
	Release of nutrients and toxins	Shoreline bank stability
	Soil oxidation	
	Changes in plant species, composition, diversity, and percentage cover	
	Nesting disturbance	
	Changed habitat	
	Disturbance of fish spawning and feeding	
	Impacts on plant growth	
	Destruction/Disturbance of benthos	
Spill control	Interruption of tidal cycle	Loss of marsh habitat
	Direct conversion of marsh to open water	Injury to birds and wildlife
	Trampling of vegetation	
	Immediate loss of marsh habitat	
	Temporary interruption of aquatic organism migration and flux of matter	
	Injury to birds and wildlife	
	Disruption of avifauna nesting	
Cleanup	Potential disruption of substrate	Loss of marsh habitat
	Removal of vegetation	Injury to birds and wildlife
	Immediate loss of marsh habitat	
	Decrease in biological production	
	Destruction of vegetation and benthic organisms	
	Potential negative impact on plant growth	
	Potential injury to wildlife	

produced inside the coastal zone and from the Outer Continental Shelf (OCS) disrupt natural hydrology. Fifth, spilled oils have an impact on wetland habitats. Sixth, spilled oil and produced water stress estuarine consumers by increasing turbidity, increasing salinity stress, introducing toxins, and so on. Finally, wetland loss decreases the value of the coastal zone as a nursery ground for estuarine consumers and the economic value to the human economy (Fig. 2).

This article reviews the multiple ecological impacts of oil- and gas-related impacts and synthesizes existing information to help researchers and managers understand how oil and gas development affects coastal wetland ecosystems in Louisiana, focusing on (1) plant physiology, (2) estuarine consumers (including the benthic community), and (3) hydrological disturbance and wetland loss.

2. IMPACTS ON PLANT PHYSIOLOGY

2.1 Impacts of Oil Spills

Wetland plants are subject to stresses from oil spilled during production and transportation (using tankers, pipelines, and tank trucks). Oil spills can have significant short- and long-term impacts on coastal ecosystems due to oil's physical effects and chemical toxicity, leading to decreased primary production, plant dieback, wildlife mortality, and marsh erosion. The mechanisms of these impacts are through (1) disruption of plant–water relationships, (2) direct impacts on plant metabolism, (3) toxicity to living cells, and (4) reduced oxygen exchange between the atmosphere and the soil. If leaves are coated with spilled oil, leaf stomata are blocked, oxygen diffusion to the roots decreases, and root oxygen stress

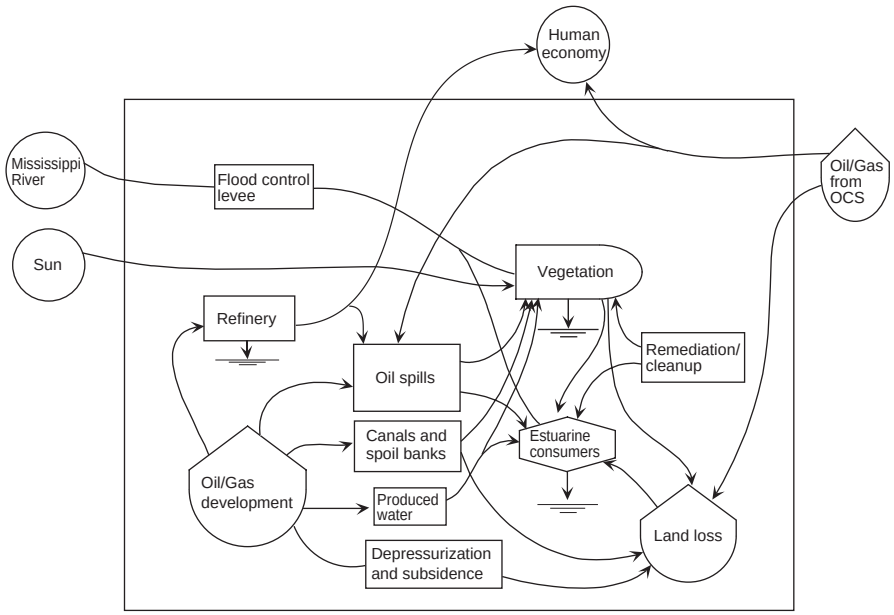

FIGURE 2 A conceptual diagram of ecological impacts of oil and gas development in Louisiana wetlands. The two main types of impacts are toxicity of hydrocarbons and hydrological changes.

increases, leading to reduction in plant growth. An oil-covered soil surface decreases oxygen movement, resulting in more anaerobic soil conditions and increasing low-oxygen stress on plant roots. Aerobic microorganisms in the oxidized sediment are more cable of degrading hydrocarbons than are anaerobic microorganisms in reduced sediment of the same pH. Oil coating on leaves results in higher mortality rates of marsh plants than does soil surface contamination.

In the short term, spilled oil can form a coating on plant foliage and the soil surface, increasing temperature stress, reducing oxygen diffusion, and reducing photosynthesis. The severity of these impacts is controlled by the amount of oil spilled, hydrological conditions (e.g., tides, winds), types of dispersed oil, and sensitivity of plants. Toxicity varies among various oil types. For example, diesel and number 2 oil are more toxic to marsh plants than is crude oil. Higher organic soils of fresh marshes are more sensitive to oil spills than is salt marsh through more rapid penetration and sorption of oil into the soil. For example, *Sagittaria lancifolia* is more tolerant than *Spartina alterniflora*, which in turn is more tolerant than *Spartina patens*.

There are longer term consequences of oil spills due to the persistence of oil or petroleum fractions in marshes. A period of 3 to 5 years may be required for natural recovery from accidental oil spills. Over time, oil concentrations are reduced in wetlands through oil evaporation, natural degradation of oil, and recovery of marsh plants.

However, plants subject to chronic exposure to oil spills accumulate oil-related pollutants through increased uptake of pollutants such as lead in contaminated sediments. The severity of biological effects of chronic spills is controlled by the volume and chemical nature of the pollutants, the physical nature of the receiving environment, and the biological character and composition of the ecosystem.

Traditional cleanup methods to remove spilled oil (e.g., water flushing, sand blasting, sediment removal, vegetation removal, sorbent application) often show limited removal efficiency. These methods can also cause potentially deleterious effects on long-term recovery of the impacted marsh system because they can result in further physical damage to both the vegetation and the underlying substrate, accelerating marsh degradation. Specifically, initial intensive cleanup by flushing and oil recovery by airboats reduces the residual oil in the marsh but also increases oil incorporation into the sediment and increases risks of physical damage to marsh plants. The negative impacts of physical removal of contaminated marsh plants can last for several years.

2.2 *In Situ* Burning

As a way in which to control oil spill impacts while minimizing physical damage to impacted wetlands, controlled *in situ* burning has been tested and used as an option to remove oil and gas condensate in contaminated wetlands. When water depth is sufficient (e.g., 10 cm) in damaged wetlands, *in situ* burning can be an efficient option because water on the surface will allow a successful burn of the above-ground vegetative component while absorbing heat produced by the fire and preventing root burning. However, flooding following *in situ* burning adversely affects plant growth in many species because the immediate reduction of plant cover decreases oxygen transportation to below-ground tissues. Full recovery of marsh vegetation from *in situ* burning reportedly takes 1 to 3 growing seasons. *In situ* burning generates atmospheric pollutants whose chemical components are a variety of gaseous sulfur (e.g., carbonyl sulfide, carbon disulfide) and carbon compounds (e.g., methane, carbon dioxide) and reduced alkylated naphthalene compounds from postburn oil.

2.3 Chemical Methods

Dispersants wash oil from surfaces such as rocks and vegetation. However, high doses (e.g., 0.3 L/m^2) reduce total and above-ground biomass significantly, at least for a short time. Another problem in dispersant application is that it is not practicable for use in coastal wetlands because there is little water to dilute the dispersed oil inside wetlands. Application of cleansers (e.g., COREXIT 9580), another chemical method, does not disperse oil but rather allows oil to be washed from surfaces, such as soils and plants, and to be collected in adjacent open water areas by boats. Plants improve their survival, regeneration, and above-ground biomass growth because the application leads to a recovery of stomatal conductance, photosynthesis, and respiration. The effectiveness of the cleanser in cleaning up oil depends on oil type, delivery mode, timing, and amount of oil. Marsh plants (e.g., *S. lancifolia*, *Scirpus olneyi, Thpha latifolia*) show different sensitivities to cleanser use. Cleanser application to brackish (*S. patens*) and fresh (*S. lancifolia*) marshes removes oil from marsh grasses and reduces the short-term impact of oil spills on gas exchange of the vegetation, but it still reportedly results in reduced above-ground biomass for the first growing season. Another problem in cleanser application is the potential impact of cleanser toxicity on various organisms in wetlands. Finally, solidifiers, which are dry, granular, hydrophobic polymers, can be used for spilled oil removal. Solidifiers react with spilled oil to form a floating cohesive and solidified mass that is easily removable, leaving very little residue.

2.4 Bioremediation

Wetland plants have the potential to enhance the bioremediation process through diffusion of oxygen from the shoots to the roots and soil, and its effectiveness can be increased through applications of fertilizer, microbial products, or soil oxidants. Fertilizer may be applied to spilled oil in water bodies before it reaches the marsh or may be applied directly to marshes already contaminated with oil. Additions of soluble inorganic fertilizers stimulate microbial activity and prolong the period of active oil degradation. The microbial activities lead to degradation of toxic petroleum products into carbon dioxide and water. However, the effectiveness of bioremediation may be limited by marsh plant tolerance to oil-related stress, risk of eutrophication, and soil type. Nutrients added to marshes may be transported to adjacent water bodies, leading to algal growth. Fertilizer application is more effective in sandy soils than in mineral soils. In some cases, the best action may be to allow the marsh to recover on its own, using no cleanup techniques.

3. IMPACTS ON ESTUARINE CONSUMERS

Benthic and nekton species are key organisms, both ecologically and economically, in coastal and wetland systems. The benthic community is an important link in transferring contaminants from the sediment to higher trophic levels, and the benthic community structure is sensitive to petroleum hydrocarbon exposure. The ecological and biological impacts of energy development on coastal marshes and estuarine environments are broad and sometimes persistent, including mortality, growth inhibition, reduced production, altered metabolic systems, and tainted flesh in fish and shellfish. Oil and gas production and transportation in coastal wetlands in Louisiana have resulted in the accumulation of polycyclic aromatic hydrocarbons (PAHs) and heavy metals in impacted areas. These compounds cause ecological impacts, including alteration of aquatic

community structure and food chains. Biodiversity and population density of the benthic community are significantly lower in oil-contaminated areas. Recruitment and feeding patterns can also be altered by oil pollution.

4. HYDROLOGICAL DISTURBANCE AND LAND LOSS

Petroleum-related activities in coastal Louisiana have several secondary and indirect impacts. These include the production of produced water, drilling-induced subsidence, and hydrological modifications due to dredging activities. Dredging results in two interrelated impacts: creation of new water pathways and spoil placement.

4.1 Produced Water

Produced water is a by-product of the oil production process. There are often substantial amounts of water contained in subsurface formations where oil and gas occur. When oil and gas are produced, this water is brought to the surface and must be disposed of in some way. Produced water contains high concentrations of volatile (e.g., benzene, toluene), and semivolatile hydrocarbon contaminants (e.g., aliphatic hydrocarbons, alkylated polycyclic aromatic hydrocarbons) as well as high concentrations of aromatic acids and aliphatic fatty acids. Some produced water also contains metals such as vanadium, arsenic, and copper. These toxic metals and organics often accumulate in wetlands due to poor freshwater flow or tidal exchange. Produced water also often contains high levels of brine. The degree of ecological impacts on wetlands is influenced by (1) discharge rate, (2) quantity and quality of the hydrocarbons and trace metals present in a particular discharge, (3) local hydrology, (4) sediment disturbances (e.g., dredging, boat traffic), and (5) sediment types (organic carbon content and texture). Volatile and semivolatile organic compounds of produced water are accumulated in organisms (e.g., oysters, freshwater mussels). However, when exposed to a contaminant-free environment, oysters release accumulated hydrocarbons. Heavy metals are reported not to influence hydrocarbon degradation in sediments at the produced water discharge site. The degradation rate of petroleum hydrocarbon in sediments exposed to produced water is controlled by oxidation, redox potential, and pH and can be increased by the addition of fertilizer.

4.2 The Delta Cycle and Wetland Loss in the Mississippi Delta

Coastal wetland loss is a major environmental problem in coastal Louisiana. The remainder of this article discusses evidence on the causes of this land loss and the role of petroleum-related activities in contributing to wetland loss.

4.2.1 The Delta Cycle

To understand the factors related to wetland loss, it is necessary to understand how the Mississippi Delta was formed. The sea level stabilized near its current level at the end of the last glaciation 5000 to 7000 years ago. Since that time, delta switching of the Mississippi River has created a series of overlapping deltaic lobes that currently form the Mississippi deltaic plain in coastal Louisiana. Delta switching occurs every 1000 years or so, resulting in new loci for sedimentation and marsh development. Rapid land building occurs in active delta lobes, whereas submergence and wetland loss occur in abandoned lobes. The Atchafalaya River is the most recent diversion in the delta switching process. Subaerial expression of the new Atchafalaya Delta began in 1973, and this area has a net gain of wetlands. Thus, the delta building process is a balance between forces that lead to growth of the delta and those that cause deterioration. The Mississippi River is the major force leading to land gain. Overbank flooding and reworking of sands have formed a skeletal framework of natural levee ridges and barrier islands within which the delta plain has formed. Deposition of both coarse and fine-grained sediments formed wetlands and maintains existing wetlands. Sediments resuspended during storms are an important source of sediments to maintain marshes. Once a wetland forms, organic soil formation by wetland plants is an important mechanism for maintaining coastal marshes.

Naturally, wetland deterioration is caused by two primary forces: subsidence and wave erosion along shorelines. Geological subsidence is caused by compaction, dewatering, and consolidation of sediments. Subsidence in deltas leads to a rate of relative sea level rise (RSLR) that is often much greater than eustatic rise. For example, whereas the current rate of eustatic rise is 1 to 2 mm/year, the RSLR in the Mississippi Delta is greater than 10 mm/year; thus,

eustatic sea level rise accounts for only 10 to 15% of total RSLR. If wetlands in deltas do not accrete vertically at a rate equal to the rate of RSLR, they will become stressed due to factors such as waterlogging, sulfide toxicity, and salt stress and will ultimately disappear. Because vertical accretion is stimulated by both outside sediment input and *in situ* organic soil formation, a reduction of sediment input or an increase in plant stress can lead to lowered accretion rates and wetland loss. Subsidence generally leads to wetland loss in interior wetlands. Wave erosion leads to wetland loss along exposed shorelines. As a deltaic lobe progressively deteriorates, wave erosion becomes relatively more important.

4.2.2 Wetland Loss in the Mississippi Delta during the 20th Century

During the 20th century, there was a dramatic reversal of the net growth of the Mississippi Delta that had taken place over the past several thousand years. High rates of land loss occurred (with estimates up to 100 square kilometers/year), and a total area of 4000 square kilometers of coastal wetlands has been lost. A number of factors have been linked to land loss, including elimination of riverine input to most of the coastal zone due to construction of flood control levees along the Mississippi River, altered wetland hydrology due to factors such as canal construction and impoundments, saltwater intrusion, wave erosion along exposed shorelines, a decline in suspended sediments in the Mississippi River, the effects of geological faulting, and high RSLR.

4.2.3 Effects of Oil and Gas Production on Subsidence

As stated previously, the regional rate of geological subsidence in the Mississippi Delta is approximately 10 mm/year. This is due to compaction, dewatering, and consolidation of sediments. Recently, Morton and colleagues showed that the rate of subsidence in producing oil and gas fields was considerably higher than this regional average (as much as 23 mm/year). They concluded that the increasing and then decreasing pattern of land loss in south central Louisiana was attributable partly to increased and then decreased oil and gas production. Decreases in subsurface pore pressures associated with production were so large that stressed faults were reactivated, leading to rapid subsidence on the down-thrust side of the fault. This enhanced subsidence led to wetland plant stress and death, as discussed previously. Thus, enhanced subsidence on top of regional geological subsidence led to much greater waterlogging stress on plants. Spoil banks associated with oil and gas fields led to reduced sediment input and lower organic soil formation, exacerbating sediment accretion deficits.

4.3 Canal and Spoil Banks

Canals have been constructed in the coastal wetlands of Louisiana since Europeans first settled in the region during the early 1700s. For nearly two centuries, these canals were dredged mainly for navigation, flood protection, and drainage. However, after the 1930s, the discovery of oil and gas fields in the coastal zone led to an explosion of canal construction related to oil and gas production. By the mid-1980s, there were more than 15,000 km of canals, the surface area of canals was equivalent to 2.3% of wetland area, and the total area of spoil bank levees plus canal surface was approximately 9.5% of wetland area.

When a canal is dredged, the dredged material is deposited along the sides of the canal, creating a more or less continuous elevated bank called a spoil bank. Spoil banks generally consist of highly organic marsh soil. As the spoil banks settle and dewater and as organic matter oxidizes, they create a levee that runs parallel to the canal (Fig. 3). Canals and associated spoil banks alter natural hydrology in two main ways. First, the canals are deep and straight, in striking contrast to the mostly shallow and sinuous tidal channels. Because of this, dredged canals tend to preferentially capture flow from natural channels. It has been shown that as the density of canals in an area increases, the density of natural channels decreases. If canals are long and deep enough (e.g., navigation channels that stretch from the Gulf of Mexico inland to freshwater areas), they can cause significant saltwater intrusion and death of freshwater wetlands. Two notable examples of this are the Mississippi River Gulf Outlet, which caused the death of extensive cypress forests southeast of New Orleans, and the Calcasieu Ship Channel, which led to loss of extensive sawgrass marshes in southwest Louisiana.

In contrast to deep canals that enhance water flow, spoil banks reduce water exchange. Spoil banks reduce or even eliminate overland flow. Because of the presence of spoil banks, partially impounded areas have fewer but longer periods of flooding and reduced water exchange in comparison with unimpounded marshes. Ponds usually develop behind canals and spoil banks, and high wetland loss is associated with areas of high hydrological changes.

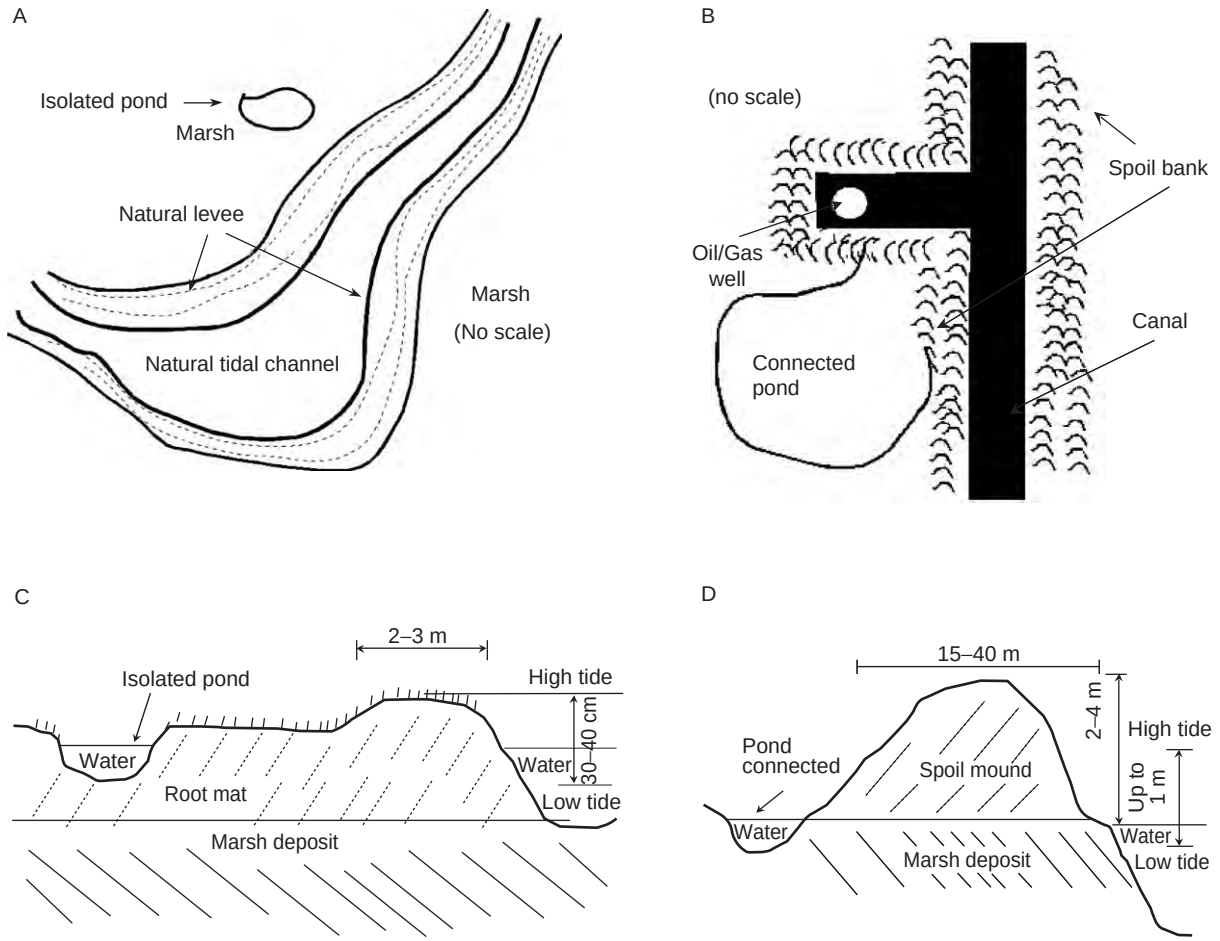

FIGURE 3 Schematic diagrams of canal dredging on coastal marshes. (A) Top view of a natural tidal channel and natural levee. (B) Top view of canal dredging showing straight canal and spoil bank. (C) Cross-sectional view of natural marsh. Note the streamside natural levee and shallow tidal channel and that high tide is higher than the natural levee. (D) Cross-sectional view of a dredged canal. Note that the dredged canal is deep, water level variation is higher than in natural channels, and the spoil bank is higher than normal high tide, preventing flooding of the marsh.

As discussed previously, if canals are associated with oil and gas fields, subsidence is enhanced through depressurization during and after oil and gas production.

Tidal currents are stronger through dredged canals than through natural channels. This, coupled with erosion from boat wakes, results in erosion of the banks. Annual increases in canal widening range between 2 and 14% per year, for a doubling time of 5 to 60 years. Canals also worsen water quality problems. Normally, nutrient- and sediment-laden point and nonpoint source runoff from uplands would naturally flow slowly through wetlands where nutrients and sediments would be assimilated. Canals short-circuit this flow, leading to direct introduction of nutrients and suspended sediments and to eutrophication in open water bodies.

4.4 Impoundment

Coastal marshes exchange water, organic materials (e.g., detritus), nutrients (e.g., nitrogen, phosphorus), and organisms with surrounding estuarine waters, supporting estuarine fish and shellfish. One impact that has affected these processes in coastal marshes is impoundment. Impoundments have been constructed for a number of reasons. Beginning in the 19th century, impoundments were constructed for the purpose of land reclamation for urban and agricultural activities. Many of these reclaimed areas failed due to excessive subsidence and flooding during hurricanes. But some remain, mainly in the metropolitan area of New Orleans. During the 20th century, many impoundments were constructed in the coastal zone to enhance conditions for waterfowl

and for marsh management. In addition to these purposefully constructed impoundments, large areas of the coastal zone have been completely or partially impounded by the cumulative impacts of canal and spoil bank construction. Approximately 30% of the total wetland area in coastal Louisiana has been impounded, either purposefully or by accident. Impoundments have been shown to have a number of detrimental impacts in that they reduce water exchange and accretion inside impoundments, lower vegetation productivity, and reduce movement of migratory fishes, leading to deteriorating marshes.

4.4.1 Petroleum-Related Activities and Wetland Loss

From the preceding discussion, a number of conclusions emerge. Naturally, wetland establishment and deterioration in the Mississippi Delta is a very complicated process involving numerous factors, including geological and geophysical (e.g., channel switching, sediment introduction and deposition, subsidence, vertical accretion, wave erosion, saltwater intrusion, sea level rise), biogeochemical (e.g., anaerobic soil formation, sulfate reduction, peat decomposition), and ecological (e.g., waterlogging and salinity increase leading to plant stress and death, rates of organic soil formation, herbivore grazing) factors. Prior to extensive alteration by human activity, there were large gains and losses of wetlands in various parts of the deltaic plain as the river changed course. But over the past 5000 to 6000 years, the net result of these processes was a large net gain of wetlands.

During the 20th century, the long-term net gain of wetlands was reversed and wetland area in the delta decreased by approximately 25%. Clearly, some of this loss was natural and would have occurred without human impacts. But it seems clear that the dramatic reversal from net gain to net loss can be attributed to human activities. Two general and interrelated processes are responsible for the losses: pervasive hydrological change and dramatically increased subsidence.

From a hydrological point of view, there have been two pervasive changes. First, the delta has been nearly completely isolated from the river that built it. Levees extend to the mouth of the main channel of the river, and 70% of sediments and water flow into the Gulf of Mexico. Only in the Atchafalaya Delta region does river water enter a shallow inshore area, and this is an area of land gain. Internally in the delta, there have been massive hydrological changes. A dense network of canals, most associated with petroleum activity, has changed the delta dramatically. These canals allow saltwater intrusion, reduce water and sediment movement, and contribute to low accretion rates. Impoundments isolate large areas of the coastal zone from adjacent estuarine areas.

4.4.2 Role of Petroleum Activity

In the vicinity of oil and gas fields, subsidence increased due to depressurization and surface hydrology was altered due to canals and spoil banks. Thus, RSLR was increased and the rate of accretion was reduced. This is due both to a reduction in allochthonous sediment input and to *in situ* organic soil formation. Some have attributed practically all wetland loss in the coastal zone to canals. There is no doubt that oil and gas activity have had a major impact on wetland loss. In areas of intense oil and gas extraction, it is likely that most wetland loss can be related to the combined impacts of increased subsidence and surface alterations. But high rates of wetland loss are also related to wave erosion, saltwater intrusion, and changes in the engineering of the mouth of the Mississippi River. Nonetheless, there is no doubt that petroleum-related activities are directly responsible for a significant proportion of the land loss in the coastal zone. It is probably not possible to put a specific value on this land loss due to the complexity of the land loss problem.

From a broader perspective, it is better to consider the functioning of the whole coastal system and the conceptual model developed earlier in this article. Both the supply side (inputs to the delta) and the receiving system (the delta plain) have been affected. Both riverine input and resuspended inputs have been reduced. At the mouth of the Atchafalaya River, oil and gas fields are not associated with wetland loss. Thus, it is the combination of all these forces, but oil and gas have had a dramatic impact.

5. CONCLUSION

Petroleum exploration, production, and transportation in the Louisiana coastal zone increased dramatically from the early 20th century to the 1970s. Oil and gas production in inshore bays and wetlands of the coastal zone then decreased beginning in the late 1970s, but there is still a high level of transportation of oil and gas through the coastal zone from the OCS and Louisiana Superport. These activities have had significant impacts on floral and faunal communities, resulting in significant deterioration of coastal and

wetland ecosystems. These impacts are related to the toxicity of spilled oil and the secondary and indirect effects of petroleum-related activities such as alteration of hydrology. The impacts of OCS development are related to construction of pipelines and navigation channels. Thus, the risks of oil spills and hydrological disruption continue, even though inshore oil and gas production has decreased.

Responses of plant metabolism to oil impacts are complex, depending on exposure type (e.g., oil-coated leaves vs soil contamination), oil type (e.g., crude oil vs number 2 oil), time of spill (e.g., after the growing season vs before the growing season), density of spilled oil, and sensitivity of various marsh plant species to oil. Another complex matter is the impact of oil cleanup on wetlands. Removal of oil has been reported to cause significant damage to wetland communities, including reduced growth of marsh plants and reduced population of benthic organisms.

Lin and colleagues suggested that methods and intensity of oil spill cleanup depend on the type and amount of spilled oil and environmental conditions at the time of the spill. If the spill is a relatively small volume and the floating oil is not continuous, light or no cleanup action is recommended. In the case of large-volume oil spills, cleanup activities consisting of sorbent application, low-pressure flushing, vacuuming, rope mops, and the like should be considered as options. However, Lin and colleagues did not recommend the use of heavy equipment and intrusive mechanical cleanup due to the concerns of physical damage to fragile marshes.

Louisiana experienced a high rate of coastal marsh loss during the 20th century. This high loss rate has been attributed to a number of factors. The immediate cause of much loss is due to plant stress resulting from both natural and anthropogenic causes, followed by plant dieback, subsequent erosion of the marsh substrate, and the formation of small ponds that then coalesce into larger open water bodies. Causes of plant stress in Louisiana marshes have been attributed to waterlogging stress (due to insufficient elevation of the marsh surface resulting from high subsidence rates in the deltaic plain and low accretion rates) and salinity stress (due to saltwater intrusion, often from storm surge events, into the more interior marshes).

Petroleum-related activities have contributed significantly to wetland loss in the Mississippi Delta. Oil and gas extraction increased the subsidence rate, sometimes by a factor of as high as 2 to 3, due to reduction of pressure that led to faulting-related subsidence. On the surface, canals significantly altered natural hydrology. Deep dredged canals altered water flow pathways and sometimes resulted in saltwater intrusion. Spoil banks reduced overland flow exchange and sediment input to the wetland surface. The combination of these two factors increased plant stress and plant death.

Glossary

base load generation Generating capacity that is kept online for long periods of time, usually due to low marginal cost combined with physical constraints on frequent starting and stopping.
demand Instantaneous use of power, measured in kilowatts or megawatts.
economic dispatch The process of determining which generators should be run, and in what combination, to minimize power production cost.
effective load carrying capability (ELCC) The demand that can be supported by the generating supply at a given reliability level.
energy Power used over time, measured in kilowatt-hours or megawatt-hours.
load following (generation) Generating capacity that can be ramped up or down to match changing levels of demand.
loss of load probability (LOLP) A measure of reliability; LOLP is the probability that there is insufficient generating supply to support electrical demand.
marginal cost The change in total cost that is caused by a given increase in energy output.
peak The maximum demand during a given time period.
regulation Changes in output from designated generators that occur over very short time frames, such as several minutes, that compensate for increasing or decreasing demand or intermittent generation fluctuations.
reliability The ability of the electrical system to meet demand, often measured by loss of load probability.
reserves Capacity that is not used directly to supply power but that can be called on quickly in event of a system emergency such as an unanticipated generator outage or an increase in demand.

The economics of wind power plants is influenced by a number of factors. These include the quality of the wind resource, technology efficiency and reliability, the availability of long-term power contracts, and the ability to forecast at least several hours ahead. Wind power plants have value that arises due to the reduction of pollution, compared with many other types of power plants, and the lack of fuel price volatility. Value also depends on the specific nature of the displaced power and energy. In regions that have a high marginal cost of energy, wind can provide a high value by offsetting a costly energy source.

1. INTRODUCTION TO WIND ENERGY ECONOMICS

Over the past few years, there have been significant changes in the electric utility industry. In many parts of the world, power markets have moved away from the regulated monopoly market structure toward more competitive markets. This evolution is not uniform; even in the United States, there are many different degrees of restructuring in the electricity markets. In some markets, restructuring has mainly involved changes at the wholesale level, whereas other market changes have occurred at the retail level. The future organization of power markets is not yet clear, and the details of these markets may have important impacts on wind integration into the power supply. For simplicity, this article uses the term "utility industry" to characterize the current mixed state of affairs as well as the future industry in whatever form it may take.

 © 2004 Elsevier Inc. All rights reserved.

Amid all of this change, there have been significant developments in the wind energy industry. Wind turbine technology has evolved with the advent of more efficient, economical, and reliable wind machines. Many utilities in Europe and in the United States now use wind power to supply increasing levels of electricity supply. Recent volatility in natural gas markets has induced a closer look at the power price stability offered by wind power plants. Although a significant fraction of wind power that has been developed in the United States resulted from regulatory action or other political decisions, wind power is now often cost-competitive with other conventional power sources.

This article examines some of the main drivers of wind energy economics in the context of large-scale power generation. In spite of the many wind installations throughout the world, surprisingly little is known about specific integration costs of wind plants. As the electric utility industry gains more experience, this knowledge base will grow.

Large-scale use of wind power plants can pose challenges to power system operations and planning. Because wind is an intermittent power source that is available only when the wind blows, the economics surrounding the use of this technology can become complicated. Because wind systems cannot respond to control systems in the same way as can conventional thermal plants, questions arise concerning the need for storage or other mechanisms that could compromise the economics of wind but would perhaps help to integrate wind into the electrical supply. Other questions concern the ability to measure the wind plant capacity in a way that helps decision makers to analyze economic trade-offs between wind and other types of power plants.

This article describes some of the recent trends in the cost of wind power plants. It discusses the economic value of wind power in the context of bulk power generation. Because of its variable nature, the use of wind power can be more effective when it can be forecast more than a few hours in advance. Furthermore, the value of wind power depends in large part on the specific characteristics of the generators in the same grid.

2. RECENT TRENDS IN THE COST AND USE OF WIND POWER PLANTS

Development of wind power systems has increased rapidly since 1986. At that time, most North American wind turbine installations were in California, resulting from significant tax incentives in that state combined with the availability of long-term power purchase agreements that regulators required utilities to offer to independent power producers. During this period, the average energy cost of wind-generated electricity fell from $0.40 in 1979 to a range of $0.04 to $0.06/kWh in 2000. During the 10 years ended in 2000, the cost of energy fell from a levelized cost of approximately $0.11/kWh (in 2000 dollars) to $0.06/kWh at moderate wind sites, with an average annual wind speed of 5.8 m/s. For high-wind sites with an average wind speed of 6.7 m/s, the cost of energy fell from just under $0.08/kWh to approximately $0.04/kWh during this same time period. These falling costs, along with a U.S. federal production tax credit (PTC), helped to increase development in the United States beginning in the early 1990s and continuing through the end of 2001. The PTC provides a $0.015/kWh credit for electricity generated by wind power plants. At the time of this writing, the PTC was set to expire December 31, 2003.

Beginning in the early 1990s, the wind industry grew very quickly in Europe, where development was heavily influenced in Germany by aggressive public policy of mandated wind purchases at relatively high prices. German policy was to help address environmental issues associated with power generation that are perceived differently in Europe than in the United States. As can be seen in Fig. 1, growth in Europe far outstripped growth in the rest of the world during the past decade or so. The graph shows the projected path of development for the period from 2002 to 2005. The primary driver of this growth is the anticipated cost-competitiveness of energy from wind compared with other power generation technologies. Wind energy cost was predicted to fall to $0.03 to 0.05/kWh by 2004, with further reductions made possible by higher towers, greater energy capture at lower wind speeds, and even more reliable technology. However, growth in the rest of the world will also be driven by enormous electrical capacity needs in regions with little, if any, existing electric power.

The cost of wind energy is a function of the technology and the wind resource at the development site. The levelized cost of energy includes both fixed and variable costs over the lifetime of the wind plant. The fixed cost depends on the ownership structure and the method used to finance the plant construction. For example, cooperative ownership generally involves a lower interest rate than could be obtained by an independent power producer. In the United States, cooperatives do not qualify for the PTC because they

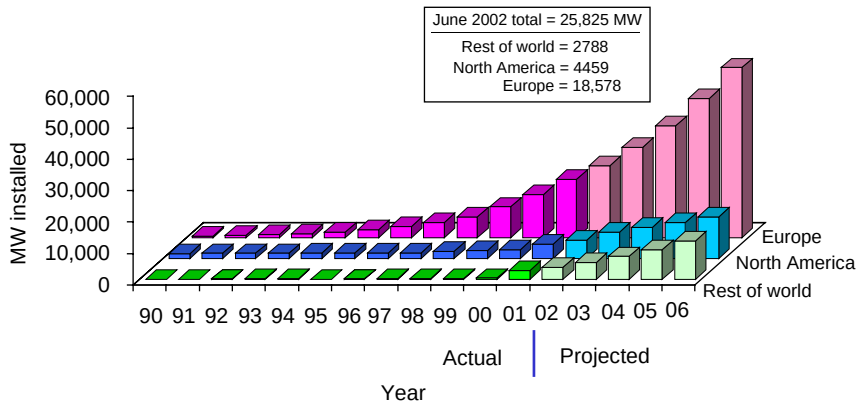

FIGURE 1 Growth of wind energy capacity worldwide. Adapted from BTM Consult ApS (March 2002) and *Windpower Monthly* (January 2002).

are nonprofit entities. Instead, such organizations can use the renewable energy production incentive, which allows nonprofits to take advantage of a similar cost reduction as would be available to their for-profit counterparts. Both types of ownership structures can use project financing or internal/corporate financing, with the latter providing a lower capital cost and, therefore, a lower levelized cost of energy.

Operation and maintenance (O&M) costs are the variable costs associated with wind power generation. These costs include labor and materials required for operation and periodic maintenance of the turbines, insurance, land lease, property tax, and general and administrative costs. At the time of this writing, average O&M costs were approximately $0.005/kWh and were expected to decline as turbine reliability improves.

Contract terms and conditions can have a significant impact on the financing terms for new projects and for major capital repairs and repowering. These financing terms can have a significant impact on the cost of wind energy.

3. ECONOMIC VALUE OF WIND POWER PLANTS

The results in this section are based largely on power production simulation modeling of real power systems. Wind power plants can provide value in three ways. First, because there is no fuel cost for a wind plant, wind energy can displace conventional generation and the fuel it consumes. Second, construction of new wind power plants can also reduce the need for building new conventional plants; this is called the capacity value of a wind plant. Third, because they can reduce the emissions created by the use of some conventional fuels, wind plants can have emissions reduction value.

Because the benefits of wind power generation depend heavily on the economic characteristics of the remaining electricity supply, this section begins with a short description of the power dispatch process, focusing on those aspects that are most relevant to the economics of wind power.

Modern power systems include a large number of generating units that are often of different sizes and types. For example, to start up a coal plant, the boiler must be brought up to operating temperature before power can be produced. This process normally takes several hours. When the plant is not needed, it can be shut down, but this process also takes time. To run this type of plant in an efficient manner, the operator will attempt to minimize these start/stop operations, running the plant for long durations of time. During this operating period, the plant may be able to produce either low or high levels of power, but a large thermal plant such as this might not be able to respond quickly to operator commands. Large coal plants generally have relatively low fuel costs, so these units are typically operated as base load units, with minimal output variations for relatively long periods. The average cost of energy can be quite low.

Other types of generators might be able to respond more quickly to operator signals, and they can be used as load-following units by increasing output to match rising demand or by decreasing output to match declining loads. This type of unit often has a higher energy cost than does a base load unit, but the former offers somewhat more flexibility in matching power generation to the load. Combustion turbines generally have much higher fuel costs, but they start/stop in relatively short time scales.

Most power systems are operated with a primary objective of providing electricity when and where it is needed at the lowest possible cost or the highest possible profit. Therefore, in either case, the power system operator must solve a complicated mathematical optimization problem that minimizes cost, subject to the operating constraints of the various generating units and subject to providing sufficient energy and capacity to satisfy electrical demand. The solution to this problem normally involves making full use of the least expensive generating unit, followed by each unit in increasing order of energy cost (and subject to the various generator constraints). After midnight, electrical demand is typically low. It would not be uncommon to find a utility running only its base load units—those with the lowest energy cost. As the electrical demand increases in the morning, progressively more costly plants must be brought online. During a few hours in the late afternoon or early evening on a particularly hot day, expensive peaking plants may be run, but only for the minimum necessary time.

Figure 2 illustrates the basic economics of a utility or generating company that owns or operates the three types of power plants. The marginal cost (MC) curve is defined as the change in total cost divided by the change in energy output. Under perfectly competitive markets, the MC curve is the same as the firm's supply curve. However, because wholesale and retail electricity markets are not perfectly competitive, the MC curve represents the upper bound on the quantity of output (energy) that an electric utility would be willing to provide at alternative prices.

The initial downward-sloping portion of the MC curve shows the effect of operating base load units at higher output levels; that is, it increases their efficiency and decreases their cost. For higher demand levels, less economical plants are added to the mix. These intermediate units have higher MCs, resulting in systemwide MC increases. Finally, peaking units provide energy during system peak times at even higher MC.

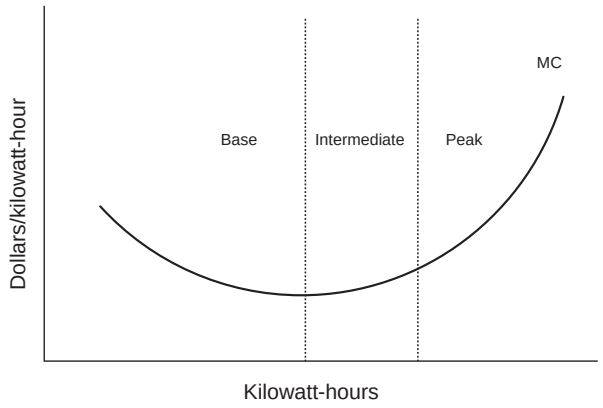

FIGURE 2 Trend in marginal cost of electricity production in relation to various types of generators.

This curve helps us to understand why the value of wind generators can vary for different utilities, different seasons, or even different times of the day. Because power demand fluctuates over time, the utility effectively moves up or down its MC curve as it brings new generators online or reduces power output as the demand falls. Because wind is fuel free and so has a near zero MC, it would always be used in an economic dispatch whenever possible. The result is that the remaining load, net of wind generation, decreases and the marginal generator's output can be reduced or eliminated over the relevant time period. Utilities with relatively high MCs would find that wind power has a high value, whereas utilities with lower MCs would find that wind energy has a lower value. Furthermore, this value would tend to change over time for all utilities due to the constantly changing nature of the electrical load. This also helps to explain why a wind plant that produces significant energy output during the night is not as valuable as a wind plant that produces during the day.

When new wind plants go into service, they can partially displace the need for conventional power plants. This displacement is called capacity credit. At the time of this writing, it was not entirely clear how this displacement, or capacity credit, would be evaluated in restructured energy markets. However, with the increasing need to fully evaluate various risks posed by power system operation, utilities have turned to financial risk theory to evaluate the more complex market environment, and it appears that probabilistically based methods to evaluate capacity credit will continue to be useful. One such measure that has evolved from power system reliability analysis is called the effective load-carrying capability (ELCC), which is based on achieving a loss of load probability (LOLP) target with two alternative generator additions. ELCC allows one to rate the equivalent perfectly reliable power plant that would provide the same system reliability as a wind plant. In other cases, it may be more useful to rate the wind plant capacity credit in terms of its reliability-equivalent gas plant. This capacity credit is computed with the help of a production simulation model or an electrical system reliability model. Such a model uses extensive power system data to calculate, among other things, the probability that generation will be sufficient to meet the projected electrical demand. The capacity credit of a wind

plant can range from very low, perhaps 10% of its rated capability, up to 40% or higher, depending on the correlation of wind power to load and other system characteristics.

Wind energy can displace emissions that are often produced by other power sources. This emissions reduction is a function of the characteristics of the marginal plant or plants and the extent to which wind power can offset other forms of power. For example, a wind plant that can displace energy from a high-emissions source would provide a higher emissions value than would a wind plant that displaces output from a modern gas turbine.

Placing a value on avoided emissions can be a difficult and controversial practice. In principle, this valuation would involve an accounting of illnesses, hospital visits, and other costs incurred as a direct result of the major emissions sources. There are some markets for emissions mitigation credits in the United States that implicitly value emissions. However, because it is difficult to follow the complex causal chain to assess actual pollution costs, specific damage values can be difficult to justify. The state of Minnesota established the cost of emissions in 1997 and updated these values in February 2002. Prior to electricity restructuring, California regulators required an explicit valuation of emissions in the various air basins as part of electric utility generation expansion plans.

Figure 3 illustrates the three components of the value of wind power systems. The calculations for this graph are based on an electricity production simulation model applied to two large utilities in the United States. (The utilities, denoted by u1 and u2 in the figure, are not identified due to prior agreement.) These utilities have different generation characteristics, resulting in differing estimates of the benefit of wind. The simulations show the impact of alternative wind sites to economic value. (Two wind sites are shown in the figure: one from the High Plains and one from a mountain pass on the West Coast.) The largest benefit results from the reduction in fuel that is needed by conventional power plants when wind is added to the system. The capacity value is based on estimates of the reduction of conventional new capacity that can be offset with wind power. And the emissions benefit is valued based on methods and data developed by the California Energy Commission.

Figure 4 shows the generation of a large utility during the annual peak day. With a hypothetical wind plant, as depicted in the graph, the generation of electricity using gas and oil units can be reduced. Large base load units, such as nuclear and some other thermal plants that cannot easily alter their output, are typically run at a constant level, as can be seen in the graph. A different pattern of wind power production would change the quantities of gas, oil,

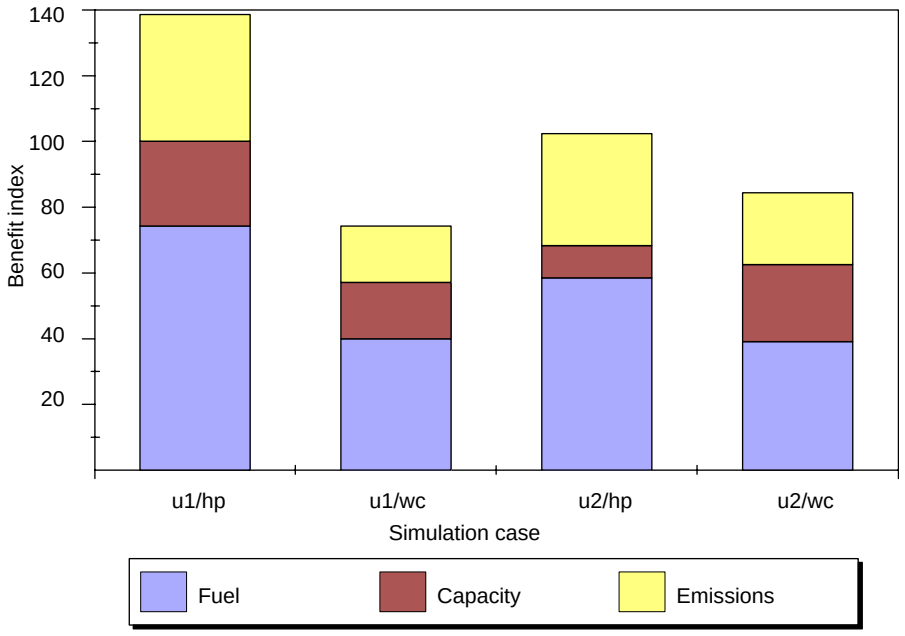

FIGURE 3 Benefits of wind power, separated into fuel savings, capacity credit, and avoided emissions, valued at prices used by the California Energy Commission. hp, High Plains; wc, West Coast.

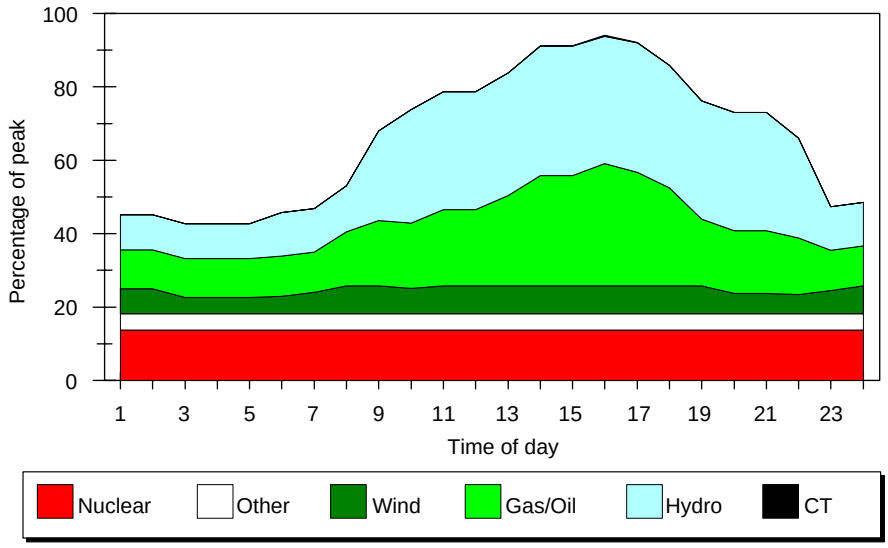

FIGURE 4 Economic dispatch of a peak day with wind energy. CT, combustion turbine capacity.

and coal required, and this could have a significant impact on the value of the wind power plant.

4. ROLE OF WIND FORECASTING AND ITS RELATIONSHIP TO THE VALUE OF WIND

Wind power is sometimes characterized as an intermittent and unpredictable resource. Although it is intermittent, the output of a wind power plant can be predicted from several minutes to several days in advance. For forecast horizons longer than a few hours, accuracy falls significantly, but newly emerging forecasting techniques can enhance the economics of wind power plants. Wind forecasting models that appear to be the most accurate are actually hybrid forecasting models. The first stage of the model is to predict local weather conditions for the forecast period. The second stage of the model applies various statistical methods that adjust the meteorological model output so that the wind power can be predicted. Statistical techniques that appear to be most promising are autoregressive moving average models, formally known as ARIMA models, and neural network models.

With a reasonably accurate wind forecast, power system operators can do a better job of scheduling enough generating resources to meet the electrical load. Accurate wind forecasts make it possible to schedule just the right level of generation, whereas inaccurate forecasts can result in either too much or not enough generation online to service the load. Assessing the cost of excess generation is conceptually straightforward and involves calculating the cost of running the generators that were not needed to supply the electrical demand. Accounting for the cost of insufficient generation might be easily assessed if a neighboring utility can provide the extra demand. But in other cases, it can be more difficult to assess the cost of insufficient generation. In a more extreme case, the generation shortfall may be large enough to cause outages in the system. Even if outages do not occur, there is a cost of increasing risk of such outages, with an economic value that can be difficult to quantify.

Figure 5 illustrates the forecast benefit for various levels of accuracy for a large utility. The graph is not symmetrical due to the specific characteristics of the MC curve. Although perfect forecasting is not feasible, the graph shows that good forecasts can increase the value of a wind plant.

5. EFFECTS OF GEOGRAPHICALLY DISPERSE WIND SITES

The economic value of wind power plants can be compromised by intermittency and inaccurate forecasting. Although this is a function of the specific characteristics of the wind resource, energy demand, and electrical supply, it is an issue that has received considerable attention. There are several ways in which to reduce this intermittency to help maximize the economic benefit to the electrical supply, and one of the most important ways is to take advantage of geographic dispersion during the design and planning

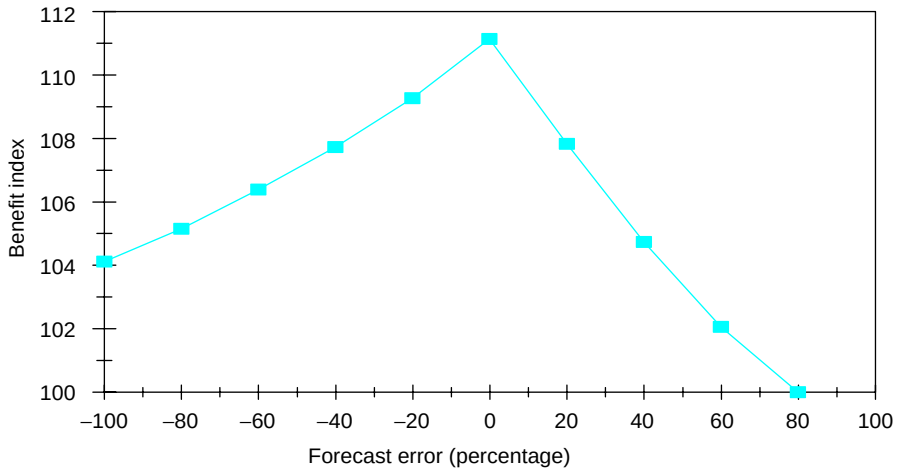

FIGURE 5 Value of a wind forecast at various accuracies during a period when wind output averages 50% of rated capacity.

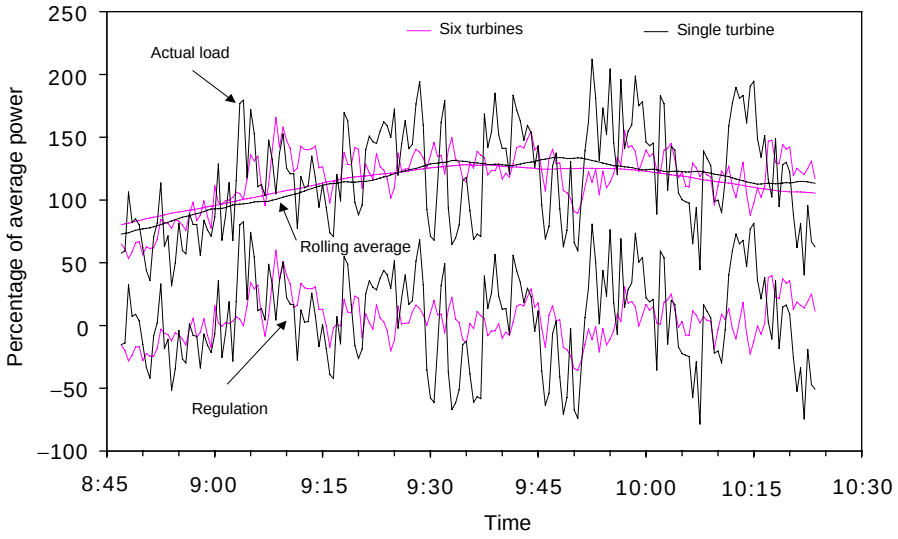

FIGURE 6 Smoothing effects of multiple wind turbines over time scales ranging from minutes to 2 h.

stages of the wind plant. The principle of geographical dispersion is simple and based on the observation that the wind speed varies over progressively larger areas. This principle applies to the many turbines within a single wind farm as well as to multiple wind plants that may be separated by up to hundreds of miles.

Figure 6 shows the impact of geographic diversity on a small time scale with only six wind turbines. The jagged lines that show the single turbine output can be compared with the significantly smoother line showing the output of the group of turbines. The figure also shows an estimate of the regulation from conventional generators that could offset the small perturbations in the output of this small wind farm.

Smoothing also occurs over larger time and distance scales. Figure 7 shows the smoothing effect over hypothetical wind farms in Iowa, based on actual time-synchronized wind speed data. Given a hypothetical wind plant of 25 MW, the graph shows the hourly variation that would occur during the month of July if the 25 MW were located at each of the 12 sites, one at a time. The final graph bar shows the dramatic reduction in the hourly output variation that would occur if the 25 MW of wind capacity were evenly split among the 12 sites.

In fact, achieving the smoothest aggregate output might not produce the best economic benefit. Economic studies have used advanced optimization techniques, such as fuzzy logic and genetic algorithms,

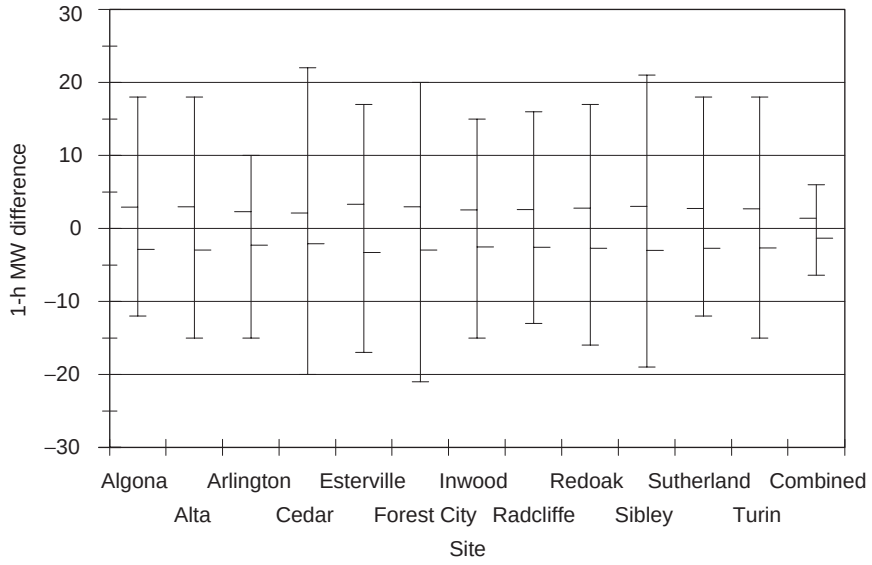

FIGURE 7 Reduction in hourly wind power output when the wind capacity is spread among 12 sites in Iowa compared with output fluctuations at single sites. Bars show maximums, minimums, means plus standard deviations, and means minus standard deviations.

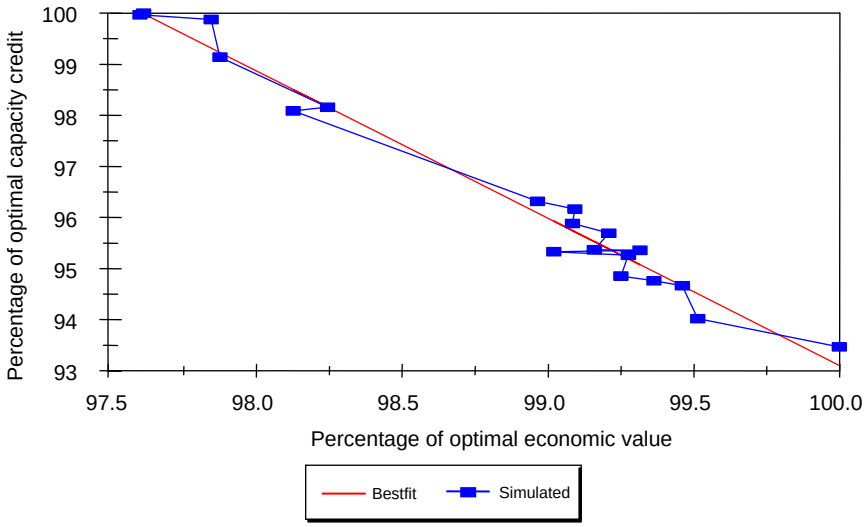

FIGURE 8 Trade-off curve between reliability and least cost power generation.

to explore the economically optimal allocation of wind capacity among multiple wind sites. The results of these analyses imply that this optimization depends on the characteristics of the specific wind regimes and on the characteristics of the remaining generating supply and the electrical demand.

The economically optimal site combination might not maximize system reliability. Figure 8 illustrates this trade-off and is based on the Iowa analysis. The graph shows a scatter of points, each of which represents a particular capacity distribution among the 12 sites. Because each capacity distribution has different reliability implications and differing economic benefits, the data can be plotted, resulting in this production possibility trade-off curve. Analyses such as these can be complex, but they can reveal important aspects of the economic viability of a wind power plant.

6. RESERVE AND REGULATION IMPACTS

As wind energy systems become more prevalent, there is increasing interest in the effect of these plants

on system reserves and regulation. Because electricity cannot be economically stored in large quantities, power system operators ensure that there is additional generating capacity that can be called on on short notice to meet unexpected increases in demand or to deal with outages of other generators or key transmission lines. This extra capacity is called "reserves." A contributing factor to the need for reserves is the overall reliability of the power supply. The intermittent nature of wind power raises the issue as to whether large quantities of wind might have an impact on the reserve level that should be available for meeting changing system demand requirements. If wind power plants were to cause reserve levels to increase significantly beyond what would be needed for competing generators, that would have a considerable impact on the economics of wind plants because additional capacity would be required to support them. However, system reliability studies that take into account the wind forecasting technology and statistical patterns of wind generation find that wind plants have only a small impact on the overall system reliability level and, therefore, do not significantly alter the level of system reserves required for reliable system operation. As more new wind power plants are developed and operated as bulk power sources, additional insights will be gained on this issue.

Similarly, there is little empirical evidence concerning the impact of wind power on regulation requirements. Regulation is the small movement in generators that compensates for very short-term variations in electric demand. If wind plants would require other generation to compensate for fluctuations in output in the seconds-to-minutes time frame, the economic value of wind would be less than if these fluctuations had no impact. Because these short-term fluctuations are generally random and uncorrelated with load fluctuations, many experts believe that regulation impacts are not significant impediments to the economic value of wind plants and current and planned rates of wind penetration. Because of the statistical independence of these fast wind and load fluctuations, it is likely that regulation impacts would not increase significantly at higher wind penetrations.

7. OTHER ISSUES: LOCATION OF WIND/LOADS/TRANSMISSION

The economic value of wind plants also depends on other factors, some of which have not been subject to systematic evaluation due to the emerging nature of this technology. Siting a prospective wind plant involves many considerations, including local permitting requirements and public reaction. Anecdotal evidence suggests that these issues can affect the overall cost of energy from wind, but they have not been systematically quantified.

One of the most important issues is the proximity of the wind plant to transmission facilities. Because wind resources are not typically found near load centers, building a large transmission line to move the power to market could potentially result in the wind plant becoming uneconomical. In transmission-constrained regions, wind plants might not be able to take advantage of periods when transmission capacity is available. Market rules that cover transmission access and financial settlement must be transparent and neutral to technology.

8. CONCLUSIONS AND SUMMARY

The economics of wind-generated electricity depends on several factors. Cost is primarily technology driven and is influenced by production technology and the effect of turbine reliability on O&M costs.

By far the most significant factors that contribute to wind energy value are related to the wind resource and the characteristics of the grid and the evolving market rules. As additional wind capacity is developed, these variables will be quantified more precisely.

Glossary

American farm windmill Chicago mill or simply farm windmill; it is a multiblade mechanical wind pump, initially made of wood and later made of metal, developed during the late 19th century in the mid-western United States and subsequently copied world-wide.

post mill Traditional European mechanical windmill for grinding grain and other materials (e.g., tobacco, paper) where the tower body is supported on a vertical post resting on a wooden trestle.

tower mill Traditional European mechanical windmill used for grinding grain and other materials as well as pumping water where a tower of wood or masonry remains stationary and only the cap with the rotor attached turns to face the wind.

windchargers Electricity-generating wind turbines used to charge batteries at remote homesteads; they were prominent before the advent of widespread distribution of central station electricity.

wind farms (or wind power plants) Multiple wind turbines or arrays of wind turbines used to produce bulk electricity for the grid.

By the first decade of the 21st century, wind power had become the best hope for the future of alternative energy. Of all the possible "new" sources of electricity, it had rather unexpectedly found itself the most touted and fastest growing alternative energy resource in the world, generating significant amounts of electricity in several countries, such as the United States, Denmark, Germany, and Spain, as well as impressive amounts in many other countries. The new era of wind development was led by the United States during the 1980s, but Europe has overtaken that ranking, accounting for two-thirds of total worldwide wind development by itself in 2001. Now a global multi-billion-dollar industry, wind energy is regaining its once prominent place in the energy firmament. For millennia, wind power has been used for everything from kite flying and propulsion to grinding and pumping, but never before has it been so important for the generation of electricity. It is an old resource applied to a new mission with unprecedented success. This article describes how wind power came to achieve this status.

1. HARNESSING THE WIND

1.1 Prehistory Use

For longer than one can grasp, winds have been churning seas, carrying silt, eroding continents, creating dunes, rustling leaves, and filling sails. They are responsible for loess soils in China, sand seas in Libya, and dust storms in Arizona. They have created, destroyed, altered, eroded, and changed the shape of land, the vegetation that would cover it, and the lives of millions of people.

Wind energy exists without end, yet at no time have humans ever employed more than a tiny fraction of its kinetic energy. Its power is so beyond human control that cultures throughout the world have paid it homage in their legends and mythologies. Creation stories of nearly all cultures involve the power of the wind.

Like the mystery of who invented the wheel, we do not know when humans first employed the force of the wind to do work. However, in terms of utility, sailing would seem to be one of the most likely early uses, perhaps 40,000 years ago when Asians migrated to greater Australia. Although we know little of these voyages, the far later water journeys of Polynesians in their double-hulled sailing craft are unquestioned. For these early sailors, wind provided the kinetic energy for the exploration and settlement of the Pacific Ocean islands, including the Hawaiian Islands, where it later led to the invention of surfing, the earliest use of wind-powered recreational activity.

1.2 Historic Uses of the Wind

As in prehistory, the first historic use of wind power involved its use in transportation. Egyptians plied the Nile River as early as 3100 BC using craft equipped with sails of linen and papyrus. In *The Odyssey,* Homer wrote of Odysseus, who sailed the Ionian and Aegean seas, eventually making a crucial error when he angered the god of the winds. Aeolus stopped the wind for 6 days, forcing Odysseus and his crew to rely on rowing, a very poor substitute. "No breeze, no help in sight, by our own folly—six indistinguishable nights and days," lamented Odysseus. The story of Odysseus reminds one of the capricious nature of the wind. Although it can be used, it cannot be put under human control any more than ocean currents can be put under human control. For this reason, wind has been successfully employed only sparingly, with inventors and engineers preferring power sources that they can manipulate as needed. Yet the importance of wind energy to human history is undeniable. From the time of Columbus until the middle of the 19th century, nations depended on sailing vessels. Advances in navigation and sail design combined to make the great age of the sailing craft feasible. In the billowing sails of thousands of ships for thousands of years, the following paragraphs trace the paths of commerce and conquest.

Whereas once the longest history of using wind power was on the sea and not the land, today the reverse is true. While the importance of sailing has faded to recreational use, the terrestrial applications of wind have multiplied. Where and when did people first turn to the wind to help in their harvests? We do not know exactly, but we do know that in the 10th century AD, windmills were turning in the blustery Seistan region of Persia (now Iran). For this, we have both artifact proof and written evidence. These were primitive windmills by modern standards, using vertical sails of reed bundles, and their owners built them to grind grain and lift water from streams to irrigate gardens. For centuries, these rudimentary yet ingenious machines were carried to other parts of the world, including India and China, where farmers employed them to pump water, grind grain, and crush sugarcane.

Independently, the post mill arose in England. Unlike the Persian sails, which follow a carousel's path around a vertical axis, the sails of the traditional European windmill follow a path around a horizontal axis. The whole assembly of the post mill, including the blades, axle, and milling cabin, rests on a massive vertical post. The miller orients the post mill into the wind by swinging the entire windmill around the post, hence the name post mill. In 1137, William of Almoner designed and constructed the first such mill in Leicester, England. For many years, historians of technology assumed that the English post mill idea was a by-product of the Christian Crusades, with the English post mill being inspired by the Persian horizontal windmills of Seistan. However, the designs of the two mills are very different, and the evidence points to multiple inventions rather than diffusion from a single source.

Environmental and social reasons help to explain why the post mill took root where it did in England. Much of the land in Leicester is level, limiting the use of water wheels. However, perhaps just as significant was social class. In England, the kings had vested the water rights in the nobility and in the established church. These rights were jealously guarded, and in a practical sense they gave control of energy production to the nobility. In this earlier world of vested and hereditary privilege came a new source of energy, one that the upper class could not control. In such an atmosphere, the wind became the great leveler of class. As the middle-class entrepreneur Herbert of Bury, Suffolk, stated in 1180, "The free benefit of the wind ought not be denied to any man."

Spreading throughout England, the use of the post mill eventually made its way to the European continent. By 1300, one saw horizontal axis windmills similar to those in England in Spain, France, Belgium, The Netherlands, Denmark, the German principalities, and the Italian states. Subsequently,

the more powerful and more elaborate tower mill replaced the simple post mill, especially in The Netherlands.

As the name implies, tower mills reached skyward by using wood framing, brick, and stone. The tower, like those of the modern wind turbine, was immovable. The cap with the rotor, horizontal axle, and gearing rested on a curb at the top of the tower. The miller pointed the rotor into the wind by swinging the cap on its curb. During the "golden age" of the European windmill, the Dutch alone operated some 10,000 tower mills, and they did more than pump water and grind grain. For example, they reduced pepper and other spices, cocoa, dyes, chalk, and paint pigments. Lumber companies employed them as primary power for sawmills. Paper companies used windmills to reduce wood pulp to paper. One authority estimated that the mills provided as much as 25% of Europe's industrial energy from 1300 to the coming of the steam engine and cheap coal during the 1800s. The remainder came from hydropower, assisted by human and animal labor.

1.3 Wind Energy in the New World

Although European countries explored and colonized the New World, there is disagreement as to whether the windmill accompanied them. The seal of New York City contains a windmill, early woodcuts of "Nieuw Amsterdaam" depicted windmills, and there are other examples of early windmills as well. But the European windmill was simply too large, cumbersome, and expensive to be easily adapted to New World conditions. Also, it was a labor-intensive device in a new land where labor was scarce and valuable. Any apparatus that required continual attention would have found limited use on North American soil. Furthermore, the climate and topography of the New England region favored water wheels, and by 1840 more than 50,000 water wheels were in operation. It was the energy source of choice.

The windmill did eventually find a home in the United States, albeit of a design different from that used in Europe, in the vast western part of the country. Inventors there came up with a blueprint for what would become known as the "American farm windmill." Adapted to a land of little rain but abundant wind, the American farm windmill was small, light, movable, self-regulating, inexpensive, and easy to maintain. It liberated groundwater in an arid area, bringing it to the surface and making agriculture possible. Between 1850 and 1900, an impressive and bewildering number of styles and brands of farm windmills appeared on the market. There is no way in which to estimate accurately how many such windmills once dotted the Great Plains, but some authorities have suggested a number as high as 6 million. These windmills added a vertical dimension to the otherwise horizontal space of the Great Plains and once were the most common landscape feature between the Mississippi and the Rockies. Today, the sight of an American windmill evokes a certain nostalgia for a simpler bucolic age. The windmill became an American icon.

1.4 The Marriage of Wind and Electricity

The development of wind power to grind grain and pump water was historically significant, but during the 21st century it has been the marriage of wind and electricity that offers the greatest promise. However, it was not a union that took place quickly. In 1748, Benjamin Franklin wrote a scientific friend that, in regard to electricity, he was "chagrined a little that we have hitherto been able to produce nothing in the way of use to mankind." It would be many years before the first practical use of electricity appeared in the form of the telegraph in 1844.

Although the telegraph was used extensively for more than half a century, little more was done with electricity until the first generating plants began operating during the final quarter of the 19th century. After that time, the use of electricity caught on quickly, and by 1900 it was becoming an essential element of the urban lifestyle. In this atmosphere of discovery, inventors contemplated the coupling of wind power and electricity. Journals such as *Scientific American* challenged American ingenuity to use "the natural forces which are in play about us." The most pressing problem was how to store this elusive form of energy. How could one use the power of the wind if one could not store electricity, especially given that the wind did not necessarily blow when one needed it? By the early 1880s, the French inventor Camille Faure had devised what he termed a "box of electricity" or storage battery. It seemed possible to generate electricity from the wind, store it, and use it when needed.

The first to build a practical large-scale wind turbine was Charles Brush, a scientist from Cleveland, Ohio, who had made a fortune through his electric arc lighting system. The basement of his Euclid Avenue mansion became his laboratory, but his experiments were limited by the lack of electricity. To resolve the problem, Brush in 1886 designed and constructed a wind turbine that was

of immense proportions. Visitors to his 5-acre backyard saw a 40-ton (46,300-kg) tower rising 60 feet (18.3 m) into the air. From the tower turned a rotor 56 feet (17.1 m) in diameter with 144 slender blades. Within the tower, he located his dynamo and the necessary gearing to drive it. In his basement, Brush installed 12 batteries. The turbine and batteries infallibly provided electricity for his 100 incandescent lights, three arc lights, and a number of electric motors. The Brush wind dynamo worked incredibly well for approximately 15 years, using "one of nature's most unruly motive agents," as *Scientific American* reported. The inventor used his machine only occasionally after 1900, which was the year Cleveland began offering the convenience of centrally generated electricity. He abandoned his machine in 1908.

Despite its success, the Brush wind dynamo was never duplicated. Although fuel was free, the machinery to capture it was not. Furthermore, Brush's extensive knowledge of both electricity and the working of the wind dynamo could not be easily replicated elsewhere. Although a smaller similar design was employed in New England by the Lewis Electrical Company (the first commercial wind turbine), it did not prove to be popular. Brush offered the public a concept, but not one that could be mass produced.

1.5 The Search for a Practical Wind Turbine

Experimentation continued sporadically between 1890 and 1920, but these decades represented the pause between invention and application. It was only after World War I that some mechanically minded Americans applied advances in aeronautics to the design of a practical inexpensive wind turbine. In 1920, few North American farmers had electricity, and those who did produced it with gasoline-powered generators such as Delco "light plants." By the late 1920s, wind turbines began to compete in the effort to provide the American farm family with the convenience of electricity. A number of companies produced wind turbines, but the most successful were Jacobs's Windelectric and Wincharger. Joe and Marcellus Jacobs were not engineers but rather farm boys with an inventive flair. They experimented on their parents' eastern Montana ranch. At first, they converted a multibladed farm windmill from pumping water to generating electricity, but it turned too slowly. Marcellus had learned to fly, and he soon realized that a three-bladed propeller might be a better solution to the problem of wind-powered electrical generation. The brothers eventually perfected the rotor blades, the blade feathering system, and a powerful generator that would characterize their wind turbine. Soon their ranch neighbors were purchasing the Jacobs's turbines. Uniquely, all of their experimentation and manufacturing took place on the family ranch. It was a perfect wind laboratory, but soon the brothers realized that truly building turbines in quantity would require relocation to a midwestern industrial center. They chose Minneapolis, Minnesota, in 1927, and between that year and 1957 the Jacobs brothers turned out approximately 30,000 small wind turbines. The Jacobs machines became legendary for their reliability. A Christian missionary in Ethiopia installed a Jacobs plant in 1938. In 1968, the missionary sent for a replacement set of generator brushes—the first repair in 30 years of operation. In 1933, Admiral Byrd installed a Jacobs plant on a 70-foot (21.3-m) tower at Little America. When Byrd abandoned his Antarctica outpost, he left the wind turbine. When his son, Richard Byrd, Jr., visited the site in 1947, the Jacobs was "still turning in the breeze," although only 15 feet (4.6 m) of the tower was free of ice. In 1955, one of the 1933 veterans returned and removed the blades from the still operating turbine because they were threatened by the advancing ice.

Although Jacobs marketed its wind turbine as the "Cadillac" of windchargers, many ranchers and farmers found that a "Chevrolet" would be sufficient. In general, they purchased a Wincharger brand from a company that produced models from 6 to 110 V and from 200 to 3000 W. R. E. Weinig, the general manager of Wincharger, testified in 1945 that some 400,000 of the company's wind plants operated worldwide. Other brands included the Miller Airlite, Universal AeroElectric, Paris–Dunn, Airline, Wind Kind, and Winpower. In 1946, the Sears Roebuck catalog marketed a Silvertone Aircharger for $32.50. Most of these turbines were small, powering a radio and perhaps a couple of 40-W lights, but nevertheless they filled the desire for electricity in rural regions of North America.

Meanwhile, active research on larger wind turbines was under way in Europe. In 1900, the world's expert on electricity-generating wind turbines was not Charles Brush but rather Poul La Cour, a Danish scientist who spent most of his professional life working on wind electric systems. By 1906, with the support of the Danish government, 40 wind turbines were generating electricity in the small nation,

beginning a tradition that has lasted to this day. To the south, Germany capitalized on La Cour's work and moved forward under the leadership of engineer Hermann Honnef and others. The editor of *Scientific American* noted that wind power in Germany "has been developed to a point that is surprising." Across the channel, the British showed a similar interest. In 1924, Oxford University's Institute of Agricultural Engineering tested seven turbines from five manufacturers. Two years later, the institute reported that the "cost of windmill-generated electricity for small lighting and small power purposes was found to be quite reasonable and, as such, justifies its wider use in rural districts where there is no general supply."

1.6 The Victory of Centralism over Individualism

By the 1930s, wind turbines had found a particular place in the rural landscape in both Europe and the Americas. However, as noted in the Oxford report, their use was recommended only "where there is no general supply" of electricity. In other words, engineers and entrepreneurs had become committed to central power systems and the creation of a grid of transmission lines to carry the electricity. The idea of individual power units was anathema to engineers who thought in terms of electrical systems that served large populations from a central generating source. Of course, private utility companies complained that getting power to rural America was costly. Stringing wires was expensive, and utility companies refused to serve rural homes unless they were in close proximity to each other and to urban centers. In 1930, only approximately 10% of American farm families could boast electricity despite a much higher percentage in urban areas. It was at this time that the Rural Electrification Act (REA) came into existence.

The REA, passed in 1936, would change these statistics dramatically in the United States. The act called for local farmers to establish cooperatives with the authority to make loans to bring electrical power to farms within their designated region. It was enormously successful. No one would deny the accomplishment of the REA, but the federally backed cooperatives sounded the death knell for the windcharger industry. Centralization and government subsidies for the cooperatives killed the industry. One wind energy executive attempted to persuade Congress to include windchargers as part of the REA in more isolated areas, but neither Congress nor REA administrators would consider such a deviation from their commitment to a centralized power system. By 1957, every American wind electric company had closed its doors.

1.7 Large Wind Machine Experiments

While federal legislation stilled the small, farm-oriented wind turbines, one engineer was thinking on a much grander scale. A young engineer named Palmer Cosslett Putnam first became interested in wind energy in 1934 when he built a house on Cape Cod and, as he put it, "found both the winds and the electric rates surprisingly high." Putnam had in mind hooking up to utility company power, using it but sparingly, and selling back the surplus from his wind turbine. However, no mechanism existed at that time to convert direct current from a windcharger to alternating current that central station power plants delivered. Putnam researched the problem, and as an engineer committed to "economies of scale," he decided to build a huge experimental wind turbine that would generate alternating current identical to that from conventional power plants.

Putnam stripped bare a rounded knoll near Rutland, Vermont. There he erected a massive two-bladed turbine with S. Morgan Smith Company, a manufacturer of large hydroelectric turbines. Truckers struggled to bring some 500 tons (90,700 kg) of material and parts to the crest of Grandpa's Knob. The 70-foot (21.3-m) length of the two 7.5-ton (6800-kg) blades posed a particular challenge. However, on October 19, 1941, the rotor began to turn. It operated for approximately 16 months, producing 298,240 kWh in 695 h of online production. On February 20, 1943, a bearing failed, resulting in a 2-year hiatus because both parts and labor were difficult to obtain during World War II. Production finally resumed, but not for long. On March 26, 1945, one of the blades separated from the rotor and crashed to the ground and on down the side of the mountain. Although Putnam promised that he and his partners would repair the turbine, the expense of doing so was prohibitive. The great turbine never turned again.

What is most remarkable about the Smith–Putnam project was not its successful operation but rather the fact that it happened at all. Putnam had to rely on private industry for machinery, expertise, and (above all) funding. Fortunately, S. Morgan Smith bankrolled his effort. A number of distinguished scientists from prominent universities participated, as did some of the leading engineering firms of the

day. Vannevar Bush, then the dean of engineering at the Massachusetts Institute of Technology, put it well when he wrote that the project was "conceived and carried through free enterprisers who were willing to accept the risks involved in exploring the frontiers of knowledge, in the hope of financial gain." Obviously, there was no financial gain, but in its brief life the turbine certainly opened new frontiers of knowledge for the wind energy field.

2. THE FIRST U.S. BOOM

2.1 The Search for Alternatives

For less than 22 years, Americans held hope in the promise that nuclear power was going to provide all of the electricity they could ever need, but it was not to be. The idea that blossomed with such promise at the Shippingport Atomic Power Station west of Pittsburgh, Pennsylvania, in December 1957 ironically shriveled in the same state with the accident at the Three Mile Island nuclear power plant near Harrisburg in April 1979. The event, including the chaotic public and governmental responses it triggered, punctured the nuclear balloon, resulting in the cancellation of dozens of nuclear power plants. None has been ordered in the United States since then, and after the 1986 catastrophe at the Chernobyl plant in Ukraine, few have been built anywhere in the world. These events, coupled with the embargoes on oil and the constraints on coal burning during the 1970s, stimulated a more serious evaluation of alternative energy resources.

Although several resources did garner more attention, there was never a wholehearted effort. Nascent public and private alternative energy programs existed in scattered, small, and even persistent forms in many areas, but they received little more than perfunctory support from government agencies and large energy companies. Even the high-profile advocacy of the Carter administration did not have much staying power in terms of national policy, although it helped to build a foundation for later advances in some locations, especially California.

California was famously short on energy resources, and these deficiencies were to become painfully obvious over the years. During the second half of the 19th century, people relied on wood, but it became scarce rather quickly. Various forms of hydrocarbons were used for lighting, and when electricity became popular, hydropower was quickly put to work. However, its practical limits were also soon reached as California continued to grow. Soon the state ranked first in economic might, and feeding its appetite required huge amounts of electricity. Having virtually no coal, insufficient natural gas, and oil that was too expensive to use in power plants, and facing rising opposition to nuclear energy, Californians turned to alternative resources that have always been available in the state. At first, geothermal energy was the resource of choice, and it grew quickly. Yet ultimately its luster dulled, and by the mid-1980s serious attention was shifting to another resource—wind.

The attention given to wind power in California resulted not from the fact that the state was a dominantly windy place but rather from the convergence of local demand, state and federal financial subsidies, a favorable political climate, and the geographical convenience that found three sites with great promise virtually in the backyards of millions of people. Anyone who has driven the stretch of Interstate 10 through San Gorgonio Pass 100 miles east of Los Angeles, or the stretch of Interstate 580 through Altamont Pass 50 miles east of San Francisco, knows the strength and persistence of winds there. Even windier, albeit less traveled, Tehachapi Pass 50 miles east of Bakersfield was the third target of early development (Fig. 1).

With all of the favorable conditions for wind development finally in place by the mid-1980s, thousands of wind energy conversion systems (WECS) sprouted with a suddenness that startled the public. In unexpected numbers and with unexpected vigor,

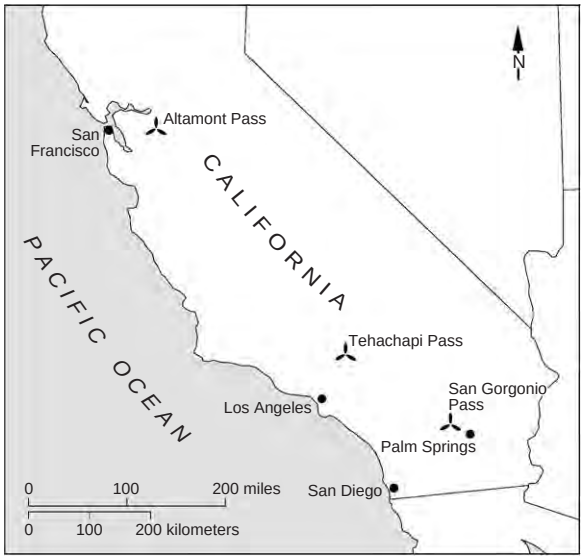

FIGURE 1 Principal developed wind resource areas of California.

people began to complain how the wind turbines changed aesthetics, increased bird mortality, produced electronic interference, and created noise. However, there was no turning back; California's experiment in large-scale development of wind power was just getting started.

2.2 Reactions and Early Lessons

The early stages of modern wind development in California faced some persistent barriers. Wind turbines are unavoidably visible and impossible to hide, especially in those locations where they were being concentrated in the state. Complaints about these new landscape additions continued, although they diminished in intensity as the technology improved and regulatory controls were imposed. Once financial subsidies ceased during the mid-1980s, wind power was left to survive on its own, and this was not possible for all installations or designs. A weeding out would soon take place as wind developers continued to face public complaints, technical difficulties, and financial challenges. Poorly sited and inoperable equipment was slowly removed, and regulators began flexing their bureaucratic muscles. The authorities who governed development in places like San Gorgonio Pass imposed controls on height, color, and reflectivity, instigated operational standards on design and noise, and required decommissioning bonds and protection of migrating birds and endangered species.

Despite the multiple regulations and engineering improvements that are now part of wind energy development in the United States, nothing can render them invisible and, at the same time, still economical to run. Simply put, the only way in which to hide wind turbines is by using the buffer of space. But in California, most wind turbines are along busy highways, always available for public scrutiny. Because of the slipshod way in which many developments were first installed, wind power received an early black eye that has taken years to heal. In the meantime, development activities picked up elsewhere, especially in Europe.

On the heels of the California experience and benefiting from improvements prompted by that experience, European wind developers began moving quickly to install their own projects. Their ambitions were encouraged by shortages of sufficient local resources, concerns about nuclear power and global warming, the political weight of "green" parties, and ample subsidies that became available to alternative energy developers. All of these factors taken together were to push wind development in Europe ahead of those in the United States during the 1990s, but Europeans' attraction to wind power had actually started years earlier.

3. THE EUROPEAN EMPHASIS

3.1 The Early Years

Denmark has assumed a leadership role in the development of wind power in Europe, but it took a path far different from that taken by the United States. Unlike American wind turbine design, which was concentrated in the hands of the aerospace industry, Danish wind technology grew out of the agricultural sector as a natural by-product of the Danish economy and the long history that Danes have with the wind. They used it to power the ships of their early conquests and to carry Norsemen as far as the New World. So-called "Dutch" windmills eventually became a common sight in Denmark, with a some 3000 of them providing the equivalent of half again as much energy as all the animal power then supporting Danish agriculture by 1890. In 1891, La Cour, the "Danish Edison," began experimenting with wind-generated electricity, and as early as 1903, La Cour's Danish Wind Power Society was fostering the idea of wind-generated electricity.

By the end of World War I, more than one-fourth of all rural power stations in Denmark used wind turbines. During the long wartime blockade, the 3 MW provided by these crude wind generators and the widespread use of small farm windmills for grinding grain were invaluable to the impoverished rural population. Although most windmills were used for mechanical power, it has been estimated that wind turbines were providing the equivalent of 120 to 150 MW in Denmark by 1920. Nearly 90 turbines were installed during World War II, including the 30-kW Lykkegaard wind turbine patterned after La Cour's *klapsejlsmølle*, and F. L. Smidth's more modern "Aeromotors." This design, like those of La Cour, used four or five wide blades resembling those of traditional windmills except that the blades were covered with metal shutters instead of cloth sails. These wind turbines were controlled by opening and closing the shutters. In contrast, the Smidth company became one of the world's first firms to marry the rapidly advancing field of aerodynamics to wind turbine design. The Smidth company's wind turbines incorporated both technologies and used modern airfoils upwind of a concrete tower.

After the war, interest in wind energy again waned, although Johannes Juul remained resolute. In 1950, he began testing a prototype wind turbine for the Danish utility SEAS, and subsequently he modified a Smidth turbine used on the island of Bogø. With the experience gained from developing these two machines, Juul began work on his crowning achievement, the three-bladed, stall-regulated, upwind rotor at Gedser that spanned 24 m (79 feet) in diameter. Installed in 1956, the Gedser mill operated in regular service from 1959 through 1967. By the late 1970s, modern wind turbine manufacturers and experimenters erected their first prototypes. By 1980, when the European wind energy conference was held north of Copenhagen, there were several designs in operation.

Meanwhile, Ulrich Hütter was designing and building wind turbines for the Nazi-owned Ventimotor company outside of Weimar, Germany, in the hope of reducing reliance on foreign sources of energy. Hütter's team experimented with several designs, including one of the first uses of a wind turbine to drive an asynchronous or induction generator directly coupled to the electric utility network. After the war, Hütter went on to become a prominent aeronautical designer who continued experimenting with wind energy. During the late 1950s, he installed a novel turbine that operated at high rotor speeds with only two slender blades.

At the opposite technical pole from Hütter, Juul was a traditionally trained engineer working outside of academia. Juul's design grew out of the Danish craft school tradition, and he built on the experience gained by Smidth during the war. Juul built a turbine for the Danish utility SEAS at Gedser incorporating the lessons learned. Meanwhile, both the British and the French installed prototype wind turbines during the 1950s and 1960s.

The availability of cheap oil from the Middle East doomed most of these programs, but Juul's turbine at Gedser and Hütter's turbine in the Schwabian Alps continued in operation for the next decade. Hütter's design and his argument for it would captivate German and American engineers for years to come. However, it was Juul's design and its adherents in Denmark that would come to dominate the field of wind energy some decades later.

Juul's simple robust design was adopted by the Danish wind revival of the late 1970s following the oil crises of the period. When the California "wind rush" began during the early 1980s, budding Danish wind turbine manufacturers were poised to seize the opportunity to export technology and expertise. Europeans of several nationalities flocked to California to seek their fortunes in wind energy, but none more so than the Danes. The trickle of Danish machines entering California in 1981 soon became a torrent. At the peak of the rush in 1985, Europeans shipped more than 2000 wind turbines, mostly Danish ones, to the United States. Later, after the collapse of the California market in 1985, Denmark looked elsewhere and helped Germany to become the leading wind power country in the world. Indeed, in 2001, Germans installed a record 2600 MW, and all of these wind turbines were technologically derived from Juul's work at Gedser.

3.2 Dependable Home Market

In 1981, Denmark set a national goal of installing 1000 MW of wind power by the year 2000. Denmark became self-sufficient in oil a decade later following discoveries in the North Sea, but the country continued its wind development program as a means of reducing greenhouse gas emissions. Denmark later increased wind's expected contribution to 10% of the nation's electricity supply by the year 2000, a target it exceeded. In 2001, Denmark was generating 16% of its electricity with wind energy (Fig. 2).

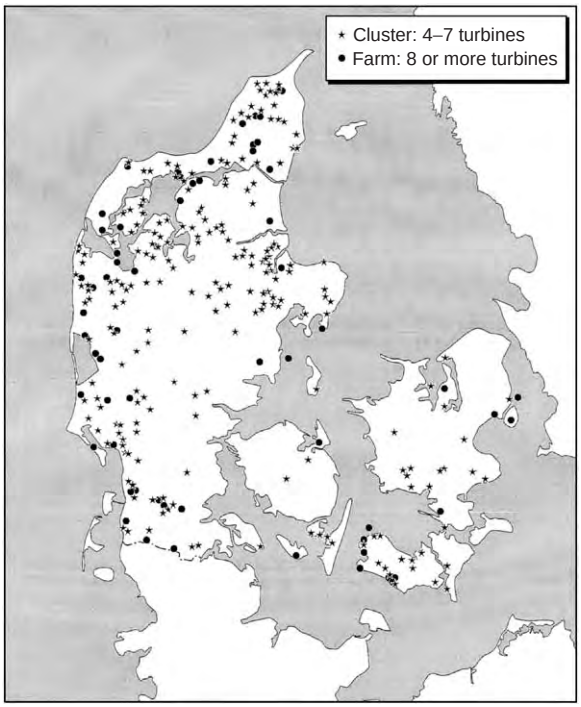

FIGURE 2 Wind-generating installations in Denmark as of February 2002.

The late 1970s brought a change that helped to further wind power development in Denmark when the European market for Danish farm equipment slackened, forcing manufacturers to seek new products for their rural customers. With generous incentives from the Danish government stimulating demand, Danish manufacturers quickly adapted their surplus capacity to the new wind turbine market. The demand for modern wind turbines by a population spread across the Danish landscape, a good wind resource off the North Sea, and a manufacturing sector accustomed to building heavy machinery for a discerning rural market all contributed to launching the world's most successful domestic wind industry. In addition, the small size of the country allowed manufacturers to service their own turbines, often directly from the factory. This spatial proximity enabled companies to learn quickly from their mistakes and to keep their turbines in operation as physical proof to potential buyers that the companies' machines were good investments.

Danes pride themselves on their unusual ability to act individually while working cooperatively. Even though most farms are owner operated, nearly all Danish farmers are members of farm cooperatives. These cooperatives process the Danish foods found on shelves worldwide. Danish wind turbine cooperatives and an association of wind turbine owners have had a profound effect on the development of wind energy in the country. Some 100,000 Danish households ($\sim$5% of the population) own shares in wind cooperatives.

Another contributor to Danish success was the Danish Windmill Owners Association (*Danske Vindkraftværker*). Formed in 1978, the group grew from a series of informal quarterly meetings of backyard experimenters, hobbyists, and environmentalists. Because many early wind turbines were unreliable, the group demanded minimum design standards. The most important element in the future success of wind energy was the requirement for a failsafe redundant braking system such as the tip brakes invented by Juul during the 1950s for use on his Gedser turbine. This single provision, more than any other, furthered Danish wind technology because it succeeded in ensuring the survival of the wind turbine when something went wrong. The owners association also compiled statistics on the reliability of Danish turbines and compelled Danish manufacturers to fulfill their product guarantees when the turbines underperformed. Collective action by Danish wind turbine owners was so successful that German wind turbine owners replicated the format south of the Danish–German border.

Wind energy grew rapidly in Denmark, not only due to early government incentives but also because Danish utilities were required to pay a premium price for wind-generated electricity. By agreement with the government, utilities paid 85% of the retail rate for electricity from privately owned wind turbines. Coupled with credits against energy taxes, Danish utilities were paying the equivalent of U.S. $0.10/kWh for wind-generated electricity during the mid 1990s in comparison with retail rates of nearly $0.17/kWh.

Many factors have contributed to the success of wind power in Denmark. One is two decades of consistent national policies supporting a strong domestic market for Danish wind machines, mostly for farmers and cooperatives. Another is the often-overlooked backing of Danish financial institutions; Danish banks and finance societies during the 1990s provided 10- to 12-year loans for 60 to 80% of the installed cost. Banks competed for wind projects by advertising themselves as "the wind banks" in local newspapers.

3.3 Nationwide Land Use Planning

Although thousands of wind turbines have been installed in Denmark by individuals without much notoriety or difficulty, Danish utilities encountered public opposition when they proposed wind projects of their own. These companies were viewed as outsiders, and the new neighbors of their proposed wind turbines considered them to be no different from conventional power plants. In response, and at the utilities' request, the government appointed a special wind turbine siting committee in 1991 to identify locations for wind turbines with a broad base of acceptability. Land use planning became necessary as wind turbines increased in size dramatically since the early 1980s and as their numbers continued to increase. The government committee estimated that the Danish landscape could absorb 1000 to 2800 MW of wind capacity, taking into account local objections and the preservation of scenic areas. Regional Danish jurisdictions now include wind energy in their land use plans. These plans designate zones where wind turbines are prohibited, where single turbines may be installed, where wind farms or wind power plants are permitted, and where clusters or single turbines may be erected with special approval.

Many municipalities, including the capital city, also include wind turbines in their local plans.

There are wind turbines in urban areas throughout Denmark and three projects within the environs of Copenhagen. One project, Lynetten, is visible from the Christianborg Palace, the seat of Denmark's parliament, the *Folketing*. The turbines are also visible from the Little Mermaid, the most visited tourist attraction in the city. Today, wind turbines in Denmark are dispersed across the landscape, in contrast to the giant wind farms typically seen in North America, India, and Spain. In fact, many Danish installations include only one turbine. In total, after 16 years of development, Denmark reached 2000 MW of installed wind capacity and paved the way for other countries to have similar success.

3.4 Germany Becomes the Leader

Wind developments in Germany differ somewhat from those in Denmark. The German market clearly demonstrates the effectiveness of their incentives to stimulate the growth of wind energy. In 1991, Germany's conservative government introduced the *Stromeinspeisungsgesetz* (electricity feed law), requiring utilities to pay 90% of their average retail rates for purchases from renewable energy sources such as wind turbines. The law, which encompassed only a few paragraphs, resulted in extensive wind development. By the early 21st century, wind turbines were in every part of Germany, from polders on the North Sea to hilltops of the central highlands (Fig. 3).

The parliament (*Bundestag*) modified the feed law in 1999, stabilizing both the price and the period during which the price would be paid. The measure ensured a stable and continually expanding domestic market. In 2001, wind turbines were producing 3.5% of the electricity in Germany, a nation of 80 million and the world's third largest economy. As a result of its precedent-setting feed law, Germany had the most dynamic and transparent markets for wind turbines in the world during the first decade of the new millennium. Like Denmark, Germany's large domestic market spawned the growth of some of the world's largest wind turbine manufacturers. Also like Denmark, many of the wind turbines in Germany were installed as single turbines or small clusters.

3.5 Other Markets

There are several other wind markets in Europe outside of Denmark and Germany. For example,

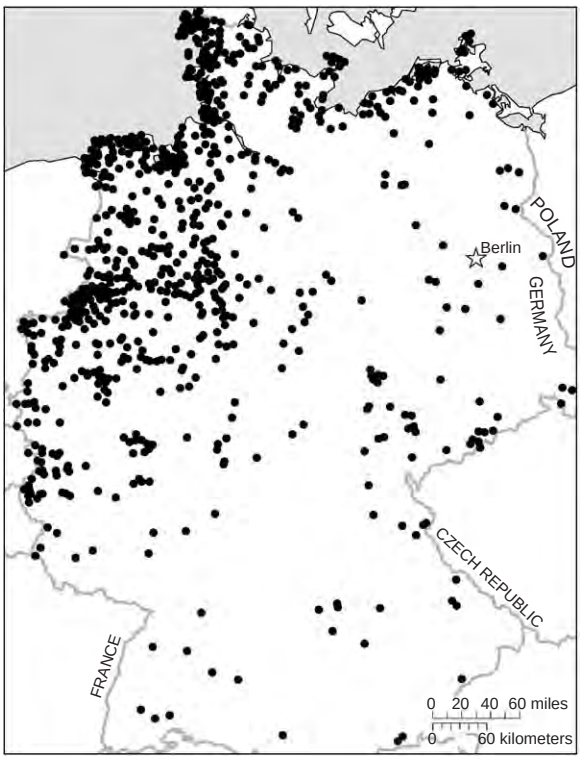

FIGURE 3 Wind-generating installations in Germany as of September 2001.

development began in earnest in Spain during the mid-1990s when the government introduced its own electricity feed law. Under the law, Spanish projects can choose a fixed price per kilowatt-hour of wind-generated electricity or the wholesale rate. Most have chosen the fixed price tariff. As a result of the combination of the country's electricity feed law, good wind resources, and supportive regional governments that see wind energy as a means of economic development, Spain has a bustling wind industry that rivals that of Germany. In 2001, Spain was the world's second largest manufacturer of wind turbines.

Great Britain and The Netherlands have decent wind energy resources, although they have had different experiences. Both countries launched wind development programs during the early 1980s but have lagged behind their European neighbors. Both misdirected research and development funds toward electric utilities and large industrial concerns in centrally directed programs that were incapable of supplying competitive products for a limited domestic market. Furthermore, programs designed to stimulate a market instead often antagonized prospective neighbors by forcing wind development onto the most sensitive sites. Although Great Britain

has the best wind resource in Europe (Fig. 4), organized opposition nearly brought the industry to collapse during the late 1990s. Despite an early beginning and an excellent wind resource, total installed wind capacity in both Great Britain and The Netherlands represented only 5% of the total installed in Germany in 2002.

France, with its longtime emphasis on nuclear power, has been one of the last European countries to turn their attention to the possibilities of wind energy. After watching how wind development was stymied in Great Britain and being familiar with the opposition to new nuclear construction, France sought to adapt the German feed law to French conditions. The French electricity feed offers three fixed tariffs: one price for windy sites, a second price for modest wind resources, and a third price for the least windy areas. It also limits the size of the wind farms that can be built under the program. These provisions encourage a greater number of smaller projects than those found in North America and spread wind development beyond just a few windy provinces such as Brittany in the west and Languedoc in the south.

Several other countries, inside Europe as well as elsewhere, are installing wind generators. Within Europe, these include Italy, Greece, and Sweden. Outside of Europe, wind development is prominent in India, particularly in the states of Gujarat and Tamil Nadu. Several large projects were also built in

FIGURE 4 Wind-generating installations in the United Kingdom as of January 2002. Courtesy of British Wind Energy Association.

North Africa and China during the late 1990s. By the turn of the 21st century, wind turbines in commercial projects were operating on every continent.

4. REJUVENATED NORTH AMERICA

4.1 The Great Plains

After the burden of bad press coming out of California, progress in wind power in the United States dwindled virtually to a standstill during the late 1990s, just as it was picking up momentum in Europe. Ironically, support and success in Europe rekindled the American market. Texas has been one of the leaders of this resurgence, followed by several other states such as Minnesota, Iowa, Oregon, Washington, and Pennsylvania (and soon perhaps the Dakotas and Massachusetts). Many reasons explain this renewed interest. First, wind technology has matured, becoming more efficient and reliable and less threatening to wildlife, especially to birds. Second, certain economic incentives now exist for utility companies to promote the resource, most specifically their ability to capture "credits" as a part of renewable portfolio standards. For example, these standards in Texas require utilities to provide a percentage of their electricity from renewable energy. Once this step was taken, Texas surged to nearly 1100 MW by 2001, second only to California's 1700 MW. Most of this new Texas capacity is in West Texas, in the vicinity of Iraan and McCamey. The quick growth in Texas is due in part to a policy that allows companies who exceed the minimum required percentage to sell their additional credits to other providers.

A third reason behind the renewed growth of wind power in the United States is that farmers have learned that wind power can make them money and help them to keep their land. For this reason, the Great Plains seem destined to assume the leadership position in U.S. wind power development and perhaps the world, a result of a combination of natural and cultural conditions. Most notably, the U.S. wind resource is concentrated there as the result of favorable climatic and topographic conditions. It was estimated that the potential in the Dakotas would match 60% of the electrical demand for the entire country in 1990 (Fig. 5 and Table I).

Another important reason for the increased activity in the Great Plains is found in the region's history of land use. More than in any other part of the country, agriculture is the economic mainstay of the region, and it has fallen on hard times, particularly at the expense of the small farm. Word has spread quickly across the Great Plains that wind turbines can substantially improve the economic return from property in the region. In fact, farmers in many areas today generate more income from electricity than from traditional farm products

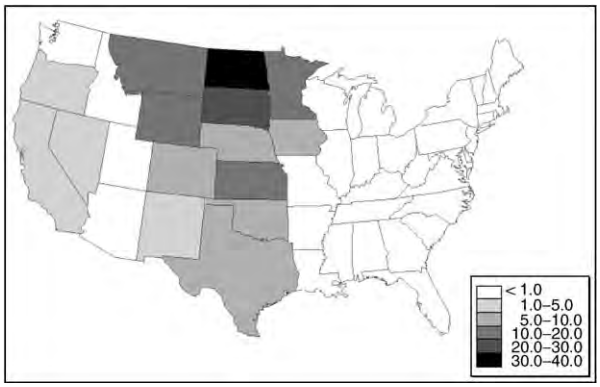

FIGURE 5 Wind energy potential as a percentage of total electric consumption. Reprinted from Pacific Northwest National Laboratory. (1991). "An Assessment of the Available Wind Land Area and Wind Energy Potential in the Contiguous United States." PNNL, Richland, WA.

TABLE I

Wind Potential in Selected States

Rank	State	Billions of kilowatt-hours
1	North Dakota	1210
2	Texas	1190
3	Kansas	1070
4	South Dakota	1030
5	Montana	1020
6	Nebraska	868
7	Wyoming	747
8	Oklahoma	725
9	Minnesota	657
10	Iowa	551
11	Colorado	481
12	New Mexico	435
13	Idaho	73
14	Michigan	65
15	New York	62
17	California	59[a]

[a] Illustrates that numerous states have greater wind potential than does California, where the majority (~90%) of U.S. wind development has occurred to date.

while at the same time using only a small portion of their land for the physical wind equipment. Ironically, the very area of the country that several decades ago was home to the greatest concentration of windmills in the world will possibly become so again, this time having them pumping out electrons instead of water.

In addition to Texas, development on the Great Plains has been most noticeable in Iowa and Minnesota, where 324 and 319 MW of generating capacity, respectively, were installed at the time of this writing. Unlike Texas, where most of the wind installations are on marginal grazing land or in spent oilfields, the wind turbines in Iowa and Minnesota are on working farms.

Also on the Great Plains, albeit farther west, wind developments have been appearing in Wyoming ranching country, where at the end of 2001 there was about 140 MW of installed generating capacity. In some locations in that state, such as near Interstate 80 west of Laramie, the wind is ferocious, and for the first time it is being seen not as a burden of life in the area but rather as an asset. In the Great Plains, NIMBY (not in my backyard) is being supplanted by a new acronym, PIMBY (please in my backyard).

4.2 The Pacific Northwest

The other location of substantially increased wind power installations has been the Pacific Northwest, an area that recently has witnessed the second fastest growth after Texas. Several sites in the windy Columbia River Gorge east of Portland are being monitored, and the Stateline Project, along the eastern border of Washington and Oregon, amounts to approximately 180 MW of capacity. Here too it is making money for local people; according to an article in the March 25, 2002, issue of the *Register Guard* of Eugene, Oregon, Northwestern Wind Power is paying 60 farmers in four counties alone to build wind turbines on at least 150,000 acres. Another developer, SeaWest Wind Power Inc., has leased tens of thousands of acres from at least 20 landowners in Oregon and Washington. In Sherman County, some farmers can expect a $10,000 sign-up payment, $15,000 for each turbine installed, and up to $5000 per turbine per year. That does not include the money that developers pay to reserve the land—approximately $2000 per month—while they conduct wind studies. Here, as in the Great Plains, wind development is becoming a profitable business.

4.3 Nantucket Sound

Objections to wind power, infrequent in the Northwest and Great Plains, still exist in some areas where population is concentrated, especially in those areas that are considered attractive tourist destinations. During recent years, such public opposition, which began in California, has been concentrated on a site off the coast of Massachusetts, where 170 turbines have been proposed to spread across the sea on a 28-acre patch on Horseshoe Shoal in Nantucket Sound, 9 miles off Martha's Vineyard and as close as 4 miles to Cape Cod. Objections, particularly from an organization called the Alliance to Protect Nantucket Sound, have focused on the visual intrusion of these turbines and to the potential disruption of traditionally productive fishing grounds. At least 10 other wind power projects are being considered elsewhere in New England, but because the $700 million Cape Wind project came first, the discussion about offshore wind power is concentrating here. Regardless of how the controversy off Cape Cod is resolved, it has underscored a key point in the future potential for this renewable energy source. In some places wind power is welcomed warmly, whereas elsewhere it is opposed with vehemence.

5. TRENDS

Wind power has become the best hope for the future of alternative energy. Of all the possible "new" sources of electricity, it has rather unexpectedly found itself the most touted and fastest growing alternative energy resource in the world, generating significant amounts of electricity in several countries, such as the United States, Denmark, Germany, and Spain, as well as impressive amounts in many other countries (Fig. 6).

Development of wind power has been following several trends. One has been the effort toward greater economies of scale that results through the use of multimegawatt turbines. Most of the early turbines of this size were abandoned by the mid-1980s after failing in three areas: hours of operation, energy generated, and contribution toward making wind technology more competitive with conventional fuels. Another round of large turbines during the late 1980s and early 1990s performed somewhat better than their forebears, renewing hope among government-sponsored laboratories that large wind turbines did have a future after all, but they too

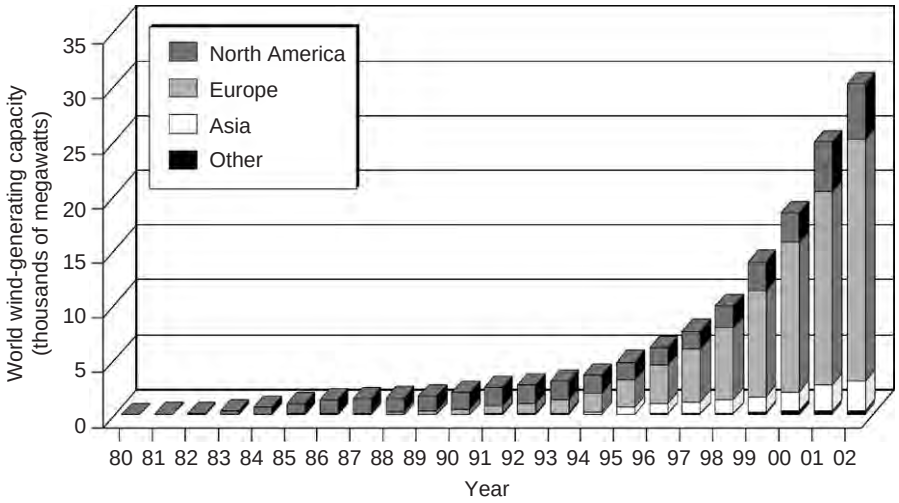

FIGURE 6 World generating capacity, illustrating the steep and recent rise in installed wind power.

were not very successful. In 1990, the European Commission intended to chart the way for a third round of funding for large wind turbine development. In contrast to the past, funds were directed toward wind turbine manufacturers rather than the aerospace industry or other large industries. European governments, like their North American counterparts, had promoted megawatt-sized wind turbines for more than a decade with little success. The European Community worried that the progression toward larger wind turbines produced by Danish and German manufacturers would take too long to reach the size that program managers in Brussels, Belgium, believed were the optimum for Europe.

Manufacturers participating in a more aggressive program erected their prototype megawatt-class turbines during the mid-1990s. Commercial production began during the late 1990s, and by early 2000 increasing numbers of the turbines were being installed in Germany. In 2000, the average wind turbine installed in Germany was exceeding 1 MW for the first time, a milestone that took much longer to achieve in the United States because development rested not with wind manufacturers but rather with the National Aeronautics and Space Administration (NASA). However, circumstances eventually improved. By 2002, megawatt-scale wind turbines, some with more than 100 turbines of 1.5 MW each, were becoming common in Europe and on large wind farms in North America.

Another trend has been to install new turbines not on land but rather offshore. This strategy has been practiced with special vigor in Europe in the hope

FIGURE 7 Visualization of a suggested offshore wind farm near Samsø, Denmark. The original idea was to place 10 turbines in a circular array. The project was expected to be built in 2003 in a linear array. Courtesy of Frode Birk Nielsen.

that offshore locations would reduce siting conflicts. Because offshore turbines require more expensive infrastructure, projects have longer lead times and must be larger than those on land. For this reason, such projects have been slow to develop, but the Danes and Swedes completed small near-shore projects during the late 1990s. One large project of 20 2-MW turbines, Middlegrunden, was installed outside of Copenhagen's harbor in 2000. In 2002, Denmark began installing 300 MW of offshore capacity, including the 160-MW Horns Rev project in the North Sea and the 158-MW Rødsand project

in the Baltic Sea. To try to visualize the impact of the turbines in advance, planners have taken to using computer visualization, for example, at Samsø (Fig. 7).

6. CONCLUSION

In most ways, wind power has come of age. The technology has improved, the economics has become more appealing, and substantial progress has been achieved in reducing environmental impacts. Planting wind turbines as a kind of semipermanent new "crop" on the Great Plains is becoming more common, making wind power more of a welcomed intrusion than a stimulus for citizen opposition.

Where public perceptions continue to slow growth in wind power, attitudes are largely influenced by benefits versus costs, and this has been most apparent off Cape Cod. Although one might argue that the sight of wind turbines helps to remind the public of the costs of their energy requirements, the proposed installation of fields of wind turbines in view of a heavily frequented tourist destinations is perhaps more than can reasonably be supported. In this case and probably others, the wind industry would be well advised to concentrate their developments where they are wanted and leave other environmentally sensitive areas alone. If one can agree that wind power has come of age, it will make a valuable contribution to providing us with the electricity we need in a world with increasing sensitivity to its environmental costs.

Glossary

end-of-row turbine A turbine that is located on either end of a turbine string; turbine strings in the Altamont Pass wind resource area usually consist of 3 to 10 turbines.

guy wire Wire or cable used to secure and stabilize wind turbines, meteorological towers, and other vertical objects in wind resource areas; most wind turbine towers are self-supporting and do not require guy wires.

horizontal axis Axis orientation where the axis of rotation of the power shaft relative to the ground is parallel to the ground; this is by far the most common axis orientation in existing wind resource areas.

horizontal lattice turbine A wind turbine tower that is composed of a steel lattice structure; many steel lattice support structures run parallel to the ground, providing considerable perching space to birds.

nacelle The housing that protects the generator and gear box in horizontal axis turbines.

rotational speed The rate (in revolutions per minute) at which a turbine blade makes a complete revolution around its axis; wind turbine rotational speeds can be fixed or variable.

rotor center The distance from the ground to the center of the circular area that is swept by the rotating blades.

rotor diameter The diameter of the circular area that is swept by the rotating tip of a wind turbine blade; rotor diameter is equal to two times the blade length.

rotor orientation (or yaw) The rotation in the horizontal plane of a horizontal axis turbine by which the rotor is oriented into the wind.

rotor-swept area The circular area that is swept by the rotating blades; doubling the length of blades quadruples the blade-swept area.

tip speed The speed (in miles per hour) that the tip of the blade travels when the rotor is turning; at comparable wind speeds, a horizontal axis turbine with a longer rotor experiences slower revolutions per minute and the tip speed remains roughly constant.

turbine height The maximum height reached by the blade tips of a wind turbine.

turbine spacing The distance between wind turbines in a string; in general, the distance between turbines is proportional to the rotor diameter.

vertical axis Axis orientation where the axis of rotation of the power shaft relative to the ground is perpendicular to the ground.

Wind energy offers a relatively environmentally benign source of electricity. However, issues have been raised concerning the feasibility of placing commercial wind developments in certain geographic locations and landscape settings. Because these issues are site specific, it is critical that potential sites be evaluated independently to determine whether there are environmental issues. Conclusions about any environmental concerns for a particular site should not be based explicitly on the experience from other sites.

1. POTENTIAL ENVIRONMENTAL IMPACTS OF WIND TECHNOLOGY

1.1 Introduction

Wind power has been used commercially to produce electricity since the early 1980s, when the world's first large-scale wind development, or wind resource area (WRA), was developed in California. In the United States, more than half of the states have developed wind resource areas: Alaska, California, Colorado, Hawaii, Iowa, Kansas, Maine, Maryland, Massachusetts, Michigan, Minnesota, Montana, Nebraska, New Hampshire, New Mexico, New York, North Dakota, Oregon, Pennsylvania, South Dakota, Tennessee, Texas, Utah, Vermont, Washington, West Virginia, Wisconsin, and Wyoming. Additional states are in various stages of the planning process. A current U.S. map identifying states with installed wind power can be found on the American Wind Energy Association's (AWEA) Web site. The AWEA is the U.S. wind industry trade organization that promotes the development of wind energy. Wind developments are also prevalent throughout much of Europe, with most developments being located relatively close to coastlines. In addition, Europe has pioneered the installation of offshore wind developments, an application that is only beginning to be explored in North America.

1.2 Potential Environmental Issues

In specific situations, wind power developments have been shown to cause environmental impacts, including impacts on animal habitat and movements, noise pollution, visual impacts, biological concerns, bird/bat fatalities from collisions with rotating blades, and health concerns. Of all the potential environmental impacts, biological concerns regarding birds and bats have been discussed and studied the most. Thus, although this article covers all potential environmental impacts, it focuses on avian-related issues. In addition, much of what is known is specific to land-based wind developments.

Various other issues associated with resource developments in general may also be of concern with wind developments; however, issues that are common to most if not all developments, such as soil erosion and water quality, are not addressed in detail in this article.

1.2.1 Impacts on Habitat and Animal Movements

Relative to other forms of energy development, most commercial wind farms occupy a large amount of space. Although the turbine pads occupy little ground area, the developments often must be spread over many miles. WRAs in the western United States have been placed primarily in open areas where they coexist with farming, ranching, and other low-intensity land uses. Figure 1 is an example of a wind farm in an agricultural setting. Figure 2 illustrates the minimal amount of land taken out of production by wind turbines, allowing ranching activities to continue on the land. Wind developments in Europe are frequently located near coastlines to take advantage of ocean winds.

FIGURE 1 Photo of 1.5-MW NEG Micon turbines installed by the Municipal Energy Association of Nebraska (MEAN) at TVIG's Kimball wind farm in Nebraska. The turbines have a rotor diameter of 72 m. From Tennessee Valley Infrastructure Group Inc. (NREL PIX12084).

FIGURE 2 Photo of Zond turbine near Lake Benton, Minnesota. Wind turbines occupy only approximately 5% of the land in a wind power plant on flat terrain. The rest of the land can be used for ranching and farming, as it was before the turbines were installed. From Warren Gretz (NREL PIX06334).

Wind farms may facilitate retention of seminatural open space where these low-intensity uses occur, resulting in long-term benefits for some bird populations. Historically, habitat that has been affected consists primarily of raptor-foraging habitat and nesting habitat for ground-nesting birds. Disruptions of animal movements, such as ungulates and carnivores, could occur but can be avoided through careful site evaluation.

Commercial wind developments in the eastern and northeastern United States often occupy ridges in wooded regions. In such situations, roads and pads must be cut, creating openings in the woodlands. Such openings create edge habitats that could potentially allow invasion of brown-headed cowbirds, a species that reduces nest success of many songbirds through nest parasitism, and potential predators of ground- and shrub-nesting birds. Figure 3 illustrates initial impacts of a wind project in a forested ridge setting. Long-term impacts have not been assessed. In Europe, developments along coastlines are often on cliffs and not in forested areas. Nevertheless, the potential exists for disturbance to coastal environments through development of roads, transmission lines, and other infrastructure.

1.2.1.1 Consideration of Impact on Animal Habitat and Movements The term "habitat" refers to the specific configuration of environmental features (e.g., vegetation, rock outcrops, water) that an animal uses at any point in time. Habitat is a species-specific concept; every animal species uses a different combination of environmental features. Therefore, no specific area is a "good" or "bad" habitat unless it is assessed in relation to a specific species. Thus, what is "good" for one species might be "bad" for another species.

This definition and discussion of habitat has relevance for all land use issues. For wind developments, issues of habitat concern (1) outright loss of a species' habitat due to development (e.g., removing trees), (2) indirect impacts due to disturbance (i.e., the animals will no longer reside near the development, and (3) disruption in animal passage through or over the development due to the addition of towers and turbines. This definition also applies to offshore situations and is applicable to foraging areas for birds, marine mammals, and fish.

Because wind developments often stretch for many miles along ridge tops, the turbines, along with the associated infrastructure (especially roads), can affect animal movements. No quantitative work has been done on the impacts of wind developments on animal movements. However, it is unlikely that wind developments will cause wholesale disruption in migratory movements of birds and other vertebrates. This is because wind developments are seldom, if ever, introduced into pristine environments. As such, migrating or dispersing animals encounter a host of potential obstructions, including highways, power line corridors, housing, farm fields and pastures, and people. Therefore, analysis of the impacts of a wind development on movements of

FIGURE 3 Photos of 6.0-MW Green Mountain power plant at Searsburg, Vermont. The power plant consists of 11 550-kW Zond Z-40FS wind turbines. Construction crews removed as few trees as possible to build this power plant. Since the completion of construction, the area around the turbines is being allowed to "brush in" and return to its natural state. Left photo from Bob Thresher (NREL PIX00638), right photo from David Parsons (NREL PIX06802).

terrestrial animals would usually focus on the additional impacts that the wind development would have on animal movements. There are also numerous methods available, developed for highways and other human developments, that could apply to wind developments and be used to lessen potential impacts on animal movements. Such strategies would include widely spacing turbines in certain locations, restricting travel along roads within wind developments (e.g., for inspection and repair only) during specific times of year (e.g., during ungulate migration), and providing appropriate habitat between turbines to facilitate animal movements.

Offshore developments have been established throughout Europe, but few studies have been conducted to determine the impact on animals. Most of these developments are small relative to onshore developments (although larger projects are being planned). Some disruption in bird flight patterns has been noted in Europe, although additional study is needed. However, there does not appear to be disruption in fish movements or populations; the effects on marine mammals need clarification. Offshore developments in North America are only in the planning stage.

Wind developments are evaluated for potential impacts on animals in the project area in the same way that most development would be evaluated. Such evaluations include close inspection of the project areas for the presence of plant or animal species of concern (inspections for cultural resources would also be conducted). For example, burrowing animals such as ground squirrels can be detected, and specific steps can be used to avoid disturbance such as moving the location of roads, pads for placing turbines, and other infrastructure items. There is a fair degree of flexibility available to the wind developer with regard to the exact location that a turbine is placed on the ground. Because most resource agencies avoid the need to use mitigation to allow permitting of a project, careful planning is an essential component of placing turbines.

The ground disturbance associated with placing a turbine, especially road cuts and cuts used for turbine pad placement, can actually attract certain species. Most notable is the use of disturbed soils by burrowing animals such as gophers and ground squirrels. In some locations, these species are rare or legally protected. In most areas, the attraction of these animals to turbines likely enhances the area for foraging raptors, thereby raising the likelihood of raptor collisions with rotating blades. As such, wind developments must consider the potential for attracting species of concern and creating conditions in which birds could be killed. Although these often conflicting issues cannot be resolved easily, they should be considered when planning a development so that major resource issues can be dealt with during the design stage.

A major concern with offshore developments is the impacts that boat and air (helicopter) traffic to and from the wind developments might have on animal behavior and movements. Again, little is known about such impacts. The primary concern is that human activity in support of the developments (e.g., delivering supplies and maintenance crews) could have negative ramifications for animal behavior that extends far outside the boundaries of the turbines.

1.2.2 Noise Pollution

Noise is defined as any unwanted sound. Concerns depend on the level of intensity, frequency, frequency distribution, and pattern of the noise source; background noise levels; the terrain between emitter and receptor; and the nature of the noise receptors. The effects of noise on people can be classified into three general categories: (1) subjective effects of annoyance, nuisance, and dissatisfaction; (2) interference with activities such as speech, sleep, and learning; and (3) physiological effects such as anxiety, tinnitus, and hearing loss.

The sound levels associated with environmental noise usually produce effects only in the first two categories. Operating noise produced by wind facilities is considerably different in level and nature than that generated by most power plants, which are typically large industrial facilities. Much of the noise emitted by wind turbines is masked by the ambient or background noise of the wind and does not carry far. Noise may, of course, concern individuals living in close proximity to a wind turbine. As such, siting of wind developments must consider adjacent land uses and zoning. Over time, residential or commercial developments might encroach on existing wind developments, much like housing often encroaches on existing airports. Conflicts often arise in these situations, especially if the wind developments are slated for expansion. In such cases, adequate setbacks from human-occupied structures need to be considered.

Several European countries, including Sweden, Denmark, The Netherlands, the United Kingdom, and Greece, have adopted noise standards for wind farm developments. These standards specify acceptable noise levels, and some take into account the existing background noise levels.

1.2.3 Visual Pollution

Determining whether a wind farm creates visual pollution is purely subjective and, therefore, is difficult to quantify. Computer modeling tools can be used to simulate how a wind farm will look from multiple vantage points when placed on a landscape. The aesthetic interpretation and visual compatibility with the surrounding setting will vary depending on the natural and cultural features that exist and how various stakeholder groups value these. Alternatives to the wind development (i.e., other land uses) may also be considered when evaluating the visual impacts.

Often referred to as the "viewshed," the impact of wind turbines on the existing project setting is a matter of local public perception. Because wind resource developments vary substantially in number of turbines (literally from one to thousands of turbines), height of the turbines and towers, spacing between turbines, and physical arrangement of towers and turbines on the landscape, there is no single solution to the impacts of wind developments on a viewshed. However, longer blades are being used on commercial-sized wind turbines, and the turbines are being placed on taller towers. Such turbines now commonly produce 1.5 MW to more than 2 MW of power, are three bladed, have a rotor-swept diameter of 70 m, and are placed on a tower 80 m tall. Therefore, modern commercial wind turbines have a maximum height measurement from ground level to the tip of the blade of 120 m ($\sim$375′) or taller. Many offshore developments have proposed turbine–tower combinations that near or exceed 160 m ($\sim$500′) in total height. In addition, onshore turbines are usually placed on ridges to capture the maximum amount of wind in some geographic locations such as the western and eastern United States. As a result, turbines can be highly visible from many miles away. Larger turbines result in fewer turbines in an observer's field of view, although the land area covered for a given wind farm megawatt capacity is approximately the same as for smaller turbines. In some locations, aircraft warning lights may be required by the Federal Aviation Administration (FAA), adding another dimension to visual considerations. Figure 4 illustrates visual impacts of various wind farm configurations. The photo on the left is an example of early wind farm layouts, using numerous smaller turbines mounted on lattice towers. The photo on the right depicts a more recent wind farm, using larger wind turbines mounted on tubular towers.

Visual aspects of wind development are a project- and site-specific issue that must carefully consider current and likely land uses. Close collaboration among the developer, government permitting agencies, and viewing public is necessary to develop collaborative strategies for siting of a development and placement of individual turbines. Although many proposed offshore developments are planned for more than 3 miles from land, they can still be seen from shore and will be visible to boaters.

1.2.4 Bird Fatalities

Researchers have conducted a large number of avian fatality surveys at WRAs in the United States and Europe. In most cases, several factors have made it difficult to compare results from one study or site with those from another. First, survey methods vary, and very few of these studies have been peer reviewed and published in scientific journals. Second, turbine designs and wind farm layouts vary considerably from site to site. Third, the wide climatic and topographical differences and range of bird species present in various locations make it extremely difficult to draw concrete conclusions from the available literature. Fourth, it is difficult to make statistical comparisons because the relatively low number of fatalities results in inadequate sample size. In addition, there has been an emphasis on raptor fatalities despite the knowledge that other birds have been affected, perhaps because raptors receive protection under a large suite of federal and state laws and because they are symbolic and have greater emotional value. A sampling bias toward raptors and other large birds also occurs because small birds are more difficult to detect and scavenging of small birds can be expected to occur more rapidly. Impacts on some passerines, including neotropical migrants, may warrant more careful scrutiny because many of them are protected under the Federal Migratory Bird Treaty Act and because some are experiencing regional population declines.

In the United States, a study of golden eagle populations in the vicinity of the Altamont Pass WRA in the state of California from 1994 to 2000 reported that 52 of 257 eagles equipped with radio transmitters were killed by wind turbine strikes. When compared with other large WRAs, it is clear that the Altamont Pass supports substantially higher resident and migratory raptor populations and experiences substantially greater raptor fatality rates caused by collisions with wind turbines.

The exact number of fatalities caused by turbines in Altamont Pass cannot be determined, although estimates based on intensive fatality surveys conclude that 40 to 60 are killed annually. Although it remains

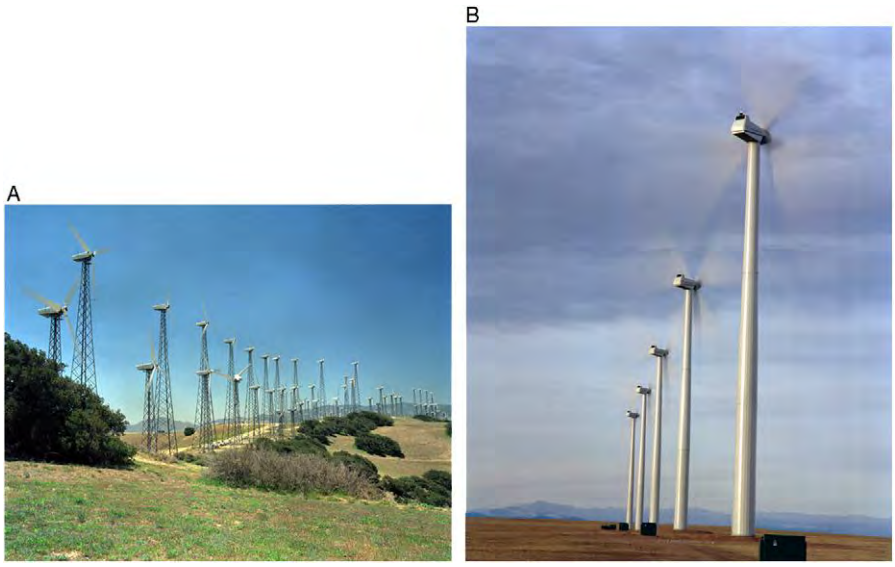

FIGURE 4 Photos illustrating visual differences between turbines installed on ridges and those installed on mesas, between small and large turbines, and between turbines mounted on lattice towers (A) and those mounted on tubular towers (B). A number of factors influence the visual impacts of wind farms, including location, size, and type of turbine. From Warren Gretz (NREL PIX01231 and NREL PIX07236).

speculative whether the eagle population in the Altamont region is declining due to turbine kills, these eagle fatalities may cause many direct and indirect impacts on its population. Direct impacts include a decline in the size of the population and change in age structure. Indirect impacts include a reduction in the number of birds that are available to disperse to other regions. Overall, the golden eagle population is thought to be declining in the Altamont Pass region.

Results of numerous studies in the United States at sites outside of California have indicated that the incidence of raptor collisions in California, particularly at the Altamont Pass WRA, is considerably higher than in other WRAs. In the United States, passerines composed the highest percentage of fatalities in the non-California studies. Reports from these studies indicate that the levels of fatalities are not considered significant enough to threaten local or regional population levels, although overall cumulative effects of human-induced bird fatalities are unknown. A major difference between the Altamont Pass WRA and other WRAs is that many other areas lack the dense populations of raptors and the diverse topography of the Altamont Pass WRA. The high number of fatalities at the Altamont Pass WRA has created awareness of potential siting problems, and in some cases more regard has been given to the level of avian use prior to construction. Figures 5A and 5B are examples of raptor fatalities found during research conducted by the U.S. Department of Energy's National Renewable Energy Laboratory (NREL) in the Altamont WRA.

Studies on avian interactions have been conducted at more than 100 sites in Europe, but most of these studies focused on solitary or small groups of turbines. As a result, it is difficult to compare these data with those of U.S. studies that focus on larger groups of turbines. Many of the European studies were based on coastal sites where waterfowl and migratory bird issues did not yield results comparable to those of California studies. Although the fatality rates in Europe are often higher than those that occur in California and the rest of the United States, many European scientists have not considered this impact to be a significant threat to bird populations in most of Europe because the number of deaths is small relative to the total number of birds using or passing through the area. Most birds killed were not raptors but rather relatively common species of passerines and water birds.

The bird–wind data on offshore wind farms in Europe are scarce. However, it is clear that concern exists about the potential impacts that offshore facilities could have on birds, as witnessed by the precautionary tone taken by many individuals. Recommendations include constructing relatively small farms, avoiding areas of high numbers of birds or areas with sensitive bird species, and monitoring intensively before and after construction (if the projects are approved).

FIGURE 5 (A) Red-tailed hawk fatality resulting from collision with wind turbine at the Altamont Pass WRA in California. (B) Golden eagle fatality resulting from collision with wind turbine at the Altamont Pass WRA. From BioResource Consultants.

Very few studies have been performed to determine the overall effects of wind turbine impacts on the population viability of an individual species. This type of evaluation is exceedingly difficult and relatively costly. Studies that are based on field-level tracking of population parameters require intensive sampling over a number of years for each species of concern. Most evaluations of wind-turbine-related avian fatalities have concluded that the affected birds are fairly common and not threatened at the population level.

However, because some raptor species are relatively less abundant and produce fewer young compared with many other groups of birds, human-caused fatalities could have a more noticeable effect on their populations. In addition, the number of fatalities relative to the population size, rather than the absolute number killed, is of concern. Thus, even a few fatalities of a locally or regionally rare species could have negative impacts on the population structure and size.

Various design features, such as perch availability, rotor diameter, rotor-swept area, rotor height, rotational and tip speeds, and fixed versus variable turbine speed, have been evaluated to determine whether they contribute to bird collision risk. Although at one time workers suggested that lattice towers might encourage birds to perch and thereby come into close proximity of rotating blades, recent studies have failed to confirm a correlation between tower type and fatality rates.

The issue of rotor-swept area and blade diameter effects on avian collision risk with turbines is important because wind developers are in the process of repowering or replacing existing, less efficient turbines with a smaller number of new, larger, and more efficient turbines. Existing studies concerning fatalities in relationship to increased rotor-swept area are inconclusive, and further research is needed.

It has been speculated that overall bird fatalities will be higher at taller turbines. It is well known that migrating songbirds are frequently killed at tall communication towers. This was attributed to higher flying, non-raptor nocturnal migrants that often constitute the greatest percentage of fatalities. Behavior differences among raptors indicate that there may be some trade-offs in benefits. For example, one species may benefit from blade tips being farther from ground level, whereas others may be exposed to greater risk from blades that reach a greater overall height. Further research is needed to determine the impact that the newer taller turbine towers have on bird kills. Rotor velocity and a corresponding increased tip speed have been

correlated with fatalities. Faster turbine rotor speeds kill more raptors than would be expected by chance.

1.2.5 Bat Fatalities

Until recently, little research has been conducted to determine the impacts of wind farms on bats. A few bat carcasses were found during earlier bird fatality studies; however, recent surveys at some newer sites have discovered higher mortalities than were reported previously. To better discern the level of collision impacts on bats, researchers have initiated studies at some of these sites. These studies include analysis of environmental features in and around wind farms that could attract bats such as roosting sites, availability of surface water, and riparian foraging areas.

1.2.6 Health Impacts

Shadow flicker, the effect caused by rotating blades cutting through sunlight, is another concern that may need to be addressed if wind turbines are installed in close proximity to inhabited areas. Modern commercial wind turbines are tall structures that will cast a shadow at certain times of the day. Concerns about shadow flicker can be minimized or eliminated with careful wind farm layout and sufficient setbacks from residences.

2. BIRD BIOLOGY AND WIND TURBINES

2.1 Bird Flight Behavior

The relatively high diversity of bird species killed in wind developments suggests a variety of behaviors, and therefore underlying risk factors, associated with wind turbines. Studies of birds approaching turbines show that most birds pass over or through turbine structures, thereby avoiding collisions. However, some birds may be more prone to collisions with turbines for a variety of reasons. For raptors, flight and hunting behavior require that they often fly at low altitudes and so may strike turbines while searching or stooping for prey. Abundance of prey may significantly increase foraging activity, and therefore collision risk, of some raptors. Age or breeding status may also be a risk factor associated with bird fatalities.

Topographical features, such as ridges that decrease the altitude of birds relative to ground level, can result in a higher collision risk. Because flight lines often follow prevailing wind directions, the placement of turbines in an optimal position and orientation for wind energy capture may result in obstacles directly in the path of local and migratory birds. For a sample of approximately 1000 turbines studied in the Altamont Pass WRA, 25% of the turbines were responsible for 100% of the fatalities recorded. Certain physical and topographical factors appear to contribute to an increased collision risk.

A summary of bird–wind interactions in Europe found that the overall kill rate was low. However, it was noted that 2 to 3% of birds passing a wind farm at rotor height were killed. It has been concluded that disturbance and habitat loss effects associated with wind developments were probably much more important than direct bird kills due to collisions. However, in Spain, relatively high levels of kills were sometimes evident. Research in Europe has indicated that individual and single rows of turbines in areas with small bird populations provide the best landscape for wind farms.

2.2 Bird Sight

The idea of birds colliding with seemingly slow-moving turbines seems paradoxical given the superb vision possessed by most birds, especially raptors. However, optical analyses indicate that as a bird approaches the rotating blades, the retinal image of the blades (which is the information that gets transferred to the bird's brain) increases in velocity until it is moving so fast that the retina cannot keep up with it. At this point, the retinal image becomes a transparent blur that the bird probably interprets as being safe to fly through, with potentially catastrophic consequences. This phenomenon is called "motion smear" or "motion blur" and is well known in human perception. It becomes especially difficult for a bird to detect the outer regions, or tip, of the blade. Although modern commercial turbines rotate at relatively slow revolutions per minute, because of their long length (often 100 feet), they move at a high rate of speed (up to 150 mph). Figure 6 illustrates the concept of motion smear.

Laboratory experiments have been conducted to determine the potential of various patterns painted on blades to increase visibility to birds. A single uniformly black blade paired with two white blades appears to be the most effective anti-motion smear pattern under the widest variety of conditions in the field. Minor increases in visibility of the central portions of the blade have been found, although painting did not increase visibility of the tips. These laboratory studies examine only the physiological

FIGURE 6 Illustration of the phenomenon of motion smear, shown by photo of the moving blades of the turbine in the foreground. Beyond a certain point, the velocity of the retinal images of the blades sweeping across the retina will overwhelm the retina's ability to keep up. The initial effect will be a smearing or blurring of the image of the blades, at which point the blades appear to be transparent. This may result in deadly consequences for birds because they interpret this as a safe place to fly. From William Hodos (University of Maryland).

response of the eye to various painted patterns; they do not examine the psychological response of the bird to the stimuli. Thus, rigorous field experimentation is needed to determine the usefulness of painted blades in substantially reducing bird collisions.

2.3 Bird Hearing

It is a myth that birds have exceptionally acute hearing. When hearing is defined as the softest sound that can be heard at various frequencies, birds on average hear less well than do many mammals, including humans. The literature suggests that birds cannot hear the noise produced by wind turbines as well as can humans. In practical terms, a human with normal hearing can probably hear a wind turbine blade twice as far away as can the average bird. Adding an acoustic cue to a rotating blade might assist with a bird hearing a blade. However, acoustic deterrent devices are not generally effective because birds habituate to them and eventually ignore them completely. Devices that purport to use sound frequencies outside the hearing range of humans are most certainly inaudible to birds as well because birds have a narrower range of hearing than do humans. However, it is entirely possible that as birds approach a wind turbine, especially under high wind conditions, they lose the ability to see the blade (due to motion smear) before they are close enough to hear the blade.

3. RESEARCH AND MONITORING

To minimize the potential risks from wind turbines, it is important to first assess what those risks are. Prior to the development of the first large commercial wind farms, protocols and methodologies for assessing risks to birds within WRAs had not been developed. Assessments of other potential environmental impacts, such as impacts on habitat and animal movements and visual and noise impacts, were only minimally considered.

During the early years of wind farm developments, specifically in California, it became apparent that collisions of birds (especially raptors) with wind turbines were occurring. Approaches to assessing potential environmental impacts needed to be developed.

3.1 Initial Site Selection and Permitting

3.1.1 U.S. Guidelines

The National Wind Coordinating Committee (NWCC), a collaborative of representatives from the environmental community, wind energy industry, state legislatures, state utility commissions, consumer advocacy offices, green power marketers, and federal and state governments in the United States, was established in 1994 to support the development of wind power. The NWCC's Siting Subcommittee was formed to address wind generation siting and permitting issues. This subcommittee prepared a collaborative document, titled *Permitting of Wind Energy Facilities: A Handbook,* to provide guidance in evaluating wind projects for all stakeholders. Some aspects of wind facility permitting closely resemble permitting considerations for any other large energy facility or other development project. Others are unique to wind generation facilities. Unlike most energy facilities, wind generation facilities tend to be located in rural or remote areas and are land intrusive rather than land intensive. Thus, they may extend over a very large area and have a broad area of influence, but they physically occupy only a small area for the turbine towers and associated structures and infrastructure (e.g., roads, transmission lines). The rest of the land may be used for other activities.

This NWCC handbook outlines the many factors that must be considered when permitting a wind

generation facility, including (but not limited to) land use, noise, birds and other biological resources, visual resources, soil erosion and water quality, cultural resources, and socioeconomic considerations. Permitting processes that result in timely decisions, focus on the critical issues early, involve the public, and avoid unnecessary court challenges will enable wind generation to compete with other energy technologies and provide a diverse supply of energy.

As summarized by the NWCC Web site, wind power developers in North America are beginning to look offshore for greater wind resources and lower costs. Because this is a new application for wind power in the United States, the NWCC noted that background information is needed about environmental, technical, economic, and political issues associated with offshore developments. Some of this information can be gathered from European sources because they have been working on offshore wind energy development for the past decade or so. However, each situation is different, so local factors need to be taken into account.

3.1.2 European and Other Guidelines

Several best practice guidelines (BPGs) have been adopted. The British Wind Energy Association (BWEA) adopted BPGs for wind energy development in 1994. The BWEA, established in 1979, functions as a professional association and an association for the wind energy industry. The guidelines provide guidance to developers, taking them through the development process. They are general in nature and do not supersede any national policies.

The European Wind Energy Association (EWEA) was established in 1982 and provides functions similar to those of the BWEA. Building on the British and other European experiences with wind industry development, the EWEA adopted its BPGs in 1999.

The Australian Wind Energy Association (AusWEA), established in 2000, adopted its own BPGs for wind energy projects. Building on the BWEA and EWEA guidelines, the AusWEA's guidelines were adapted in 2002 to include experience from the first wind farms developed in Australia.

3.2 Sampling Protocols

Sampling protocols and methods of quantifying bird fatalities in the field must be rigorous and scientifically valid. Failure to establish rigorous protocols and methods results in data sets that are subject to criticism and not ideal for determining how to reduce wildlife fatalities in wind developments.

The NWCC's Avian Subcommittee, formed in 1994 to address avian interactions with wind developments, identifies research needs and serves as an advisory group. In March 2003, the committee was renamed the Wildlife Work Group to reflect the concern for a broader group of species. To address differences in methodologies, lack of adequate control or baseline data in existing studies, and the resulting lack of interstudy comparability, the committee developed a guidebook titled *Studying Wind Energy/Bird Interactions: A Guidance Document*. The document provides a comprehensive guide to standardized methods and metrics to determine impacts to birds at existing and future wind farm sites. A stated purpose of the guide is to promote efficient cost-effective study designs that will produce comparable data and reduce the overall need for some future studies.

The guidance document identifies three levels of surveys of increasing intensity that should be applied to a proposed or developing wind development. Although focused on birds, these general guidelines can be applied to most aspects of the environment. "Site evaluation" or "reconnaissance" surveys are relatively nonrigorous and use primarily published literature and nonpublished reports, expert opinions, and other sources of information to make a first determination as to whether a proposed site will likely result in environmental problems. Such reconnaissance surveys are cursory in nature but should help to eliminate problematic sites from further consideration. If the reconnaissance survey indicates that the site should be suitable for development, a "level 1" protocol is indicated, where more intensive and quantitative on-site surveys occur, usually for a minimum of 1 year prior to a decision to proceed with development. Such level 1 surveys include on-site sampling of wildlife movements and other activities (e.g., foraging, nesting), quantification of the presence and abundance of sensitive species, and development of projections on potential bird and bat fatality levels based on risk assessment. If a decision is made to proceed with development after level 1 surveys have been evaluated, the data set also serves as the "before" data to be compared with changes in environmental conditions following ("after") development. In rare cases, the results of level 1 studies indicate that more intensive study is necessary, for example, when the presence of a legally protected, threatened, or endangered species is located.

The methodology used to conduct fatality searches will vary, depending on the terrain and rigor required to adequately assess a site. The level of rigor often is dictated by the budget available for the task. Ideally, the appropriate budget will be allocated to conduct the level of work required for the specific site under consideration. Search methods have been developed and have proved to be very successful under research studies funded by the U.S. Department of Energy's National Renewable Energy Laboratory. These search methods have been developed for both flat and steep terrain. Figures 7A and 7B illustrate the search method used for conducting fatality searches on steep and flat terrain, respectively.

To aid bird risk evaluations, there is a need to define the "level of take" that is acceptable from avian species' interactions with wind turbines; that is, the level of fatalities that can occur without reducing that species' population. The level of assigned risk will vary among species. If threatened or endangered species are affected, incidental take permits can be issued under the federal Endangered Species Act, but "no take" may be the targeted goal. There is no accommodation for take under the Migratory Bird Treaty Act, which applies to a large number of birds, including raptors and passerines, that have been killed by collisions with wind turbines. To date, the U.S. Fish and Wildlife Service has been somewhat tolerant of existing conditions at WRAs. However, future wind plant approvals, particularly in California where existing avian fatality issues have not been resolved, may be modified due to enforcement of this act.

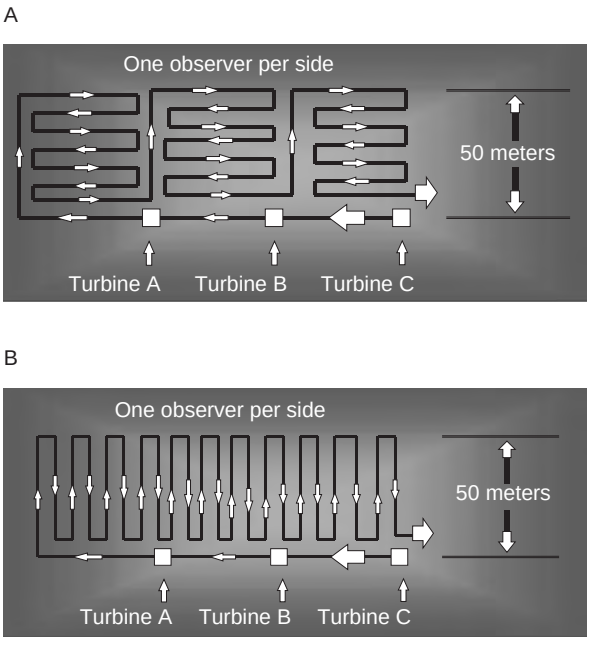

FIGURE 7 (A) Searcher method for conducting fatality searches on steep terrain. (B) Searcher method for conducting fatality searches on flat terrain. From BioResource Consultants.

The United Kingdom limits offshore wind farms to 30 turbines (even if 2-MW turbines are used, this amounts to only 60 MW) to reduce environmental and visual impacts and to ease the cost of decommissioning and dismantling when problems arise. One of the benefits of limiting the size of farms (e.g., to 150 MW) is that if problems are identified at a farm, the farm can be shut down without a great disruption to the grid and loss of value because the turbines can be used at another site. Thus, various governments in Europe have chosen to limit the size of individual wind farms due to a variety of environmental and other siting concerns.

4. RISK REDUCTION

4.1 Wind Farm Operation and Location

Recognition of the potential avian fatality risk has influenced the selection criteria used in developing some new WRAs. Along with providing a framework for the development of more robust experimental field design, use of standardized protocols has greatly enhanced researchers' ability to compare and analyze data among studies from various WRAs.

Decreasing operation time of problem turbines or WRAs has been suggested as a risk reduction measure. Critical shutdown times could be seasonal (e.g., during migration periods) or based on inclement weather or nighttime periods when visibility is reduced. For example, permitting requirements for a new wind development in Maryland included the option for restricting turbine operations if bird fatalities were found to occur during peak migration periods. Economic consequences of any kind of adjustments to operation time should be considered prior to construction of a site so that the developer can make a feasibility assessment. Most of the newer wind turbines in the Altamont Pass repowering areas will increase operation time by as much as 55%. The effect that such an increase in operating time will have on bird fatalities is unknown and worthy of study. As noted previously, some European governments limit the size of wind developments to ease the financial ramifications of closing a development.

Design and maintenance characteristics of roads and structures may indirectly contribute to higher

bird fatality rates by increasing prey densities. It has been suggested that vertical and lateral edges and other features associated with roads, turbine pads, and maintenance areas may create suitable burrow sites for raptor prey in the vicinity of wind turbines, with a corresponding increase in raptor foraging activity. Newer facilities that are built with larger, more efficient turbines require fewer roads and have a greater amount of space between them. In addition, many of the newer facilities have underground transmission lines, greatly reducing the likelihood of wire collisions and electrocutions. Offshore developments in Europe manage the movement of maintenance crews to minimize disturbance to birds and other animals.

4.2 Turbine Characteristics and Location

Lights seem to play a key role in attracting birds, and the lighting of tall structures appears to contribute to avian fatalities. Illuminating other taller aerial structures to make them more visible to aircraft has resulted in increased bird fatalities. Migratory species generally migrate at night and appear to be most susceptible to collisions with lit towers on foggy, misty, rainy nights with low cloud ceilings. Passerines migrating at night during poor visibility conditions appear to be particularly susceptible. Solid or blinking red lights seem to attract birds on foggy misty nights more than do white strobes, which may flash every 1 to 3 seconds. Preliminary research suggests that the longer the duration of the "off" phase, the less likely a light will attract birds. The advent of turbines with longer blades that are mounted on tall towers could require the use of warning lights for aircraft in certain locations.

Studies indicate that tower placement is a site-specific phenomenon, but several key conclusions have been found. First, irregularly spaced turbines might increase fatalities because birds try to negotiate the apparent gaps between turbines. Second, turbines placed close to the edge of ridges show higher fatality rates because raptors often hover in such locations. Finally, turbines placed near a gully have higher fatalities because birds often use these locations as flight paths.

Although no research has been conducted on auditory deterrents to birds approaching wind turbines, audible devices to scare or warn birds have been used at airports, television towers, utility poles, and oil spills. Most studies of auditory warning devices have found that birds become habituated to these devices. As discussed previously, birds do not hear as well as humans, and minor modifications to the acoustic signature of a turbine blade could make blades more audible to birds while at the same time making no measurable contribution to overall noise level. Under certain conditions (e.g., high wind), birds might lose their ability to see a turbine blade before they are close enough to hear the blade. Currently, there is no research under way that tests the effects of auditory deterrents, and because of the low likelihood of developing a successful application, none is planned for the foreseeable future.

As discussed previously, motion smear, which makes the blade tips of wind turbines appear to be transparent at high speeds, could be reduced under laboratory conditions. Results suggest that a single solid black blade paired with two white blades (inverse blade pattern) could be effective at reducing visual smearing of blades. In addition, motion smear and a very narrow blade profile encountered when approaching from the side could be very risky for birds. One potential solution is a rectangular attachment to the outer tip at right angles to the long axis of the blade. The visibility and practicality of these attachments have not yet been evaluated.

4.3 Habitat Management

The density of raptors at the Altamont Pass WRA is, at least in part, a result of high prey availability. The San Gorgonio and Tehachapi WRAs in California have lower prey densities, lower raptor densities, and lower per turbine fatality rates. Prey densities appear to be highest at disturbed sites such as roads and turbine pads, the latter of which would exacerbate collision risk. Reducing prey populations within the vicinity of wind turbines might reduce high-risk foraging activities for raptors. Suggested methods include county-sponsored abatement programs, reduced grazing intensities, and revegetation with higher stature plants that pocket gophers and ground squirrels tend to avoid. However, these measures could affect other populations, including special status species such as the San Joaquin kit fox, burrowing owl, and badger.

It has been suggested that in areas where high densities of gopher burrowing systems are found, controlling populations in the immediate vicinity of wind turbines could be effective. However, small mammal abatement efforts by ranchers in surrounding areas could exacerbate the effect of burrow clusters in the vicinity of turbines by increasing the focus of raptor foraging. This effect occurs when there is rapid recolonization and higher than average

densities of gophers on edges of abatement areas. Research would have to evaluate reduced grazing or revegetation with higher structure plants to determine its effects on fire management, watershed protection, and other land management practices.

Habitat modification to reduce prey densities has been discussed as a possible avian risk reduction technique. There have been some efforts to reduce ground squirrel populations in portions of the Altamont Pass WRA, but no results of the effects on reducing raptor moralities have been published. The effects of a widespread control program would have to take into account the effects on other wildlife such as protected species that prey on ground squirrels or depend on their burrows for nesting and cover habitat. Widespread use of rodenticides or other measures to remove prey may prove to be controversial and costly. Feasibility of more benign habitat modification measures, such as manipulation of annual grassland grazing practices and conversion to perennial grassland, may be worth studying. However, any reduction in habitat quality would likely result in an ultimate, although indirect, negative impact on birds. For example, although reducing prey in wind developments might lower bird fatalities, it could also result in bird starvation or fatalities in other locations.

In The Netherlands, turbines adjacent to the Wadden Sea showed a higher rate of bird kills relative to turbines in upland areas. These higher kills appeared to be related to the large number of birds in and around the sea relative to the upland locations. Unfortunately, virtually no information is available on fatalities at offshore wind farms in Europe.

4.4 Turbine Treatments

Effective visual treatments could provide a cost-effective method to reduce risk from turbines determined to cause fatalities. Laboratory and field tests of treatments that make turbine blades more conspicuous to raptors and other birds are needed.

4.5 Repowering

Repowering refers to the replacement of existing, less efficient turbines with a smaller number of larger, more efficient turbines. Replacement ratios will range from 7:1 to 10:1. The impacts of repowering on avian fatality rates, particularly raptors, have not been evaluated. However, at Altamont Pass, no significant differences in the number of fatalities have been seen between relatively small, faster rotating turbines (100 kW) and relatively large, slower rotating turbines (up to 750 kW). The tip of the blade on the newest generation of turbine can reach more than 400 feet into the air at the apex of rotation. Studies have begun on the collisions of birds and bats with these larger turbines.

5. SUMMARY AND RECOMMENDATIONS FOR REDUCING WIND TURBINE IMPACTS ON BIRDS

Newer wind facilities throughout the world have fewer raptor fatalities than do those documented at the Altamont Pass WRA. Much of this improvement has not been by design; rather, these wind energy facilities were sited in areas that typically have lower raptor densities and less topographic diversity than does the Altamont Pass WRA. Some avoidance has been due to preconstruction site evaluations and a standardized approach to evaluating wind power projects developed by the NWCC. In addition, reduced concentrations of turbines in newer WRAs, and possibly newer turbine designs, may have contributed to avoiding the high number of raptor fatalities that occur at the Altamont Pass WRA. However, researchers still need more information on how to reduce fatalities at existing facilities. In addition, it is not known whether the newer generation turbine designs slated to replace many of the old turbines will reduce avian fatalities. Finally, little is known concerning the impacts of large offshore developments (in Europe and North America) on animals.

Consequently, research should still focus on other risk-reducing measures that involve changes in turbine design and microsite selection. As reviewed in this article, specific protocols exist to identify potentially negative environmental impacts of wind turbines on wildlife prior to project development. In addition, turbines can be placed in locations that are less likely to cause substantial bird or bat fatalities, operating times can be modified to avoid periods of peak migration (if birds are found to be killed during these times), and various habitat management techniques might be implemented to reduce the attractiveness of turbines to birds. Environmental analyses of proposed wind farms also must consider the visual impacts that the newer generation of taller towers and longer-bladed turbines has on the surrounding community or viewshed. These types of analyses will

help to ensure that the benefits outweigh the risks in establishing a wind farm in a specific locality.

Glossary

capacity credit The fraction of a power plant's rated capacity, which is in average available at the time of peak demand or, alternatively, the relative amount of additional conventional capacity that is needed in the absence of wind energy in order to obtain the same loss-of-load-probability (LOLP).

environmental impact assessment An evaluation of a number of conditions with a view to select possible areas for location of wind farms. These conditions include scenic aspects, bird sanctuaries, raw material extraction, archaeology, fisheries, shipping routes, and military areas.

mesoscale model The numerical atmospheric model that is similar to numerical weather prediction models used for the daily weather forecasts. The mesoscale model calculates the flow field over a region of typically 200×200 km with a resolution of one to five km. The output is used as input to the microscale model.

microscale model The numerical atmospheric model that can calculate the flow field over a farm site with a high accuracy. Is used for micrositing.

micrositing The determination of exact position of each wind turbine in a wind farm.

siting Investigation of an area/region/district with the purpose of selection of the location (site) for a wind farm.

sizing The decision on the size of a wind farm in terms of land area and installed capacity.

wake The wake behind a wind turbine is characterized by a wind velocity deficit and increased turbulence. The wake affects power output and loads on downstream wind turbines.

wind energy The mean power density in the wind, which is equal to the average kinetic energy flux per unit area perpendicular to the flow, is calculated as half of the air density multiplied by the mean value of the third power of the wind speed.

wind farm efficiency The ratio between the annual production of a wind farm and the production of corresponding number of isolated wind turbines located in identical but undisturbed wind conditions.

wind farm layout The configuration and arrangement of the individual wind turbines' locations within the selected site.

A wind farm (often also called a wind park) can be defined as a cluster of wind turbines that acts and is connected to the power system as a single electricity producing power station. Generally it is expected that a wind farm consist of more than three wind turbines.

1. INTRODUCTION

Many independent studies have led to the conclusion that to solve the increasing energy need of the world's growing population, it is inherently necessary to increase the amount of energy produced by renewable energy sources. In fact, it is believed that in 2050, more than 80% of energy should be renewable, 20% of which should be wind energy. A large fraction will come from wind turbines placed in clusters (i.e., wind farms) at land or at sea. A wind farm (often also called a wind park) can be defined as a cluster of wind turbines that acts as one electricity-producing power station. Generally, it is expected that a wind farm consists of more than three wind turbines. However, the rapid development in the size of wind turbines can make such a

 © 2004 Elsevier Inc. All rights reserved.

definition superfluous: Tomorrow's single wind turbine might exceed 10 MW, whereas several of yesterday's wind farms are below 5 MW.

The development has led to a division of the technology into three categories, depending on application and capacities:

- Land-based and offshore grid-connected wind farms varying in size from about 10 MW to several 100 MW; WTs larger than 1.5 MW.
- Decentralized and single operating machines connected to the grid; WTs less than 1.5 MW.
- Decentralized units for grid-connected operation and for hybrid and standalone operation; WTs less than 0.5 MW.

Here we are only concerned with the first category, which is formed by large-size grid-connected wind turbines for land-based and offshore applications. From the early 1980s, development has steadily moved toward larger machines and larger wind farms; for example, in 1995 only 20% of all wind farms were larger than 5 MW, whereas in 2002 nearly 70% exceeded 5 MW (a 5 MW wind farm may, on the average, supply 2500 to 3000 north European households with electricity—if they do not use electricity for house-heating).

Because wind turbines are clustered into bigger units, system integration requires special attention. It is estimated that a penetration (supply fraction) of wind energy on a large grid can be as much as 20% without special precautions to secure grid stability. Turbines equipped with state-of-the-art power electronics may even add stability to the grid. For an even larger penetration, special attention has to be focused on control systems of wind farms, improvements of power quality, system and grid stability, operational management systems, system reliability, and output forecasting. Large wind farms are very visible and this together with a number of environmental concerns, such as possible disturbance of migrating birds, play an important role in the planning process and can result in selection of sites with less than optimal conditions.

Good wind conditions are essential for the economics for any wind project. With the advent of the mega–wind farms the requirements to good wind resource assessment methods have led to methodologies where all available knowledge on meteorology, climatology, and topography is used on the ever-increasing amount of information on the atmosphere and the earth's surface that comes from satellites and ground measurements. Large computers combine models and data to estimate the wind resource at the wind farm sites and to predict the output from the farms days ahead. The wind resources vary dramatically over a few kilometers as well as from one region to another, depending on topographical conditions and the overall weather systems. As an example on the variation, if a wind turbine produced full power all year round, one would say it had 8765 full last hours; in southern Germany it would produce 1000 hours; in northern Germany, 2000 hours; in the North Sea, 4000 hours; in Dzungar Gate between Kazakhstan and China, 4000 hours; in the Gulf of Suez, 6000 hours (all approximate and dependent on the exact location and the size of the wind turbine).

Modern wind turbines have a high quality, which results in technical availability of typically 98 to 99%. The high level of availability is a result of the reliability of the machines and, for most land-based machines, the easy accessibility for repairs and maintenance. However, under offshore conditions, the situation is different. Because of the poor accessibility of the site, a higher degree of reliability is one of the necessary conditions for arriving at an acceptable level of availability. Precautions concerning operation and maintenance has led the operators of the 200 MW wind farm 20 km off the coast of Jutland in the North Sea—the Horns Rev Wind Farm—to equip each turbine with a helicopter platform and a survival room for the service personnel (see Fig. 1).

As noted earlier, in a not-too-distant future a considerable amount of the necessary energy will and must come from renewable energy technologies. With this perspective, we will see many very large wind

FIGURE 1 Access by helicopter to one of the wind turbines at Horns Rev offshore wind farm in the North Sea, 20 km from the Danish coast. It was constructed in 2002 and consists of 80 turbines, each of 2 MW. The area of the farm is 20 km^2. From ELSAM.

farms, distributed all over the world (and not as in 2002, where 85% of all the world's wind turbine capacity was placed in five European countries). Many of the wind farms can be expected to be located in environmentally sensitive areas; hence, environmental awareness and public acceptance will be key issues for the large wind farm projects to come.

2. WIND ENERGY STATUS

The revival of wind energy began in the end of the 1970s as a consequence of the concerns for energy supply security after the oil crises. This, as well as environmental concerns about global warming from the use of fossil fuels, has caused many nations to promote the development and use of wind energy for electricity generation. In general, two approaches have been used: (1) development support for the wind technology in terms of research, development, and demonstration and (2) market development using instruments like fixed power purchase contracts, investment or production subsidies, tax credits, wind resource studies and physical planning, setting aside areas for wind energy development, preferential finance, and so on. Especially when they are combined, these instruments have been successful in developing modern wind energy, both as a technology and as a significant and growing energy source.

Whereas the initial development in general consisted of single wind turbines, dispersed in rural areas, the first major development of wind energy capacity and wind farms took place in California in the early 1980s. The development was supported by subsidies for building wind farms through tax credits and by premium payments for the produced electricity; within a few years the installed capacity reached approximately 1500 MW. Figure 2 shows an example of a Californian wind farm. The wind turbines were rather small, less than 100 kW, and the operating record was rather poor due to immature technology and difficulties with the electrical integration into the power system.

After some years with a limited installation of new capacity, growth accelerated in the mid-1990s, this time with Europe as the world leader in technology and installations. Figure 3 shows the global development of wind power capacity since 1983. During 2002, new wind energy installations reached 7227 MW, bringing the total global installed capacity up to 32,000 MW supplying 0.4% of the world's

FIGURE 2 A wind farm in Palm Springs, California. From the Risø National Laboratory.

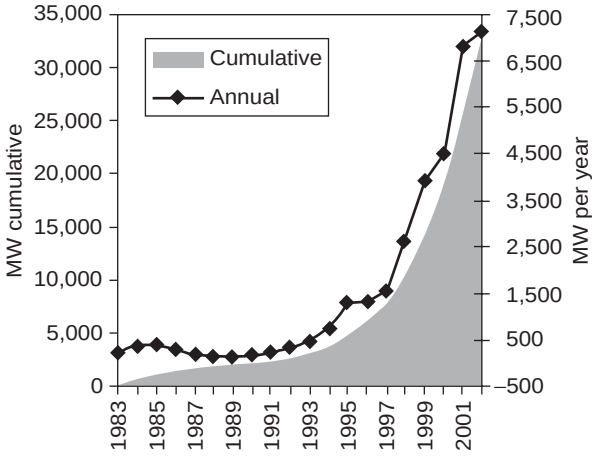

FIGURE 3 Annual and cumulative installed wind power in the world. From World Market Update 2002, BTM Consult Aps, March 2003.

electricity demand and with more than 61,000 wind turbines installed worldwide; 85% of the total capacity is installed in Europe, led by Germany, Spain, and Denmark.

An interesting trend in the market is that a growing part, currently two-thirds, of the new installations is made up of large wind farm projects. As wind energy becomes more economically attractive, larger developers such as subsidiaries of power utilities are becoming involved, utilizing their expertise in logistics and finance. The trend toward larger projects is seen even in Denmark and Germany, otherwise known for dispersed and small-sized projects. The development of market segments is shown in Table I.

The emerging development of offshore wind farms will add to the trend of larger projects, where the economics of grid connection, infrastructure, installation, and O&M in particular favors large projects.

TABLE I

Segment Distribution of Installed Capacity 1995–2002

Market segment	Percentage of world market							
	1995	1996	1997	1998	1999	2000	2001	2002
Dispersed development, single wind turbines and small wind farms < 5 MW	75	70	60	45	42	46	35	32
Commercial and utility owned wind farms > 5 MW and up to 199 MW	24	28	40	54	57	53	64	65.5
Other niche markets (e.g. off shore)	1	1	1	1	1	1	1	2.5

Source. World Market Update 2002, BTM Consult Aps, March 2003.

Offshore wind farms are still only a time fraction of the globally installed wind capacity. By the end of 2002, a total of 279 MW wind farm capacity was installed offshore, 233 MW of which was in Denmark. It is expected that during 2003–2007, the wind farm capacity offshore will grow to approximately 5000 MW, primarily with British and German projects.

3. WIND FARM SITING ISSUES

3.1 Wind Farm Sizing and Optimal Layout

Following a decision to extend the electricity production capacity by one or more wind farms, one has to decide where to place the wind farms (siting), the size of the wind farms (sizing), and the optimum layout of the wind farms.

The size of a wind farm is often determined with respect to a number of constraints, such as planning legislation; local and national development plans and policies; land availability, access, and transport infrastructure; power system (present and future); wind turbine size; financing; the electricity market; and environmental impacts.

The optimal size of a wind farm, economically and financially, for society and investors at given conditions may vary for different sites; hence, sizing and siting are integrated activities. Furthermore, sizing involves aspects that may not easily be quantified in monetary terms.

The site for a wind farm most often ends up being based on a comparison of selected candidates with respect to issues such as the possibility of obtaining planning authorization and approvals; the successful outcome of local hearings; potential wind energy production; environmental costs and benefits; sustainability, assumptions, uncertainties, and risks; the availability of land and infrastructure; power system development; investments and investors; design safety, reliability, and lifetime; wind farm and power system operation and maintenance; and economic and financial viability.

The wind farm layout may be determined according to different principles. No single layout concept is universally acknowledged as ideal and preferred, so no universally true automatic method for determining optimal wind farm layouts is therefore available. There are tools that can assist the analyses and could or should be applied as a part of the development and optimization exercises, but there is no way around human judgment—at least when it comes to aesthetics and visual impact.

As an example, the Middelgrund offshore wind farm outside the harbor of Copenhagen, was first planned as a straight line, but due to aesthetics grounds it was changed to an arch as shown in Fig. 4. Other examples are the early and famous wind farms in California, where Fig. 2 shows a wind farm sited in a very regular pattern, and Fig. 5 (Alta Mesa) shows a wind farm located along mountain ridges. In the United Kingdom, some of the wind farms are placed in an irregular pattern, required by legislation due to constraints on visual impact.

3.2 Wind Farm Production Estimation

Because the terrain height variations—the orography—over a wind farm site causes large variations of the available wind resource for each wind turbine, a correct and detailed terrain description is a necessary prerequisite for optimizing wind farm layouts. When the wind moves over hill and ridges, it speeds up, and the effect can easily extend to the turbine height and, because the power output of a wind turbine for aerodynamic reasons is proportional to the third power of the wind speed, taking care of this effect is essential when siting any wind turbine at a land site. This is done is by using a detailed topography map of the site as input to a so-called microscale numerical

FIGURE 4 The Middelgrund offshore wind farm outside Copenhagen Harbour. Constructed in 2000 and consists of 20 2MW wind turbines. Bonus.

FIGURE 5 The Alta Mesa Wind Farm, California. From the Risø National Laboratory.

model, which in short is able to calculate a detailed wind flow field over the wind farm site, which again is used to produce a detailed map of the variation of the wind resource over the site. Besides the orography, the model also uses as input a detailed description of the surface characteristics (i.e., the roughness of the terrain). Open farmland has a low roughness and forests have a high roughness. When the wind blows from a low roughness to a high

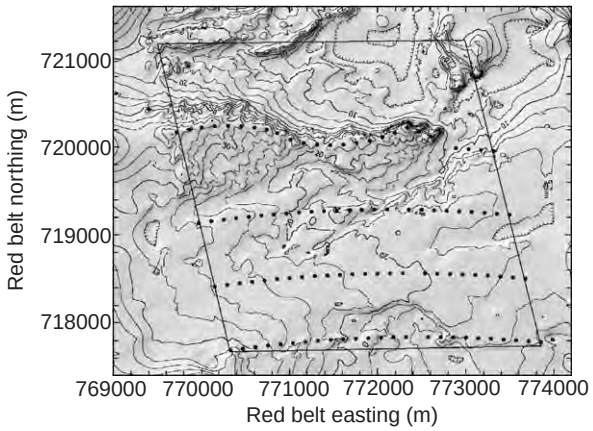

FIGURE 6 An example of an elevation map of a wind farm site (Zafarana, Egypt). An accurate description of the overall geometry of the terrain surface is a prerequisite for reliable modeling of the wind flow over the terrain. The map was established by a site-specific survey employing GPS techniques. The height contour interval in the map is 2 m, but it is possible to draw 1-m contours as well. Four sample wind farms, each consisting of 25,600-kW wind turbines, are indicated by black dots.

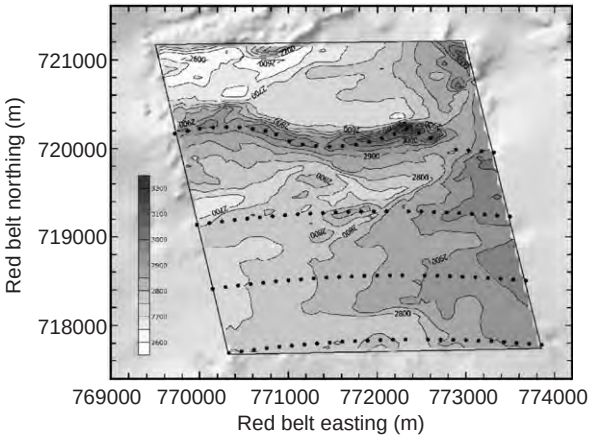

FIGURE 7 An example of a resource map of a wind farm site (Zafarana, Egypt). Estimated annual energy production for a 600-kW wind turbine. Hub height is 45 m a.g.l and the power production is calculated in a regular grid with a grid spacing of 50 m. Height contour interval is 2 m. Even within this fairly small and homogeneous site, the estimated production varies by more than 20%. The accuracy of the map has been verified by measurements at nine meteorological masts at the site. From Clausen, N.-E., *et al.* (2003). "Wind Farm Planning at the Gulf of Suez." New and Renewable Energy Authority, Cairo, Egypt and Risø National Laboratory, Roskilde, Denmark.

roughness, the wind speed decreases. Figure 6 (Zafarana topography) and Fig. 7 (Zafarana, wind resource) show the topography and wind resource for a coming wind farm site at Zafarana in Egypt. Figure 8 shows the wind resource dependence on topography in a three-dimensional way.

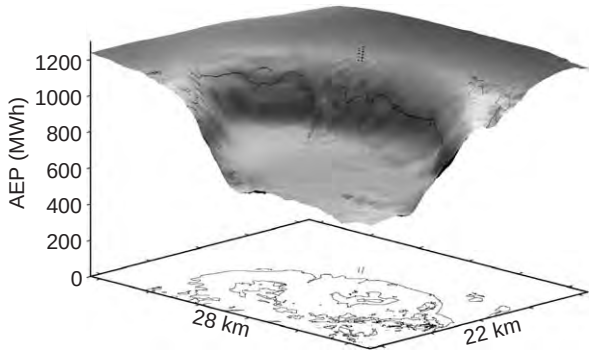

FIGURE 8 Variation of the wind energy potential at coast. The dramatic increase in the potential going from land to sea is due to the change in the surface roughness. The modeling was done in connection with the planning of the Vindeby offshore wind farm, which is shown on the figure. Vindeby was the first offshore wind farm in Denmark and has been operating since 1991. It consists of 11 Bonus turbines of 450 kW each. AEP, estimated annual energy production per wind turbine.

The estimate made by a microscale model of the average yearly power output that is produced by a wind farm over its life span—usually considered to be 20 years—is very dependent on the physical realism of the model and on the quality of the input to the model, basically topography and the wind measurements.

The most obvious way to obtain an estimate of the wind and the wind resource at a wind farm site is to perform meteorological measurements—especially wind speed and wind direction—at relevant heights and locations. But because the wind is a local characteristic, influenced by topography such as surrounding hills and changes of surface characteristics (water, forests, open farmland, desert, etc.), one needs measurements in a dense network of high meteorological masts. Such measurements are costly to carry out, and it takes a long time to obtain climatological estimates (i.e., estimates of wind energy potential over the lifetime of the wind farm). Therefore, numerical meteorological computer models are needed for the interpolation between measurements, for extrapolation to the relevant heights (the hub height of the wind turbines, which is the center of the rotor), and for the prediction of the wind climate over the lifetime.

An efficient and commonly used method of predicting the surface wind climate is to combine a mesoscale model and a microscale model. The mesoscale model simulates the regional wind climate like flow over and around mountain ranges and in large valleys. A mesoscale model is a specially adapted smaller version of the large numerical weather prediction model, which is used by the national weather services to forecast the daily weather and the weather days ahead. Mesoscale models require very large computers.

The microscale model calculates the speed-up and sheltering by hills, local obstacles, and local roughness conditions. The procedure is illustrated in Fig. 9. The mesoscale model calculates the mesoscale wind field using as input a description of the large-scale climatology obtained from the large international databases on meteorological, climatological, and topographical global information. The area will typically be 200×200 km, and the resolution 1 to 5 km.The climatology of the simulated wind fields—commonly called wind atlas data—and the local orography and roughness are subsequently used by the microscale model to predict the local wind climate at specific locations with resolutions of a few meters.

3.3 Environmental Impact Assessment

Wind turbines produce energy without pollution, eventually leading to a reduction in the emission of carbon dioxide, nitrogen oxide and sculpture dioxide. The use of wind energy may therefore contribute to reduce global climate change, acid rain and other serious environmental problems.

Although the environmental impact of wind energy obviously is lower than that of conventional energy sources, there are some potentially negative effects on the environment, especially when it comes to establishing large wind parks of several hundred large wind turbines. Over the years the main environmental concerns when constructing wind farms have been visual impact, noise, and the risk of bird collisions.

Modern wind turbines are extremely durable and the danger of parts of a turbine such as a blade part hitting buildings or persons must be regarded as remote. Furthermore, wind turbines have several braking systems to stop the rotor blades in case of extremely strong winds or a malfunction. As modern well constructed wind turbine are also very quiet it normally possesses little problems to build wind turbines close to human settlements. The visual effects of wind turbine may, however, create some controversy, as some people believe they are having a severe negative visual impact of the landscape while others find them beautiful.

The impact on plants and animals is not very well established despite a sizable number of studies, but as it is with most power plants a certain amount of

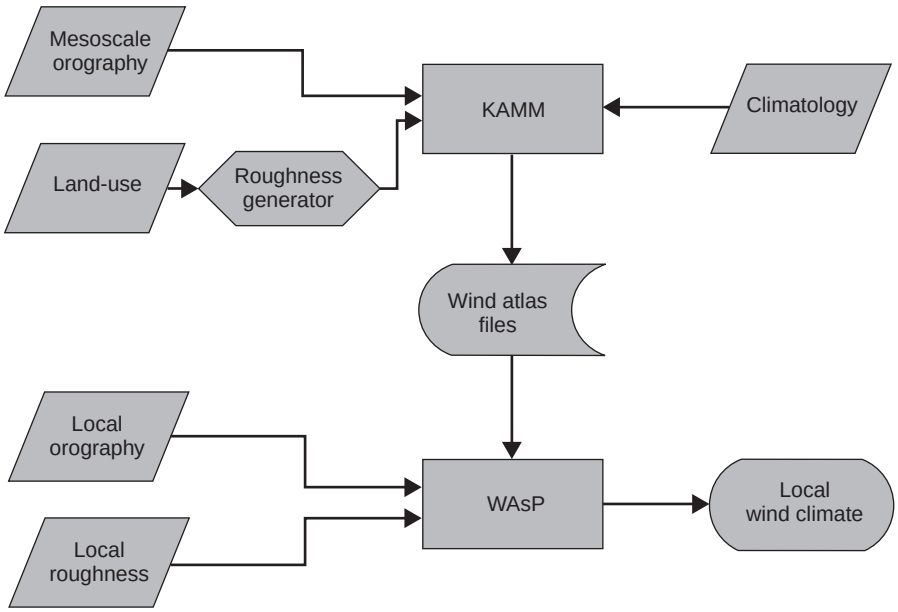

FIGURE 9 Predicting the wind climate by combining a mesoand microscale meteorological model. Flowchart showing the principle behind the calculation of a local wind climate by means of a mesoscale model (KAMM, the Karlsruhe Atmospheric Meso-scale Model) and a microscale model (WasP, the Wind Analysis and Application Program). For both models the main input is orography, surface roughness and long-term wind climatology. For the microscale model, the long-term wind climatology is produced by the mesoscale model and is named wind atlas files.

disturbance to flora, fauna birds and mammals will happen. Still the largest concern is on bird strikes and associated effect on bird population and migration paths. It is not alone the turbines that constitute a danger to the birds, associated utility structures in particular lines that connect the wind turbine farms with the electrical grid possess a danger to birds as they can collide with the cables or get electrocuted when landing on the towers.

The large wind farms located or being located along the Gulf of Suez in Egypt are placed just in the world's major bird migrating routes with large numbers of raptors, storks and other spices sometimes occurring at very low altitudes—clearly, the bird-wind turbine collision issue is of special concern to Egypt. It is expected that crucial information on the collision issue will be obtained by the intensive ornithological studies being performed.

4. TECHNICAL WIND FARM ISSUES

4.1 Turbine Spacing and Wakes

Most of the technical issues with wind farms are associated with the close spacing of multiple turbines. The close spacing implies that the extraction of energy by wind turbines upwind will reduce the wind speed and increase the turbulence, which may cause reduced efficiency and higher loads on downwind turbines. Another technical issue for large wind farms is the grid connection and the integration into the power system. This will be covered in the next section on power system integration.

When a wind turbine extracts energy from the wind, the rotor creates a pressure field that reduces the speed of the flow and expands the flow stream tubes around the wind turbine. As the air crosses the rotor plane, the pressure decreases suddenly, and in the immediate downstream region there is a deficit of pressure and axial velocity. The tip vortices, which form helical trajectories, can be seen as a cylindrical shear layer that separates the outside flow from the slower moving flow in the wake. As the air moves downstream, the velocity inside the wake decreases and the pressure increases until ambient pressure is reached in about one turbine diameter length from the rotor plane. The flow close to the rotor is illustrated in Fig. 10, where smoke is released near the tip and midway on the blade.

Further downstream, the wake diffuses due to turbulence caused by the shear in the wake as well as from the ambient turbulence, and approximately three rotor diameters downstream the wake is fully developed and is characterized by the mean velocity profile, the growth of the wake, and wake turbulence. The flow velocity in the wake is

FIGURE 10 Flow visualization showing tip vortices and the reduced flow velocity in the wake of a wind turbine. From Risø National Laboratory.

gradually restored by the diffusion of energy from the wind field above, making the wake shallower but broader. In general, the initial wake velocity deficit is assumed to depend on the thrust coefficient of the wind turbine, which again depends on the wind speed. The wake growth depends on the ambient plus the wake turbulence, although it is often assumed that the wake increases linearly with the downstream distance.

4.2 Wind Farm Efficiency

The reduced wind speed in the wake behind means that a wind turbine operating in the wake of an upstream wind turbine will produce less energy. Deep in a wind farm a wind turbine may experience several wakes, and a wind farm will thus produce less energy than the same number of turbines operating isolated under equal wind conditions. The ratio between the annual production of a wind farm and the production of corresponding isolated turbines is the wind farm efficiency. Several wake models have been developed to calculate production of a wind farm. A simple model, which assumes linear wake growth, is illustrated in Fig. 11. The effect of several wakes on one wind turbine is calculated by adding the deficits. While such a model is sufficient for smaller wind farms, the models does not account for the effect on the ambient wind climate from the wind farm, and caution should be exercised for very large wind farms.

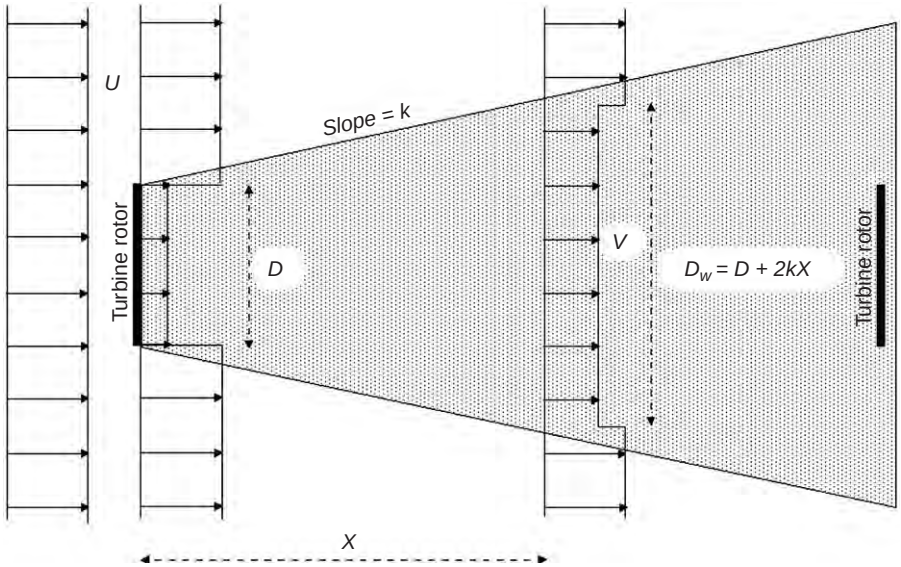

FIGURE 11 Principle of a simple wake model. The wake decay constant k ~ 0.1 and the velocity deficit is given by $\delta V \triangleq U - V = U(1 - \sqrt{1 - C_t})(D/(D + 2kX))^2$. From Katic, I., Højstrup, J., and Jensen, N.O. (1986). "A Simple Model for Cluster Efficiency." Proc. European Wind Energy Conference, October 7–9, 1986, Rome, Italy.

Using a wake model, the wind farm efficiency for a given wind farm layout can be calculated. For a given layout, the efficiency also depends on wind direction distribution, and at sites with a prevailing wind direction, the separation between turbines in this direction is often larger than perpendicular to the prevailing wind direction. In the micrositing process, the production from a given farm layout is optimized taking into account the terrain, needs for roads and power connections, and land use. Most wind farms, except in homogeneous terrain or offshore, will show an irregular layout and follow, for example, a ridge in the terrain. A thorough analysis should always be carried out, but as a rule of thumb, an efficiency of 90% is expected for a layout, where the downwind distance between turbines times the crosswind distance is 50 times the rotor diameter D squared (i.e., a spacing of $7\,D \times 7\,D$ or $10\,D \times 5\,D$).

4.3 Wind Farm Loads

In addition the wind farm efficiency, the wind turbine loads are affected by the farm layout, as the variations in the wind flow field from the wake velocity deficit and the wake turbulence will increase in particular the fatigue but also the ultimate loads. The load increase depends on the distance to the wind turbine and on the wind speed. Thus, the relative load increase is largest at lower wind speeds, where a high proportion of the energy is extracted from the flow, and smaller at higher wind speeds, where relatively less of the energy flow is extracted in order to limit the power and load on the wind turbine drivetrain. However, most fatigue damage and ultimate loads on the wind turbine structure occur at high wind speeds where the attention should be focused. At very high wind speeds, where the wind turbines are standing still or idling slowly and so to speak transparent to the wind, the wake effects are negligible. Furthermore, the relative load increase is largest when the ambient turbulence is small. This is the case over water, and due consideration of wake effects is essential for the determination of dynamic wind turbine loads during operation in an offshore wind farm.

In a wind farm with wind turbines arranged in a row perpendicular to the prevailing wind, the separation between the wind turbines may be less than three rotor diameters. When the wind is along the row, the wind turbines are thus in the near wake, where the shape of the wake is very distinct and where the highest loads occur during half wake situations. In terms of the equivalent load (a constant amplitude load causing the same fatigue damage as the real random amplitude load) on the wind turbine blade in the flap wise direction, the wake may double the load at lower wind speeds compared to the loads on a similar freestanding turbine. While this wind situation is rare, loads on closely spaced wind turbines are still a research topic, and caution should be exercised in this situation.

When the wind turbines are spaced further away from each other, the effect of being in the wake of an upstream turbine is still noticeable up to a distance of about 20 rotor diameters. A number of measurement investigations have been carried out for wind farms with spacing larger than three rotor diameters, including at the Danish offshore wind farm at Vindeby, where the wind turbines are installed in two rows with a spacing of 8.5 rotor diameters. It is interesting to notice that the loading and the turbulence levels are closely related, as is demonstrated in Fig. 12, where the added turbulence and the increase in load (equivalent flap wise blade load) in the wake situation are clearly identifiable. The figure also suggests that a practical way to represent wake loads in load calculations is in terms of an added wake turbulence or an effective turbulence intensity, which depends on the wind turbine behavior, the spacing to the closest wind turbines, and the ambient turbulence. For fatigue loads, the effective turbulence intensity must also include the nonlinear fatigue damage sensitivity to higher loads for the used material. This is the approach used in the international IEC standard giving design criteria for wind turbines.

5. POWER SYSTEM INTEGRATION

5.1 Capacity Credit

The capacity of wind farms as defined here varies from less than 1 MW to several hundreds of MW. Consequently, the power system integration issues vary significantly, from incorporation of a small negative load in the distribution system with local power quality concerns to requiring a large wind farm connected to the power transmission system to possess power plant characteristics and share responsibility for power system stability and power balance. The size of wind farm projects has become larger, in many cases with wind farm capacities greater than 100 MW. This is especially the case with offshore wind farms, which are being planned and implemented along the northern European coasts. In the following discussion, we shall present the power

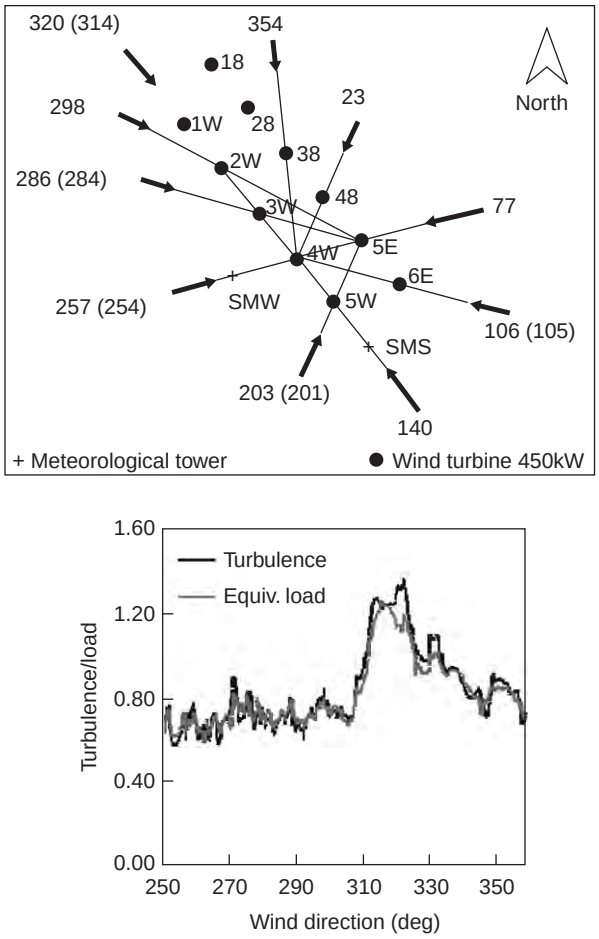

FIGURE 12 Layout and wake situations for the Vindeby offshore wind farm. The plot at the right shows the normalized equivalent blade flapwise load of turbine 4W and the normalized turbulence level at mast SMS. The turbine and the mast are in identical wake situations. From Frandsen, S. (2003). "Turbulence and turbulence-generated fatigue loading in wind turbine clusters." Risø-R-1188.

system issues of greatest concern for wind farm integration, namely capacity credit, short-term variability of wind power production, control, power system stability, and power quality. Finally, some system solutions for connecting wind farm to the power transmission system are discussed.

Because of the intermittent nature of the wind resource, a wind farm cannot be relied on to operate at a certain capacity at any given time. The question therefore arises, can a wind farm substitute for conventional generation capacity and if so, how much? This is expressed by the capacity credit, which is usually defined as the fraction of a power plant's rated capacity, which is on average available at the time of peak demand, or alternatively, the relative amount of additional conventional capacity that is needed in the absence of wind energy in order to obtain the same loss-of-load-probability (LOLP). The LOLP method is commonly used to assess the reliability of a power system with conventional generation and calculates the probability that the generation system cannot meet the required electricity demand due to random and scheduled outages of generating capacity. Both definitions give similar results for small penetration levels.

The capacity credit is determined by a number of factors, such as the average wind speed, the wind speed variability, the percentage of total electricity demand covered by wind energy (penetration), the correlation between the wind at different wind farms in the power system and the correlation between wind speed and demand. For small penetration levels, the capacity credit of dispersed wind farms in a large grid is generally close to the average output of the plants—that is, the installed capacity times the capacity factor of the wind plants (500 MW of wind farms with capacity factor of 25% can be expected to have a capacity credit of 125 MW).

5.2 Short-Term Variability of Wind Power Production

While wind farms can thus substitute for conventional generation capacity in a power system, the fluctuating character of the wind farm production needs to be addressed. As conventional generation capacity may take a while to prepare for generation, an amount of unused generation capacity, spinning reserve, is kept on line to respond to fluctuations in wind power as well as load. To take full advantage of wind power, to control the dispatch of conventional generation, and to trade the power production on markets operating on a 48 h timescale, systems that predict the wind power production 1 to 2 days ahead are necessary. Quite a few methods for short-term prediction of the wind farm production have been developed and implemented in load dispatch centers in, for example, Denmark and the United States. Most methods constitute a numerical weather prediction model, a physical model of the wind farm to relate wind speed to production, accounting for farm layout, power curves as well as wake and terrain effects, measurements of production and statistical analysis, and, finally, preparation of output in terms of, for example, energy production from the wind farm in hourly steps from 0 to 48 h ahead.

The accuracy of short-term prediction models can be evaluated by comparing their prediction with the result of the persistence model, which simply

assumes that production at any given time is equal to the production during the previous time period. As weather systems develop slowly, the persistence model is actually quite accurate and difficult to outperform. Figure 13 presents an example comparison between the persistence and a short-term prediction model based on the weather forecast for an actual 5.2 MW wind farm in Denmark and based on 1 year of data. The mean error (circles) and the mean absolute error (squares) are shown for the persistence model (filled symbols) and for the prediction model in absolute values as well as relative to the wind farm capacity. Note that the weather prediction–based model first outperforms the persistence model after 6 h and that the mean absolute error is almost constant at 15% of the wind farm capacity up to 36 hours. In general, state-of-the-art weather prediction–based models are expected to reduce the mean absolute error to half the error of the persistence model.

Finally, a subjective evaluation of the performance of prediction models can be made by plotting the actual performance of the model together with the observed production. An example is shown in Fig. 14.

5.3 Energy Storage

Another way to improve the integration of wind farms by reducing the power fluctuations is through the use of energy storage. Most storage technologies such as lead-acid batteries are not suited for large-scale application, but new storage technologies with promise have emerged. One is based on the Redox flow technology, which has a high efficiency (80%) and a long lifetime (>10 y). A Redox flow plant consists of a cell stack in which two electrolytes can interact through a membrane and storage tanks for the two electrolytes. The power capacity is given by membrane area, while the storage tank volumes determine the energy capacity. Hence, the ratings of the energy and the power capacity are independent. Another promising technology is reversible fuel cells and hydrogen. In case of surplus electricity, the fuel cells produce hydrogen, which, in case of a deficit can be used for power production or transportation.

5.4 Control and Power System Stability

A high wind power penetration imposes additional control needs on a power system. This is especially of concern for large wind farms connected to the transmission system at a high-voltage level (>60 kV), where the wind farm behavior may influence the power system stability. In Denmark, two large offshore wind farms of 150 MW each were installed in 2003 in a power system where wind energy already covers 15% of the electricity demand. Due to their rated capacity, the wind farms are connected to the transmission system, and new requirements have been developed by the Danish Transmission system operators, Eltra and Elkraft System, giving specifications for connecting wind farms to the transmission system, which can be seen as indicative for future requirements to wind farms with regard to control, stability, and power quality.

Not surprising, specifications are given for grid frequencies, voltages, reactive power compensation,

voltage quality, and fault protection. Moreover, to enable wind farms to substitute conventional power plants, a requirement for production control and more stringent stability requirements and requirements for operation during faults have been introduced. Traditionally, wind turbines have been equipped with protection functions that disconnect and stop the turbines in the case of a temporary or permanent grid fault. This philosophy has been abandoned, and wind turbines are now required to be able to ride through temporary faults and contribute to system services such as momentary reserves and short-circuit capacity.

The requirements for production control constitute the ability to do the following:

- Control the production from the wind farm so that it does not exceed a certain MW limit (i.e., a production limit)
- Control the production limit by a single central signal
- Control each wind farm individually
- Have the control act on the individual wind turbine
- Control the production quickly (i.e., a reduction from 100% to below 20% of maximum power in less than 2 seconds)

Furthermore, high wind speeds may not cause all turbines to stop simultaneously.

5.5 Power Quality

Wind farms influence the quality of power in the electricity grid of the power system. The term power quality is not well defined, but it usually includes two aspects of power supply: voltage quality and supply reliability. The voltage quality part disturbances such as rapid changes, harmonics, interharmonics, flicker, unbalance, and transients, reliability involves longer duration phenomena such as interruptions, voltage dips and sags, over and under voltages, and frequencies. Methods for measurements and assessment of the influence of wind turbines on the power quality are given in the international standard IEC 61400-21. The standard includes measures for maximum power, reactive power, voltage fluctuations, and harmonics. In general, the main power quality issue for wind farms with a large number of turbines is the steady-state voltage increase, while for individual large wind turbines in a weak grid, voltage fluctuations and flicker become an additional important issue. This is due to the power smoothing effect from the averaging of usually close to uncorrelated power fluctuations from the individual wind turbines. Wind turbines will normally increase the voltage level in the distribution system due to their production of active power, while reactive power consumption will decrease the power level. Capacitor banks and transformer tap changers are the most common ways to control the steady-state voltage level. It is generally desirable to reduce the active power consumption, either to reduce losses in the system or to avoid reducing the production capacity of strained generation capacity. Reactive power consumption may also affect the power system stability, as a voltage instability or collapse may occur if the power system cannot supply a change in reactive power demand from a rapid change in power production. A fast control of reactive power compensation is necessary to deal with such power stability issues in wind farms. This may be accomplished by the use of wind turbines with active voltage control or by the use of external compensators such as static var compensators (SVCs).

5.6 System Solutions

Four different system solutions for connecting large wind farms to the high-voltage transmission system are shown in Fig. 15. To meet the requirements for production control, the wind turbines in the wind farm are equipped with blade angle control (pitch or active stall) and can therefore also contribute to the frequency control by regulation of the active power. Furthermore, wind turbines or installation with power converters are also able to control the reactive power supply to the power system.

In the traditional solution A, the reactive power consumption in the wind turbine induction generator is compensated by shunt capacitors in the individual wind turbines. The power is the transformed to the medium voltage level (10 to 40 kV) in the farm distribution system before being transformed to the high voltage level (>60 kV) of and transmitted to the grid transmission system at the connection point. The solution relies on a strong grid and power system and may be supplemented with a reactive power compensation unit for the fast reactive power control at a point before the high-voltage transformation.

In solution B, each wind turbine is equipped with a power converter, which in general keeps the power factor close to unity (no reactive power demand) and smoothes the power fluctuation through variable speed operation. The power converter may also be used for voltage control by regulation of the reactive power supply.

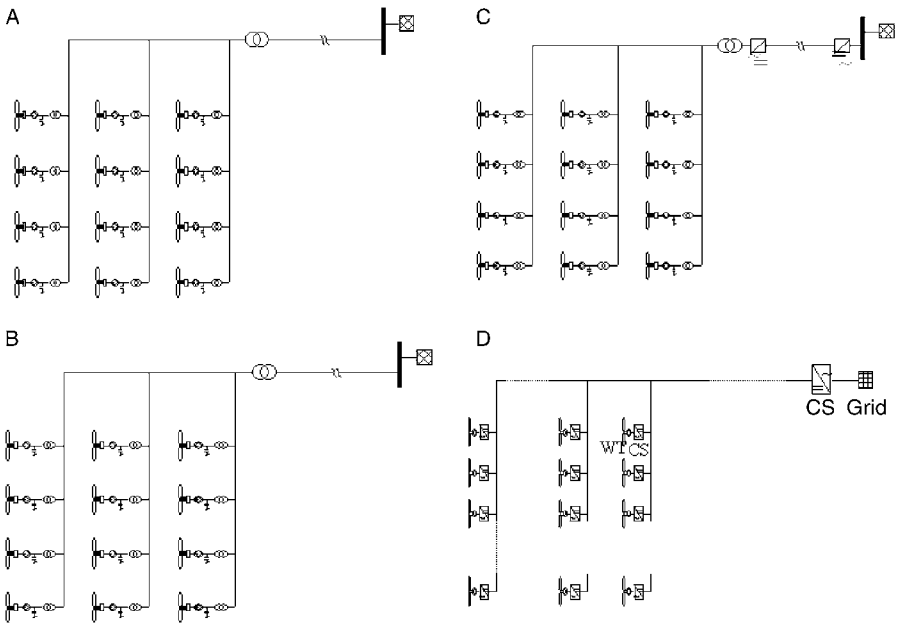

FIGURE 15 System solutions for connection of wind farms. AC and HVDC transmission of power from the wind farm to the grid. From Hansen, L. H., *et al.* (2001). "Conceptual Survey of Generators and Power Electronics for Wind Turbines," Risø-R-1205 (EN).

TABLE II

Characteristics of System Solutions for Grid Connection of Wind Farms

System solution	A	B	C	D
Active power control	Yes	Yes	Yes	Yes
Reactive power control	Yes	(Central)	Yes	Yes
Active at faults	Yes	No	Yes	Yes
Short-circuit power contribution	Yes	Yes	No	No
Regulation bandwidth	10–100 ms	200 ms–2 s	10–100 ms	10 ms–10 s
Ancillary services	Yes	No	Yes	Yes
Flicker contribution	Yes	Yes	No	No
Drive train load reduction	No	Yes	No	Yes
Soft starter needs	No	Yes	Yes	Yes

One of the most widely discussed concepts for grid connection of large wind farms is high voltage direct current (HVDC). A modern HVDC link consists of two fully controllable AC/DC converter stations linked with a DC cable. The DC cable is less expensive than an AC transmission cable, but the cost of the converter station makes this solution more expensive than an AC link, unless the distance is very long. The development of power electronics reduces the cost of converter stations rapidly and may make HVDC viable for many applications. The viability of HVDC may be reached earlier for offshore wind farms. When the critical cable length for AC transmission is reached, a compensation unit is required on the AC transmission system, which is also expensive offshore. In addition to the advantages to the power system of having a fully controllable DC/AC converter at the connection point to the transmission system, a HVDC link opens new possibilities for wind turbine control, as the frequency of the wind turbine connection grid in the farm can be controlled independently of the power system frequency.

The simplest HVDC solution is the group connection in C, where the HVDC link connects the power system and the wind farm AC grid. The converter at the wind farm end can supply the wind turbines with reactive power, and the most obvious

FIGURE 16 Placing the wind turbines at the Nysted offshore wind farm. Offshore wind farm technology was developed in 2003 to a point where on the average it took one day to erect each of the 110 m high wind turbines (Compagnies Bonus and A2Sea). From Jan K. Winther.

FIGURE 17 The Nysted wind farm, showing rows of the 2.1 MW Bonus turbines and the transformer station. From Energi E2.

solution is to equip the wind turbines with directly coupled induction generators without capacitor banks for reactive power compensation or with a simpler constant no-load compensation. The control of the wind farm grid frequency, and hence the rotational speed of the turbines, allows aerodynamic efficiency optimization. However, compared to individual speed control, the total efficiency is smaller due to variations in wind speed and thus optimum rotation speed from wind turbine to wind turbine. Neither can the benefits of variable speed operation with individual power converters such as smoothing the power fluctuations and reducing drivetrain load transient be obtained.

The solution in D appears to have all the benefits of individual wind turbine power converters, if the AC/DC converters in the wind turbines are based on forced-commutated semiconductors. Then the frequency and hence the turbine rotation speed can be controlled independently to reduce drivetrain loads and power fluctuations. The benefits and limitations of the four solutions are listed in Table II.

TABLE III

Main Data of Two Offshore Wind Farm Examples

Wind farm characteristics	Horns Rev wind farm	Nysted wind farm
Installed capacity	160 MW	158.4 MW
Number of turbines	80	72
Wind turbine type	Vestas 2 MW	Bonus 2.2 MW
Expected annual production	600 GWh	595 GWh
Hub height	70	70 m
Wind farm area	20 km^2	24 km^2
Water depth	6.5–13.5 m	6–9.5 m
Distance to shore	14–20 km	10 km
Distance between rows	560 m	850 m
Distance between turbines in rows	560 m	480 m
System solution type	B	A
Internal grid voltage	34 kV	33 kV
Transmission to shore voltage	150 kV	132 kV

6. WIND FARM EXAMPLES

This article has presented several illustrations of large offshore wind farms, namely the Horns Rev offshore wind farm and the Nysted offshore wind farm, Figs 16 and 17 (also see Table III). These wind farms, each of approximately 160 MW, have been built as large-scale demonstration projects according to an agreement between the electricity sector and the Danish government. These wind farms use wind turbines adapted to offshore conditions with capacities of 2 to 2.2 MW. The expected electricity production corresponds to almost 3% of the electricity consumption in 2002 in Denmark. These

are the first Danish wind farms designed according to the new requirements from the transmission system operators, where the wind farms are considered power plants with responsibilities for control, stability, and power balance.

While large, these wind farms are not the largest in the world. At present, the record goes to the King Mountain Wind Ranch in Texas with a capacity of 278 MW and consisting of 214 1.3 MW Bonus wind turbines. Nor will the turbine size in future offshore wind farms be limited to the 2 MW size; most major wind turbine manufacturers are testing or developing wind turbines in the 3 to 5 MW range for offshore (and onshore) wind farm applications. Even 10 MW turbines seem realistic with modern technology.

Glossary

exclusion zone An area that cannot be used for wind power development because of environmental, legal, topographic, or other reasons.
frequency distribution of wind speed The percentage of time that the wind is blowing at each speed (14% at 2–3 m/s, 8% at 3–4 m/s, etc.).
geographic information system (GIS) The computer hardware, software, and technical expertise that inputs, stores, maintains, manipulates, analyzes, and outputs geographically referenced data. A GIS combines the power of spatial database management with high-resolution graphic display to effectively present information.
grid-connected A project that is connected to a utility distribution system.
power class A single number representing a range of wind power densities (WPD). A typical power classification scheme divides the WPD range from 0 to $>800\,W/m^2$ into seven power classes.
Weibull distribution A mathematical function that is often a good approximation to the frequency distribution of wind speeds at a site.
wind electric potential The total number of megawatts of wind energy generating capacity that could be installed in a given area.
wind power density The average wind power over one square meter expressed in Watts per square meter (W/m^2) in a vertical plane perpendicular to the wind direction.
wind resource A measure of how much wind energy is available at a given height at a given point or over a given area. It can be expressed in values of Watts per square meter, power class bins, or estimated yearly energy production.
wind resource base The collection of all data about the wind resource in a given area. The data set may include average speeds and power densities, measures of variability, and energy production statistics.
wind shear A measure of the change in wind speed or power with height above the ground.

A major barrier to the deployment of wind energy in many regions of the world is the lack of reliable, detailed wind resource data. Wind resource assessments are crucial in determining the feasibility of wind energy projects and are essential for government and industry to identify areas of potential wind energy development. Accurate assessments can also aid the development of policies and regulations that can enhance wind energy deployment. This article summarizes the techniques used to conduct wind resource base assessments and the status of past, present, and future assessment activities.

1. INTRODUCTION

Wind is a renewable energy resource that can generate significant amounts of electricity for both grid-connected and standalone applications. Major strides in wind technology development have increased efficiencies and reduced wind energy costs so that they are competitive with other generation technologies in regions with good-to-excellent wind resources. However, a major barrier to the deployment of wind energy in many regions of the world is the lack of reliable, detailed wind resource data. Wind resource assessments are crucial in determining the feasibility of wind energy projects and availability of these data is essential for government and industry to identify areas of potential wind energy development. Accurate assessments can also aid the

development of policies and regulations that can enhance wind energy deployment.

Wind resource assessments produced from the 1980s to early 1990s, such as the U.S. and European wind atlases and a worldwide wind resource map, identified general areas of good wind resource and provided the basis for preliminary estimates of the wind-energy potential. However, these assessments were of limited use, primarily because of the lack of detail on the spatial variability of the wind resource and, in many regions of the world, the lack of reliable surface measurement data that largely provided the basis of the resource estimates.

Advances in wind resource assessment are leading to improved wind resource maps, even in areas with little or no surface measurements. This article describes the process of wind resource assessment and describes the newest techniques for generating wind resource maps and databases.

2. BASICS OF WIND RESOURCE

2.1 Wind Speed and Direction

Wind speed is the simplest representation of the wind at a given point. Anemometers or other calibrated instruments measure wind speed. Wind speeds can be calculated as an average or expressed as an instantaneous value. Wind speed averaging intervals commonly used in resource assessment studies include 1- or 2-minute (weather observations), 10-minute (the standard for wind energy monitoring programs), hourly, monthly, and yearly periods. It is important to know the measurement height for a given wind speed because the wind speed can vary significantly with height. It is also desirable to know the exposure of a particular location to the prevailing winds because nearby obstacles such as trees and buildings can reduce the wind speed.

Wind direction is measured with a wind vane, usually located at the same height as the anemometer. Knowledge of the prevailing wind direction(s) is important in assessing the available resource for wind turbine siting and spacing. Correct alignment of the wind vane to a reference direction is important to accurately measure the wind direction. Wind direction observations at meteorological stations are often based on a 36-point compass (every 10°). Some wind direction data are expressed in less precise 8-point (every 45°), 12-point (every 30°), or 16-point (every 22.5°) intervals.

The wind direction distribution is often presented as a wind rose (a plot of frequency of occurrence by direction). Wind roses can also represent quantities such as the average speed or the percentage of the available power for each direction.

2.2 Wind Power Density

Although the wind resource at a site can be roughly described by the mean wind speed, the wind power density (WPD) provides a truer indication of a site's wind energy potential. Wind power density expresses the average wind power over one square meter (W/m^2) in a vertical plane perpendicular to the wind direction. The power density is proportional to the cube of the wind speed and to the air density. Because of this cubic term, two sites with the same average wind speed but different speed distributions can have very different WPD values. The wind power density, in units of W/m^2, is computed by the following equation:

$$WPD = \frac{1}{2n}\sum_{i=1}^{n} \rho_i \cdot v_i^3,$$

where WPD is the wind power density in W/m^2, n is the number of records in the averaging interval, ρ_i is the air density (kg/m^3) at a particular observation time, and v_i^3 is the cube of the wind speed (m/s) at the same observation time.

This equation should only be used with individual measurement records (hourly, 10-minute, etc.) and not with long-term average speeds such as monthly or yearly values. Using this equation with long-term averages will underestimate the WPD because long-term averages will smooth out most of the higher speed records that would more accurately represent the fundamental nature of the wind resource. Long-term averages of WPD should be computed by averaging the WPDs computed over many shorter intervals.

The air-density term is dependent on temperature and pressure and can vary by 10 to 15% seasonally. If the site pressure and temperature are known, the air density can be calculated using the following equation:

$$\rho = \frac{\mathrm{P}}{\mathrm{R} \times \mathrm{T}},$$

where ρ is the air density in kg/m^3, P is the air pressure (Pa or N/m^2), R is the specific gas constant for air ($287\ J/kg \cdot K$), and T is the air temperature in degrees Kelvin (°C + 273).

An approximation based on altitude alone is

$$\rho = 1.225 - (1.194 \times 10^{-4})Z,$$

where Z is the elevation in meters.

This air density equation can be substituted into the WPD equation for the determination of each instantaneous or multiple average values.

2.3 Wind Speed Frequency Distribution

The wind speed frequency distribution characterizes the wind at a given location in two ways. First, the frequency distribution determines how often a given wind speed is observed at the location; second, it identifies the range of wind speeds observed at that location. This analysis is often accomplished by sorting the wind speed observations into 1-meter-per-second (m/s) bins and computing the percentage in each bin. The wind speed distribution is important because sites with identical average wind speeds, but different distributions can have substantially different wind resources. These differences can be as great as a factor of two or three.

The wind speed frequency distribution in many areas can be closely approximated by the Weibull distribution function. The Weibull function is defined as

$$f(V) = (k/c)(V/c)^{k-1}\exp(-V/c)^{k},$$

where $f(V)$ is the Weibull probability density function, the probability of encountering a wind speed of V m/s, c is the Weibull scale factor, which is typically related to the average wind speed through the shape factor, expressed in m/s, and k is the Weibull shape factor, which describes the distribution of the wind speeds. Detailed explanations of the Weibull distribution function and its application are available in many texts.

Common values of k for measured wind speeds are around 2.0, with a typical range of 1.5 to 3.0. Higher values of k indicate a narrower speed distribution (more constant winds). Because of the cubic nature of the wind power equation, lower k values have higher average wind power densities for the same average wind speed. Figure 1 shows the appearance of the Weibull distribution at different k values. Values of k are useful for describing frequency distributions, deriving power classes from wind speeds, synthesizing missing data, and other uses.

A useful approximation for k is

$$k = \left[\frac{\sigma}{V}\right]^{-1.086},$$

where σ is the standard deviation of wind speed, and V is the average wind speed.

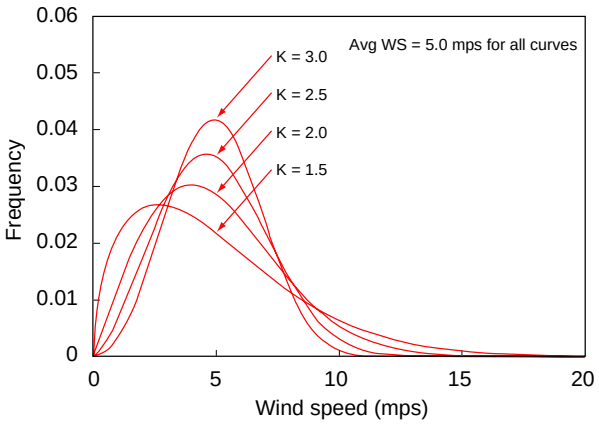

FIGURE 1 Weibull distribution function for four values of k. All curves have an average wind speed of 5.0 m/s.

2.4 Spatial Variation

Mapping spatial variations in wind resource is crucial to any wind resource assessment project. The wind resource in an area can vary widely, even on a scale as small as a few hundred meters. The resource also varies with height, usually increasing with height above ground.

2.4.1 Wind Shear and the Power Law

Frictional effects cause the wind speed near the surface to be lower than that at greater heights above ground. In the near-surface layer (< 300 m above ground level [agl]), the wind shear, or variation of wind speed with height, often approximates a power law:

$$V_2 = V_1\left[\frac{h_2}{h_1}\right]^{\alpha},$$

where V_1 is the wind speed at height h_1 above ground, V_2 is the wind speed at h_2, and α is the shear exponent.

The value of α is around 1/7 (giving rise to the so-called one-seventh power law) for smooth terrain but can climb as high as 0.5 in areas of high surface roughness or drop lower than 0.1 over very smooth surfaces such as water or ice. A similar law can be derived for wind power density, but the exponent will be 3α, because the power density is proportional to the cube of the wind speed. This increase of wind power density with height is the driving force behind the trend toward increasingly tall wind turbine towers. Figure 2 shows how the wind speed and power vary with height for different values of α.

The power law equation can be used to extrapolate measurements made at low levels up to the expected turbine hub height. This can be particularly useful when trying to adjust meteorological station

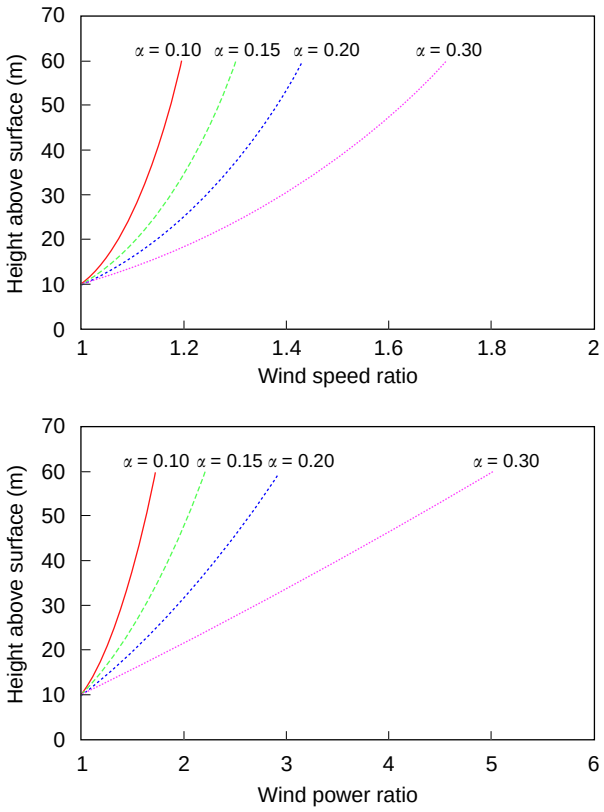

FIGURE 2 Wind speed and power shear curves for different values of the wind shear exponent α.

data or other measurement data to the hub heights of modern wind turbines. Above the near-surface layer, other effects can dominate the frictional effects, causing a departure from the power law.

2.4.2 Geographic and Climatological Effects

Global circulation patterns, such as the mid-latitude westerly winds and the equatorial trade winds, dominate the wind climate in some regions. Large-scale geographic features, such as the shape and location of continents and oceans, can modify these patterns and create regions of good wind resource. An example is the Isthmus of Tehuantepec in Oaxaca, Mexico, where the high pressure found in the Gulf of Mexico and the low pressure of the Pacific Ocean combine to form a strong north wind during much of the year. In other regions, differential heating of oceans and land masses causes seasonal winds such as the monsoon in the Indian Ocean.

2.4.3 Topographic Effects

Topographic features can have a major effect on wind speeds and directions. Winds accelerate as they pass over hilltops and ridges that are oriented perpendicular to the wind direction. High wind resources can occur at relatively low elevations in mountainous regions where the air flow is channeled through constrictions or corridors that enhance the wind speeds. However, the higher wind speeds can be accompanied by increased turbulence, so careful study of such areas is needed before wind turbines are installed.

Topography can lower the wind speed as well as raise it. Examples of low wind areas include the lee side of ridges, the areas immediately upwind and downwind of hills, and areas of rough (many small hills and valleys) terrain. Differential heating between two areas at different elevations can also affect the regional wind resource.

2.5 Temporal Variations

Because the wind speed and direction change over time, the wind developer must take these variations into account when designing a wind project.

2.5.1 Interannual Variation

Annual average wind speeds at a given site can vary from year to year. This variation is often up to $\pm 10\%$ in wind speed, which translates into a ± 20 to 30% variation in wind power density. Shorter measurement periods (1 to 5 years) increase the uncertainty of the annual averages.

2.5.2 Seasonal Variation

Wind variations that tend to repeat at the same time of the year are called seasonal patterns. Seasonal patterns in many areas of the world are complex and are best determined by measured data. A single peak in wind resource lasting 2 to 3 months is often observed, although some regions have double-peak or other seasonal patterns.

2.5.3 Diurnal Variation

Wind variations that tend to repeat on a daily basis are called diurnal patterns. Many of these occur as a pronounced maximum wind speed at the same time (often the afternoon) each day. There may also be an associated directional pattern. Diurnal patterns may vary over the course of the year with different seasonal conditions.

An example of a diurnal pattern is the onshore/offshore winds found at coastal sites, where the wind blows toward the land during the day and toward the sea at night. Diurnal patterns may vary by height above ground and elevation above sea level. For example, some sites may exhibit a daytime maximum

near the ground (10 m) but a nighttime maximum near turbine height (50 m). Exposed ridge-crest locations frequently have a nighttime maximum and a daytime minimum, both at the ground and at turbine hub height. Some sites, such as offshore locations, do not exhibit significant diurnal variations.

2.5.4 Turbulence and Medium-Scale Variations

The wind can vary at timescales much shorter than the seasonal and diurnal scales. Rapid variations in wind speed and direction can significantly affect turbine performance. Typically, inflow variations are modeled using some type of inflow simulation tools that capture both the temporal and spatial variations in the wind. These very rapid fluctuations, on a scale of a few seconds or shorter, are usually characterized as inflow turbulence. The effects of turbulence on a wind turbine are outside the scope of this particular work.

3. BASELINE WIND RESOURCE STUDIES

3.1 Global Wind Resource

A worldwide wind resource map was produced in 1981 by the U.S Department of Energy's (DOE) Pacific Northwest Laboratory and published in a World Meteorological Organization document on wind energy utilization. The map, shown in Fig. 3, was based on an analysis of available wind data, primarily from meteorological agencies, and other information to estimate the broad-scale distribution of annual average wind power throughout the world. Vast areas of the world had very little or no reliable surface wind measurement data. Thus, regional climatological information and upper-air wind data were used to estimate the wind resource in many regions. In spite of these limitations, this world wind map has provided a good basis of information for preliminary estimates of the wind resource on a broad scale. The map shows that every major continent has substantial areas with good wind resource. With the exception of the equatorial regions, the offshore wind resources are vast.

The worldwide wind resource map was first used in developing estimates of the global wind energy potential in 1991. A study by the University of Utrecht in the Netherlands estimated that 25% of the world's land surface has at least moderate wind resource and 13% has at least good wind resource. In estimating the wind potential, the study assumed that wind turbines would be installed on 10% of the windy land area. The resultant global potential for onshore wind power production from the higher wind resource areas was estimated to be slightly more than the world's electricity consumption (1 terawatt [TW]) in 1987.

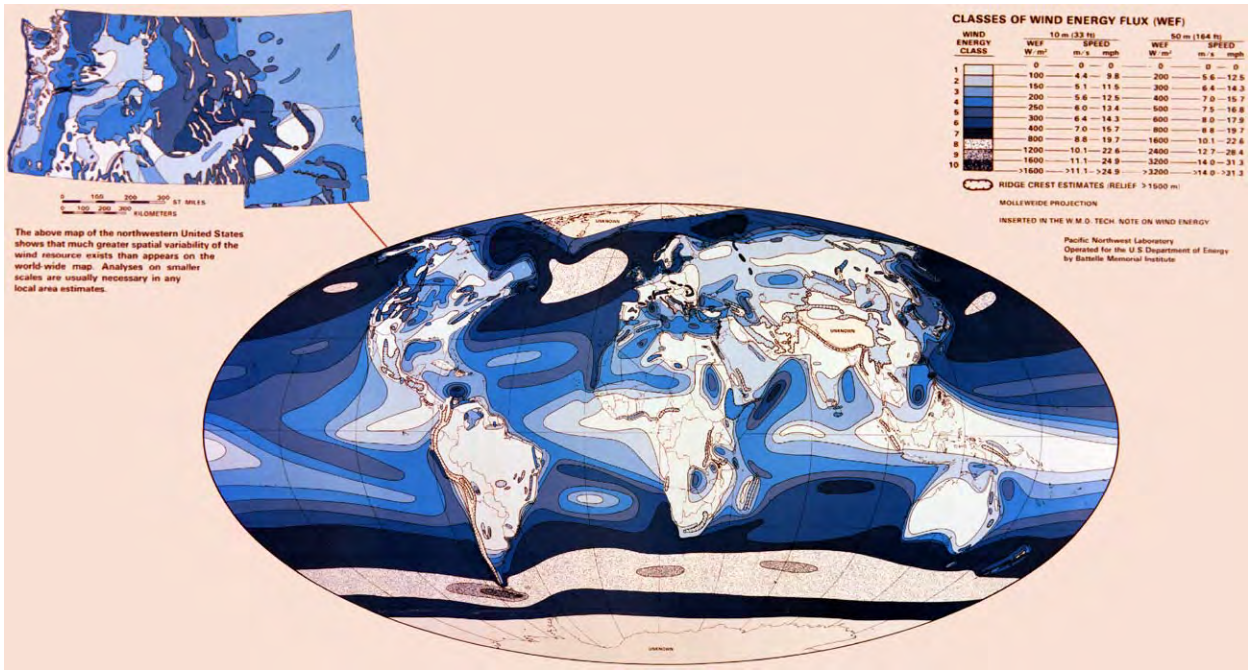

FIGURE 3 World wind resource map (1981).

3.2 United States Wind Resource

In 1987, the DOE published the "Wind Energy Resource Atlas of the United States." This assessment found that areas potentially suitable for wind energy applications are dispersed throughout much of the United States. Figure 4 shows the distribution of the annual average wind resource estimates throughout the United States. Major wind resource areas include much of the Great Plains from northwestern Texas and eastern New Mexico northward to Montana, North Dakota, and western Minnesota; the Atlantic coast from North Carolina to Maine; the Pacific coast from Point Conception, California to Washington; the Texas Gulf coast; the Great Lakes; portions of Alaska, Hawaii, Puerto Rico, the Virgin Islands, and the Pacific Islands; exposed ridge crests and mountain summits throughout the Appalachians and the western United States; and specific wind corridors throughout the mountainous western states. Updated high-resolution wind resource (1-km or finer) maps have been completed for many states and are either in progress or planned for additional states.

In a study completed for DOE in 1993, estimates of the electricity that could potentially be generated by wind power and of the available windy land area available were calculated for the contiguous United States. The estimates were based on wind resource data published in the 1987 U.S. wind atlas and excluded windy lands that are not suitable for development as a result of environmental and land-use considerations. Despite these exclusions, the potential electric power from wind energy was surprisingly large. Good wind resource areas, which cover 6% of the contiguous U.S. land area, have the potential to generate more electricity than the total U.S. electricity consumption in 1990. To provide 20% of the U.S. electricity, the study estimated that only about 0.6% of contiguous U.S. land area would have to be developed with wind turbines.

3.3 Other Countries or Regions

In addition to the United States, wind resource surveys have been conducted for many other countries and regions of the world by various organizations. For example, the comprehensive "European Wind Atlas" published in 1989 describes the wind resources in the European Community countries. More detailed wind-mapping studies, including high-resolution wind resource maps, have been completed or are being planned for many areas of the world.

3.4 Offshore Areas

Offshore development in areas of high resource has the potential to greatly expand the use of wind

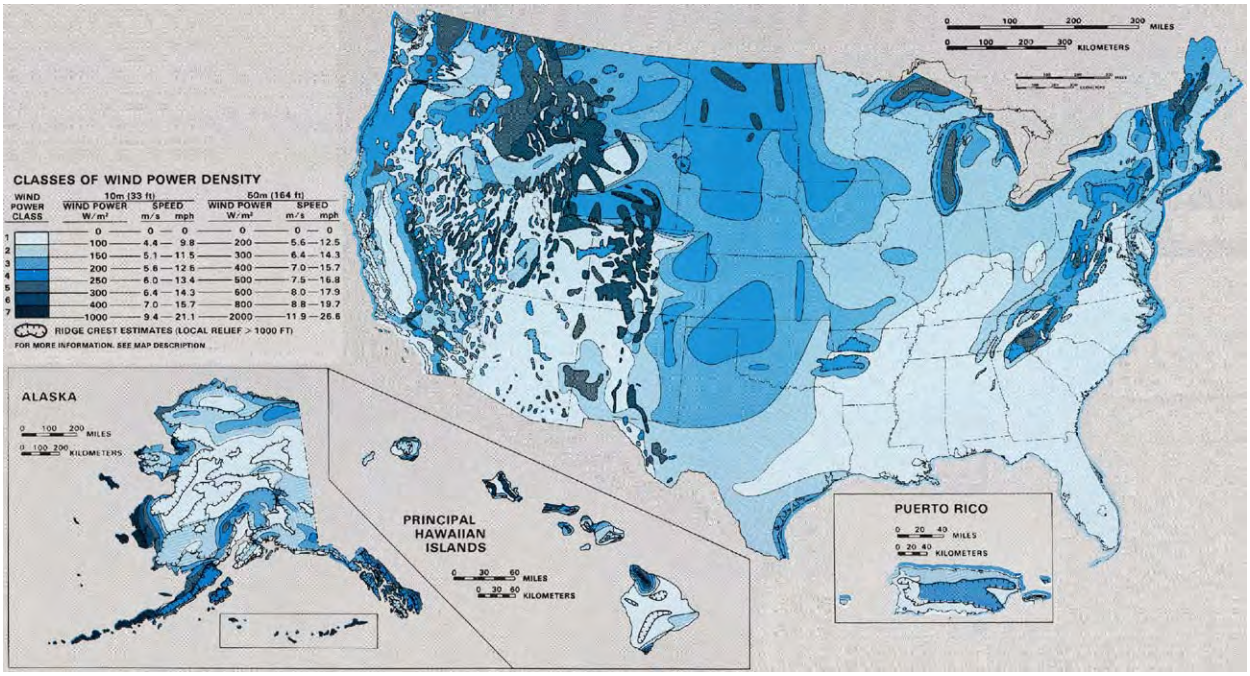

FIGURE 4 United States wind resource map (1987).

power, as seen in western Europe. Offshore wind resource assessments have been completed for areas of Europe and the United States.

4. DATA SETS AND ANALYSIS METHODS

An accurate wind resource assessment is highly dependent on the quantity and quality of the meteorological data input into a wind mapping system. Successful wind assessment methodologies used by the National Renewable Energy Laboratory (NREL) and other organizations rely on two major activities: (1) acquisition and development of comprehensive global data sets and (2) critical meteorological analysis of these data.

Advances in the available global data sets and analytical tools permit modeling and prediction of the wind resource without having to rely on surface wind data. This is important because in many regions of the world, high-quality surface wind data are sparse and often not available for areas of interest. The use of upper-air (weather balloon) and satellite-derived ocean wind data in an advanced computer mapping system enables NREL and other organizations to produce wind resource maps with valuable information even if high-quality surface wind data are not available. Where available, reliable surface wind data can be used to verify the model estimates.

A broad variety of wind data sets (including surface observations, marine data, and upper-air data) should be analyzed as the initial step toward understanding the wind climate in a study area. The use of multiple data sets is necessary because the quality of data in any particular data set can vary and because high-quality data can be quite sparse in many regions of the world. Some of these major global data sets are described here. Local or regional meteorological data sets should also be evaluated. Local data sets may be provided by independent organizations, individual consultants, or governmental departments.

4.1 Surface Data

High-quality surface wind data from exposed stations can give a good indication of the magnitude and distribution of the wind resource in an area. The U.S. National Climatic Data Center (NCDC) is a source for many global surface meteorological data sets. NREL has used is the DATSAV2 Surface Climatic Database in much of its assessment work. DATSAV2 contains hourly surface weather observations from more than 20,000 meteorological stations throughout the world. NREL has about 30 years of global DATSAV2 data in its archive that span the period from 1973 to 2002. The NCDC is developing new global surface data sets that will be used in future assessments.

Many meteorological stations are located at airports or in cities rather than at the potential wind energy sites. The wind climate may be radically different a few kilometers away from these meteorological sites. A drawback to airport or city observations is that the anemometer heights are usually between 6 m and 10 m above ground and must be extrapolated to heights that are useful for wind resource assessment.

Marine wind data can be used to estimate the wind resource for offshore areas. These data can also be extrapolated to estimate wind resource at coastal and inland sites that are well exposed to the ocean winds. NREL uses two global marine data sets. The first is the Marine Climatic Atlas of the World, derived from historical ship observations and summarized on a 1-degree grid. The other data set that has proved to be quite valuable contains ocean wind speeds at 10-m height derived from the special sensor microwave imager (SSMI) measurements taken as part of the Defense Meteorological Satellite Program. NREL has SSMI data covering the period from 1988 to 2001 and is examining some other satellite ocean data sets. One advantage of the SSMI data over the ship data is the much more uniform coverage—ship data is concentrated in the primary shipping lanes.

4.2 Upper-Air Data

Upper-air data can be useful in estimating the wind resource at low levels just above the surface and vertical profiles of wind resource aloft for extrapolation to elevated terrain features. An important data set for wind resource analysis is the global upper-air observational ADP data from the National Center for Atmospheric Research (NCAR) archive of the U.S. National Centers for Environmental Prediction (NCEP). This data set contains upper-air observations from rawinsonde instruments and pilot balloons for approximately 1800 stations worldwide beginning in 1973. The ADP data is supplemented in areas without adequate upper-air data by two numerical weather model-derived climatological

upper-air data sets. One is the Global Gridded Upper-Air Statistics data set obtained from NCDC. This data set contains monthly means and standard deviations of climatic elements from 1980 to 1991 for 15 atmospheric levels on a 2.5-degree grid. The other model-derived upper-air data set is the Reanalysis data set created by NCEP and NCAR. There are more than 40 years (1958 to 1997) of global Reanalysis data, which contain wind, temperature, and other variables on a 208-km grid. Reanalysis data are available in two different forms: constant pressure-level data and Sigma-level (terrain-following) data. NREL uses the Sigma-level Reanalysis data for wind resource analysis because they have good vertical resolution in the lower boundary layer where the wind climate characteristics have a large influence on the available wind energy potential.

4.3 Data Analysis Methods

This section describes the steps that NREL uses to analyze meteorological data. NREL processes the raw data into useful summaries to perform detailed analysis of the important wind characteristics. Meteorological parameters such as wind speed, wind power density, wind direction, temperature, and pressure are extracted from the hourly observations and used to create statistical summaries of wind characteristics.

Statistical summaries of the surface station data include interannual, monthly, and diurnal variabilities of the wind speed and power, and the wind speed and frequency by direction. The upper-air ADP data are processed to construct approximate vertical profiles of the wind resource by geopotential height and other wind characteristic summaries similar to those processed for surface data in order to evaluate the change of wind resource with elevation. NREL processes the SSMI satellite ocean wind data on a 25 km grid to evaluate wind resource in the vicinity of islands and coastal areas.

A critical analysis of the climatic data is performed to evaluate the quality of the data and determine the most representative data for a particular area. For example, the interannual data are evaluated to identify obvious trends in the data or periods of questionable data. Figure 5 shows an example of the "disappearing wind syndrome" that occurs at meteorological stations throughout much of the world. The data in the figure are from 79 meteorological stations in southeast China (examined as part of a detailed wind resource assessment) and show the ratio of wind power in each year relative to that in 1974, the first year of data. The downward trend in the data indicates that the apparent wind power in southeast China decreased by 60% in 20 years. There is little chance that this decrease actually reflects a gradual change in the wind climate caused by physical processes. It is more likely that the reduction in measured wind speeds is caused by new construction or vegetation growth around the meteorological stations and possibly some degradation of the measurement equipment.

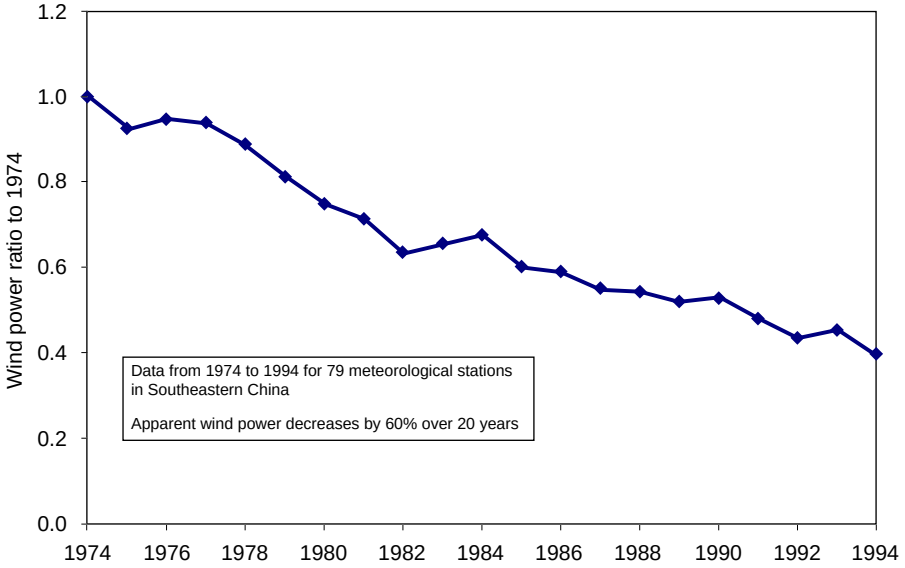

FIGURE 5 Graph of disappearing winds at southeast China stations.

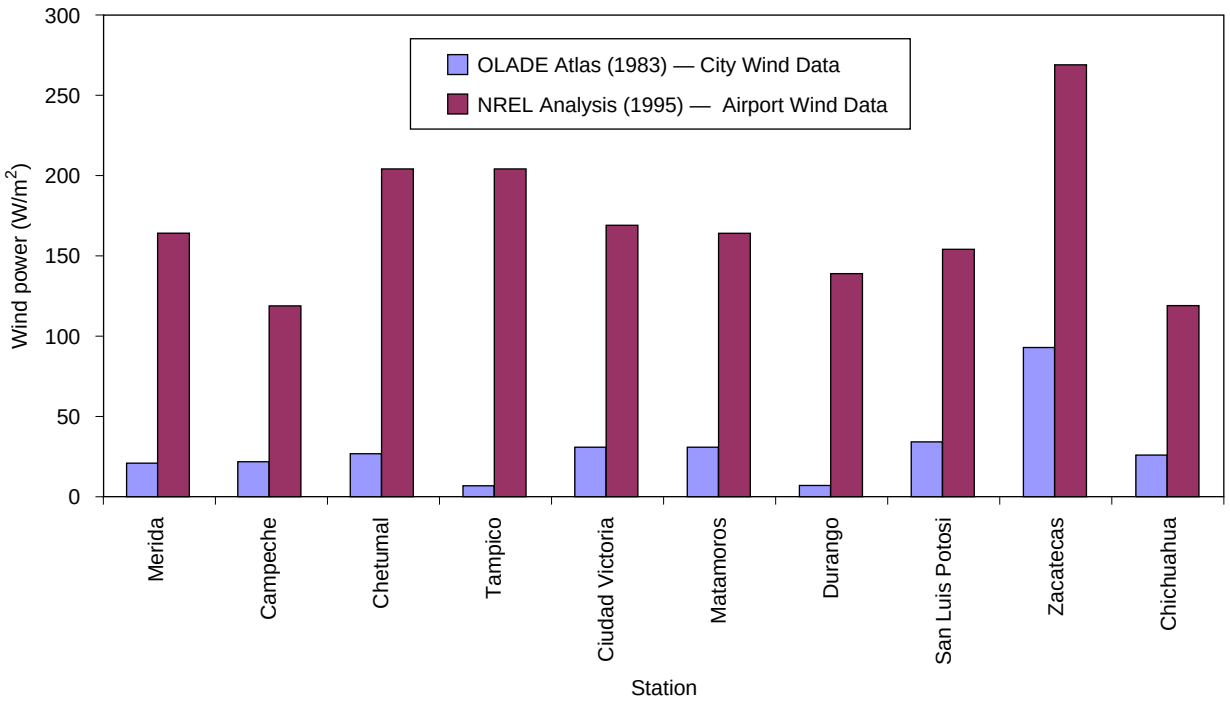

FIGURE 6 Comparison of wind speeds from Mexican city and airport stations.

Data from any nearby stations are compared to help assess the data quality. For example, Fig. 6 shows a comparison of wind power estimates from city and airport locations in Mexico. Wind data from airports are, in general, more reliable than data collected at other locations in urban areas where the wind measurements are likely to be reduced by buildings and trees. A small reduction of just 1 m/s in the measured wind speed can result in a large reduction (such as 30 to 50%) in the wind power density.

5. RESOURCE ASSESSMENT METHODS

This section discusses the NREL methodology, plus other current wind resource assessment methods. Wind resource assessment for wind energy development is usually conducted in three stages of increasing detail. The first stage, wind prospecting, identifies candidate regions for further investigation. Tools used in this stage are numerical and empirical wind resource models as well as previous wind surveys. The next stage, area wind resource evaluation, uses wind measurement systems and modeling tools to identify the best potential areas for more detailed evaluation. Micrositing is the final stage where locations of turbine sites are determined by a combination of measurements and fine-scale modeling.

5.1 General Wind Mapping

Regional wind resource maps are very useful tools in the wind prospecting stage of a project. Such maps cover an area of a few hundred to around a thousand kilometers on a side and show estimates of the wind power class on a grid. In the 1987 U.S. wind resource atlas, the grid size was about 25 km by 25 km, but the grid resolution of many maps is 1 km or finer.

5.1.1 Empirical Models

A computer mapping system developed by NREL in the 1990s uses an empirical and analytical approach to determine the wind resource value for a particular location. This wind mapping system does not use explicit atmospheric boundary layer equations or geostrophic adjustment equations like some other wind-flow models. It is designed to display large areas of detailed wind resource distributions at a spatial resolution of 1 km^2. These high-resolution wind maps help identify areas where wind energy projects are likely to be economically feasible.

Underlying the empirical technique is the major meteorological assumption that there are empirical relationships among the free-air (higher than 100 to

200 m above the ground) wind speed, the wind speed over the ocean (where applicable), and the distribution of the wind resource over the land areas. Empirical relationships have been determined in previous NREL wind resource assessment work for well-exposed (i.e., unobstructed by trees or buildings, local terrain features) locations in diverse areas of the world. Accordingly, the wind resource values presented on the NREL wind maps are estimates for nonsheltered locations with low roughness. NREL uses a top-down method for adjusting much of the available wind data. This approach takes the free-air wind speed and power profile in the lowest few hundred meters above the surface and adjusts these down to near wind turbine hub height (most often 50 m above ground). In this way, a wind resource map with valuable information can be produced even if high-quality surface wind data are not available.

The quality of the final wind resource map depends on the quality of the meteorological data input into the wind mapping system. It is important to review and analyze the climatic data sets to select the highest quality data to develop the conceptual model and meteorological inputs to the mapping system. The data analysis and screening process is designed to allow an analyst to develop a conceptual model of the physical mechanisms that influence the wind flow in the study region. The conceptual model guides the development of the empirical relationships that serve as the basis of the algorithms that calculate the wind power values seen on the maps.

The mapping system combines meteorological input, wind power calculation modules, and digital terrain data to produce the final wind resource maps. The global terrain data have a resolution of 1 km^2, and higher resolution terrain data sets are available in some areas. The meteorological inputs are wind power roses, vertical profiles of wind power, and open ocean wind power where appropriate. The meteorological data are initially used in determining a base wind power value for each grid cell. The mapping system calculates the final wind power density by adjusting the base wind power density. The factors that increase or decrease the base wind power density include terrain considerations, relative and absolute elevation, aspect (slope of terrain relative to the prevailing wind direction), distance from ocean or lake shoreline, and the influence of thermal or other types of small-scale wind-flow patterns.

The final wind resource maps are generated using commercially available geographic information system (GIS) software packages and custom GIS-based tools developed at NREL. These complex packages feature a large number of routines for scientific analysis along with tools used to display spatial information.

5.1.2 Numerical Models

The numerical model wind mapping system combines two types of computer models. The first type is a scaled-down version of a numerical weather prediction model. These prediction models solve the equations of motion and explicitly account for boundary layer processes such as energy balance and fluxes, surface moisture and reflectivity, and local temperature differences. The internal physics of these models are the basis for predicting the evolution of the atmosphere in the study area for specified times from the start of a model simulation. The scaled-down versions contain only those algorithms that account for physical processes that affect the wind flow. Scaled-down versions are used to reduce the time and cost it takes to complete all the simulations necessary to produce a representative wind map. Climatological data is used as the initial condition for each simulation as well as lateral boundary conditions for the model. There are a variety of methods that can be used to prepare the climatological data for input. Each simulation generates wind and other meteorological variables throughout the model domain, for a particular day, and the information is stored by set intervals.

In addition to climatological data, there are geophysical inputs into the numerical model. The geophysical inputs include elevation, soil moisture, and land cover data. The models translate these data into important surface parameters such as energy fluxes and surface roughness.

The numerical models are generally run with horizontal resolutions from 1 to 5 km, depending on the particular study region. There is no physical limitation to the horizontal resolution used by these models, although higher resolution requires longer computing time.

Often, a mass-conserving wind-flow model is used in conjunction with the numerical prediction model to produce wind resource estimates for horizontal resolutions lower than 1 km^2. The wind-flow models take the results of the numerical models as input and use surface roughness and terrain to estimate the wind resource for the smaller grid cells. Though the wind-flow models are not as sophisticated as the numerical models, they are much less expensive to use for the higher resolution estimates and the results are similar to what the numerical models produce.

5.1.3 Model Validation

The results of any wind resource model must be validated in order to have confidence in its estimates. Validation is the process of comparing selected wind resource estimates from the model with actual measured data from the same location. By comparing actual measured data from many sites with the model output, a measure of prediction quality can be derived. If the quality is not as good as desired, the model can be refined and if necessary rerun, generating a new set of estimates that can be compared to reality. A good wind resource model will estimate values at most validation points that are within 10% in wind speed and 20% in wind power density and will not show a consistent bias toward either over- or under-prediction.

5.2 NREL's Products

5.2.1 Wind Power Classification

The values on the wind resource maps produced by NREL are based on the wind power density, not wind speed. Wind power density is a better indicator of the available resource because it incorporates the combined effects of the wind speed frequency distribution, the dependence of the wind power on air density, and the cube of the wind speed.

To simplify the display and comparison of wind power, a seven-level wind power classification scheme was devised. The choice of levels was made solely for convenience in categorizing regions of similar wind resource and is not indicative of any physical or meteorological boundaries.

Table I shows the wind power classifications for utility-scale applications. Wind resource areas of Class 4 and higher are considered suitable for utility-scale wind power development with 2003 technology and energy costs. Rural or off-grid applications generally require less wind resource to be viable. Class 2 and higher resources may be sufficient for these applications.

TABLE I

Wind Power Classification

Class	Resource potential (utility-scale)	Wind power density (W/m^2) @ 50 m agl	Wind speed[a] (m/s) @ 50 m agl
1	Poor	0–200	0.0–5.6
2	Marginal	200–300	5.6–6.4
3	Fair	300–400	6.4–7.0
4	Good	400–500	7.0–7.5
5	Excellent	500–600	7.5–8.0
6	Excellent	600–800	8.0–8.8
7	Excellent	>800	>8.8

[a]Mean wind speed is estimated assuming a sea level elevation and a Weibull distribution of wind speeds with a shape factor (k) of 2.0. The actual mean wind speed may differ from these estimated values by as much as 20%, depending on the actual wind speed distribution (or Weibull k value) and elevation above sea level.

5.2.2 Wind Resource Maps

The primary product of NREL's mapping system is a wind power density map in units of W/m^2 for a specified height above ground, typically 30 or 50 m. Figure 7 is a wind resource map for the central coast of Fujian Province in southeastern China. The region's geographical features include an indented shoreline with hills along the coast, a narrow coastal plain in some areas, and mountainous terrain within 50 km of the coast. The best resources are found on exposed coastal areas and higher inland ridges. The maps developed for southeastern China are helping wind energy developers concentrate their efforts on the areas with the greatest resource.

Figure 8 compares the old wind resource map of North and South Dakota from the 1987 U.S. wind atlas to the new high-resolution (1-km) map generated by NREL's wind mapping system in 2000. The most striking difference between the two maps is the precision of the wind resource pattern on the newer map. The new map clearly depicts the variation in the wind resource that results from subtle terrain features. In fact, the considerable variation of the wind resource across the seemingly flat terrain of this region was one of the primary results of this project. The older resource estimates were generated using a manual interpretation of terrain maps and meteorological data. The new resource estimates were generated using GIS software, high-resolution terrain data, and more sources of meteorological input data. The end result is a resource map that depicts the potential wind resource in more detail and with better accuracy. The new map was validated using data from seven 40-m towers installed by utilities. At six of the seven sites, the wind power estimates were within 20% of the measured WPD values. This level of accuracy (>80% of validation sites within 20% of measured power) is typical of the updated maps that NREL has produced.

To make the wind maps more useful, other information, such as transmission lines and voltages, federal lands, exclusion zones, or Indian reservations, is often added. In addition to maps of the wind resource, the GIS system can also produce other types of maps that can be used in combination with

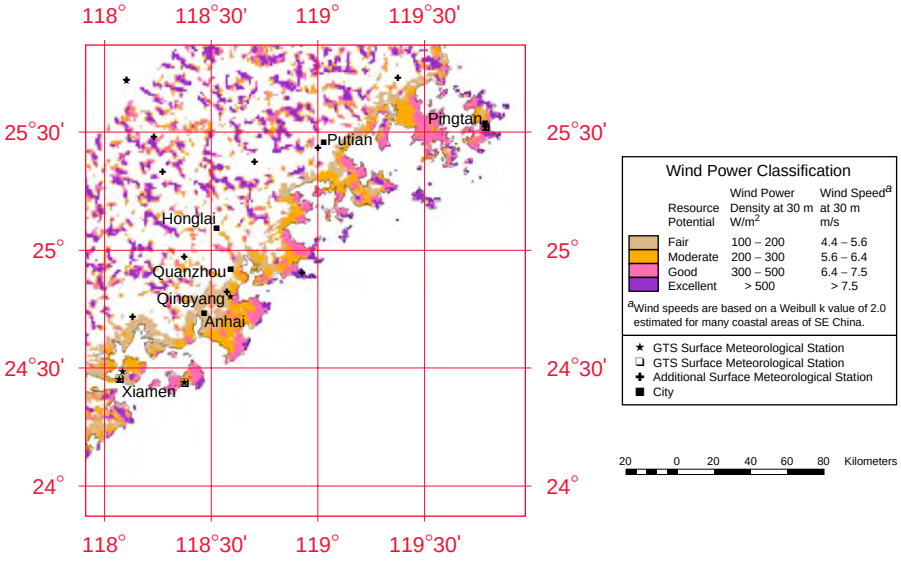

FIGURE 7 China coastal region wind resource map (2002).

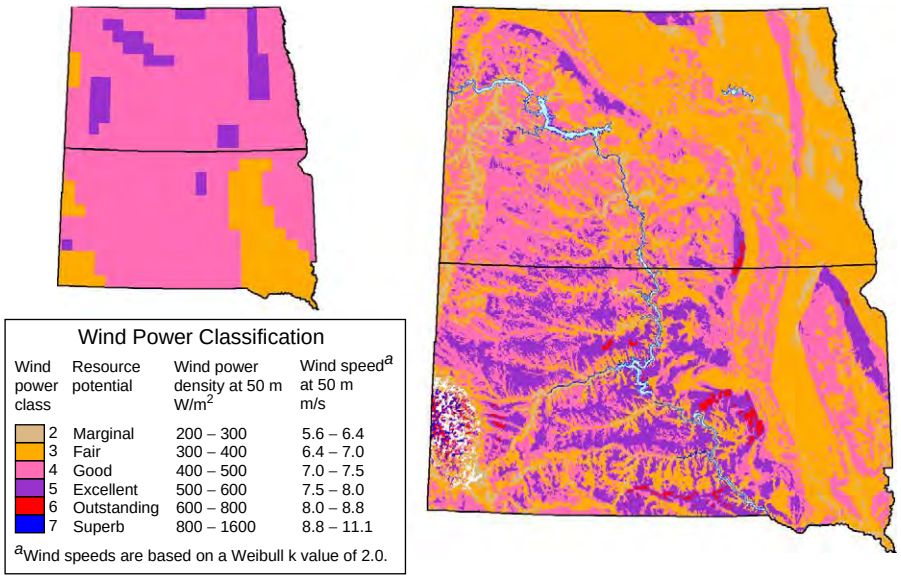

FIGURE 8 North and South Dakota 1987 (left) and 2000 (right) wind resource maps.

the wind resource maps, such as maps of color-coded elevation, hill-shaded relief, political features, meteorological stations, and other measurement sites. An example of a final validated wind resource map for Wyoming that includes transmission lines and Indian reservations is shown in Fig. 9.

5.3 Wind Electric Potential

Several factors determine the amount of land area suitable for wind energy development within a particular grid cell in a region of high wind energy potential. The important factors in NREL's assessment of wind electric potential are land-use and environmental restrictions for each grid cell.

Not all areas identified in a basic wind resource assessment will be suitable for wind energy development. Areas that may be excluded from development include the following:

- Developed or urban areas
- Parks and wilderness
- Wildlife habitat

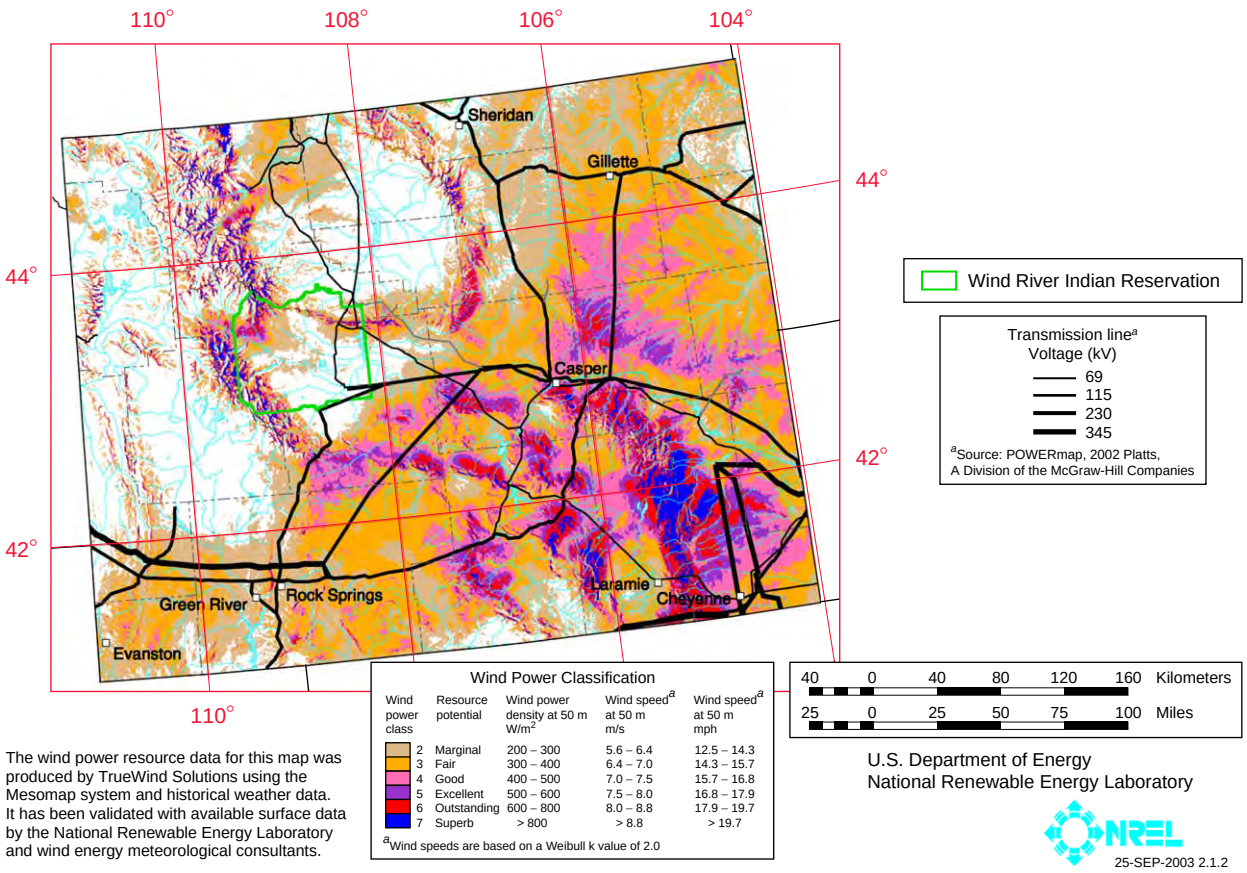

FIGURE 9 Wyoming wind resource map (2002).

- Wetlands
- Areas of steep (>20%) terrain and other topographic exclusions
- Areas too far from the electric grid

These areas are readily identified within a GIS software package, which provides spatial analytical capabilities. The GIS allows a more precise estimate of wind resource potential by directly overlaying the exclusions with the wind resource. The spatial databases that describe the exclusions are easily updated and reapplied to accommodate changing policy perspectives and new data.

The wind electric potential per grid cell is calculated from the available windy land and the wind power classification assigned to each cell. The amount of potential electricity that can be generated depends on several factors, including the estimated wind resource, spacing between wind turbines, the efficiency of the machines, and the estimated energy losses caused by factors such as wind turbine wakes and blade soiling. A conservative estimate of potential installed capacity can be obtained by using a factor of 5 MW/km^2 of available land. Values can be substantially higher depending on the wind climate and terrain, but those factors are generally evaluated at the micrositing level.

5.4 Area Wind Resource Evaluation

5.4.1 Wind Monitoring Programs

A properly-run wind monitoring program should follow the identification of prospective wind energy development areas. Measurement towers installed at various locations throughout the area can confirm the estimates made by the models, help locate turbine installation sites, and provide estimates of the final wind energy production of the project.

5.4.2 Equipment

The minimum configuration for a wind monitoring site consists of a single anemometer and wind vane mounted on a tower. The minimum tower height should be 10 to 20 m. If trees or other obstructions exist near the tower, the tower height should be increased. A data logger located at the bottom of the

tower records the wind data at 10-minute or 1-hour intervals. If funds permit, a taller tower (40 or 50 m in height) can be installed, and other instrumentation, such as redundant anemometers, multiple measurement levels, and other sensors (e.g., temperature, pressure, solar radiation), can be added. Taller towers are preferred in order to obtain measurements at or near the hub heights of modern wind turbines.

5.4.3 Instrument Siting

The tower and instruments must be installed at locations that are representative of the resource in the area while minimizing the effects of any nearby obstructions (e.g., trees, buildings). Proper siting of a tower to ensure the highest quality data collection requires considerable skill, and the use of experienced consultants is recommended.

5.4.4 Time Period

Each site must record data for a minimum of 12 months to get a complete picture of the seasonal variation. Although 18 months to 2 years of data will give better confidence in the measurements, the time period must be balanced with other project constraints.

5.4.5 Data Analysis

The first step in data analysis is quality control of the data. Erroneous data can be caused by factors such as anemometer icing, equipment failure, and operator error. Bad data must be identified and removed. The data can then be analyzed and statistics computed on both monthly and annual bases. There are many statistical quantities that could be computed, with some of the most useful being:

- Annual average wind speed, wind power density, and power class
- Speed and power by month (seasonal)
- Speed and power by hour (diurnal)
- Frequency and speed by direction (both annual and monthly)
- Wind speed frequency distribution
- Wind shear (if using more than one measurement level)

Tabular and graphical displays of these statistics aid in the analysis.

5.5 Micrositing

The final stage of project development is micrositing, where the precise locations of wind turbine installation sites are determined. Special microscale modeling software produced by various companies and organizations can greatly aid this process.

6. STATUS OF WIND RESOURCE PROJECTS

High-resolution wind resource maps and comprehensive wind resource atlases have been produced for various countries or areas of the world. For example, NREL and its collaborators have performed wind resource assessments and generated high-resolution wind maps of Armenia, the Dominican Republic, the Maldives, Mongolia, the Philippines, and Sri Lanka. Assessments were also done for specific areas of Chile, China, Indonesia, Mexico, Russia, and the United States. As suggested on the cover of the Mongolia wind atlas shown in Fig. 10, the wind resource information is intended to be useful for both small wind turbine and utility-scale applications. Many of NREL's international wind resource maps, and some produced by others, can be found at www.rsvp.nrel.gov. High-resolution wind resource maps for additional countries have been produced by organizations such as TrueWind Solutions, Risø National Laboratory, and Garrad-Hassan.

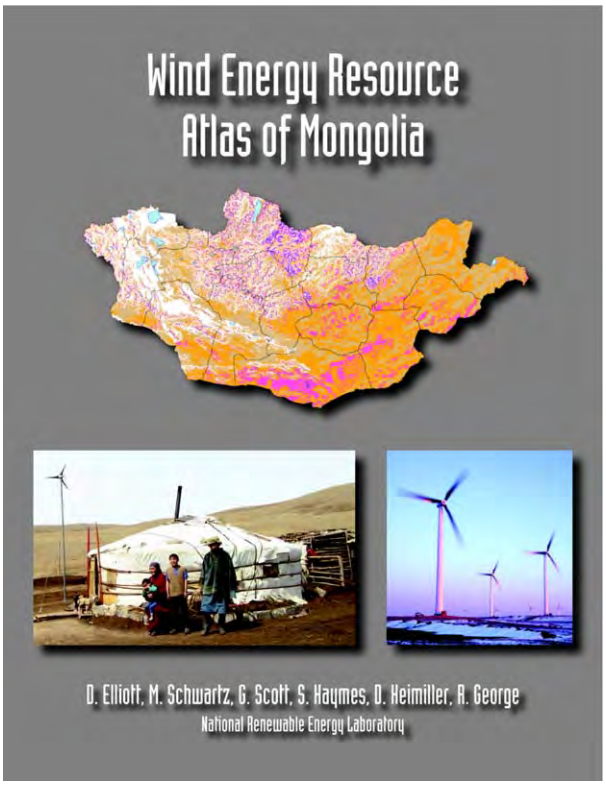

FIGURE 10 Mongolia wind resource atlas cover (2001).

Detailed wind maps and other resource data have facilitated the rapid identification of good wind resource areas and led to more successful prospecting and measurement efforts. This new wind resource information has accelerated the use of both small wind and utility-scale wind energy technologies. As government and industry groups seek information to more accurately assess the wind energy potential and identify promising locations, the interest and demand for detailed high-resolution wind resource maps and other relevant data are intensifying.

A project funded by the United Nations Environment Programme (UNEP) is expanding wind mapping to many additional areas of the world. In addition to wind resource maps, the UNEP Solar and Wind Energy Resource Assessment (SWERA) project will include the development of solar resource maps and a GIS interface. In the first phase of this project, high-resolution wind maps are being developed for six countries in Latin America (Cuba, Guatemala, El Salvador, Honduras, Nicaragua, and Belize), three countries in Africa (Ghana, Ethiopia, and Kenya), and three countries in Asia (Nepal, Bangladesh, and specific regions of China).

In the United States, efforts such as U.S. Department of Energy's (DOE's) Wind Powering America program are stimulating interest in wind energy and the development of updated wind resource information in the form of maps and data. High-resolution wind resource maps have been completed for many states, and projects are under way or planned for many additional states. The primary approach is a public/private cooperation between NREL and U.S. companies to produce and validate the wind resource maps. These new maps are instrumental in helping state and local officials, project developers, utilities, and landowners identify suitable wind sites for more detailed evaluation.

Glossary

contextualization Taking the prevailing political, social, and economic environment into account in analyzing situations and making recommendations.
decentralized systems Typically electricity-generating facilities that are isolated and not connected to a centralized grid; the power can be generated from any fuel source (e.g., diesel).
energy service The activity that can be derived from injecting energy (e.g., grain milling).
gender A socially constructed relationship between men and women.
informal Not in the conventional macroeconomic framework.

Women and energy in the developing country context is a theme that is being advanced by some energy analysts and practitioners as a response to advocacy to enhance gender equity. The link between women and energy has been mainly within the household framework and in the rural context. Women have culturally been largely responsible for cooking and, hence, providing energy for this purpose. Biomass fuels are the main source of energy in rural areas, and its procurement involves drudgery. The fact that this drudgery has been experienced by women justifies the case for a focus on women and energy. The extent to which this approach has contributed to gender equity and poverty alleviation remains to be established.

1. INTRODUCTION

Inequity along gender lines has been one of the main factors driving the establishment of women-focused programs and calls for gender mainstreaming. The issues of "women and energy" and "gender and energy" have been on the agenda since the 1970s and 1980s. An important response to women and energy issues is the allocation of budgets to women and energy programs by donor agencies, necessitating suitable responses in the form of project proposals and projects. In development circles, a call has been made for the inclusion of women in energy projects. Specially targeted projects are also common. In such interventions, women are identified as recipients of project and program benefits.

The suffering of women and children in fuelwood procurement has been the main rationale for women-focused energy initiatives. The resultant initiatives have been in the form of projects and policy suggestions. Projects include promoting improved stoves and enabling the adoption of solar home systems through women-targeting financing

mechanisms. Activities have also been undertaken to help incorporate women into various energy policies, programs, and projects at national, regional, and international levels.

Many initiatives are responses to the documentation on links between women and energy—links ranging from physical burdens to health problems. Most of this literature has been based on ideological concerns where women are seen as the weaker sex and so naturally disadvantaged in energy matters. The perception of women as victims of men shapes the analyses of their roles in energy procurement and use. As a result, the root causes of the problems relating to energy tend to be downplayed and rarely explored sufficiently in the literature on women and energy. Most of the literature suffers from inadequate empirical investigation. In many cases, evidence is presented in a manner that seems biased toward ideology rather than facts; old data and data from a restricted number of studies are recycled with the aim of demonstrating the women/energy-linked problems and justifying special attention to women. In this way, the myths are sustained.

The consequence of the formulation of women and energy issues has been focused largely on the provision of energy as an isolated commodity. But as often is indicated, energy is not an end in its own right; rather, the service from energy is what is important. The extent to which the women and energy approaches have achieved the intended goals of alleviating women's energy-related problems remains limited. It is likely that this could be attributed to the conception of the problem. This article explores the literature with the aim of determining the realities of the issues as perceived and attempting to chart a way forward.

The women and energy approach has been predominantly a developing country phenomenon. Why have the issues not attained similar importance in the developed world? The answer lies in the far higher level of economic growth and access to modern energy carriers in developed countries. Energy services in the developing countries are survival–developmental issues, a stage the developed world has passed. As Martine and Villarreal highlighted in a 1997 study, the rural and traditional loci of gender issues by extension render the related energy problems gender irrelevant in the developed countries. This prompts the question of whether a gendered approach can address the real issues—a question that guides the discussion in the rest of this article. In a 1995 report, Parikh justified gender-related energy policies in developing countries on the basis that they are made necessary by the low incomes in these countries.

The rest of the article is structured as follows. First, it provides a historical context on the issue with the aim of endeavoring to understand why the women and energy issue is addressed in the manner it is. Using leading questions, the article then attempts to understand whether current initiatives can meet the objective of improving women's energy problems. Finally, the article concludes by identifying areas for further research.

2. HISTORICAL CONTEXT

The role of women, particularly rural women, in energy procurement began to receive attention after the energy crisis of the 1970s, mainly because escalating oil prices forced an increased shift toward biomass. At the same time, there was more attention being paid to the poor, emanating from the basic needs approach. The growing focus on rural development during the mid-1970s also drew attention to the dependence of rural people on the products from forests, woodlands, and trees, particularly on fuelwood. A 1975 publication noted the increased demand for woodfuel and the perception that demand outstripped supply and was responsible for deforestation, raising concern for what was referred to as "the other energy crisis" and necessitating better understanding of the supply-and-demand situations. This resulted in application of the "gap theory" by various authors, including O'Keefe and Raskin in 1985 and Anderson in 1986, identifying a gap between supply and demand and resulting in country forecasts that predicted critical shortages. Although the gap theory has been challenged extensively in various works, such as those by Bradley and Campbell in 1998, it nevertheless formed the basis for defining the woodfuel crisis. This definition focused on the biological yields of biomass, ignoring the socioeconomic, cultural, and historical factors that influenced the management of the resource. The crisis was also simplistically defined in terms of the time and labor required to gather fuelwood. Furthermore, conclusions for most regions and countries were based largely on extrapolating results from a few samples from a limited number of countries.

The women's dimension of the energy problem was highlighted through works done by the International Labor Organization (ILO) and others during the 1970s and 1980s, including those by Cecelski, Agarwal, and

Eckholm. The economic crisis caused by the oil price hikes had kick-started interest in the whole question of energy, and studies started to be conducted showing that in developing countries households were principal energy consumers and the bulk of this energy was for cooking and was woman based. For the first time, the dominant role of women in procuring this vital resource was recognized and highlighted as a major problem, both because a large amount of women's time appeared to be absorbed in energy-related activity and because of the drudgery of carrying heavy loads of firewood over long distances (up to 10 km was regarded as normal). Later, the role of children in gathering fuelwood was also recognized.

However, this women's dimension was contextualized largely in a rural situation, perhaps because the entry point had been the fuelwood energy crisis and a large number of the women resided in rural areas. In a 1995 report, Skutsch noted that donor programs had an implicit bias toward rural rather than urban household energy. Therefore, the early work captured mainly the women and energy issues within rural household economics and time budget/labor discourses. The time spent and the drudgery suffered by women and children in gathering fuelwood and other biomass fuels for household cooking needs were (and still are) highlighted as the main problems and rationale for intervention. In a 1975 report, Eckholm provided graphic descriptions of further hardships suffered by the fuel gatherers as a result of deforestation. Some works, such as a 2003 study by Laxmi and colleagues, also reported that the burden involved is so large that children are kept out of school to gather biomass fuels. The amount of time spent on gathering fuelwood and the distances covered are widely cited, although only a few empirical studies have actually been undertaken. In many articles, the time is cited without a reference point, for example, a 1997 article in which Nyoni referred to a study finding that 37.8% of respondents in Zimbabwe spent 1 to 2 h collecting firewood but did not indicate frequency.

As a result of these kinds of studies, the idea arose that in developing countries household energy is essentially a women's problem and, consequently, that women-centered approaches should be taken in dealing with the problem. What was happening in the energy field is also a reflection of the general trend in paying increasing attention to women. The works of Boserup during the 1970s, articulated in her book *Women's Role in Economic Development*, drew attention to the economic disparities between women and men, the lack of integration of women in the development programs in developing countries, and the role of technology in this matter. This initiated the establishment of Women in Development (WID) networks in the North, which later formed links with the South.

Within the WID discourse, women were the focal points and the number of women participating in a program was considered to be a key indicator of progress. WID also generally considered women as a homogenous group and hinged the argument of women as a special group to a welfare approach. Predominantly, during the 1970s, there was a feeling that women's welfare had been ignored in the past, so in the context of energy, stove programs were set up to reduce drudgery. WID emphasized support for women within their traditionally defined roles (e.g., as mothers, as household carers). From an energy perspective, household energy, particularly energy for cooking, became the main focus. As Skutsch noted in a 1995 study, WID aimed at improving women's welfare without making women self-sufficient. These shortcomings with the WID approach resulted in a divergent school of thought during the late 1980s: distinguishing sex from gender. The emerging concept was referred to largely as "gender and development" (GAD). GAD placed more emphasis on the participation of women in the whole process. In the energy context, this meant considering energy not just for welfare reasons but also as a means of empowerment (e.g., women as energy entrepreneurs, women as decision makers about energy). This also meant focusing not just on stoves but also on types of energy that would "empower" women, giving them more chances to earn income, broaden their horizons, and so on.

Increasing global environmental concerns, motivated by Brundtland's report on *Our Common Future* in 1987, captured the attention of ecofeminists on the link between environment and women, resulting in a women, environment, and development (WED) discourse, making women the central focus of environmental concerns, and arguing that women have an affinity with the environment and are best placed to safeguard it. The WED discourse, which Jackson noted in a 1993 study is driven largely and sustained by nongovernmental organizations (NGOs) and oriented to radical ecofeminism, advances the theory that women naturally care for the environment and have profound knowledge of plants, animals, and ecological processes. In the energy context, women are seen as victims of environmental degradation and, as a result, suffer drudgery in gathering fuelwood. Another dimension that is increasingly gaining favor

is the perception of women as guardians of the environment, with women being expected to adopt renewable energy and decentralized energy technologies because these are considered to be environmentally friendly. In a 1999 report, Tisch noted that at the community level, women are effective and efficient managers of renewable energy systems and that, once these alternatives to ecologically damaging energy resources are made available, rural women use renewable energy technologies and benefit from the improved standards of living, enhanced economic opportunities, and cleaner and more sustainable environment they offer. Although the WED thinking is largely unproven, it seems to have had a substantial influence on women and energy approaches. In fact, the literature reveals that it is not uncommon to make conclusive and influential statements on links between women and energy without empirical evidence.

In general, women are seen as the procurers and managers of energy, particularly in rural areas. On the other hand, despite these important roles, women are also seen as lacking decision-making power on issues relating to the energy system. The contextualization of the women and energy issues and responses to them demand rethinking, particularly given ongoing reforms in the energy sector and calls for gender mainstreaming. It is important to evaluate the achievements of past approaches on women and energy issues and to establish their relevance. To this end, the following discussion aims to address some leading questions. Certain presuppositions are considered, including that the problems are fundamentally women's problems, that certain technologies will solve the problems, that women's needs are unique, and that increasing energy access will improve women's incomes.

3. A WOMEN'S OR A POVERTY PROBLEM?

Although rural women and girls may generally bear a larger burden of gathering biomass fuels than do men and boys, the underlying factors might not have been fully accommodated in the design of solutions. By socialization, women tend to be responsible for cooking and, by extension, for cooking fuel procurement. However, this might not necessarily imply that women do so because they are women; it may be due to many factors, including the financial status of households. Availability of fuelwood also influences women's involvement. The World Energy Council (WEC) noted in 2000 that, despite intense degradation of the biomass energy resource base in some areas, investments to improve kitchens, stoves, and cooking fuels either do not figure in the hierarchy of household expenditures or appear low on the list, mainly because the livelihoods of these households are also under pressure and this is a more urgent priority.

In well-off households, either fuelwood and other biomass fuels are gathered by paid help or the wood is bought and delivered to the house by motorized transport, mainly by men. In a study of rural India reported in 2002, the Energy Sector Management Assistance Program (ESMAP) noted that lower income groups spend more time collecting fuelwood mainly because they cannot afford to purchase it or access alternatives but also partly because the resources nearby are depleted to serve the commercial market created by higher income households whose members purchase fuelwood in large quantities. As reported by Miah and colleagues in 2003, rich rural households in Chittagong, Bangladesh, purchase 47% of their biomass fuel from the market and obtain the rest from homestead and agricultural fields. They noted that medium-category households purchase 36% of their needs, whereas the poor only collect biomass fuels from forests and fields. Furthermore, poor men and women sell their labor for agricultural activities and are partially paid with residues that they use as fuel.

Rural areas lack access to modern energy forms that are generally easier to procure elsewhere (e.g., in towns). However, where they are available in rural areas, the predominant limiting factor to their consumption in households is cost. A study of rural Rajasthan, India, reported by Laxmi and colleagues in 2003 found that as fuelwood became scarce, households switched to either commercial fuels or lower value fuels such as dung and straw, depending on income group and/or geographical area. In another Indian study published in 2002, ESMAP noted that although electricity has reached 90% of the villages in India, only 40% of rural residents have adopted it and most of the remaining households are poor. Depending on where a house is located with reference to a substation in a grid-connected area, costs of connection can be prohibitive. Decentralized technologies for household electrification are also not cheap, and in most cases only well-off households can access them. Women and energy advocates argue that special financing programs targeting women should be set up to provide women with

access to cheap loans for advanced technologies and modern energy procurement, particularly electricity and gas. Whether such measures address the real energy problems of women is an issue that is explored in later sections of the article. An important aspect that has not been well researched is the impact of such programs targeting different members of the household on the social structure. A 1998 report by the Food and Agricultural Organization (FAO) noted that targeting women can result in a backlash of resentment by men against what they see as an excessive emphasis on women in development programs. This confirms need for better understanding of the implications in the energy sector.

The focus on women as the providers of cooking energy may have shortcomings, and some important factors are sometimes missed. For example, in their work in rural Rajasthan, published in 2003, Laxmi and colleagues reported that the share of households purchasing fuelwood had increased to 14% from the 2% reported in 1996. This has two implications. The first is that concerns about women's time and drudgery connected with fuelwood collection might not be of primary importance. The second is that the availability of modern fuels would facilitate a shift from fuelwood given that there is clearly some financial resource available. In addition, various changes are noticeably taking place in the energy procurement process that need to be considered in designing solutions to women's energy problems. There is evidence that men play a more important role in fuelwood gathering than is sometimes reported. The ESMAP study found firewood collection by men in six states of rural India to be significantly higher than that by women, citing increased distances and effort as the reasons. Based on their work in rural Zimbabwe, Vermeulen and colleagues in 2000 reported similar trends, with men collecting firewood with carts. This increased involvement of men in firewood collection requires the adoption of a more comprehensive approach in addressing fuelwood shortage issues. The ability of men to meet their other household responsibilities and the possibility of women having to undertake these responsibilities should be investigated in the process of seeking sustainable solutions.

The importance of availability of modern fuels cannot be underestimated in influencing shifts from fuelwood. In a 2003 report, Gupta reported that the availability of liquefied petroleum gas (LPG) and biogas in an area where the improved Astra stove had been disseminated over a 7-year period resulted in a shift away from firewood in 35% of households. In their 2003 study, Laxmi and colleagues found that nonavailability of kerosene for cooking restricts its use more than does nonaffordability. By paying more attention to such trends that are unrelated to gender issues, strategies can be established to enable households to shift. Under such circumstances, a more open approach, rather than a narrow orientation toward women, might produce effective solutions.

The inability to purchase appliances and get connections certainly limits any switch to modern fuels. Various efforts have been made to enable women to acquire household energy appliances. In July 1999, the state government of Andra Pradesh, India, launched the Deepam Scheme, which pays the initial LPG filling fee for women who belong to self-help groups and whose households are classified as being below the poverty line. Beneficiaries have to meet the appliance and gas refill costs. Despite this free gas, most households continued to use wood, mainly because they could not afford refills. This problem is further illustrated by the relatively low consumption rate in rural areas, where the average refill rate was once in 7 months. Although time saving in cooking is reported as a major benefit of this project, there is no report on how the time saved is spent. The low consumption levels of LPG have meant a lack of entrepreneurial interest in LPG distribution service, so that households still have to travel relatively long distances to obtain gas. The report on the study does not indicate whether LPG procurement was done by women or men, and it is difficult to establish whether women's fuelwood collection time was indeed saved or merely shifted to LPG procurement.

Increased urbanization obviously has meant more women moving to urban areas. In many low-income urban neighborhoods, biomass remains an important cooking fuel. Although a part of it is gathered, the bulk of it is bought, often in informal markets near the households. As such, the time, labor, and drudgery associated with fuelwood procurement in rural areas are less important. Access to money is more so; here, poverty is the main determinant of access to biomass fuels. The fuelwood and charcoal are sold by both women and men who obtain it from the cities and transport it by road or rail over relatively long distances. Because this business does not necessarily require large capital investments for entry, competition from men is increasing as retrenchment levels rise with the restructuring of economies in several countries.

Low-income urban settlements tend to be informal. In most of urban Sub-Saharan Africa, informal

settlements and slums have long been the norm, increasing along with rural–urban migration. These settlements are characterized by temporary housing structures, poor sanitation, and lack of other basic services, including water and electricity. Much of the housing is classified as "illegal" and, hence, not likely to be serviced and connected to electricity. Residents sometimes resort to drastic and potentially dangerous measures to access electricity and energy services, including illegal connections—an activity implicitly attributed to men. A case reported in 2003 by Khupiso involving a woman in South Africa is useful to draw attention to the unconscious bias involved. The woman, who owned a Reconstruction and Development Program house in Mamelodi East, Pretoria, was on the run from police for illegally connecting 15 of her neighbors in an informal settlement. She had laid underground electricity cables from her house to these settlements and had been supplying them with electricity for 2 years at a flat rate of R150 (~U.S. $19) per month per connection. She also provided, for a fee, refrigeration services to some *spaza* (retail) shop owners. Of course, if viewed from a different standpoint, this could serve as an example of female entrepreneurship in the energy sector. Establishing ways in which to legalize such informal electricity trade could offer opportunities for women and men to generate income.

4. DO STOVE PROGRAMS ADDRESS WOMEN'S ENERGY PROBLEMS?

Mahatma Gandhi is credited with having inspired the production of the smokeless *chulha* in India by drawing attention to the cooking stove as a means of improving the living conditions of the rural woman. In general, the original interest in improved stoves was in improving the indoor environment rather than efficiency. The 1970s witnessed the beginning of the appropriate technology movement within which improved stoves were promoted as solutions to deforestation. To address the woodfuel crisis and the consequent problems for women, closing the woodfuel gap through demand-and-supply management strategies was seen as the logical solution. On the underlying assumption that woodfuel was likely to be the main fuel source for a long period of time, improving woodfuel efficiency has been a dominant measure. In rural areas, improved stove efficiency was (and still is) deemed a method of reducing fuel collection for women and girls. This is despite the experiences of the 1980s, where most of the improved stove projects failed.

As early as 1987, the ILO concluded that cooking stoves that are designed to reduce the quantities of fuelwood used can be expected to be successful (adopted easily by local women) only in areas where there is an acute fuel shortage (e.g., rural areas with an ecologically degraded environment, peri-urban and urban areas where fuel costs are high). It was recommended that stove programs should not be exclusively concerned with biomass fuels given that consumers prefer to have alternatives, and it was noted that fuels and technology are used depending on the season, ease of use, and availability. A 1985 study by Gill highlighted the reasons why improved stoves failed to achieve widespread adoption in developing countries.

Although it lost favor during the 1980s, interest in improved stoves seemingly was revived during the subsequent decade. In a 1994 review, the World Bank reaffirmed the value of cooking stove projects, claiming that the social, economic, and environmental benefits of promoting improved stoves under suitable circumstances are quite large, and existing successes demonstrate the usefulness of well-managed programs. Various programs and projects have been launched, mainly with support from donors, to promote improved biomass stoves. Women have always been regarded as a special target group to which donors, governments, and NGOs direct aid in various ways to facilitate adoption of the stoves. One of the reasons provided for the poor performance of initial projects was poor targeting; that is, women were excluded. The underlying rationale for supporting women-targeted programs continues to be that improved stoves would save fuelwood, so that women would spend less time and energy in gathering it. As reported by Khandelwal in 2000, the government of India has a national program on improved stoves that provides direct subsidies to women from select castes and tribes to enable them to adopt these stoves. By 2000, the program had been sustained for 16 years with central government budgetary support. However, as noted by Lombard in 1995 and by Nathan in 2001, the performance of this program has not been particularly satisfactory. Reporting on the *upesi* rural stoves program in Kenya in 2001, Njenga concluded that the benefits to men and women include improved health and time savings for the users. However, it should be noted that there are no reported systematic observations and empirical evidence to support this conclusion. On the other hand, the women producing and

promoting the stoves earned some additional income that Njenga noted made them enjoy a significantly higher standard of living.

The extent to which improved wood stoves benefit women with respect to time, labor, and financial savings in rural areas is limited by a variety of factors. In many countries, improved stoves are produced by artisans in informal situations with limited technical skills and quality control, so that the stoves do not always achieve the expected fuel savings. Most rural households do not buy fuelwood and, therefore, experience no direct monetary savings. In a 1997 report, Nathan noted that China experienced success in improved stove programs, with some 150 million (or 70%) of farm households adopting improved stoves sold to them at commercial prices by 1991. On the other hand, in India, only approximately 15% of farm households had adopted improved stoves by 1992, even though the improved stoves were offered at highly subsidized prices. Nathan noted the difference as being the monetary value of women's time. Women were involved in income-generating activities in China, whereas they were not in India. Savings in time spent on fuelwood collection had direct value in China because the time was reallocated to the enterprises, but this was not the case in India. Nevertheless, having some free time does have welfare benefits. However, not surprisingly, financial savings have been reported for urban households that purchase fuelwood and charcoal after acquiring improved stoves.

In general, the roles of women in the improved stoves process has received a good deal of attention. More than two decades ago, Hoskins reported in 1981 that adoption and use of improved stoves would not be possible without the active involvement of women. In a study reported in 1991, the FAO noted that energy-efficient earthen stoves in a village in Himachal Pradesh, India, became popular in areas where women were trained to make such stoves and introduce them to other women.

Stove programs have rarely met the fuel-saving objectives, partly because the goals were not based on realistic scenarios. Various factors influence the amount of fuel used (e.g., the skills of the cook, the cook's interest in the task of cooking, the stove, cooking utensils). As noted way back in 1987 by Evans, women's main interests have been largely misconstrued by stove project managers as saving fuel. In reality, women prefer having a better fuel, not a better stove.

It would appear that the effectiveness of the improved stoves in saving women's time and labor is rather limited and dependent on various external factors that are not always taken into account in stove programs. Financial savings from reduced fuelwood consumption occur only where fuelwood is purchased and also where the technical performance of the stove meets the expected efficiency levels. Notably, as acknowledged by Leach and Gowen as far back as 1987, during times of fuelwood scarcity, coping strategies associated with traditional stoves are reported to outweigh the benefits associated with improved stoves.

5. HOUSEHOLD ENERGY AND HEALTH: A WOMEN'S PROBLEM?

There is general acceptance that exposure to biomass and coal smoke, generally classified as indoor air pollution, increases the risk of a range of diseases and impinges on the health of adults and children. This pollution affects health in two main ways: through having direct effects, such as carcinogens and toxins causing cataracts, and through damaging or weakening the immune system, thereby making it more susceptible to attack. Impacts include acute respiratory infections, chronic obstructive pulmonary diseases (e.g., chronic bronchitis), lung cancer, tuberculosis, adverse pregnancy outcomes, and asthma attacks. However, current information on smoke as causal is indicative and not always conclusive; there is uncertainty associated with exact risk estimates. For example, a 2000 report noted that although there is increasing evidence of links between PM10 and PM2.5 and health, available evidence does not allow a clear judgment on levels of particulate concentration above which adverse effects would occur. There is growing awareness that various factors contribute to these health impacts, and more evidence is needed to establish the cost-effectiveness of measures associated with smoke reduction and elimination. Poverty, poor nutrition, poor living standards, poor sanitation, overcrowding, and low-quality medical care are significant (and possibly more important) determinants of health impacts associated with indoor air pollution. Nevertheless, indoor air pollution has been receiving increased attention, and in 1992 the World Bank designated it as one of the key global environmental problems. The World Health Organization (WHO) noted that a pollutant released indoors is more likely to reach people's lungs than is a pollutant released outdoors.

Literature identifies women and children as the most vulnerable because they are the most exposed,

particularly in poor rural and urban households. However, it is likely that the attention paid to women and children tends to hide the fact that adult men may also suffer indoor pollution-associated ailments. In an analysis of the prevalence of respiratory disease symptoms in rural Rajasthan, Laxmi and colleagues found no significant difference between male nonsmokers and female nonsmokers, although they had expected the males to act as a control group because they did not cook. In addition, the results suggested that male nonsmokers, as compared with female nonsmokers, have a higher prevalence of symptoms and are more vulnerable to coughing, phlegm, wheezing, chest illness, and blood in sputum. (The researchers noted, as a shortcoming of their study, an insufficient male representation due to the work having been designed to study females cooking with biofuels.) Including the male dimension is particularly important because increased urbanization means that more men are cooking and that the size of dwellings is relatively small and often lacking separate rooms for cooking, with men and women occupying the same rooms.

The physiology of children, particularly underdeveloped lungs and relatively faster breathing rates, makes them liable to absorb large quantities of pollutants. Smith and colleagues, in a study published in 2000, reported that acute respiratory infections related to biomass fuel combustion are the leading causes of deaths in children under 5 years of age, with 75% caused by pneumonia. It is estimated that half a million children and women die in India annually from indoor air pollution. However, findings are not always consistent. A study in south Kerala, India, focusing on children under 5 years of age, as reported by Shah and colleagues in 1994, found that the fuel used for cooking was not a significant risk factor for acute respiratory infections. Based on a 1998 study on infants in Delhi urban slums where wood and kerosene are used, Sharma and colleagues noted no significant difference in prevalence of acute respiratory infections and fuel type.

The chemical composition of smoke and the concentration of particulates determine the level of attributed harm. Smoke generally includes suspended particles, nitrogen oxide, carbon monoxide, sulfur oxide, and carcinogens (e.g., formaldehyde, benzene, polyaromatic hydrocarbons). The extent of the impacts of composition vis-à-vis the particles is contested. In addition, the combustion characteristics affect the pollutants. For example, sulfur dioxide is dependent on fuel content, whereas concentrates, formaldehyde, and nitrous oxide depend on the efficiency of the combustion process. Carbon monoxide is released in relatively large quantities when biomass fuel is burned, as compared with kerosene or LPG, with short-term effects to exposure being headaches, dizziness, and nausea (extensive inhalation can cause death). In a 1991 study, Smith estimated that 38, 17, 5, and 2 g of carbon monoxide are released during the cooking of a meal using dung, crop residues, wood, and kerosene, respectively. In a 1995 report, Patel and Raiyani noted findings of carbon dioxide levels of 144, 156, 94, 108, and 14 mg/m^3 air during cooking with dung, wood, coal, kerosene, and LPG, respectively, in Ahmedabad, India.

Indoor air pollution has generally been linked with rural areas due to high household consumption of biomass and coal, but the urban phenomenon should not be underestimated. The WHO estimated that indoor air pollution contributes 50 and 25% of the diseases in rural and urban areas, respectively. Reports from India published by ESMAP in 2002 show that cooking smoke may be responsible for more than 400,000 premature deaths annually. There is evidence that many of the people moving to urban areas tend to settle in low-income neighborhoods where they use biomass or coal. Rising urbanization levels and the share of urban poor will further exacerbate the situation. Indoor pollution effects in low-income urban households are likely to be more aggravated than in rural areas due to overcrowding and the outdoor pollution effects.

In a 2002 review of indoor air pollution aimed at making recommendations for further research, Smith categorized three impacts based on the level of evidence: strong, moderate, and suggestive. Acute respiratory infections, chronic obstructive pulmonary diseases, and lung cancer fall into the first category. Cataracts, tuberculosis, asthma, and adverse pregnancy outcomes fall into the moderate evidence category. However, it is important to state, as noted by Ezzati and Kammen in their 2002 study, that most of the studies on health impacts of exposure to indoor air pollution have focused on these three diseases. Studies undertaken in China, including those reported by Smith and Liu in 1994, by Xu and colleagues in 1995, and by Lan and colleagues in 2002, provide evidence of an increased risk of lung cancer among women from exposure to coal smoke, but there is little evidence relating to biomass fuels. Lan and colleagues also reported that the duration of cooking food on an unvented coal stove was strongly and positively associated with lung cancer incidence in both men and women (even though men started cooking later in life and tended

to cook for a shorter period of time). This is important because more men are cooking, particularly in urban areas.

Links between biomass fuels and chronic obstructive lung disease (e.g., colds) have been reported. In a 1996 report of a study involving 1200 women (218 of whom were monitored for air pollution) in low-income areas of Maputo, Mozambique, Ellegard reported finding cooking wood smoke as being associated with chronic respiratory illness among women. The study found that wood users were exposed to significantly higher levels of particulate pollution during cooking time (1200 $\mu g/m^3$) than were charcoal users (540 $\mu g/m^3$) and modern fuel users (e.g., LPG, electricity) (200–380 $\mu g/m^3$). Although wood users were found to have significantly more cough symptoms than were other groups, there was no difference in cough symptoms between charcoal users and modern fuel users. However, there are no studies in developing countries linking heart disease to biomass fuels. In a study published in 2000, Bruce and colleagues noted that biomass fuels have been linked to cancer of the mouth and larynx but that the findings are inconclusive. Studies conducted in India show the incidence of chronic cor pulmonale to be similar between men and women despite the fact that 75% of the men and only 10% of the women were smokers. In addition, the condition was more common among younger women, occurring 10 to 15 years earlier than in men. This difference was attributed to indoor air pollution from burning solid biomass fuels leading to chronic bronchitis and emphysema, both of which result in chronic cor pulmonale.

Although it has been reported that indoor air pollution causes birth-related complications, including prenatal mortality and low birthweight, there is hardly any statistically representative work that validates this. The one study frequently cited on perinatal mortality was conducted in Ahmedabad and was published by Mavalankar in 1991. This study found a link between exposure to indoor air pollution and stillbirths and deaths during the first week of life with an odds ratio of 1.5 (95% confidence interval: 1.0–2.1, $P = 0.05$), although exposure was not assessed directly, implying marginal significance. Only one published study has reported wood smoke as affecting birthweight. This study, reported by Boy and colleagues in 2002, was conducted in rural Guatemala, where babies born in households using woodfuel were 63 g lighter than those born in households using gas or electricity.

Procurement of energy may also have health impacts on women. In a study conducted in Sri Lanka and published by Wickramasinghe in 2001, women reported fatigue, headaches, pain in joints and the chest, and weak joints and back resulting from head loading wood and walking over long distances several times per week. However, it is not evident from the report that carrying wood was the only or dominant head loading done by the women. In general, there is insufficient reliable empirical data on weights of fuelwood loads. Work done by the ILO during the 1980s indicated that women carry loads of up to 35 kg over long distances, whereas a maximum of 25 kg is frequently cited as the weight that can be borne over such distances without seriously threatening the physical health of women. Cuts, falls, bites, back injuries, and sexual harassment have also been associated with fuelwood collection. Fuel scarcity is noted to force women to move to foods that cook faster or to eat more raw foods, increasing health risks to entire families. Obviously, this is due to household poverty rather than to physical fatigue and poor health, viewed nearly exclusively as a problem affecting women.

6. WILL IMPROVED STOVES IMPROVE THE HEALTH SITUATION?

There are various measures to reduce exposure to indoor air pollution. In their study reported in 2000, Ballard-Tremeer and Mathee categorized three main types of interventions relating to source (emissions), living environment (concentrations), and the behavior of the user (exposure). The type of fuel and stove used influence indoor air quality. The fuel–stove interface is a significant determinant of emissions generated. Based on their evaluation, Ballard-Tremeer and Mathee noted that the most effective interventions, and those most beneficial to the user and society as a whole, would involve a shift from wood or charcoal to kerosene, LPG, biogas, or grid electricity.

Based on an empirical study conducted on 67 caregiver–child combinations living in poor unelectrified areas in rural South Africa, Barnes and colleagues in 2000 identified four core behaviors for intervention to reduce child exposure: improving stove maintenance practices, improving the quality of ventilation practices, reducing the time spent close to burning fires, and reducing the duration of burning. The authors put much emphasis on the

recommendations made by the caregivers. Hence, while acknowledging fuel switching as the most effective intervention, they omitted it because the caregivers noted that the associated costs would be prohibitive. Changing the location of a stove to better ventilated locations in the kitchen was dismissed for similar reasons. Improved stove maintenance, including cleaning chimneys and replacing missing cooking plates, has also been recommended as a strategy to reduce indoor air pollution. It was noted that women in most cases already open windows and doors (when available) while cooking. Applicability and effectiveness of behavioral changes remain to be verified. Clearly, the changes have cost and labor implications.

Improved stoves have been widely advocated as a measure to reduce indoor air pollution, and this is supported by various studies, including those by Ezzati and Kammen in 2002, Albalak and colleagues in 2001, and Wafula and colleagues in 2000. (However, it is imperative to note that this rather common reporting can be misleading because it is essentially the presence of a mechanism to vent out the smoke that contributes to reduction. The term "improved stoves" is not used exclusively for stoves with chimneys; it is also used for higher efficiency stoves without chimneys.) The first stove program launched by the Indian government aimed to get rid of smoke from the kitchen by using chimneys. In an analysis of 21,232 farmers in rural Xuanwei, China, Lang and colleagues noted that a shift from unvented coal fire pits to coal stoves with chimneys was strongly associated with a reduction in the incidence rate of lung cancer. Such chimneys extract smoke by increasing draught and, hence, the combustion rate. In the process, fuel savings are compromised. However, depending on the height of the chimney, the measures do not get rid of the pollution problem completely but instead transfer it from the kitchen to the vicinity of the dwelling. In an environment where houses are constructed close to each other, smoke builds up and remains in the neighborhood. This is aggravated where outdoor air pollution level is high, as is often the case with low-income environments of large industrial cities. Reporting on findings in China, Edwards and colleagues noted in 2003 that flues and chimneys are not much above the height of houses; hence, emissions result in elevated neighborhood and regional pollution that penetrates back to the indoor environment. Notably, where the heights of the chimneys are low, the smoke can travel back into the houses through doors and windows. Chimneys can be ineffective if the smoke returns through windows and doors.

Evidence on the ability of improved stoves to reduce indoor air pollution is contentious. It has been reported that such stoves can actually increase indoor emissions. Smoke is a result of incomplete combustion that occurs due to insufficient oxygen. Improved stoves save fuel by controlling the burning rate and, hence, the air flow. The effectiveness of improved stoves depends on maintenance and, therefore, on age or hours of use. Stoves that are poorly maintained are unlikely to contribute to reductions in indoor pollution. The way in which a stove is used influences emissions levels. For example, closing the door prevents smoke from coming back into the house from the chimney. On the other hand, when using wet fuel, it is usually necessary to open the door to facilitate ignition and combustion. Edwards and colleagues, in their recent study on improved fuelwood stoves in China, noted that thermal efficiency is improved at the expense of combustion efficiency, resulting in increased emissions of human-damaging pollutants and greenhouse pollutants.

7. DOES INCREASING THE SUPPLIES OF BIOMASS FUEL HELP?

Retreating forests have always been viewed as threats to fuelwood availability in rural areas and, hence, to women's time and labor. Social forestry to grow trees for fuelwood has been a commonly pursued solution. Despite evidence that the fuelwood availability issue is more complex than a simple gap theory implies, and that most of the wood produced through afforestation practices is destined to become timber rather than fuel, considerable resources have been directed to these activities. Community-based forestry is encouraged as a source of revenue where fuelwood is traded for urban consumption. Women have been promoted as managers in such projects. In these community-based projects, men's and women's groups, with assistance from the forest departments, sell firewood as a source of income. Projects target women as producers and potential beneficiaries. However, not all of the community-based forestry benefits women. In a 2001 report, Sarin noted that in Uttra Pradesh, India, women were worse off after the introduction of village joint forest management because they could no longer get jobs as forest guards and had no control over decisions relating to forest use.

The validity of afforestation programs aimed at providing fuelwood has been challenged. Using data

from dry tropical areas of Niger and Mali, Foley in 2001 raised serious doubts regarding the woodfuel scarcity problem and the solutions proposed, which have been mainly planned interventions on use of improved stoves and tree planting. There have been considerable efforts, through projects and programs, to involve women in tree planting for fuelwood. Various community-based resource management projects targeting women, on account of the suffering they encounter in gathering fuelwood, have been implemented. However, these efforts are not justified given that communities naturally undertake the necessary activities without external intervention. Findings from rural Rajasthan, where 47% of households in the study used fuelwood gathered from their own farms, support this thinking.

Within the context of afforestation and tree management for fuelwood, some works have differentiated "men's trees" from "women's trees." The former are defined as straight-stemmed species useful for timber and poles, whereas the latter are defined as trees that yield a broad range of products such as fruit, fodder, and firewood. The aim of such works has been to influence the choice of trees planted under social forestry programs and, hence, to protect women's interests. Poor access to fuelwood by women is also blamed on their lack of land tenure, implying that women are reluctant to plant trees because the trees would be "hijacked" by men. In a 1995 report, Kelkar stated that a group of men invited to jointly plan a community forestry project told the foresters that they wanted to plant hardwood tree species to make furniture and wood carvings for sale. When women were consulted, they indicated a preference for softwood fast-growing species for fuel and fodder. The Regional Wood Energy Development Program (RWEDP) of the FAO, in a 1996 report, also noted that women prefer trees for fuel, fodder, and fruit, whereas men prefer timber trees. In addition, the RWEDP noted that women prefer trees that yield shorter term returns and smaller returns spread over a long period (e.g., fruit trees rather than timber trees). Women's unique responsibility for day-to-day care of their families was given as the reason for the different preferences.

It has also been claimed that men, as primary owners of land, have better access to fuelwood and are in a better position to dominate decisions about tree species in forestry projects at the expense of women. However, it is worth noting that ownership of land does not guarantee access to fuelwood given that the competition for land for food and outputs more beneficial than fuelwood has meant that farmers (including women) give low priority to the latter. Increased demand for cash necessitates trading most farm products, and in communal lands most of the forested land has been cleared, so that even if women owned the land, their access to fuelwood might not necessarily improve.

8. WILL ELECTRICITY HELP WOMEN?

Rural electrification is another area that draws attention to energy procurement by women. Electrification has 7been justified on the basis that it results in economic progress, but recent thinking has acknowledged that electricity is an insufficient, albeit a necessary, catalyst for this. Some, such as Clancy in a 1999 article, have characterized electricity as a basic good necessary to empower women. Cecelski, in a 2000 report, called for rural electrification on the basis that it would meet women's needs for labor saving, time saving, improved health, security, and income. But as noted by various authors, including Mehlwana in 1997, ESMAP in 2002, and Wamukonya and Davis in 2001, electricity in rural areas is used mainly for lighting and other light load activities such as powering radios. ESMAP's study of 5048 women in six states in India in 1996 concluded that household electrification affects leisure time available to women and provides channels to increase knowledge and awareness through facilitating reading and watching television. A seemingly contradictory finding from this study involves the decrease in fuelwood collection times, even in poor households that reportedly use electricity only for lighting and entertainment.

Because the bulk of the time expenditure, drudgery, and health impacts related to energy procurement by women is in reference to cooking fuels, rural electrification cannot solve these problems unless it is provided for cooking. Lack of electrical cooking appliances and the high cost of power are major limiting factors. Even in countries where the governments have made concerted efforts to electrify their populations, the electricity consumption for cooking remains low. Despite an aggressive electrification program in South Africa, Mathee and colleagues noted in a 2001 report that more than $3\frac{1}{2}$ years after provision of electricity, 44% of the households in North Western Province had not acquired electric stoves. However, unless electricity production costs are very low, it is difficult to justify targeting it as a cooking fuel.

Decentralized electrification in rural areas has gained favor largely as environmental concerns move to the forefront and the cost of extending the grid to remote areas with relatively low-load consumption patterns becomes prohibitive. This is manifested mainly as mini- and micro-hydro in areas where hydro resources are available, but largely as household photovoltaic (PV) systems. In fact, as a response to the sustainable development movement, donor agencies abandoned grid extension policies in favor of stand-alone systems based on PV, mini-hydro, or biomass. Solar home system projects are proliferating all over the developing world. Martinot and colleagues, in a 2000 report, provided a comprehensive list of some Global Environmental Fund (GEF) solar home system projects, and Martinot and colleagues in 2002 give an overview of this market. However, capital cost is a major barrier to accessing these systems, whose promotion has been justified on cost-effectiveness. In view of this, governments, with assistance from donor grants and loans, have established innovative financing mechanisms to provide loans to consumers. Despite these, there have been concerns that women are unable to access credit for solar home systems, so facilities targeting women have been established or concerted efforts to reach women have been made within existing frameworks. Enersol, a U.S.-based organization aimed at deploying solar-based technologies for rural electrification, has established such a system to enable women to acquire its solar home systems. In its microenterprise training courses to NGOs, Enersol emphasizes the importance of women as borrowers. Although Smith noted in 2000 that the women use savings from energy replaced by the solar system, no information was provided on volume and type of energy expenditures prior to and after acquiring the system.

The extent to which these systems benefit women is questionable. Evidence documented in a United Nations Environment Program (UNEP) 2001 publication shows that typical solar home systems are consumer goods. The solar home system electricity does improve household welfare with respect to better quality lighting, but at a relatively high cost compared with conventional electrification systems. Therefore, women end up getting loans to acquire systems that provide strictly limited and costly services and that do not address the key energy concerns—cooking and its associated hardships—so that gathering of fuelwood and other biomass fuels continues even after acquisition of the solar home systems.

As a measure to facilitate access to electricity, there have been recommendations to target women in dissemination of solar home systems. Enersol has been targeting women as users and promoters of solar home systems in the Dominican Republic. However, Smith noted in a 2000 report that despite a concerted effort to train and support women, of the 30 active businesses supported by Enersol, only 2 have women in significant leadership positions and 1 relies on a female technician for system installation and maintenance. After one of Enersol's women-only training programs, no microenterprise dedicated to marketing and installation of PV systems emerged from the group of 10. This may imply that the main barrier was not necessarily being women. It is worth noting that Enersol has depended mainly on USAID financial support to train and support women entrepreneurs.

9. WILL SAVING TIME HELP WOMEN TO ENGAGE IN MORE PRODUCTIVE ACTIVITIES?

It is often argued that the time spent by women and children in gathering fuelwood could be employed for more productive purposes. However, there are inadequate empirical data indicating this, and proxies are normally used to calculate the value of this time and labor. It cannot be ascertained that the time freed from fuelwood gathering could be used for more productive purposes. Interviews with Namibian rural women in 1999 revealed that they would spend the time freed from fuelwood gathering on housework and not necessarily on leisure or income-generating activities. The main reasons for not this were lack of opportunities and lack of capital. ESMAP reported in 2002 that in India, rural electrification has not influenced the time spent by women in productive activities.

It is important to acknowledge that time saved from procuring energy sources is not automatically reallocated to income-generating activities. Only where the other more important factors are available does this happen. If the objective of an initiative is to save women's time from fuelwood gathering for use in income-generating activities, the initiative needs to provide the other complementary factors. A study conducted in Nepal found that only the women who already were involved in income-generating activities and were using biogas engaged in these activities by using the time saved from fuelwood gathering. In more than 80% of the households, social work and domestic chores were the main activities that women spent more time on (where they did not already have

income-generating enterprises). In a study published by Rana-Deuba in 2001, it was noted that women receiving microenterprise training in Nepal were able to start businesses mainly because the training was backed by access to credit. In 2001, Chaieb and Ounalli reported that in Tunisia, rural electrification had increased income-generating opportunities for women mainly in sewing and hairdressing businesses, but this was feasible only because state development programs donated the equipment to households. After installation of biogas plants in Pura village, India, to provide electricity for lighting, water pumping, and using high-quality fertilizer, women were able to earn a small amount of money transporting fertilizer to the fields of farmers. It must be noted that such an activity is supported by the availability of the fertilizer as a by-product, requiring no extra capital outlay. Only where the environment is conducive to this activity, and where other factors exist, are time savings used for productive activities.

Fuel switching—from fuelwood to modern energy carriers—is often advocated as a measure to reduce women's drudgery from fuel collection. However, a shift from fuelwood might not necessarily help women and children in this way. A study conducted by Britt and Kapoor in 1994 in Nepal, measuring the increase in women's leisure time and time spent visiting relatives, found that women without biogas plants actually had more leisure time and more time to visit relatives than did women with these plants. Biogas use has been noted for not really reducing women's time expenditure on fuelwood procurement because women have to collect water for the digesters. The same situation was reported in reference to Tanzania.

10. DO WOMEN REALLY HAVE ENERGY NEEDS DIFFERENT FROM THOSE OF MEN?

Paying special attention to women is normally justified on the basis that women's energy needs are different from men's energy needs. This thinking is advanced while promoting certain technologies. Decentralized technologies, particularly renewable energy technologies, are increasingly lauded as the "natural solution" to women's energy problems, particularly in rural and remote areas. This is often in reference to using these technologies for electricity provision. It is noted that women use electricity differently than do men due to the former's different household and productive activities. Rural women's energy needs are said to be water pumping, agricultural processing, security, work productivity, and health, and rural men would seem to have the same needs. It would be expected that in urban areas as well, there is little real difference between women's and men's energy needs.

There are also reports that women tend to see the benefit of electricity differently than do men. In a synthesis report on micro-hydro power published in 2000, Khennas and Barnet noted that women in Sri Lanka saw the benefits largely in terms of reduced workloads, better health, and reduced expenditures, whereas men saw the benefits in terms of leisure, quality of life, and education of children. In a study reported in 2000, Cecelski lamented the fact that few studies have examined the impacts on women from renewable energy interventions. In a 2002 report, Parikh recommended that energy ministries assign special tasks to their renewable energy divisions to assist women in evaluating possible energy alternatives. However, it is again important to note that energy is not important in its own right; rather, it is the service energy provides that is useful. Therefore, singling out decentralized or renewable energy technologies may be counterproductive if the technologies do not meet the services needed, and they might even contribute to "locking in" the women. The focus should be on service rather than on the technology. The technology chosen should be the least cost option, but the costing should take into account the ability of technology to meet development objectives, particularly poverty alleviation.

11. ENERGY DECISIONS: ARE THEY ALL MADE BY MEN?

There is a widespread belief that women lack decision-making power. The WEC, in an analysis of factors determining energy–women linkages published in 2000, noted that women, by virtue of their position (or lack thereof), stand disadvantaged in decision-making processes in their families, communities, and countries as well as in accessing productive assets. This thinking is used in designing women-targeted energy programs and projects.

Renewable and decentralized energy technologies targeting women are recommended as a measure to empower women in the decision-making process. According to a study by Smith in 2000, decentralized energy technologies are particularly relevant to women because women have direct control of

acquisition, design, placement, and consumption decisions, whereas they often exert less control over male-dominated, utility-centered grid systems. Decentralized technologies have also been deemed favorable because they provide more opportunities for women to be involved in energy system management, decision making, and control than do centralized grid systems. In addition, such technologies provide opportunities for women entrepreneurs. However, this involvement is not automatic. In Sri Lanka, women were not considered to be decision makers in the Electricity Consumer Societies formed in some of the communities with micro-hydro plants, whereas they were encouraged to participate in others. Women have been targeted by various programs as trainees on maintenance and installation of PV systems, including solar cookers, as a measure to improve their decision-making powers. However, even the decision to engage in an enterprise is not necessarily limited by gender. In a report published in 2000, Balakrishnan stated that after a women's training program in India in 1993, 2 of the 45 women started renewable energy businesses, with 1 reported as having "gone a long way" into wind farms in Karnataka, and a 3rd woman joined a UN agency as a consultant. It is difficult to understand what "a long way" entails because no data were provided on sales or other aspects of business performance.

As noted earlier, there are calls for providing finance to women to enable them to adopt renewable and other energy technologies, but also specifically for acquiring solar home systems. One of the justifications for extending loans to women for energy technology procurement is the fact that they are rational and would purchase technologies that are valuable and address their household needs. The usually implicit (but occasionally explicit) counterargument is that men are irrational and would spend money on their own entertainment rather than purchasing technologies that would benefit their households. It has been noted that men are systematically biased in favor of their own leisure time and that this has resulted, for example, in underinvestment in devices that save women labor time and fuel. Nathan, in a 1996 report on work done on Hani people in Yunnan, stated that money was spent on cassette players (for men's listening pleasure) and not on getting piped water or on improved stoves. If these observations are justified, extending loans to women for the typical solar home systems might also be labeled as irrational given the service limitations. Along the same lines of thought, it is normally implied that women do not value entertainment from radio and television and would rather acquire cooking appliances because they lack the time for entertainment. Laxmi and colleagues, in a 2003 report, noted that cooking and energy-saving appliances are accorded lower priority than are luxury goods (where the luxury goods identified are durables such as pump sets, bullock carts, fans, and radios/tape recorders) due to little involvement of women in decision making. It is worth noting that this is a mixed bag of goods given that some of these "luxury goods" are actually vital for the survival of households. It is perhaps worth mentioning that from the data presented by these authors, the number of households owning kerosene stoves is higher than the number of households with pump sets.

Lack of decision-making power among women in households has been stated as a rationale for targeting women to facilitate making the appropriate choice on energy matters. Comparing a nonelectrified village in South Africa with an electrified one, Mathee and de Wet in 2001 noted that women in the nonelectrified village indicated that an electrical cooking appliance would be the first electrical appliance they would like, whereas women in the electrified village indicated that this was among the last appliances bought there. The authors attributed this discrepancy to the dominant economic decision-making power and the preference of men at the household level. However, this conclusion is not supported by any empirical evidence on decision-making processes. In advocating measures to enable women to influence household decisions (e.g., through self-help groups), an article in a World Bank newsletter in 2000 noted, in a similar manner, that "when it comes to commercial fuels which are bought for cash, the problem often is that income decisions are made by the male heads of the household, while women have to bear the burden of collecting fuelwood and using it for cooking." In 1997, Dutta remarked that although women are the potential users of improved cooking stoves and other cooking innovations and, therefore, are in the best position to assess their advantages and disadvantages, it is the men who handle household cash and make decisions on how it is to be spent. The differences in rationality between men and women where acquisition of household energy appliances is concerned are contentious and, as noted earlier, are rarely supported by empirical evidence. For example, that women from all income classes would watch television if one were available was one of the findings of the ESMAP study of six Indian villages.

Community-based forest management was initially promoted as a measure to restore degraded forests and to improve access to fuelwood for sale and household consumption. Women were expected to benefit from these initiatives, but their lack of decision-making power has largely been blamed for the negative impact that community-based forestry has had on access to fuelwood by women. To revisit an earlier point, decisions regarding what trees should be grown in farm forestry are made by men, and this prevents households from planting trees for fuelwood. Sarin and colleagues in 2003 reported that in a study of four villages in Orrisa, India, women had decision-making power on forest use in only one of the villages. The authors noted the delays in relaxing rules on restricting fuelwood collection, and they blame this on domination of men in the relevant committees. The same reason was given to explain why rules on timber extraction were elaborated, whereas those on fuelwood were not. Clearly, controlling fuelwood extraction is rather difficult compared with controlling timber extraction, and this may have been the principal reason for the delays. There is an underlying assumption that men benefited more from timber than did women.

Some argue that the problem of women's exclusion from energy-related decisions at the household, community, and national levels is compounded by their underrepresentation in decision-making processes related to energy policy and planning. The underlying assumption is that women decision makers would address women's energy needs more effectively. It is reported that engendering of policies is on the increase as a result of advocacy by women's groups. The main indicator of this engendering has mainly been the number of times "women" appears in the relevant documents. Whether this is an effective indicator is subject to debate. Advocating for an increase in the number of women in decision making certainly has its merits, particularly because it creates employment opportunities. However, using the number of women in any given institution as an indicator of representation has various drawbacks. First, the representation system runs the risk of abuse, where nepotism and favoritism are used to select women who are likely to become mere "rubber stamps." This would weaken the whole decision-making process to the disadvantage of both men and women. Second, women politicians and other decision makers are not always able to alter energy decision making to cater for women's concerns, due mainly to a general lack of comprehensive understanding of the policy impacts and interference by stakeholders with vested interests. Third, because the proportion of women professionals in the energy sector is relatively low, focusing on having women on-board as a prerequisite to addressing women's concerns may derail the issue, if there is indeed an issue, and may reduce opportunities for open dialogue to establish what the main concerns are and how to tackle them. Even where there are affirmative action policies or quotas reserved for women, it is difficult to get qualified personnel. Obviously, it will take a while before there can be a critical mass of women professionals in the energy sector. But as is argued here, energy issues are not so much about women as about poverty. A woman professional will be a better candidate than a man in the energy sector only if she can design and implement frameworks that use energy to alleviate poverty.

A strategy that has also been used to increase the participation of women, as well as to raise the profile of gender issues in the energy sector, is the establishment of gender desks in energy and other ministries staffed nearly exclusively with women. Despite a shift to gender and development, this is a typical reflection of the women in development approach that found expression in small female-staffed gender cells devoted to women's projects. These offices are meant to integrate gender into policy and action plans. However, they tend to be isolated and without links to other relevant ministerial or external (e.g., utility) stakeholders. Other staff members consider these offices as dealing with "women's affairs," that is, issues they regard as not relevant to themselves and their work. As such, the energy gender offices remain largely figureheads, with little influence on the energy agenda. If they are to function effectively, there has to be a broadly shared understanding of the issues and tools to effect change. An important element would be to employ both men and women. Most of the energy gender offices lack dedicated budgets to operate, relying instead on mainly donor funding, the intermittent nature of which makes it difficult to have an impact because there is no guarantee of continuity of the necessary projects such as awareness raising.

12. WILL ACCESS TO ENERGY INCREASE WOMEN'S INCOME-EARNING POSSIBILITIES?

Access to financing for acquiring energy and other inputs for income generation has been cited as a key barrier to women's involvement in entrepreneurship.

Lack of collateral and, more important, networks makes it difficult to obtain loans. A strategic solution that has been gaining favor is the establishment of women-only financial institutions, which are justified on the basis that women do not receive adequate attention in men-dominated institutions. Another justification is the need to end women's dependence on loan sharks who demand exploitative interest rates, keeping women in a vicious poverty cycle. Most of the women-targeting institutions tend to be operated mainly by women. Although this has merit so far as increasing employment opportunities for women is concerned, the women-only approach can be detrimental to the overall objective. The institutions are generally isolated from the conventional male-dominated business world, and this limits networking and makes the opportunities to transit into normal business cycles difficult.

As a way of facilitating participation of women in entrepreneurship, their projects are evaluated less stringently than those of their male counterparts, and projects that might not be financially viable are funded. For example, the Mpongwe Women's Bank, managed by Credit Management Services Limited in Zambia, does not undertake a detailed loan appraisal process but rather relies on the assessments and character references provided by the women's clubs of which the applicants are members. Many of the projects fail because they have not been built on sound economic principles, leaving the women worse off than they might have been if the projects had never existed because they have to repay loans from other sources. The failure erodes confidence in women as business entrepreneurs, both among women themselves and among the conventional financial institutions. Although it may be important to make concessions for women, these should be done in a manner that makes business sense and in which women are integrated into the normal business world through addressing their weaknesses such as business management skills and seeking good market outlets. So long as women are operating enterprises within the conventional environment, provision of kick-starting financial support is only a small part of the equation for a successful business.

Another particularly important aspect of the loans is their size. Most credit programs established to serve women provide only small loans that are typically insufficient to generate a sustained process of capitalization. Credit Management Services gives maximum loans of U.S. $250 per applicant. In 1999, the average loan size (with share of women loan clients in the MFI in parentheses) from Get Ahead (92%) in South Africa was U.S. $192, from Citi Savings and Loans (71%) in Ghana was U.S. $363, from ACEP (30%) in Senegal was U.S. $526, from K-rep (58%) in Kenya was U.S. $878, from EBA (12%) in Egypt was U.S. $841, and from CERUDEB (27%) in Uganda was U.S. $1110. Most of the credit schemes rely on donor funding in a manner that reflects the original approach during the 1970s, when donors and NGOs provided special assistance to women in a primarily welfare-oriented approach. As such, these agencies are also quite unsustainable. Although there is a rationale for providing small loans to the poor, because they are high risk, there is the greater danger of entrapping them in this state. In addition, this largely limits the choice of enterprises to just a few.

The typical enterprises in which women invest are food processing, sewing, basket weaving, and so on, with little diversification across loan beneficiaries in a given area. As a result, competition is stiff, particularly because most of the entrepreneurs lack access to external markets. Cecelski, in a 2000 report, advocated increasing access for credits to women to purchase renewable energy technologies for domestic use and microenterprises. However, as noted earlier, most of the focus has been on solar home systems that provide limited service and are basically consumer goods that do not, by themselves, offer opportunities for income generation.

Overall, in most cases, access to credit for energy has not particularly improved women's poverty status in any significant way. The microcredit, small player perspective seems to have been picked up by the New Partnership for Africa's Development, which identified improving access to credit by small-scale and women farmers as a strategy for promoting women. Although the idea of extending credit to women is commendable, this should be done as part of an integrated approach if the goal is to yield sufficiently sustainable benefits and to allow households to graduate from poverty.

13. CONCLUSIONS: AREAS FOR FURTHER RESEARCH

A review of the literature reveals gaps that exist in the women and energy discourse. As a conclusion to this article, questions for further research are posed. It is expected that such research would contribute to identification and implementation of effective activities that result in sustainable development.

Although women and children in rural areas have been largely dominant in fuelwood procurement for household needs, it seems imperative to question the role of settlement pattern (rural vs urban). In the past, more men than women migrated to the cities; hence, the share of women in rural areas has been rather high. This migration is generally triggered by lack of income-generating activities in rural areas. However, it has had an impact on the division of labor. Hence, there seems to be a need to determine whether women in rural areas suffer energy poverty because they are women or due to the locality. Is access to modern energy not determined more by density of demand than by gender or sex?

Poor households in rural and urban areas tend to consume relatively low quantities of energy. Would provision of modern energy services within close proximity to poor households improve their energy and livelihood status? Would the women in such households cease to suffer from the drudgery associated with energy procurement? Or, is this feasible only when the energy is provided as a service facilitating income generation?

So far, the women and energy discourse has focused mainly on the household sector. Even when the debate moved into income generation, there has been a tendency to place it in the household context on the basis that women's income-generating activities are mainly household based. But to what extent are the referred activities women oriented? Would provision of energy result in income generation for women? There is evidence that there are more societal benefits accruing from providing energy in the public sphere than from providing energy in private entities. Would public benefits emanating from modern energy provision in health care centers, schools, and growth points not be more effective in facilitating growth than those emanating from women-targeted energy projects? Should this approach not be the main focus, particularly in rural and low-income urban settlements?

Having women as decision makers in the household and at the policy level is recommended as a strategy to improve women's energy status. But has this been verified empirically? Can it be verified? Cultural factors limit understanding of the decision-making processes in households. In most cases, outsiders tend to identify who the decision makers are on the basis of the preconceived expectations of the outcomes. There is insufficient information on whether women decision makers necessarily make decisions that are more favorable to women. Even if this turns out to be the case, would it be socially desirable?

Many developing countries are experiencing energy reform where the private sector is expected to play a dominant role in energy service provision. Consequently, a market approach where the focus is profit will be adopted. In such an environment, would women-targeted energy projects be viable and effective in alleviating poverty?

Acknowledgments

I am extremely grateful to Margaret Skustch for her concise guidance on the article. I also thank Sami Kamel, Ogunlade Davidson, and Lawrence Agbemabiese for their critical comments and encouragement to publish. I appreciate the support provided by John Christensen that enabled me to have the space and time to develop and document the ideas contained in the article. Lastly, I cannot forget to thank Tim James for language editing.

Glossary

Bronze Age A period between the Stone and Iron Ages characterized by the manufacture and use of bronze tools and weapons. This smelting required huge volumes of wood.

Mycenaean Age in Greece (**600–1100** BC) A period of high cultural achievement, forming the backdrop and basis for subsequent myths of the heroes. It was named for the kingdom of Mycenae and the archaeological site where fabulous works in gold were unearthed. The Mycenaean Age was cut short by widespread destruction ushering in the Greek Dark Age.

smelting To melt or fuse a metal-bearing ore for the purpose of separating and refining the metal.

Wood was the primary fuel for the entire world from the discovery of fire to the age of fossil fuels. It remains the primary fuel to this day for those living in much of the developing world.

1. THE IMPORTANCE OF WOOD IN HUMAN EVOLUTION

It may seem bold to assert wood's crucial place in human evolution. However, consider that trees have provided the material to make fire, the key to humanity's domination over all other animals. It allowed *Homo erectus*, from which *Homo sapiens* evolved, to migrate from their warm niche in equatorial Africa to lands throughout the Old World, where heat from fire made these colder climates habitable. Increasing the range of habitat gave humanity better odds for survival. Light from wood fires permitted *H. erectus* to work after nightfall. Hence, the discovery freed humanity from the strictures of the diurnal cycle. Wood fires also enhanced humanity's access to food. With torches, *H. erectus* hunted at night. This gave them the element of surprise in killing diurnal animals and added nocturnal animals to their diet. Fire also widened the types of available food, freeing them from the constraints of the hunt. Vegetable matter such as tubers, when cooked over fire, became eatable. A diet based on local plants promoted population stability because humans no longer had to follow migrating herds to eat. A wider choice of food also enhanced survival and proliferation (Fig. 1). Fire also provided humans with greater security. They could safely live indoors out of harms way because they had the means of illumination. Lighting also warded off nocturnal predators. It lessened the chance of stepping on venomous snakes or tripping over rocks by improving vision at night. Wood fires changed not only the social evolution of humanity but also its physical development. Eating food softened by cooking led to smaller molars. Although many animals, such as chimpanzees and otters, have used tools as aids, no other animal except the human genus beginning with *H. erectus* has ever built fires.

2. THE IMPORTANCE OF WOOD IN THE DEVELOPMENT OF CIVILIZATION

Only by cooking grains over wood-fueled fires do grains become edible, thus enabling the agricultural revolution of the past 10,000 years (Figs 2 and 3). In charcoal-fueled kilns, potters turned earth into

durable ceramics in which goods could be stored and shipped. Providing an efficient means of storage stimulated trade on land and sea. Charcoal-fueled fires also gave humanity the capability to extract metal from ore, resulting in tools and weaponry so revolutionary that historians categorize society's evolution according to the dominant metal in use at the time. Wood fuel, in fact, is the unsung hero of the technological developments that brought us from a bone and stone culture to the industrial revolution.

3. THE IMPORTANCE OF WOOD APPRECIATED BY OUR ANTECEDENTS

Lucretius, probably the most scientifically oriented thinker of Antiquity, believed that the discovery of fire made civilization possible. He conjectured that the technique of metallurgy was born when great fires "devoured the high forests and thoroughly heated the earth," melting metal embedded in rock. When people saw the hardened metal, "the thought then came to them," according to Lucretius, "that these pieces could be made liquid by heat and cast into the form and shape of anything, and then by hammering, could be drawn into the form of blades as sharp and thin as one pleased, so they might equip themselves with tools." Lucretius remarked that tools, in turn, made forestry and carpentry possible, enabling humans "to cut forests, hew timber, smooth, and even fashion it with auger, chisel, and

gouge." By this process, in Lucretius' opinion, civilization emerged.

Ibn Khaldun, writing in the 14th century AD, discussed the crucial role that wood fuel played in the world of Islam. In "The Muqaddimah," his major work, he noted that "God made all created things useful for man so as to supply his necessities and needs. Trees belong among these things. They give humanity its fuel to make fires, which it needs to survive."

The English of the 16th and 17th centuries also recognized the crucial role of wood fuel in their lives. Gabriel Plattes, writing in 1639, observed that all tools and instruments are made of wood and iron. Upon weighing the relative importance of the two materials, he chose wood over iron because without wood for fuel "no iron can be provided."

4. EXAMPLES OF WOOD USED FOR FUEL OVER THE MILLENNIUM

4.1 Bronze Age Greece and Cyprus

Mycenaean Greece attained an unprecedented level of material growth during the late Bronze Age. However, it did not have much copper to make sufficient quantities of bronze, the essential metal of the time. To sustain the booming economy of the Mycenaean states, abundant and reliable sources of copper had to be found. Fortunately, there was one area close by, Cyprus, that had lots of copper ore and plenty of wood with which to smelt and refine it. In response to this need, the Cypriots smelted as much copper ore as they possibly could for the overseas market. However, the growing demand put a great burden on the island's woods because charcoal was the fuel for smelting and refining copper. One hundred and twenty pine trees were required to prepare 6 tons of charcoal needed to produce 1 ingot of copper, deforesting approximately 4 acres. Underwater archaeologists found on board a Bronze Age shipwreck 200 ingots of copper that had been mined and smelted in Cyprus. The production of just this shipload cost the island approximately 24,000 pine trees. The lively commerce in ingots during the 14th and 13th centuries BC surely consisted of many such shipments and the concomitant deforestation of a large expanse of woodlands. The industry's consumption of wood deforested approximately 4 or 5 square miles of woods per year. Another 4 or 5 square miles of forest was cut to supply fuel for heating and cooking and for other industries, such as pottery works and lime kilns. The cumulative effect of deforestation on such a scale must have been felt quite soon on an island of only 3600 square miles.

Cutting trees for fuel apparently made significant changes in the flora of Cyprus during the late Bronze Age. Bronze axes found dating to this period suggest that logging was an important occupation. Those wielding the axes cleared the majority of forest along the coast and hillsides near the larger late Bronze Age sites in Cyprus. As a result, pigs, which thrive in a moist, woody habitat, could no longer survive, giving way to sheep and goat tending, which flourish in a relatively barren environment.

With the forest cover gone, natural calamities struck. Silting of major harbors and an increase in flooding and mudslides in urban areas ensued. The Tremithos River, for example, transported tons of soil from the deforested hills below the Troodos Massif and deposited them into the Mediterranean. Currents moved these deposits of sediment toward the important late Bronze Age town of Hala Sultan Tekke. So much alluvium accumulated near the mouth of its harbor that during the 12th century BC. Hala Sultan Tekke was sealed off from the sea and could no longer function as a port.

Similarly, excessive amounts of alluvium carried by the Pedieos River, which flowed through Enkomi, a major Bronze Age city that faced the Near East, formed a delta as it drained into the ocean, changing Enkomi from a coastal to inland city. The number and severity of floods and mudslides also increased as a consequence of deforestation, periodically transforming the streets of the city into raging torrents full of mud and other debris.

With wood difficult to come by, interest heightened in the search for ways to stretch limited supplies, resulting in technological advances and recycling. The adoption of hydrometallurgy to prepare copper ore for smelting appears to be one of the strategies chosen by late Bronze Age Cypriot metalworkers to conserve fuel. The process required the exposure of mined ore to the elements so that the ambient moisture would leach impurities. The leached ore could be directly smelted, circumventing an initial roast and reducing the number of smelts needed to reduce the ore. Hence, the amount of fuel expended in this phase was decreased by one-third. In another move to save fuel, metallurgists collected old and broken tools in order to resmelt them. Recycling bronze became a major source of the metal during the period of wood depletion on Cyprus.

Despite such highly innovative ways to save energy, metallurgists could not sustain the high productivity

of the previous two centuries. Copper production peaked in approximately 1200 BC, and the last copper furnaces were shut down in 1050 BC. During the same time period, 90% of the island's settlements were abandoned and the population withered away, as did the economy and material culture.

The depressed state of the Cypriot copper industry apparently affected the entire eastern Mediterranean region. Bronze was in such short supply that the smiths throughout the area bought whatever pieces they could find, whether virgin ingots, ingots composed of recycled bronze, or scrap.

Often, smiths in southern Europe could obtain only minute quantities of bronze because of copper shortages. Such was the case in Greek Messenia in approximately 1200 BC. With so little bronze available, everyone suffered. Without metal hoes, plowshares, and scythes, farmers were far less productive. Without axes, adzes, and saws, few ships could be built for commerce or war. Without enough arrowheads, spearheads, and blades for swords, soldiers were no match for a well-armed foe.

Taking advantage of Messenia's vulnerability, a group of insurgents overpowered local forces and destroyed the palace at its capital, Pylos. After the catastrophe, the populace did not attempt to rebuild. Events at Messenia presaged trouble that other societies in the eastern Mediterranean would soon face. Just as bronze gave these civilizations the material to expand to heights never before attained, conversely, the lack of bronze played a major role in their demise.

In this sea of troubles, new hope for future generations arose. The fuel crisis that had caused copper production to decline served as the incentive for metallurgists to begin working with iron. Because Bronze Age Cypriots smelted copper ore that contained 10 times more iron than copper, metallurgists could obtain more useable iron than copper with the same investment of fuel. Hence, common sense dictated switching to iron smelting when fuel was at a premium. Furthermore, the refuse from Cypriot copper smelting contained significant amounts of iron. As long as there had been plenty of fuel, metallurgists smelted virgin ore and ignored the slag that had accumulated. When fuel became scarce and forced production cuts, metallurgists began to mine their industrial garbage. They discovered that the slag contained a great amount of iron, which could be removed simply by hammering. Taking iron out of the slag manually permitted metallurgists to bypass any processes requiring fuel and still obtain usable metal. The labor-intensive nature of working in this manner drastically reduced the overall output of metal on Cyprus and yielded relatively small amounts of iron. However, the success metallurgists had in working with iron at this early stage laid the foundation for the coming of the Iron Age in the Mediterranean as well as the rest of Europe.

4.2 Classical Greece

In classical Greece, the silver smelted at Laurion, southeast of Athens, near the sea, paid for the Athenian fleet that defeated the Persians at Salamis, turning the tide in the war against the Persians. Coins minted with Laurion's silver were accepted as the currency of the Greek world. With its treasury full of bullion, the Athenian economy could well afford to spend lavishly. Miners did not recover pure silver at Laurion but galena ore. Once mined, metallurgists had to heat the ore to very high temperatures to extract the silver. Charcoal was the fuel metallurgists at Laurion used in the smelting process and trees, or course, had to be cut down to produce this charcoal (Fig. 4). To extract the silver from ore at Laurion required the burning of more than 24 million pines or more than 52 million oaks. The largest outlays of fuel occurred during the two most active periods of mining, from 482 to 404 BC and from the second decade of the fourth century BC to its end. The surrounding areas could supply only a fraction of Laurion's fuel, forcing metallurgists to locate their furnaces on the coast so they could easily receive fuel imported from Thrace by ship.

4.3 Classical Rome

Rome financed its growth largely with silver extracted from Spanish ore. Production increased

FIGURE 4 Ancient Greek urn depicts a worker stoking a metallurgical furnace with charcoal. From Perlin Forestry Archives.

considerably during the end of the republic and the first years of the empire. However, this was accomplished only by great expense to the Iberian woodlands since silver smelting consumed more than 500 million trees during the 400 years of operation. Woodsmen had to deforest more than 7000 square miles to provide fuel for the furnaces. Near the end of the period of peak production, the need to sustain high output so strained the area's fuel supplies that it merited intervention by the Roman state. Under the reign of the emperor Vespasian, the Roman government directed all mining areas of southwestern Spain to prohibit the sale of burnable wood by those who ran bathhouses in the region (Fig. 5).

To produce enough silver to support the habits of a succession of rulers who spent as extravagantly as Caligula and Nero, a time had to come when the tree supply in Spain would dwindle and production in silver would decline accordingly. Conservation laws could only temporarily stave off wood shortages when silver was spent so wastefully. At approximately the end of the second century AD, the inevitable occurred: Silver production declined. Further output was limited not by the supply of ore, which remained abundant, but by the accessibility of fuel.

The decline in silver production offered later emperors two choices: cut expenditures or find alternative financing. They unanimously chose the latter but differed in methodology. The emperor Commodus "stretched" silver money by adding base metal, which comprised 30% of the coin. He also went on a killing spree, enraged that the empire's revenues could not meet his expenditures. When he finally calmed down, he decided to auction off whatever he could, offering provincial and administrative offices to the highest bidder.

Septimius Severus, who ruled a few years after Commodus, added 20% more alloy to the silver coinage, thus reducing the silver content to a mere 50%. Because Roman money was now so badly debased, Severus instituted the requisitioning of commodities rather than collecting worthless currency through taxation. Further debasements forced the government to search for creative ways of staying afloat. Most of the methods chosen circumscribed the freedom of Rome's citizens. Providing the government with the provisions it needed became compulsory. The government also established guilds, expecting them to produce according to obligations it set but rewarding members with monopolies in their respective trades.

FIGURE 5 Longshoremen loading a log destined to fuel the baths of Rome. From Perlin Forestry Archives.

By the end of the third century AD, Rome's currency had lost 98% of its silver content, and the public placed as little value on it as did the government. People increasingly took to trading in commodities and services so that by the first part of the fourth century AD barter had become institutionalized.

To keep those in Rome from becoming too anxious over the declining economy, the rulers of Rome had to constantly find ways to keep the population placated. The later emperors were well aware of the Romans' love of bathing and added many new baths to the city, eventually bringing the total to more than 900. The largest held as many as 2000 bathers at a time. Bathwater had to be hot if the Romans were to remain happy. Because keeping the Roman populace satisfied was paramount in the minds of those in power, the authorities were willing to go to great lengths to ensure a constant flow of fuel to the bathing establishments.

In the third century AD, the emperor Severus Alexander saw to it that entire woods were cut down to keep the baths in Rome well heated. When these forests gave out a century later, the authorities founded a guild with 60 ships at its disposal that was solely responsible for supplying the baths with wood. Sometimes, wood could be obtained as close to home as the Campania region. Usually, though, the guild had to make its wood runs primarily to the forests in North Africa. That Romans would travel such great distances for fuel indicates just how little wood was left in its vicinity and how dependent the Romans had become on foreign supplies.

Interestingly, the rise and decline of fuel supplies in Rome closely parallel the fortunes of the empire. The pioneering ecologist George Perkins Marsh demonstrated the fact by describing the changes in brick and masonry work in Rome over the centuries. Bricks in early buildings were extremely thin, well fired, and held together by liberally applied quantities of lime mortar. In contrast, as the imperial

period progressed, the opposite proved true: Bricks were very thick, usually poorly fired, and held together by a minimum of mortar. Marsh hypothesized that the difference was "due to the abundance and cheapness of fuel in early times, and its growing scarceness and dearness in later ages." He elaborated on his observation:

> *When wood cost little, constructors could afford to burn their brick thoroughly and burn and use a great quantity of lime. As the price of firewood advanced, they were able to consume less fuel in brick and lime kilns and the quality and quantity of brick and lime used in building were gradually reversed in proportion.*

4.4 England, 1500s–1700s

At the beginning of the 16th century, England depended on the Continent for its shot and artillery. However, Henry VIII's apostasy resulted in an arms embargo and a threat of invasion. Self-sufficiency seemed the only recourse. Henry therefore saw to the development of a local arms industry in Sussex, where rich veins of high-phosphorous iron were particularly advantageous for the casting of guns and where oak and beech would provide ample fuel for the gun founders. They did not smelt their iron in simple hearths but used blast furnaces and an accompanying forge. They chose the blast furnace and forge over the simpler hearths because the former could produce approximately 20 times more iron than the latter. The blast furnace and forge also consumed much more charcoal (Figures 6 and 7). By the late 1540s, the new English arms industry annually consumed approximately 117,000 cords of wood, causing great destruction of nearby woods. People living in the vicinity viewed these blast furnaces and forges as menacing since the wood they consumed was essential to the locals' survival, who used it to heat their homes, cook their meals, make their tools and fishing boats, and build and repair their houses. By the 1700s, the iron industry had deforested such a large area of southeast England that the iron masters had to ration the amount of iron ore they could smelt. To increase iron production required learning to smelt ore with coal without adding its impurities to the finished metal. By discovering how to make coal as close to charcoal as possible, the English freed themselves from the constraints of its dwindling forests and began the industrial revolution, an age that has qualitatively separated people living since the mid-19th century from those throughout the rest of history.

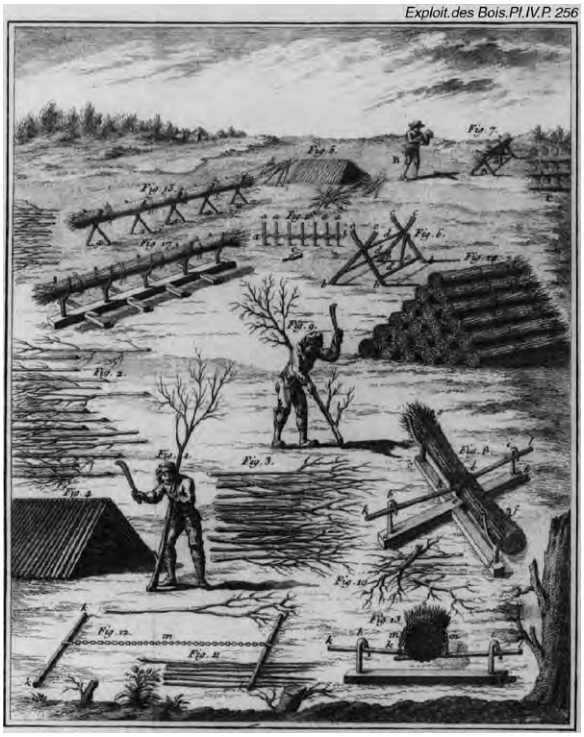

FIGURE 6 Wood cutters chop off tree limbs to be used as charcoal. From Perlin Forestry Archives.

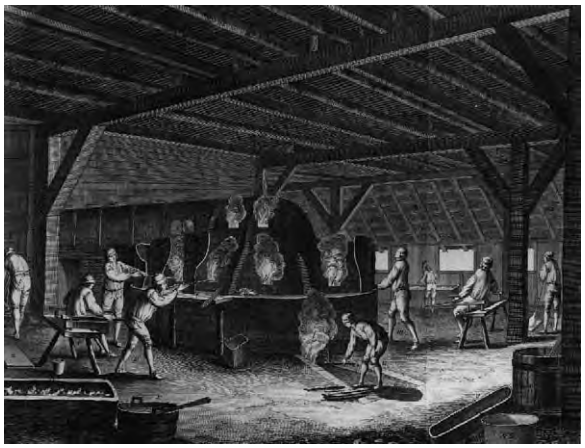

FIGURE 7 Charcoal fires also fueled English glassworks. From Perlin Forestry Archives.

4.5 Madeira, West Indies, and Brazil, 1400s–1600s

Sugar brought great wealth to those who raised the commodity. Hence, when the Portuguese landed on the warm, greatly forested, fertile, and well-watered island of Madeira, they immediately started to plant cane. Once the juice was forced out of the stalks, workers poured the extracted liquid into kettles.

A fire, rarely extinguished, burned underneath each pot. The wood from linden trees furnished much of the fuel. No doubt cedar was also used, being the most common wood on Madeira. Sugar workers aptly called the room in which the cane juice was boiled the "sweet inferno." The juice continued boiling until judged ready for removal to an area where it would solidify into sugar. By the end of the 15th century, the island's sugar industry required approximately 60,000 tons of wood just for boiling the cane. Four of the 16 mills operating on Madeira consumed 80,000 pack animal loads of wood per year.

Almost immediately after the discovery of the West Indies and South America, Europeans recognized that the land offered the same ideal conditions for growing and processing sugar as existed on Madeira. The Spanish planted sugarcane on Espanola soon after Columbus's first journey to the New World. As expected, the cane flourished, and by the end of the 16th century 40 sugar mills were operating on the island. It was no different in other parts of the Indies, and sugarcane proliferated and became the area's main source of revenue. Nor did the Portuguese, after their success on Madeira, wait long to establish sugar plantations after taking possession of Brazil. Near the end of the 16th century, a visitor reported 70 sugar mills at work in the Pernambuco region and 40 in the area of Bahia. Experts in sugar production in the New World estimated that six to eight slaves had to be constantly employed in cutting fuel in the forest and transporting it to the mills for optimum efficiency. Providing fuel for 1 mill stripped approximately 90 acres of forestland each year.

Such large-scale consumption of wood took its toll on the forests of the New World. Two hundred and forty years after the Portuguese had found Madeira so thickly wooded that they called it "isola de Madeira" (island of timber), it had become the island of wood in name only, so deforested that those passing it by ship could find absolutely no greenery in view. Likewise, the very thickly forested island of Espanola had become an open land. The pace of deforestation on Barbados exceeded that on Espanola and Madeira. In little more than 20 years, the representatives of the planters admitted to having used and destroyed all the timber formerly growing on the island.

4.6 American Colonies

America's great forests offered the pilgrims a higher standard of living than that of their peers in England since they had upon arrival more wood fuel with which to heat than did most noblemen in England. Families also used the enormous fireplace around which they huddled for lighting. The fireplace was so huge as to require logs of dimensions that could only be dragged into the house by a horse or oxen.

America's plethora of wood gave rise to a large and prosperous iron industry. Despite the fact that American woodcutters earned three times more than their counterparts in England and Americans who coaled the wood made approximately twice as much as those who did the same work in England, because a cord of wood cost 14 times more in England than in America, American ironmasters could manufacture pig iron in the Colonies and export it to England, underselling English iron.

Iron furnaces and forges first began operating in the backwoods of Virginia and Maryland and then spread to Pennsylvania and New Jersey. They not only produced iron for the English market but also produced cast iron goods for local use. The proliferation of home-produced iron goods frightened the English, whose mercantile economy was based on buying raw materials from the Colonies at bargain prices and selling back finished products at much higher prices. The English therefore passed a law in 1749 that encouraged the importation of pig iron from the American Colonies, because wood shortages had hindered England's iron production, while forbidding the Americans from developing forges to turn out finished iron products.

The act stirred already growing feelings for independence among many of the colonists. It hardly seemed fair or rational to Americans that they had to send to England the iron they produced in order to buy it back again as manufactured items, costing them almost twice as much compared to if they done the entire process at home. The intent of the act reminded many of the servile conditions forced upon the Children of Israel by the Philistines when the Jews were not allowed any smiths of their own. The prohibitory nature of the act aroused revolutionary rhetoric among the more radical Americans such as James Otis, credited by John Adams as the father of the idea of independence, and John Dickinson, who later authored revolutionary America's "Declaration of the Causes of Taking Up Arms." Both feared that prohibiting the manufacture of iron goods was the first step in stopping the construction of any machinery that would further develop the Colonies' economy.

Despite the anger the act aroused in America, it did increase American exports of pig iron to

England. By 1769, approximately half of the pig iron worked in English forges came from America. By 1776, as much iron was produced in the Colonies as in Britain. Even more encouraging to those favoring revolution, and frightening to those wishing to hold onto the American Colonies, was the fact that not only did America's innumerable iron mines and endless forests give it the very sinews of power but also a certain type of iron produced in America, called best principio, was judged as good as any in the world for making shot and cannon.

4.7 America after Independence

Alexander Hamilton, probably the greatest advocate of industrialization during the early republic, predicted that America was very fortunate to have vast supplies of iron ore and wood with which to make charcoal. Trench Coxe, a colleague of Thomas Jefferson and James Madison, predicted that America's rich store of wood fuel would provide invaluable to the rise of industry and turn America into the most powerful country in the world.

Breweries, distilleries, salt and potash works, and casting and steel furnaces all needed heat to produce finished products. Francois Michaux, a French botanist who studied America's trees at the beginning of the 18th century, found that the bakers and brick makers of New York, Philadelphia, and Baltimore commonly consumed prodigious quantities of pitch pine. Hatters of Pittsburgh, on the other hand, preferred charcoal made from white maple. Boats sailed along the Erie Canal picking up wood to fuel the nation's largest salt works, located in upstate New York. Boiling rooms, in which the salt water was evaporated over charcoal fires, produced 2 million bushels of salt per year. The salt went to Canada, Michigan, Chicago, and all points west. Farmers were the largest purchasers, using the salt for preserving meat that they marketed. Steam engines, which in the 1830s began to replace factories run on water power, usually burned wood as their fuel.

Americans could see the Hand of Providence at work in providing great amounts of wood and iron next to each other. Wood- and iron-rich western Pennsylvania, northern Michigan, and southeast Ohio became the principal producers of iron in 19th-century America. Throughout the nation, charcoal-burning iron mills produced 19 million tons of iron between 1830 and 1890. To truly appreciate the magnitude of the output of America's wood-fueled iron furnaces, comparison to the amount of iron produced during the heyday of the British charcoal-burning irons industry, which dated from the 1640s to the 1780s, is in order. In its most productive years, England's charcoal-run ironworks produced approximately 1 million tons of iron in 60 years.

The steamboat opened the old American west (lands east of the Mississippi River, north of the Ohio River, and west of the Allegheny Mountains) to settlement (Fig. 8). How else could farmers in places such as Ohio, Indiana, and Illinois expect to move their goods to distant markets except by navigation? Had farmers had to rely on land transport instead, they would have needed 5000 miles of good road, which did not exist at the time, and 250,000 wagons to transport the same amount of goods annually carried by steamboat. Steamboats were lauded by mid-19th-century pundits as the most important technological development to have occurred in the United States because they contributed more than any other single development to advance the prosperity of those living in the Mississippi and Ohio River basins.

Great quantities of wood were needed for fuel. The large steamboat Eclipse's 15 boilers consumed wood by the carload. Thousands of wood yards were located along the banks of every navigable river simply to provide steamers with fuel. Backwoodsmen brought the timber they had cut to these depots and hacked it into the proper size for the ships' furnaces. At night, the owners of these wood lots kept gigantic

FIGURE 8 Hauling timber to fuel steamboats. From Perlin Forestry Archives.

fires blazing so those onboard the boats could see the yards and fuel up.

Railroads liberated Americans from their dependence on waterways for shipping freight and personal travel. They slashed the cost of and the time required to travel. With plenty of timber growing along the right-of-way of most railroads, or at least close by, locomotives used wood as their only fuel from when the first tracks were laid in 1830 to the beginning of the Civil War. Fuel needs of engines owned by the New York Central Line required the railroad to build 115 woodsheds along its track. If the woodsheds were stacked side by side, they would have stretched approximately 5 miles. A wood yard for trains at Columbus, Nebraska, was half a mile long.

Between 1810 and 1867, approximately 5 billion cords of wood was consumed for fuel in fireplaces, industrial furnaces, steamboats, and for railroads. To obtain such a quantity of wood meant the destruction of approximately 200,000 square miles of forest land, an area nearly equal to all the land that comprises the states of Illinois, Michigan, Ohio, and Wisconsin.

4.8 Use of Wood for Fuel, the Present

Today, half of the wood cut throughout the world is used for fuel. Eighty percent of all wood used for fuel is consumed in the developing world. In fact, the majority of people in the developing world depend on wood as their primary energy source. Charcoal and firewood in the Cameroons, for example, account for 80% of all energy consumption. The demand for firewood and charcoal is also increasing as the population increases. In Africa, the amount of wood consumed for energy purposes increased from 250 million m^3 in 1970 to 502 million m^3 in 1994. In Latin America, the vast majority of the rural population uses wood as its primary fuel. The true danger to the forests of the developing world is that growing numbers of people exploit local forests, threatening their viability and forcing people to travel greater distances for wood fuel. One person can ably supply himself with firewood from 0.5 ha of forestland; today, however, usually approximately 15 people try to supply themselves with firewood from 1 ha of woods. Such overexploitation will surely cause local supplies to quickly diminish, forcing people to seek wood in more distant forests. Demand for wood and charcoal in growing urban areas of the developing world has introduced a new and growing problem—the industrialization of acquiring firewood and charcoal. Instead of individuals fanning neighboring woods to cut down trees for fuel, well-capitalized charcoal dealers search throughout the countryside for supplies. Bangkok's 5 million citizens obtain a large amount of their charcoal in this manner from forests throughout Thailand. There is no question that as the population in the developing world grows, so too will the demand for firewood and charcoal and deforestation will continue to accelerate.

1. Introduction
2. Wood Burning at the Household Level
3. Alternatives to Wood Burning and Possible Future Directions for Households in Less Developed Countries

Glossary

biomass energy Energy derived from any nonfossil organic fuel; sources of biomass energy include wood and wood by-products (e.g., charcoal) as well as nonwoody materials (e.g., crop residues, human or animal waste).
charcoal A wood product that is made by heating wood in the absence of sufficient air for full combustion to occur; heating releases the wood's volatile compounds, leaving behind a lightweight and cleaner burning fuel that is 70 to 90% carbon.
cooking stove Any device used for cooking food; a cooking stove can range from an open wood-burning fire to a gas burner.
heating value The energy that is released by ideal combustion per unit mass of fuel; for any fuel, heating value can be reported in two quantities: higher or lower heating value.
liquefied petroleum gas (LPG) A gaseous mix of light petroleum distillates (primarily butane and propane) that is liquefied at high pressure; it is a high heating value fuel used for cooking.

Roughly 40% of the world's population, highly concentrated in less developed countries, use woodfuels as their principle source of household energy. This prevalence of woodfuel consumption is associated with a number of socioeconomic and environmental issues that relate to poverty and gender, land use change and deforestation, indoor air pollution and public health, as well as climate change and greenhouse gas emissions. These factors have been the impetus for a wide range of interventions into the way that people in less developed countries meet their energy needs. This article discusses these issues and the interventions that have been attempted over the past two decades.

1. INTRODUCTION

1.1 Wood as a Source of Household Energy

Since the beginning of human history, people have relied on wood to provide energy for subsistence. As people mastered wood burning, it became a valuable tool for industrial uses as well as basic household needs. Centuries of technical progress have seen many different fuels brought into use that are preferable to wood for a number of reasons. However, widespread changes in the industrial sector have not been mirrored in the residential sector. Between one-third and one-half of the world's population continues to use wood and other biomass fuels to meet their energy needs. The use of wood as a household fuel is overwhelmingly concentrated in less developed countries where, for a number of reasons that are explored in this article, alternative fuels such as natural gas, kerosene, liquefied petroleum gas (LPG), and electricity have not been widely adopted.

The implications of such widespread wood consumption extend across a range of social and environmental issues. Household woodfuel consumption is associated with social and environmental problems, including health problems associated with indoor air pollution (IAP) and environmental change associated with both greenhouse gas (GHG) emissions and the depletion of local forests and woodlands. In addition, woodfuel use creates high labor demands and potentially hazardous conditions for household members. However, it is important to recognize that a direct causal link between woodfuel consumption and any one of these problems does not always exist. These problems rarely arise as a result of wood consumption alone; rather, they are the

 © 2004 Elsevier Inc. All rights reserved.

result of complex relationships among wood consumers, the environment in which they live, and the larger political economy. Therefore, understanding the problems associated with household woodfuel consumption is possible only by considering the social, political–economic, and environmental contexts in which they arise.

The aim of this chapter is to examine the use of wood as a source of household energy, focusing on the less developed countries where it is most prevalent. The article discusses some of the larger socioeconomic and environmental issues to which household energy is linked and explains why wood remains one of the most common household fuels for so many people. It closes with an examination of some possible improvements and alternatives to common wood-burning practices that can help to mitigate some of the negative impacts associated with woodfuel consumption.

1.2 The Household Energy Sector and Household Fuel Choice

Household energy use consists of energy used for space heating, water heating, and cooking. In locations where electricity is available, households also use energy for running a number of household appliances for washing, preserving food, and entertaining the family. In some countries, households also use energy for productive activities, including brewing beer, firing bricks, and cooking or drying food for commercial sale. These activities are not usually part of the formal economy, and the energy consumed is often unaccounted for in national energy balances, but such activities constitute a significant fraction of energy consumption within communities where they are practiced.

Globally, the demand for residential energy depends on many factors, including climate, locality, the level of wealth of the household, and the availability of resources. The fuels and the technology used to convert the fuels' energy for use in the household are equally variable. Even in less developed countries where the majority of households rely on wood or other biomass fuels, the variety and performance of cooking stoves are surprisingly diverse.

Typically, fuels for household use are divided into modern fuels and traditional fuels. The former category includes refined liquid and gaseous fuels such as natural gas, LPG, and kerosene as well as electricity. The latter category includes solid fuels such as coal and biomass. Modern and traditional fuels are often characterized as commercial and noncommercial, respectively. Although this distinction is

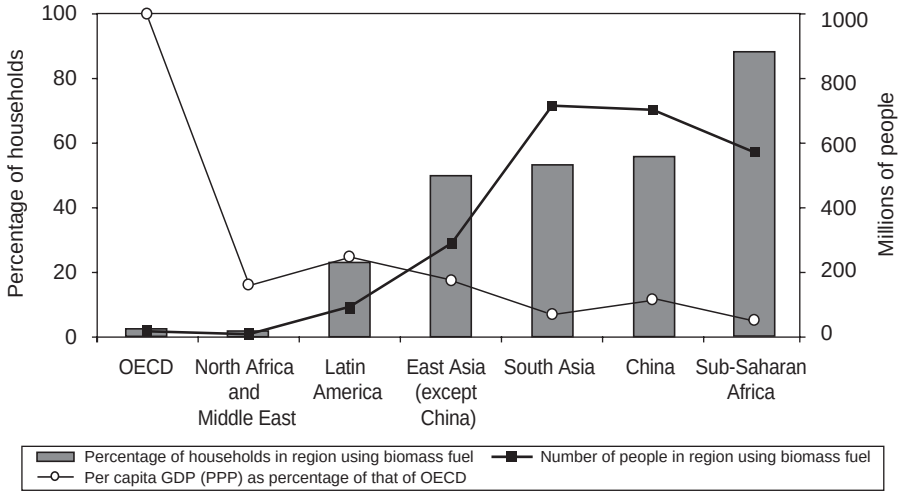

FIGURE 1 Biomass fuel users by world region: 2000. The figure shows estimations of the numbers and fractions of households cooking or heating with biomass fuels by world region. The fraction of households in each region is indicated by vertical bars and measured on the left vertical axis. The number of people using solid fuels in each region is indicated by the dark line with squares and is measured on the right vertical axis. The lighter line with circles indicates the per capita gross domestic product (GDP) adjusted for purchasing power parity (PPP) for each region relative to the OECD's per capita GDP, also measured on the left vertical axis. All data except OECD data are from the International Energy Agency. OECD data are from a database developed by Lawrence Berkeley National Laboratory in 1999 and are used with permission. This graph is based on data compiled by the author in collaboration with Prof. Kirk Smith and Sumi Mehta of the University of California's School of Public Health originally for their assessment of the impact of solid fuel consumption on the Global Burden of Disease.

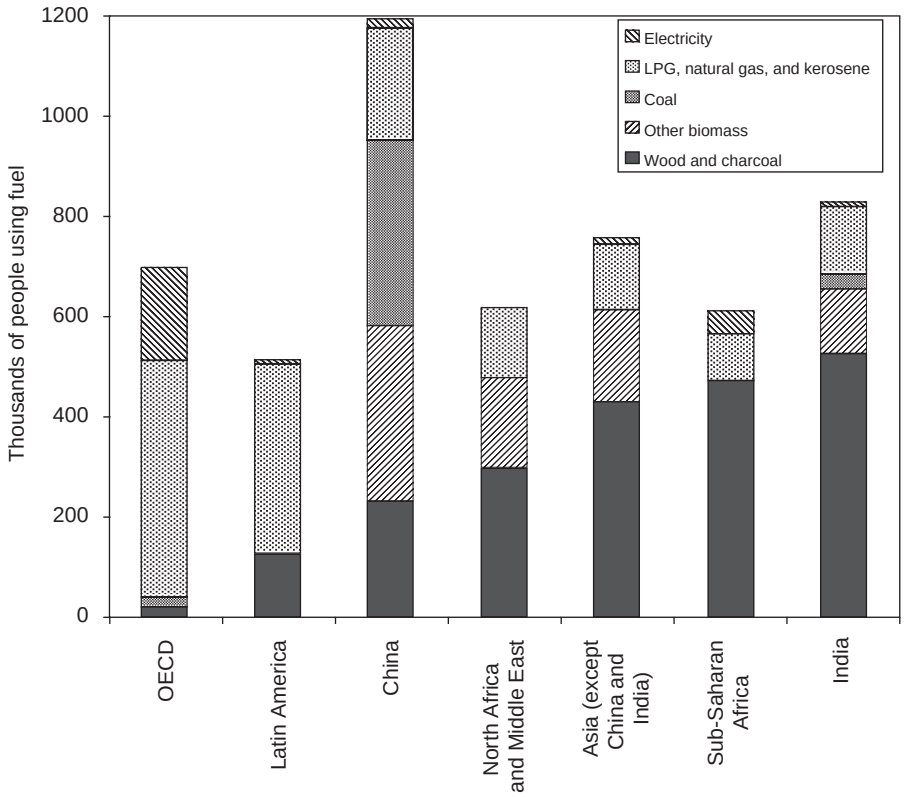

FIGURE 2 World household fuel choice by region: 1990–2000. The mix of fuels used by households in various regions of the world is based on a wide range of census and survey data compiled throughout the 1990s regarding households' primary cooking fuel. In reality, many households use multiple fuels, but this is difficult to account for at the national or regional level. Note the "other biomass" includes crop residues and dung.

occasionally useful, it can also be misleading because it implies that markets do not exist for solid fuels. On the contrary, there are often well-developed markets for different types of traditional fuels, and some (e.g., charcoal) are traded internationally.

One factor that correlates well with residential energy demand and fuel choice is the degree of industrialization in the country. Households in highly industrialized countries rely primarily on commercial liquid and gaseous fuels or electricity for their residential energy needs, with a few regional pockets where solid fuels—primarily wood and coal—are used. In contrast, households in less industrialized countries tend to use much higher fractions of solid fuels. Figure 1 shows a recent estimate of the number of biomass fuel users in the world from the International Energy Agency (IEA). The graph also shows regional gross domestic product (GDP) per capita adjusted for purchasing power parity (PPP) and indexed to the Organization for Economic Cooperation and Development (where OECD = 100%). South Asia (India, Pakistan, and Bangladesh) has the highest number of users, whereas Sub-Saharan Africa has the highest rate of use.

Within a country or region, there are many additional factors that contribute to household fuel choice. These include access to fuels and residential energy technologies, rural–urban settlement patterns and development policies, household income and gender dynamics of household decision making, and important sociocultural preferences affecting household behavior and cooking practices. Figure 2 shows the range of household fuel choices in various regions of the world.

2. WOOD BURNING AT THE HOUSEHOLD LEVEL

Household energy demand includes energy for cooking, water heating, and space heating as well as for some productive end uses. In developing countries, the primary end use is often cooking, although other applications are also important. People who rely solely on wood or other solid fuels often use the same technology to cook, heat water, and (in colder regions) heat their homes, in contrast

to industrialized countries where most people have access to a range of specialized energy conversion technologies. Because the stove is the most common wood-burning tool, this section focuses primarily on cooking stoves and cooking activities with the understanding that the stove is often used for noncooking tasks.

2.1 Wood-Burning Technologies for Household Use

One of the oldest methods of cooking with wood, the "three-stone fire," is still the most prevalent cooking technology in the world. The three-stone fire consists of a pot supported a short distance above the ground by three stones. Figure 3 shows an example of a three-stone fire from Kenya. This stove is indoors, although cooking may also be done outside, depending on local practices. The three-stone fire is favored by many people because it is free and requires no special equipment to build. It accommodates a range of pot shapes and sizes, and it provides heat, light, and a measure of security for the household. However, it also produces smoke as a result of incomplete combustion. This leads to very high concentrations of IAP that have serious consequences for the health of household members (discussed in more detail later).

Although the basic three-stone fire is very common, it is also modified in countless ways throughout the world. Common modifications to the basic three-stone fire include sinking the combustion zone below ground level and constructing a barrier around it to shield the fire from drafts. Figure 4 shows a stove from Bangladesh with the combustion zone sunk below the ground, and Fig. 5 shows a makeshift

FIGURE 3 Three-stone fire from Kenya. Photo by Majid Ezzati.

FIGURE 4 A variation of the three-stone fire from Bangladesh showing the fire sunk beneath ground level. Originally appeared in Stove Images (photo by IFRD/BCSIR, Dhaka, Bangladesh), reproduced with permission of the author and publisher.

FIGURE 5 Variation of a three-stone fire from India with protection from outside drafts. Originally appeared in Stove Images (photo by Dorsi Germann), reproduced with permission of the author and publisher.

stove from India that has been shielded from the wind. Reducing drafts has the effect of reducing heat loss and, thus, directing more of the fuel's energy into the cooking pot.

More extreme adjustments to the open fire involve fully enclosing the combustion zone, as this allows for some degree of air control and directs the hot gases produced by combustion more toward the cooking pots and less toward the surrounding environment. Some stoves include a flue or chimney that directs the exhaust out of the room, whereas others vent their exhaust past the pot and out into the room where cooking is taking place. A well-functioning chimney can reduce the concentration of pollutants inside the household dramatically by directing smoke outdoors. It also creates a natural draft in the stove that can improve combustion, further reducing pollution. Figures 6 and 7 show examples of stoves with completely closed combustion chambers from India and Nepal, respectively. The Indian stove has no flue so that the combustion emissions are vented into the room, whereas the Nepalese stove has a flue (built into the wall at the rear of the stove) so that emissions are vented outside. Additional modifications include insulating parts of the stove to reduce heat losses and adding dampers or secondary air inlets to improve air flow and combustion characteristics. More complex designs even preheat incoming air to facilitate combustion. There are hundreds of stove models incorporating various combinations of these technical design principles. Moreover, there are many nontechnical factors that constrain stove design and adoption (discussed in more detail later).

2.2 Impacts of Household Fuelwood Use in Less Developed Countries

As discussed previously, there are a number of problems associated with household fuelwood use in less developed countries. Deforestation is a frequently cited example, but the links between woodfuel consumption and deforestation are, in most cases, quite weak. Other problems, although less visible, are more strongly associated with household energy demands. The remainder of this section discusses these issues in more detail.

2.2.1 Woodfuel Scarcity and Deforestation

Historically, the most frequently cited problem with household woodfuel consumption has been deforestation, which has reached crisis levels in many rural areas of less developed countries. Closer scrutiny has shown that other factors, primarily land clearing for cultivation, timber extraction, and woodfuel supply to urban markets, dominate the loss of tree cover in most of the regions that suffer from forest degradation.

FIGURE 6 Stove from India with closed combustion chamber and no chimney. Photo by Kirk Smith.

FIGURE 7 Stove from Nepal with closed combustion chamber and chimney to vent emissions outside. Originally appeared in Stove Images (photo by Dorsi Germann), reproduced with permission of the author and publisher.

Household fuelwood rarely comes from mature trees in forests or woodlands; people prefer gathering fallen branches and dead wood. People may also collect wood from their own household compounds or from fallow land. However, problems arise when access to woodlands is denied or when the woodlands are cleared *en masse* for timber extraction or cultivation. The latter is often accompanied by processing of the cleared wood into charcoal or firewood, but that is marketed for urban consumption; in either case, the cleared wood is inaccessible to local users. In addition, whether land is held in common or is privately owned, population and economic pressures can force people to shorten fallow periods or expand the areas they cultivate, reducing both the time and the space in which their homegrown wood accumulates. Hence, although it is unlikely that energy demand is the primary cause of fuelwood scarcity, scarcity still affects many rural communities and can have a significant impact on household welfare.

2.2.2 Rural–Urban Energy Issues in Less Developed Countries: The Energy Ladder, Fuel Substitution, and Charcoal

2.2.2.1 Rural–Urban Energy Issues Less developed countries are often marked by a clear distinction in the level of development between urban and rural areas. This distinction is visible in many socioeconomic arenas, including household energy. Urban households have a greater range of energy options, and most of their fuels are procured through market transactions. This is in contrast to rural households, where choices are limited but fuel is often gathered freely by household members.

In places where wood is a common rural fuel, charcoal is often popular in cities and towns. However, patterns of household fuel use in urban households depend not only on the supply of wood in the country but also on the degree to which other household fuels are available, and the latter itself depends on state policies created to develop and/or regulate fuel markets. In addition to charcoal, other fuels used in urban areas include coal, kerosene, LPG or natural gas, and electricity. Households in rural areas have fewer options because markets do not evolve where transportation is more expensive and household purchasing power is much lower.

2.2.2.2 The "Energy Ladder" Household fuels can be ranked by order of user preference in an "energy ladder," which is a simple conceptual model that has been developed to explain and predict relationships between household fuel choice and economic development. The concept of the energy ladder model is based on two premises: (1) that a ranking of fuels in order of user preferences correlates roughly to the ease of use, cleanliness, and energy efficiency of the fuel and (2) that users move up or down the ladder as household income rises or falls or, more broadly, as economic progress advances or recedes.

Problems with the energy ladder model arise from the simplified way in which the model is applied to policymaking, as this can lead to the mistaken conclusion that fuel choice is determined purely by economic factors. An increase in household income will not necessarily be spent on cooking stoves or fuel. A great deal depends on which household member controls expenditure decisions and how that person prioritizes expenditure in relation to other household needs. Moreover, cultural preferences may lead people to retain a particular fuel to cook certain foods or to use on special occasions so that complete fuel switching is quite rare. Finally, ease of access and consistent availability of fuels both are important factors that determine the extent and/or permanence of fuel switching in any household. Some of these dynamics are illustrated by an example from Kenya shown in Fig. 8.

2.2.2.3 Charcoal Charcoal is the principal woodfuel in urban areas of many less developed countries. There are a number of reasons why people in dense urban settlements favor charcoal over wood. It has a higher energy density, it burns cleaner (reducing exposure to harmful pollutants), and it is easier to transport, handle, and store. In addition, many people favor charcoal because it is considered a more modern fuel than wood and is a kind of status symbol.

Domestic charcoal use in less developed countries is possible only with a thriving charcoal industry. Charcoal production is most prevalent in Africa, although it is also common in several other countries such as Brazil, India, and Thailand. Table I shows the 10 largest charcoal-producing, -importing, and -exporting countries. Brazil is a bit of an anomaly; it produces as much charcoal as do the next five largest producers, but charcoal is used mainly in the iron industry and is not a major household fuel in that country. In contrast, in many African and Asian countries, charcoal is an important urban household fuel. In addition, a small amount of international trade occurs, as the table indicates.

Charcoal is often derided as wasteful and destructive to the environment because traditional charcoal

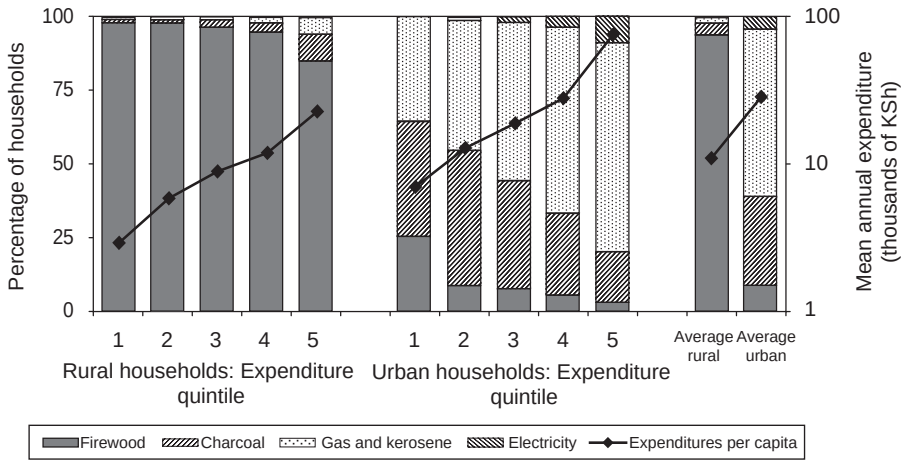

FIGURE 8 Fuel choice and household expenditure in rural and urban Kenya by expenditure quintiles: 1994. The figure shows per capita expenditure and primary cooking fuel for Kenyan households disaggregated by rural and urban areas and grouped by expenditure quintiles. The differences between rural and urban groups are more apparent than the differences between income groups within either area. The wealthiest 20% of rural households have higher mean annual expenditure than do 60% of all urban households. However, 85% of the wealthy rural households use wood as their primary cooking fuel. In contrast, 53% of households in the third urban quintile and 35% of the poorest urban quintile choose gas (LPG) or kerosene. This may indicate that fuel preferences are different between urban and rural households, or it may reveal that markets for alternative cooking fuels have failed to penetrate rural areas (the latter is more likely to be the case). From "World Bank African Development Indicators: 2000 Database" (citing a 1994 Welfare Monitoring Survey conducted by the Kenyan government in which more than 10,000 households were sampled).

TABLE I

Top 10 Charcoal Producers, Importers, and Exporters: 2000

Top charcoal producers	Tons	Percentage of world production	Top charcoal importers	Tons	Top charcoal exporters	Tons
1. Brazil	12,063,000	29	Japan	129,000	Indonesia	148,700
2. Nigeria	3,057,000	8	Germany	96,500	China	83,800
3. Ethiopia	2,907,000	7	South Korea	95,000	Malaysia	61,200
4. Kenya	2,475,000	6	China	70,538	South Africa	44,500
5. India	1,654,000	4	Italy	46,000	Argentina	44,000
6. Democratic Republic of the Congo	1,418,000	3	United Kingdom	45,000	Poland	40,000
7. Thailand	1,222,000	3	Norway	43,000	Mexico	38,100
8. Egypt	1,196,000	3	Saudi Arabia	37,200	Somalia	33,678
9. Tanzania	1,165,000	3	Singapore	28,000	The Philippines	30,000
10. Zambia	1,040,000	3	France	27,746	Nigeria	28,000
World total	40,615,004	100	World total	921,312	World total	851,314

Note. Charcoal data are from the UN Food and Agriculture Organization's (FAO) online statistical database (http://apps.fao.org/page/collections? subset = forestry) with the exception of Kenya. Data for Kenya are from a recent domestic survey. This survey, based on household consumption data, is nearly 300% higher than the numbers given for Kenya in the FAO's database. Many other discrepancies exist in national-level charcoal data from other countries. The FAO is currently undertaking an effort to identify and correct these errors.

production methods can be inefficient. In an earth-mound kiln, the most common method of making charcoal in Sub-Saharan Africa, between 5 and 10 tons of wood is needed to make 1 ton of charcoal—a mass-based conversion efficiency of 10 to 20%. In these circumstances, between 60 and 80% of the wood's

energy is lost in the production process. The process depends on a number of variables such as scale of production (production can range from <100 kilos up to 30 tons), moisture content and size of the wood, and time taken for the process (this also depends on the scale of production and can range from 2 to 10 days). Efficiency varies with the skill of the producers and the techniques they employ, which are likely to be a function of wood scarcity. Producers will adopt labor-intensive steps to conserve wood only if they perceive wood scarcity as a threat to their own livelihood.

More efficient methods of charcoal production using special kilns or retorts can reduce energy losses to between 30 and 40%. However, this equipment is expensive relative to traditional methods. It is not likely to be widely adopted without outside intervention, particularly in regions where wood is accessible for little or no financial cost. Nevertheless, the comparative efficiencies of charcoal and fuelwood should not be based solely on production. Cooking with charcoal can be more efficient than cooking with wood (typical efficiencies for charcoal stoves are 20–30%, whereas those for three-stone wood fires are usually 10–15%). If a person cooks a meal using a charcoal stove that is 30% efficient and the charcoal he or she uses was produced at 20% efficiency (based on wood-to-charcoal mass, this is high but has been observed in practice), that person uses less wood than does a person cooking the same meal with an open wood fire at 10% efficiency (a low but not uncommon efficiency). This simple comparison indicates that generalizations about the wastefulness of charcoal should be scrutinized carefully, particularly in light of charcoal's cleaner burn and other favorable attributes.

In addition to the question of energy efficiency, charcoal production is often considered environmentally destructive for two reasons: deforestation and pollution. The links between charcoal production and deforestation are stronger than the links between rural fuelwood consumption and deforestation because charcoal production involves cutting mature trees. However, rural land is often cleared for other purposes such as expanding cultivation, and charcoal is produced as a secondary activity following land clearing. In these situations, the cause of forest loss is not primarily charcoal because the land would have been cleared regardless of whether charcoal was produced, although charcoal can make the activity more lucrative. Furthermore, when land is cleared specifically for charcoal production and is not subsequently used for cultivation or grazing, trees can grow back. Permanent damage is limited to the area underneath the charcoal kiln, usually 2 to 3% of the cleared woodland. However, not all ecosystems are equally resilient. When trees are cleared from moist tropical forests, they might not recover as readily as do wooded savannah.

Although woodfuel demand in urban areas does not have a dominant influence in the overall loss of a nation's tree cover, it can have severe impacts on specific locations. This is especially true in nations with weak regulatory mechanisms governing the harvesting of forest resources, where outsiders can clear large tracts of woodlands on which rural communities rely without offering rank-and-file community members any compensation for their lost resources. Devolving control to local communities can ensure that they benefit from the exploitation of forest resources, although the benefit stream is very sensitive to the structure of institutions that usually does not favor local control.

The second environmental concern associated with charcoal is the emissions of GHGs (discussed in more detail later).

2.2.3 Energy, Poverty, and Gender

Recent analyses from the World Bank and other development institutions have introduced the concept of energy poverty to development discourse. Linking energy to poverty implies that a lack of access to clean and efficient energy services is one factor that contributes to persistent poverty in less developed countries. Energy services include not only electricity and clean cooking fuels but also the activities or end uses that fuels and electricity can provide (e.g., lighting, heating, motive power). Access to these services is strongly correlated to the level of development in a particular country or region. Figure 9 shows a plot of cross-sectional data from 125 countries in seven regions of the world indicating that well-being, as measured by the UN Development Program's Human Development Index (HDI), is well correlated to the degree of "modern" energy services consumed in each country. However, correlation should not be mistaken for causation. The relationship between poverty and lack of access to "modern" energy services is not a simple matter of cause and effect. High rates of poverty are not likely to be eased simply by providing clean cooking fuels or electricity without addressing the many structural factors that contribute to poverty. Furthermore, although the general trend shown by the linear fit is an interesting outcome of the figure, it is equally interesting to identify the outliers on the plot—those that lie well above or below the general trend—and

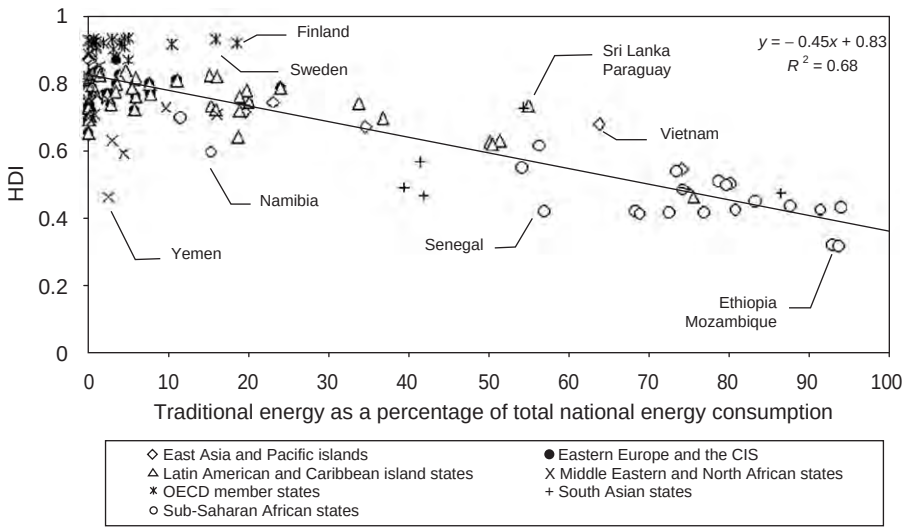

FIGURE 9 Human Development Index (HDI) and fraction of national energy consumption from biomass. HDI is plotted against biomass energy consumption for 125 countries. The countries are divided into seven regions, indicated by different symbols in the figure. HDI is a relative indicator of national development developed by the UN Development Program (UNDP). Biomass energy consumption is plotted as a percentage of each country's total energy consumption. This percentage is a reasonably accurate indicator of access to "modern" energy services, although there are exceptions. For example, in Finland and Sweden, households have 100% access to modern energy services, but industry and government both use biomass energy to a much larger extent than do similarly developed nations. Other countries that deviate from the main trend are also labeled in the figure. Data from UNDP, "Human Development Report, 2001" (www.undp.org); World Resources Institute, "Earth-Trends Database" (http://earthtrends.wri.org/index.cfm).

to question what sets those countries apart from the rest, for better or worse.

Of course, energy is a critical input for any productive activity, whether it is for household needs, commercial enterprise, or cottage industry. Without clean and efficient forms of energy, the possible range of productive activities are limited and even simple tasks are time-consuming and physically strenuous exercises. Increasing access to improved energy services will likely lead to improvements in the quality of life for many people; however, the critical questions arise as to how to provide those services and whom to target for increased access. Services that are given away for free or heavily subsidized are unlikely to be sustained in the long term as budget priorities shift over time and as donors' interests shift to new types of projects. Alternatively, services that are provided only through free market mechanisms are unlikely to reach the poor households that need them the most.

Figure 10 shows the effects of Kenya's largely unregulated household energy market. Household fuels are differentially affected by subsidies and other distortions with no clear policy goal; charcoal is effectively unregulated, kerosene is not directly subsidized but is exempt from most of the taxes levied on other petroleum products, and LPG is taxed significantly more than is kerosene. The figure shows a range of initial costs and annual operating costs for various cooking technologies accessible to consumers in Nairobi, a city of approximately 3 million people, many of whom live below the poverty line. The results are presented in ranges rather than point data to show that, realistically, consumers face a range of stove costs, lifetimes, and efficiencies as well as variable fuel costs. The fraction of urban Kenyans using each stove–fuel combination is shown in parentheses beneath the label on the x axis. The inputs used in the model are described in Table II. The interesting result of this estimate is that all stoves show significant overlap in their operating costs amortized over the lifetimes of the stoves, but they differ significantly in initial costs. There are few credit mechanisms to allow consumers to spread out the costs of the stoves over time, particularly for the poor. Thus, nearly half of the urban population still burns charcoal in unimproved stoves, the cheapest initial option, despite the likelihood that doing so is more expensive than using improved charcoal stoves, kerosene, or even LPG in the long term.

If free market provision of improved energy services is unlikely to reach the poor, subsidies are one alternative, but they need to be targeted properly

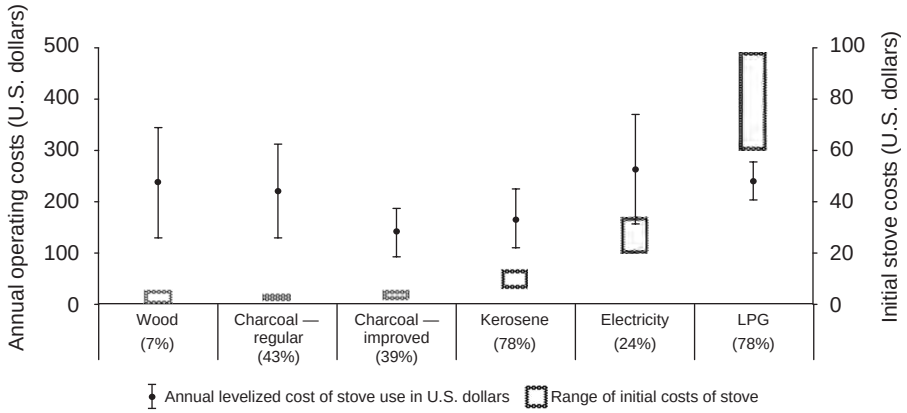

FIGURE 10 Operating costs for urban household stoves in Nairobi, Kenya. The figure shows an estimation of operating costs for commonly used stoves and fuels based on recent price data. Calculations are for an average-sized urban household (four people) assuming that the household uses one stove–fuel combination and consumes the useful energy equivalent of 1.3 GJ/year (the average urban household cooking energy consumption adjusted for stove efficiency reported in a recent Ministry of Energy survey). The vertical lines represent a range of operating costs based on several inputs (see Table II). The open bars represent a range of initial costs for the stove (also explained in Table II). The numbers in parentheses on the *x* axis are the percentages of urban households reporting use of the various types of stoves. (The LPG stove costs include the cost of a small [6-kg] gas tank and regulator.) These numbers add to greater than 100%, indicating that many households use more than one type of stove. This implies that the figure does not accurately model most Nairobi households, but it is still useful for comparing relative costs of household energy technologies.

TABLE II

Input Data for Annual Operating Costs of Typical Stove–Fuel Combinations in Nairobi, Kenya, Shown in Fig. 10

Stove type	Range of fuel costs per unit of sale	Energy content per unit of sale	Range of stove efficiencies (percentage)	Range of initial stove costs (KSh)	Stove lifetime (years)	Annual fuel consumption per household	Annual operating cost at 12% discount rate (U.S. dollars)
Charcoal (improved)	13–19 KSh/kg	28 MJ/kg	25–35	150–300	1–3	531–743 kg	128–342
Charcoal (regular)	13–19 KSh/kg	28 MJ/kg	15–25	100–200	2–4	743–1238 kg	128–310
Electricity	0.07–0.12 U.S. dollars/kWh	3.6 MJ/kWh	50–70	1500–2500	5–10	2063–2889 kWh	92–186
Kerosene	33–45.5 KSh/L	35 MJ/L	40–60	450–900	4–6	246–369 L	108–222
LPG	80–83 KSh/kg	48 MJ/kg	45–60	4600–7400	5–10	181–241 kg	156–369
Wood	6–8 KSh/kg	16 MJ/kg	10–20	0–300	1–3	1625–3250 kg	201–275

Notes. *Stove efficiencies*: Stove efficiency, defined as the fraction of the fuel's heating value that enters the food, is a compound measure of two interdependent quantities: combustion efficiency (CE) and heat transfer efficiency (HTE). CE indicates how much heat is released from the fuel relative to ideal combustion, whereas HTE indicates the fraction of the heat released by combustion that enters the food in the pot. Typical values for CE range from 80 to 90% for solid fuels and from 98 to 99% for liquid and gaseous fuels. Typically, values for HTE range from 50 to 60% for solid and liquid stoves and from 10 to 30% for solid fuels. Net efficiency is the product of the CE and HTE.
Fuel prices: Prices for charcoal, kerosene, and LPG were reported by Matthew Owen, an expert on Kenyan energy markets (personal communication with the author). Wood prices are from a Ministry of Energy survey. Electricity prices are based on the tariff structure currently used by Kenya's national power company. The tariff ranges from approximately U.S. $0.07/kWh for consumption of 50 kWh/month to U.S. $0.12/kWh for consumption of more than 2000 kWh/month. A household cooking purely with electricity would likely be at the higher end of this range, but the lower prices are included to reflect what the costs would be at the lower tariffs.
Stove prices: Prices are based on the author's observations reflecting a range of stove types. Kerosene stove prices reflect two sizes of wick stoves. LPG stoves are one- or two-burner stoves with a small (6-kg) tank and regulator (these retain their value and can be resold but are still unavoidable costs to the consumer). Electric stove prices reflect tabletop models with either one or two burners.

to have their desired effect. Subsidies are particularly important where current practices are associated with high external costs such as the severe impacts on public health associated with the use of wood and other biomass fuels. These impacts are borne disproportionately by women and young children as a result of their role in the household. The remainder of this section addresses the special role of women in the energy–poverty interaction.

As international attention was directed to the fuelwood question due to its perceived environmental effects, it became apparent that in many less developed countries the responsibility for the supply of household energy and the impacts of its consumption were largely, if not exclusively, the domain of women. Many early efforts to address fuelwood-related problems failed because they targeted men, who had little awareness of the work that their mothers, wives, and daughters were doing. This bias in project targeting is compounded by cultural norms that discourage women from interacting with outsiders and vocalizing their opinions within the community.

Importantly, although it is usually women's responsibility, household energy is not the only household task for which women are responsible. The division of labor varies across societies and cultures, but in most rural areas of less developed countries women are responsible for child care, cultivation of staple food crops, water collection, and looking after the elderly and sick. In many places, as men leave the home to seek wage labor, more and more women are also running small businesses or cultivating cash crops. Another near universal commonality among rural households is that women often have little say in household expenditure decisions.

Hence, energy-related impacts and responsibilities fall largely on women's shoulders, but they might not prioritize energy-related problems, even if they are fully cognizant of them, because their responsibilities are so far-reaching. These common factors make it particularly important to be sensitive to female voices in designing household energy policies and programs at all levels, from national legislation to community interventions. Importantly, sensitivity to female voices does not imply that men should be excluded from the process, only that special effort needs to be made to ensure that women's needs are addressed effectively.

2.2.4 Indoor Air Pollution and Health

Although the direct link between household energy and deforestation has been largely discredited, widespread fuelwood consumption does have another significant, albeit much less visible, global impact. Burning wood and other solid fuels within the household leads to very high concentrations of IAP. Exposure to these pollutants, which include carbon monoxide (CO), particulate matter (PM), and unburned hydrocarbons (HCs), can lead to a number of acute and chronic health impacts. The most prevalent of these impacts is acute respiratory infection (ARI), caused primarily by exposure to smoke or PM. ARI is one of the leading causes of death in children under 5 years of age worldwide; roughly 2 million deaths occur each year. In addition to ARI, exposure to IAP from solid fuel combustion causes chronic obstructive pulmonary disease and some types of cancer. Furthermore, exposure to solid fuel combustion emissions is associated with increased incidence of asthma, tuberculosis, and cataracts and elevated risk of CO poisoning. As a result of these health impacts, the World Health Organization estimates that exposure to IAP from solid fuels is the eighth leading cause of illness and death in the world. This impact is highly concentrated in poor developing countries, where IAP is the fourth leading cause of illness and death.

The effects of IAP are further concentrated within particular populations. As a result of the division of labor within the household, ARI and other health impacts associated with IAP are felt disproportionately by women and young children. Moreover, there are a number of health risks associated with fuelwood that are independent of exposure to combustion emissions. Prominent among these are burns (common among young children), risk of injury from gathering and transporting heavy loads of fuel over long distances, and exposure to possible harassment for girls and women gathering wood far from home.

2.2.5 Woodfuels and Greenhouse Gas Emissions

The same processes of incomplete combustion that cause the emissions of health-damaging pollutants also result in the emissions of GHGs. Wood and other forms of biomass are essentially HC fuels with a few trace elements. Perfect biomass combustion should produce only carbon dioxide (CO_2), water vapor, some trace gases, and ash. Water vapor produced by combustion is negligible compared with the natural stock of water in the atmosphere, and it has a short atmospheric residence time so that the impact of anthropogenic water vapor is negligible. CO_2 emissions from wood combustion add to the stock of GHGs in the atmosphere, but the effect of this additional CO_2 can be effectively "cancelled out" if the wood that is consumed is "replaced" by an equivalent stock of wood because photosynthesis

removes CO_2 from the atmosphere. Hence, wood-burning stoves can, in theory, be GHG neutral if two conditions are satisfied: (1) if wood undergoes complete combustion and (2) if an equivalent amount of wood is grown to replace the wood that was burned.

For household stoves burning solid fuels, the first condition (complete combustion) is never attained. The second condition (sustainable harvesting of fuel) is related to the question of deforestation. This condition may be satisfied, but in reality it is difficult to verify for a large number of people because woodfuel consumers obtain their fuel from many different sources and harvest trees for many different end uses. The remainder of this section explains the consequences of the failure to meet the first condition in more detail.

Small-scale household stoves cannot achieve complete combustion. (Even stoves that burn liquid and gaseous fuels do not reach that ideal, although they come closer than do most solid fuel stoves.) The physical design of these stoves is such that the fuel cannot vaporize and mix sufficiently with air at high temperatures, which are the conditions required for complete combustion. When fuels do not fully combust, pollutants such as CO, methane (CH_4), and nonmethane hydrocarbons (NMHCs) as well as PM are released. If nitrogen is present in the fuel or if temperatures are high enough to oxidize atmospheric nitrogen, combustion also creates nitrogenous compounds such as N_2O and NO_x. Fuelwood typically has less than 0.5% nitrogen, but bark, leaves, and other types of biomass consist of up to 1 or 2% nitrogen. Thus, small quantities of nitrogen compounds are present in wood combustion emissions.

GHGs trap heat in the atmosphere in a process called radiative forcing. The impact of GHGs on the earth's climate is a product of radiative forcing and the length of time it takes a portion of gas released into the atmosphere to be removed. From these two quantities, a global warming potential (GWP) is defined, indicating the time-dependent warming effect of a mass or volume of gas released relative to the effect of CO_2, the most prevalent anthropogenic GHG. Wood combustion releases GHGs that have large GWPs; thus, even if wood is used sustainably such that all of the CO_2 released during combustion is absorbed by future photosynthesis, wood burning has an impact on the climate.

Only CO_2, CH_4, and N_2O are subject to control by the UN Framework Convention on Climate Change (UNFCCC). However, CO, NMHCs, and PM can also have an effect, although their influence is less certain. Table III indicates the GWPs for biomass combustion emissions.

For each pollutant, emissions from wood and charcoal stoves can be described by an emission factor indicating the mass of pollutant released per

TABLE III

GWPs of Greenhouse Gases Commonly Emitted from Biomass Combustion on a Molar Basis

Compound	20-year GWP	100-year GWP	500-year GWP	Comment
CO_2	1	1	1	CO_2 GWP is 1 by definition for all time horizons.
CO	2.0–6.0	0.6–2.0	0.2–0.6	Range of values is reported by IPCC: lower values consider CO effect on OH radicals; higher values also consider ozone production.
CH_4	22.5	8.4	2.5	From IPCC's third assessment report.
NMHC[a]	12	4.1	2.3	From IPCC's 1990 report; subsequent reports do not offer values for NMHCs due to the high degree of uncertainty.
N_2O	275	296	156	N_2O was not measured in this study and is included here for comparison only.

Source. Adapted from Smith *et al.* (2000).

Note. GWP, global warming potential; IPCC, Intergovernmental Panel on Climate Change; PM, particulate matter. The time-dependent behavior of the GWP arises from the atmospheric lifetimes of the compounds and their decay products. There is no single GWP for PM, although estimations exist for the net effect of PM on radiative forcing. There are two types of PM from combustion, and each has a different effect on climate. Black carbon particles can contribute to climate warming, whereas organic carbon particles can contribute to cooling, but the level of scientific understanding of both effects remains low.

[a] The molecular weight of NMHCs is assumed to be 18 g/mol C. The molar GWP of NMHCs effectively counts moles of C, rather than moles of a mix of compounds that generally have more than one C atom per molecule. This facilities comparison with single-carbon compounds such as CO and CH_4.

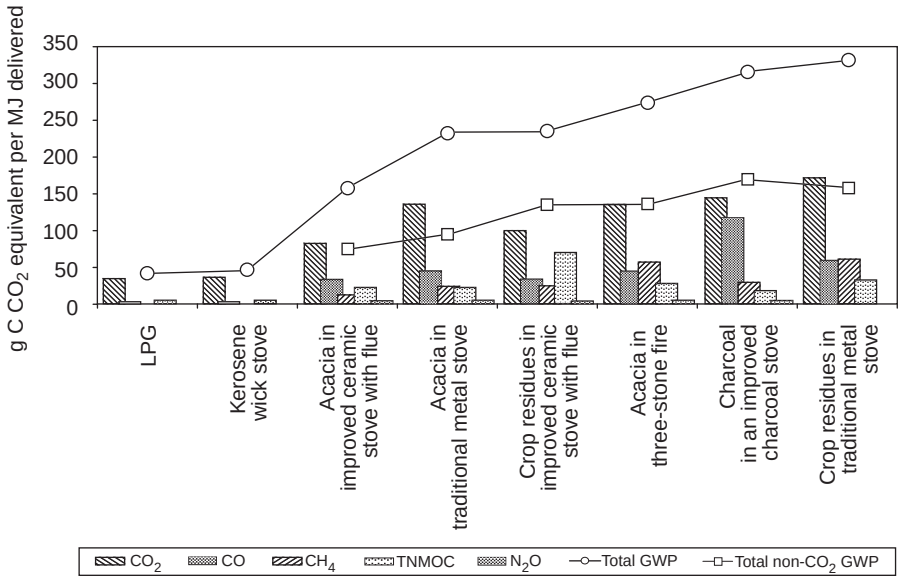

FIGURE 11 Emission factors of GHGs from common Indian household stoves and fuels weighted by 20-year GWPs. The emission factors were measured in a study of Indian cooking stoves using a variety of fuels and were calculated with respect to energy delivered to the cooking pot. The vertical bars indicate the emission factors for each individual pollutant. The lines indicate the sum of emission factors from each stove-fuel combination both with CO_2 (open circles) and without CO_2 (open squares). Including CO_2 in the total warming effect accounts for the impact of unsustainable harvesting, while omitting CO_2 from the calculation shows the net warming effect when the fuels are harvested sustainably so that stocks of trees or other biomass are allowed to regenerate (of course, this "sustainable" option is not possible for LPG or kerosene). Created by the author based on a selection of data from Smith *et al.* (2000). "Greenhouse Gases from Small-Scale Combustion Devices in Developing Countries Phase IIa: Household Stoves in India," EPA-600/R-00-052. U.S. Environmental Protection Agency, Washington, DC.

unit of fuel or energy consumed. Emission factors vary depending on the physical characteristics of the stove, the condition of the fuel, and the behavior of the stove user. Figure 11 compares the emission factors of some common Indian cooking stoves weighted by GWPs. The graph shows that as a result of poor combustion processes, biomass stoves result in higher GHG emissions than do fossil fuels, even when the biomass fuels are harvested sustainably so that CO_2 is not included. However, this result includes only end uses. A fair comparison of emissions from fossil fuel- and biomass-based cooking technologies must account for the emissions from production and transportation. Accounting for charcoal production effectively doubles the emission factors for charcoal shown in the figure, whereas "production" of fuelwood is essentially emissions free. A full life cycle analysis of GHG emissions from household fuels commonly used in developing countries has yet to be performed. But even with out a full comparison, the problems arising from poor combustion of wood and other biomass fuels should be apparent from the results illustrated in Fig. 11 as well as on the previous discussion on health impacts.

3. ALTERNATIVES TO WOOD BURNING AND POSSIBLE FUTURE DIRECTIONS FOR HOUSEHOLDS IN LESS DEVELOPED COUNTRIES

There have been many attempts to solve the problems associated with household woodfuel consumption, ranging in scope from national-level policies to community-based interventions. Across these scales, interventions fall into two general categories: increasing supply of woodfuel through silvicultural methods and decreasing consumption by promoting improved cooking stoves, promoting alternative fuels, and even prohibiting tree cutting and/or wood collection. Many projects try to address both approaches, but the methods required to increase supply are significantly different from those that seek to reduce consumption.

Both approaches can lead to many benefits for the communities involved, including decreased household labor requirements and lower energy expenditure as well as a range of environmental benefits associated with increased tree cover. In addition, there are significant health benefits associated with

reducing IAP by using more efficient stoves or alternative cooking fuels. Linkages among household energy, public health, and community development have become the focus of significant effort among researchers and policymakers since the mid-1980s.

However, improvement in one or all of these areas is not guaranteed simply by introducing an intervention. The extent of any changes in welfare that result will depend on many factors, some of which are not directly related to household energy. These factors include agricultural production, labor markets, local gender dynamics and power relations, and the community's past experiences with outside intervention that directly affects the feasibility of future projects. It is also important to recognize that changes in household energy technologies and consumption patterns can occur without any outside intervention. The remainder of this section explores some of the ways in which changes in woodfuel supply, demand, and cooking practices have been initiated or attempted in various parts the world and closes with a discussion of some possible directions that household energy provision in less developed countries may take in the future.

3.1 Supply-Side Interventions: State Forestry, Social Forestry, and Agroforestry

To outsiders, the immediate response to woodfuel scarcity is to plant trees. In some cases, this response coincides with local needs. Indeed, communities may have the desire to reforest their landscapes but may lack access to seeds or land on which to plant. However, planting and maintaining trees can be a time-consuming, labor-intensive process for local communities. People are unlikely to plant trees for fuelwood if there are alternative sources of fuel or if the land can be put to more lucrative uses. Tree planting as a response to wood scarcity is complicated by local property institutions that can be quite different from Western notions of private property. In many countries, the property rights in trees and their products are different from, as well as separable from, the property rights for the land on which the trees grow. In addition, in many postcolonial societies, there is a long history of land appropriations and forced evictions. Interventions initiated by environmental crises were one mechanism through which the government gained control of the land. Thus, these types of interventions may be justifiably viewed with suspicion by local communities and are often ignored or resisted. These are not arguments against tree planting; rather, they are simply points that must be considered when wood scarcity is identified as a local problem and tree planting is proposed as a solution.

When wood scarcity is identified as a problem and increasing supply is the favored response instead of, or in conjunction with, demand reduction, there are two broad categories of practices that are generally attempted: centralized tree management through state- or community-run forestry and individual tree management through farm- or household-level forestry.

State forestry institutions are often antagonistic toward local communities, restricting or prohibiting access to state-owned forests. Despite this general trend, some governments have successfully established woodlots or managed forests specifically for community wood production. However, establishing tree plantations is expensive, particularly when state bureaucracies are involved, and centralized state forestry is not an economical way in which to mitigate woodfuel scarcity. On the other hand, if state-owned forests are already established (e.g., as a timber reserve), the state can ease wood scarcity by allowing local communities to have access to dead wood, fallen trees, and pruned branches or by allocating a section of the forest for community access.

In contrast to state forestry, community forestry places forest management directly in community hands. The managed trees may be a section of natural forest, a plantation, or a woodlot. It may lie on land held in common by the community, or it may lie on state-owned land with management responsibilities vested in the community. Fuelwood provision is one of many possible dimensions of community forestry, and fuel collection is likely to be one of many rights that members of the community claim on the trees and land under their control. Other claims include the right to graze livestock, fish, hunt, and extract a variety of forest products such as food, medicine, leaves, and thatch. To preserve the resource, fuel gathering may be limited to dead wood and fallen or pruned branches, commercial sale of wood may be prohibited, and extraction may be limited to head loading only, with carts or animal loading also prohibited. Alternatively, community forestry may be practiced specifically for timber production.

Local wood scarcity can also be mitigated by tree planting at the household level. For example, much of the fuelwood consumed in Sub-Saharan Africa does not come from forests or woodlands; rather, it is cut or gathered from boundaries and fences, cropland, private woodlots, and roadsides as well as from

neighboring farms. Rural farmers throughout the developing world maintain significant numbers of naturally occurring and cultivated trees on their own land. Many do this without assistance from outsiders, although outside intervention can help to provide seeds and technical advice.

As with community forestry, trees on farms are rarely grown solely for fuelwood; rather, they are grown for a wide range of uses. Agroforestry techniques, which integrate trees with cultivation and livestock systems, are particularly effective for maintaining trees on the homestead. These techniques use favorable characteristics of specific tree species and can bring a wide range of benefits to farms. For example, farmers who plant nitrogen-fixing trees in their fallow fields for several years before replanting food crops can experience yields that are several times higher than those from unfertilized plots, that is, yields that are equal to plots fertilized with costly commercial fertilizers. In addition, farmers can harvest the young trees for fuel when the fields are ready to be sown. In a typical area of the subhumid tropics, a 1-ha plot can yield roughly 5 tons of fuelwood for each year of fallow, and this can satisfy a family's fuel needs for a year.

3.2 Demand-Side Interventions

Attempts to reduce woodfuel consumption fall into two broad categories: improved woodfuel stoves and substitution of woodfuel for other fuels.

3.2.1 Improved Stoves

In addition to tree-planting measures, the early connections between fuelwood consumption and deforestation led to the development and dissemination of fuel-conserving cooking stoves. Critics of the three-stone fire and other traditional cooking stoves pointed to their low efficiencies and assumed that they could improve on them through the application of basic engineering principles. Improved cooking stove programs have been implemented throughout the world with mixed degrees of success. Projects vary by scale, type of stove, and target population. Some projects target individual households, whereas others target stove producers or marketers. Table IV shows the number of stoves disseminated in some of the more prominent programs.

As discussed earlier, there are hundreds of variations of cooking stoves. Technical considerations weigh equally with many other factors in determining the design of the stoves. With the benefit of two decades of hindsight, much has become apparent to people working in cooking stove design and dissemination. Some of the more common lessons learned are discussed in what follows.

TABLE IV

Improved Cooking Stove Dissemination through the 1990s

Country	Number distributed	Years of dissemination
China	185,000,000	1982–1998
India	4,100,000	1985–present (number given is stoves disseminated by mid-1990s)
Kenya	1,450,000	1983–present
Thailand	300,000	1985–present (number given is stoves disseminated by mid-1993)
Burkina Faso	200,000	1983–present
Niger	200,000	1984–present
Uganda	52,000	1985–present
Central America	9,000	1990–present (projects are in different countries, and number of stoves disseminated is valid as of 1995)

3.2.1.1 "Improved" Is a Subjective Measure of Newly Introduced Stoves Not all new stoves lead to improvements over "traditional" cooking practices. As in all development interventions, the priorities of the beneficiaries might not agree with the priorities of the implementers and/or donors. A well-designed stove using sound engineering principles will be adopted only if consumers perceive fuelwood as scarce or costly to obtain and if substitute fuels are also costly to obtain. Even if fuelwood scarcity is an acute issue within the community, an "improved" stove will be adopted only if it is easy to use and well matched to local cooking practices. Contrary to some stereotypes that portray them as rigid and traditional, people in less developed countries are willing to change their behavior; however, like people in industrialized countries, they are more likely to choose convenience over conservation. A fuel-saving stove that requires constant attention or fine-tuning is not likely to be widely adopted.

Moreover, improved stoves that fully enclose the fire and remove harmful pollutants through a chimney do not provide the other benefits that an open fire offers: primarily warmth and light but also a degree of cultural value that is difficult to replace.

3.2.1.2 Although It Is Possible to Improve the Efficiency of Traditional Wood- and Charcoal-Burning Stoves, It Is Also Possible to Perform Far Worse than Traditional Stoves In the hands of an experienced user who is consciously trying to conserve fuel, a three-stone fire can be more than 15% efficient. Many "improved" stoves do no better. For example, one common method in constructing improved stoves encloses the fire in an earthen combustion chamber in an attempt to insulate the fire and minimize heat losses. Although the fire appears to be insulated because the outside of the stove remains cool to the touch, most of these stoves actually use more wood for a given cooking task than do many traditional stoves. The exterior of the stove remains cool to the touch because it is made of hundreds of kilos of rock and soil and also has very high thermal mass but relatively poor insulating qualities in the combustion zone. Rather than insulate the fire, the high mass draws heat from it and dissipates it throughout the massive structure. Stoves of this type may have efficiencies of much less than 10% and may have very high emissions due to relatively cool combustion temperatures. However, if the stove has a chimney, the pollutants will be removed from the kitchen, resulting in indoor concentrations of CO and PM that are lower than those in a household using a more fuel-efficient open fire. Figure 12 shows an example of a high mass earthen stove from Nicaragua. Note that the stove has no chimney and that the walls are blackened from years of exposure to smoke. Drawing on these lessons, some stove designers now employ insulating materials, such as ash and pumice, around the combustion zone to maintain high temperatures and minimize heat loss to the body of the stove. Figure 13 shows a sequence of pictures of an insulated stove with a chimney designed for use in Central America. A technician is filling the stove body with vermiculite, which is a cheap mineral with very good insulating properties.

3.2.1.3 Improving the Efficiency of Heat Transfer from the Stove to the Pot Can Save Wood but Lead to Higher Emissions of Harmful Pollutants The discussion of stove efficiency in the note to Table II defined combustion efficiency (CE) and heat transfer efficiency (HTE). The relation between them is such

FIGURE 12 High mass earthen stove from Nicaragua. Originally appeared in Stove Images (photo by Beatrix Westhoff), reproduced with permission of the author and publisher.

that the two quantities can work in opposite directions. For example, moving the pot closer to the stove improves the flow of heat into the food, but the pot is "cold" ($\sim$100°C) in relation to the burning wood and quenches the hot combustion gases, reducing CE and causing higher emissions. The trade-off between CE and HTE is difficult to quantify; it is dependent on the type of stove and fuel, and it is sensitive to user behavior. Even when it is quantifiable, deciding on the "correct" combination requires a trade-off between fuel savings (which are linked to local resources and household labor) and emissions (which are linked to health impacts and GHGs). An informed decision about this trade-off requires making value judgments that are not easy to make.

3.2.1.4 Users Usually Know What Works Best People who cook with woodfuels every day have valuable knowledge about stoves, fuels, and cooking practices more generally. Outside "experts" also have valuable knowledge but are often less equipped to design a stove for local use than are the users themselves. Users need to be involved in all steps of the design process, including design, testing, and dissemination. However, stove users might not be aware of some of the less visible impacts of woodfuel consumption, particularly health-related problems. This is where outside expertise becomes especially important and can be used to reinforce local knowledge so as to develop a safe and appropriate stove.

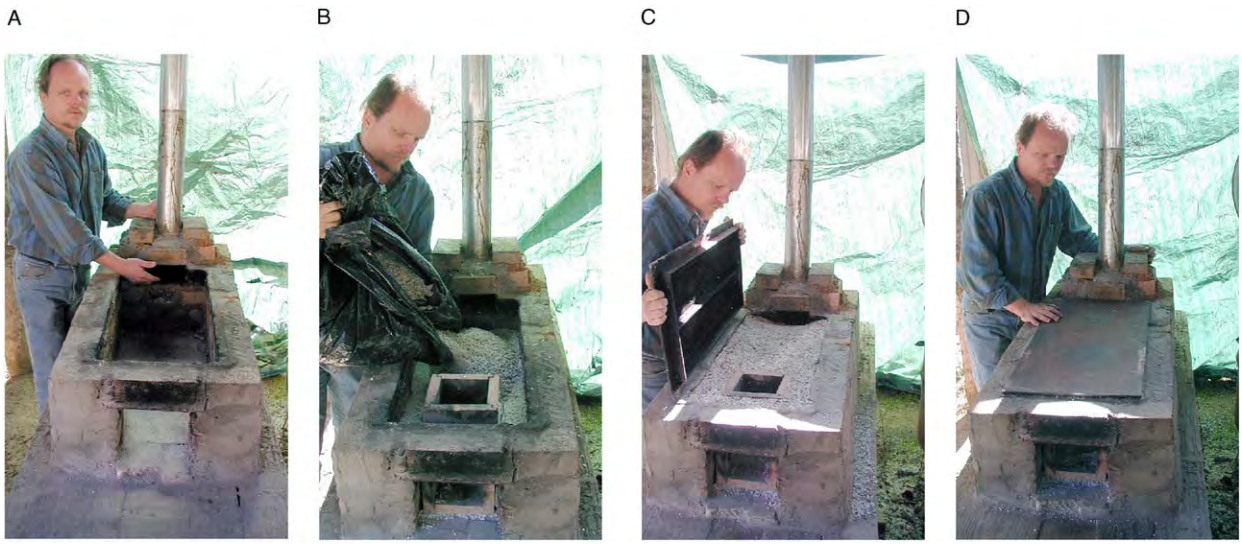

FIGURE 13 Improved stove with insulated combustion chamber. The sequence of photographs shows Brad van Appel of the Aprovecho Institute putting vermiculite insulation into an improved wood-burning stove. (A) Photo shows the brick body of the stove. This type of stove can be made from any durable material such as cement, clay, soil, or sheet metal. (B) The insulation is filled around the combustion chamber. In this stove, the combustion chamber is made from clay tiles placed together to form a hollow elbow. (C) A shallow channel is left on the surface of the insulation to force the flames and hot gases very close to the metal cooking surface before exiting through the chimney at the rear of the stove. (D) The metal cooking surface (called a *plancha* in Spanish) is installed over the insulation. Variations of this type of stove are being disseminated in parts of Central America, where many people prefer a flat metal surface for cooking. Photos by Dean Still (Aprovecho Institute).

3.2.2 Alternative Stoves and Fuels

Fuel switching, discussed earlier in the context of the energy ladder, is another way in which to mitigate the problems associated with household wood consumption. As the energy ladder model suggests, people may switch from wood to cleaner burning fuels as a result of increasing income. Alternatively, they may substitute fuels due to shifting household preferences or changing patterns of fuel availability that occur independent of changes in income. Although these factors can evolve without intervention, there are also policies and programs that influence these changes. For example, education campaigns about the health-damaging effects of woodfuel emissions can change household preferences, leading people to prioritize clean cooking fuels over other expenditures, whereas tax breaks for clean cooking fuels or subsidies for stoves encourage market expansion, making alternative fuels available to a wider range of consumers.

Substitution of wood for other fuels can go "up" or "down" the energy ladder. In rural communities where wood is scarce, households may switch to burning crop residues, dung, or processed briquettes made from wood waste, paper, or agricultural wastes. These fuels generally do not burn as well as does wood in conventional stoves, but fuel switching can be facilitated by the dissemination of specialized stoves made to burn alternative biomass fuels. In communities where wood scarcity is not a serious issue, better off households may decide that charcoal is preferable to wood, a fuel switch that may increase their net wood consumption due to inefficiencies in charcoal production. This switch also changes their patterns of exposure to harmful pollutants. Charcoal burning emits fewer particulates than does wood burning, reducing the risk of ARI, but charcoal also emits more CO, raising the risk of CO poisoning. Even more substantial decreases in exposure to harmful pollutants result from fuel switching to kerosene, LPG, or other gaseous fuels. Rural households rarely have the option of buying these fuels, but urban households do have that range of choices (see Fig. 8 for an example of this from Kenya). However, poor households do not have the same opportunity to switch to cleaner fuels due to the high initial costs of the stove relative to wood and charcoal stoves. Well-targeted subsidies, favorable credit mechanisms, and/or microfinance schemes can reduce the initial costs or spread them out over several years so that the initial costs are affordable by the poor (see Fig. 10).

In addition to kerosene and LPG, other clean alternatives to wood and charcoal exist, although

they are less common. These include biogas, a methane-rich gas produced by the anaerobic breakdown or digestion of human and/or animal waste, and producer gas, a low heating value gas derived from the thermochemical breakdown of biomass or coal. Both biogas and producer gas are used to some extent in India and China. Alcohol-based fuels are a third possibility for fuel switching. These can be derived from either woody or nonwoody biomass and are very clean burning; however, alcohol-based fuels need to be mass produced to take advantage of economies of scale. Thus, alcohol is very rarely used for cooking in less developed countries, although some projects have been attempted (e.g., an ethanol-based "gel fuel" is currently being promoted in parts of Southern Africa where ethanol production facilities have existed for some time). In any less developed country, alcohol would need to be cost-competitive with kerosene, a cheap and relatively clean-burning fuel that is often subsidized.

Ultimately, the policies and programs designed to influence fuel choice at the household level should reflect both community and national priorities. Household energy in less developed countries sits at the intersection of many important policy questions: forest conservation, public health, GHG emissions, and fossil fuel dependency. Weighing these issues together with more specific local needs so as to decrease the impacts of household energy consumption and increase the quality of life for people who are still reliant on wood for their energy needs remains an unmet challenge in most communities throughout the developing world.

Glossary

energy A fundamental property of a system referring to its potential to influence changes to other systems by imparting work (forced directional displacement) or heat (chaotic displacement/motion of system microstructure); energy exists in many forms—electromagnetic, electrical, nuclear, chemical, thermal, and mechanical, where electromechanical energy may be kinetic or potential—and thermal energy represents overall chaotic motion energy of molecules and related microstructure.

energy conservation May refer to the fundamental law of nature that energy and mass are conserved, that is, cannot be created or destroyed but only transferred from one form or one system to another; another meaning of energy conservation is improvement of efficiency of energy processes so that they could be accomplished with minimal use of energy sources and minimal impact on the environment.

energy conversion A process of transformation of one form of energy to another, for example, conversion of chemical to thermal energy during combustion of fuels or conversion of thermal to mechanical energy using heat engines.

energy efficiency Ratio between useful energy of a process and energy used to accomplish that process; energy, as per the conservation law, cannot be lost (destroyed), but part of energy input that is not converted into "useful energy" is customarily referred to as energy loss.

fuel cell Device undergoing electrochemical cycle where electrical work is obtained during ionization of fuel and oxidant molecules, reacting into product molecules at constant pressure and temperature, thereby avoiding heating and loss of work potential into thermal energy of the reaction products, like during combustion.

heat Inevitable (spontaneous) energy transfer due to temperature differences, to a larger or smaller degree, without control (dissipative) via chaotic displacement/motion of system molecules and related microstructure (in all directions, nonpurposeful), as opposed to controlled (purposeful and directional) energy transfer referred to as work.

heat engine Device undergoing thermomechanical cycle with mechanical expansion and compression net work obtained as difference between heat transferred to the engine from a high-temperature heat reservoir and rejected to a low-temperature reservoir, thereby converting part of thermal energy into mechanical work.

nonrenewable energy sources Energy sources created and accumulated over a very long period in the past, such as fossil and nuclear fuels, whose creation rate is many orders of magnitude smaller than the consumption rate, so that they will be depleted in a finite time period at the current rate of consumption.

power The energy rate per unit of time.

renewable energy sources The continuously or frequently available (renewed daily or at least annually) energy sources, such as solar energy, wind, water flows, ocean and tidal waves, and biomass, that are expected to be available forever for all practical purposes.

work A type of controlled energy transfer when one system is exerting force in a specific direction and, thus, is making a purposeful change (displacement) of the other systems; it is inevitably (spontaneously) accompanied, to a larger or smaller degree, by dissipative (without control) energy transfer referred to as heat.

A global overview and general concept of energy, its forms and classifications, and its manifestation as work and heat transfer is presented in this article with an objective to preserve the completeness and exactness of the fundamental concepts. The emphasis is given to work as the most useful energy transfer. However, because most work currently is obtained from fossil fuels using heat engines, and because all work is ultimately dissipated via heat to thermal

energy, they are presented in the article, along with fuel cells, as promising devices to convert chemical fuel energy directly into electrical work without degradation of energy as in the combustion processes. The efficiencies of diverse energy-to-work conversion processes are provided. Finally, the latest developments and worldwide energy production and consumption data are effectively summarized, and diverse energy sources, reserves, and a future outlook are given.

1. BASIC CONCEPTS

Energy is the "building block" and fundamental property of matter and space and, thus, the fundamental property of existence. Energy exchanges or transfers are associated with all processes (or changes) and, thus, are indivisible from time. It is no wonder that energy is often defined as the ability to perform work, that is, as a potential for energy transfer in a specific direction (displacement in force direction) to achieve a purposeful process, as opposed to a dissipative (less purposeful) energy transfer in the form of heat. This definition of energy could be generalized as the ability to perform change.

Work is a mode of energy transfer from one acting body (or system) to another resisting body (or system), with an acting force (or its component) in the direction of motion, along a path or displacement. A body that is acting (forcing) in motion direction in time is doing work on another body that is resisting the motion (displacement rate) by an equal resistance force, including inertial force, in the opposite direction of motion. The acting body is imparting (transferring away) its energy to the resisting body, and the amount of energy transfer is the work done by the acting onto the resisting body, equal to the product of the force component in the motion direction multiplied by the corresponding displacement or vice versa (force multiplied by the displacement component in the force direction) (Fig. 1). If the force ($\vec{F}$) and displacement vectors ($\overrightarrow{ds} = \overrightarrow{dr}$) are not constant, integration of differential work transfers from initial state 1 to final state 2, defined by corresponding position vectors $\vec{r}$, will be necessary (Fig. 2).

The work is a directional energy transfer; however, it is a scalar quantity like energy, and it is distinctive from another energy transfer in the form of heat due to random motion (chaotic, in all directions) and collisions of bodies' molecules and their components.

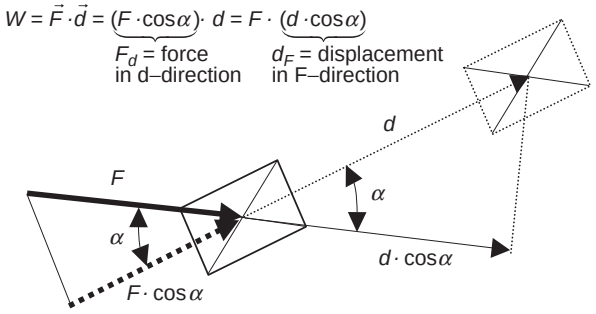

FIGURE 1 Work, force, and displacement.

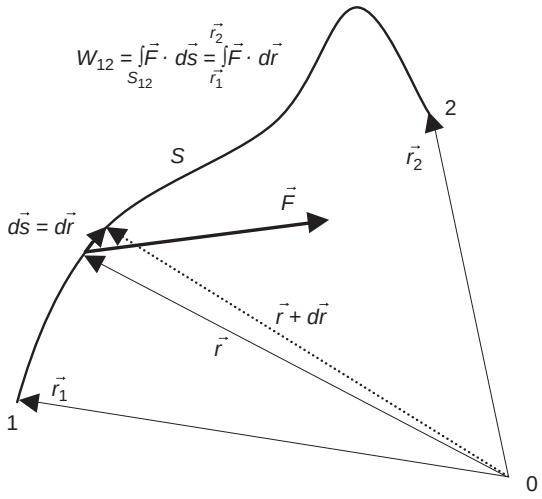

FIGURE 2 Work along arbitrary path.

1.1 Power

Energy transfer in the form of work or heat is taking place in time, at a finite rate, and cannot be instantaneous. The energy transfer per unit of time, or energy rate, is called power, usually in form of the work rate, although it may also be heating power, that is,

$$\dot{W} = \frac{dW}{dt} = \frac{\vec{F} \cdot \overrightarrow{ds}}{dt} = \vec{F} \cdot \vec{v}, \quad \text{or} \quad W_{12} = \int_{t_1}^{t_2} \dot{W} \cdot dt. \tag{1}$$

Therefore, energy (as a body or system property) and work and heat (as energy in transfer from one system to another) are interrelated. All have the same dimension (Force × Length), and related different units could be converted to each other (Table I).

Work transfer cannot occur without the existence of a resisting body or system, nor can it occur without finite displacement in the force direction. This might not always be obvious. For example, if

TABLE I

Energy Units with Conversion Factors and Energy Equivalents

Energy unit	J	kWh	Btu
1 joule (J)	1	2.78×10^{-7}	9.49×10^{-4}
1 kilowatt-hour (kWh)	3.6×10^{6}	1	3.412×10^{3}
1 kilocalorie (kcal = Cal = 1000 cal)	4187	1.19×10^{-3}	3.968
1 British thermal unit (Btu)	1055	2.93×10^{-4}	1
1 pound-force foot ($lb_f \cdot ft$)	1.36	3.78×10^{-7}	1.29×10^{-3}
1 electron volt (eV)	1.6×10^{-19}	4.45×10^{-26}	1.52×10^{-22}
1 horsepower × second (HP · sec)	745.7	2.071×10^{-4}	0.707

Energy equivalent	J	kWh	Btu
1 barrel (42 gallons) of crude petroleum	6.12×10^{9}	1700	5.80×10^{6}
1 ton (2000 lb) of bituminous coal	2.81×10^{10}	7800	2.66×10^{7}
1000 cubic feet of natural gas	1.09×10^{9}	303	1.035×10^{6}
1 gallon of gasoline	1.32×10^{8}	36.6	1.25×10^{5}
1 gram of uranium-235	8.28×10^{10}	2.30×10^{4}	7.84×10^{7}
1 gram of deuterium	2.38×10^{11}	6.60×10^{4}	2.25×10^{8}
2000 dietary food calories (2000 kcal)	8.374×10^{6}	2.326	7.937×10^{3}
1 solar constant × $(cm)^2$ × minute	8.374	2.326×10^{-6}	7.937×10^{-3}

one is holding a heavy weight or pushing hard against a stationary wall, there will be no work done against the weight or wall (neglecting its small deformations). However, one will be doing work internally due to contraction and expansion of one's muscles (force with displacement) and that way will be converting (spending) a lot of chemical energy via muscle work and then dissipating it into thermal energy and heat transfer (sweating and getting tired).

1.2 Energy, Power, Work and Heat Units, and Energy Equivalents

Energy is manifested via work and heat transfer, with the corresponding Force × Length dimension for work ($N \cdot m$, $kg_f \cdot m$, and $lb_f \cdot ft$ in SI, metric, and English systems of units, respectively), and the caloric units in kilocalories (kcal) or British thermal units (Btu), as heat needed to increase a unit mass of water (at a specified pressure and temperature) for 1° of temperature, so that the water-specific heat is 1 kcal/(kg °C) = 1 Btu/(lb °F) by definition, in the metric and English systems of units, respectively. It was demonstrated by Joule that 4187 N · m of work, when dissipated in heat, is equivalent to 1 kcal. In Joule's honor, 1 N · m of work is named after him as 1 joule or 1 J, the SI energy unit, also equal to electrical work of $1\,W \cdot s = 1\,V \cdot A \cdot s$. The SI unit for power, or the work rate, is the watt (i.e., 1 J/s = 1 W) as well as corresponding units in other systems of units, for example, Btu/h. The horsepower is defined as $1\,hp = 550\,lb_f \cdot ft/s = 745.7\,W$. Other common units for energy, work, and heat, and for energy equivalents for typical fuels and processes, are given in Table I.

2. FORMS, CLASSIFICATIONS, AND CONSERVATION OF ENERGY

As stated in the previous section, energy is a fundamental concept indivisible from matter and space, and energy exchanges or transfers are associated with all processes (or changes) and, thus, are indivisible from time. Energy transfer is needed to produce a process to change other system properties. Among all properties, the energy is the only one that could be converted to mass and vice versa, that is, $E = mc^2$ (known in some literature as mass energy, the c is the speed of light in a vacuum); thus, the two are interrelated.

Any and all changes (happening in time) are caused by energy exchanges or transfers from one body or substance (system or subsystem) to another. A part of a system may be considered as a subsystem if energy transfer within a system is taking place; conversely, a group of interacting systems may be

considered as a larger isolating system if they do not interact with the rest of the surroundings.

There are many forms and classifications of energy (Table II) all of which could be classified as microscopic (internal within a system microstructure) and/or macroscopic (external as related to the system mass as a whole with reference to other systems). Furthermore, energy may be quasi-potential (associated with a system equilibrium state and structure, i.e., system property) or quasi-kinetic (energy in transfer from one system or structure to another in the form of work or heat).

Every system in an equilibrium is defined by its state potential, where the system structure is "held" by forces (i.e., the forces "define" the system potential and state, and vice versa—action and reaction); otherwise, a system will undergo dynamic change (in time), with quasi-kinetic energy exchange toward another equilibrium. Atoms (mass) are held by atomic and gravity forces; otherwise, mass would disintegrate ("evaporate" into energy) as it does partly in nuclear reactions (nuclear energy). Molecules are held by electrochemical bonding (valence) forces (chemical reactions—chemical energy). Solids are held by "firm" intermolecular forces (melting of solids when energy is increased by heating—latent thermal energy). Liquids are also held by latent intermolecular forces (evaporation when kinetic energy of molecules is further increased by heating—latent thermal energy again). Sensible thermal energy represents energy of molecular motion and is related to temperature of a system. "Holding" potential forces may be "broken" by energy transfer (e.g., heating, high-energy particle collisions). States and potentials are often stable or "hooked' and, thus, need to be unhooked or broken to overcome the existing "threshold" or equilibrium, as in igniting combustion or starting a nuclear reaction. Energy can be directional (purposeful or organized) or chaotic (dissipative or disorganized). For example, mass-in-motion (mechanical kinetic energy) and electricity-in-motion (electrical kinetic energy) are organized kinetic energies, whereas thermal energy is disorganized chaotic energy of motion of molecules and atoms. System energy may be defined with reference to position in a vector force field such as elastic potential (stress) energy, gravitational potential energy, or electromagnetic field energy.

Energy transfer may be in organized form (work transfer due to force action) or in chaotic disorganized form (heat transfer due to temperature difference). Energy transfer into a system builds up energy

TABLE II

Energy Forms and Classifications

Scale			Type			Transfer (release)	
				Kinetic (motion)		Quasi-kinetic (motion)	
Macro/external (mass based)	Micro/internal (structure based)	Form	Potential (state or field)	Directional[a]	Chaotic dissipative	Work directional[a]	Heat dissipative
		Mechanical					
X		• Kinetic		X		X	
X		• Gravitational[b]	X			X	
X		• Elastic	X			X	
		Thermal					
	X	• Sensible			X		X
	X	• Latent	X				X
	X	Chemical	X				X
	X	Nuclear	X				X
		Electrical					
	X	• Electrokinetic		X		X	
	X	• Electrostatic	X			X	
	X[c]	Electromagnetic	X[c]			X	

[a] Electromechanical kinetic energy type (directional/organized, the highest energy quality) is preferable because it may be converted to any other energy form/type with high efficiency.

[b] Due to mass position in a gravitational field.

[c] Electromagnetic form of energy is the smallest known scale of energy.

potential (called simply potential for short, e.g., pressure, temperature, voltage) over energy displacement (e.g., volume, entropy). Conversely, if energy is transferred from a system, its energy potential is decreased. That is why energy is transferred from higher to lower energy potential only.

All organized kinetic energy will, in part or in whole (and ultimately in whole), disorganize/dissipate within the microstructure of a system (over its mass and space and in time) into disorganized thermal energy. Entropy, as an energy displacement system property, represents the measure of energy disorganization. Contrary to energy and mass, which are conserved in the universe, the entropy is continuously generated (increased) due to continuous disorganization of energy in transfer ("spreading" of energy toward and over lower potentials in time) and, thus, degradation of quality of energy.

Often, one wants to extract energy from one system to purposefully change another system, that is, to transfer energy in organized form (as work). That is why energy is often defined as the ability to perform work, and a special quantity exergy is defined as the maximum possible work that may be obtained from a system by bringing it, in a process, to equilibrium with reference surroundings. The maximum possible work will be obtained if one prevents energy disorganization or dissipation, that is, within so-called reversible processes. Because the energy and mass are conserved during any process, only in ideal reversible processes will the entropy (measure of energy disorganization) and exergy (maximum possible work with reference to the surroundings) be conserved, whereas in the real irreversible processes, the entropy will be generated and exergy will be partly (or even fully given enough time) destroyed. Therefore, heat transfer and thermal energy are universal manifestations of all natural and artificial (manmade) processes, whereas all organized potentials and/or quasi-kinetic energies are disorganized or dissipated in the form of thermal energy in irreversible and spontaneous processes.

As stated previously, there are many different energy forms and types (Table II). One is usually not interested in (absolute) energy level; instead, one is usually interested in the change of energy (during a process) from an initial state (i) to a final state (f), so that zero reference values for different energy forms are irrelevant and are often taken arbitrarily for convenience. The following are basic correlations for energy changes of several typical energy forms often encountered in practice: motion kinetic energy (E_K) as a function of system velocity (v), spring elastic potential energy (E_{Ps}) as a function of spring deformation displacement (x), gravitational potential energy (E_{Pg}) as a function of gravitational elevation (z), and sensible thermal energy (E_U) as a function of system temperature (T):

$$\Delta E_K = \frac{1}{2}m\left(v_f^2 - v_i^2\right);\ \ \Delta E_{Ps} = \frac{1}{2}k\left(x_f^2 - x_i^2\right)$$
$$\Delta E_{Pg} = mg(z_f - z_i);\ \ \Delta E_U = mc_v(T_f - T_i). \qquad (2)$$

If the reference energy values are taken to be zero when the initial (i) variables are zero, these equations will represent the energy values for the final values (f) of the corresponding variables. If the corresponding parameters, spring constant k, gravity g, and constant-volume specific heat c_v, are not constant, integration of differential energy changes from initial to final states will be necessary.

Energy transfer via work W and heat transfer Q may be expressed as the product of related energy potentials (pressure P or temperature T) and corresponding energy displacements (change of volume V and entropy S, respectively), that is,

$$W_{12} = \vec{F}\cdot\vec{d} = \left[(P\cdot\underbrace{A\vec{n}}_{\Delta V})\cdot\vec{d}\right] = P\cdot\Delta V_{12}|_{P\neq const}$$
$$= \int_{V_1}^{V_2} P\cdot dV \qquad (3)$$

$$Q_{12} = T\cdot\Delta S_{12}|_{T\neq const} = \int_{S_1}^{S_2} T\cdot dS. \qquad (4)$$

Note that in Eq. (3), force cannot act at a point but is distributed as pressure P over some area A (with orthogonal unit vector $\vec{n}$), which when displaced will cause the volume change ΔV.

In the absence of a nuclear reaction (no conversion of mass into energy, $E = mc^2$), mass and energy are conserved separately for an isolated system, a group of isolated systems, or the universe. For example, for a given process (energy exchange) between two systems, isolated from the surroundings, during time period Δt, the energy conservation law may be expressed as

$$\sum_i E_{1,i}(t+\Delta t) + \sum_j E_{2,j}(t+\Delta t)$$
$$= \sum_m E_{1,m}(t) + \sum_n E_{2,n}(t), \qquad (5)$$

where $\sum_i E_{1,i}(t)$ is the sum of all existing energy forms i of system 1 at time (t) and of system 2 and/or at time $t+\Delta t$. Then, from Eq. (5), energy transfer from system 1 to system 2 for period Δt may be in the

form of work W and/or heat Q, that is,

$$\begin{aligned} W_{12} + Q_{12} &= W_{1\to 2} + Q_{1\to 2} \\ &= \sum_i E_{1,i}(t+\Delta t) - \sum_m E_{1,m}(t) \\ &= -\left[\sum_j E_{2,j}(t+\Delta t) - \sum_n E_{2,n}(t)\right] \\ &= -(W_{21} + Q_{21}) = -(W_{2\to 1} + Q_{2\to 1}). \end{aligned} \tag{6}$$

Note that for nonexistent terms in these equations, their values should be zero, and if the energy transfers (work and heat) are negative, they are actually in the opposite direction than was specified. Correlations are similar for mass conservations. Furthermore, the power is defined as energy transfer rate per unit of time; conversely, energy transfer is equal to the product of power and time or the integral of power over a time period, see Eq. (1).

3. WORK OF CONSERVATIVE AND NONCONSERVATIVE FORCES: WORK–ENERGY PRINCIPLE

Work against conservative (also known as internal, volumetric, or space potential field) and/or inertial forces is path independent, and the mechanical energy is conserved during such a process. However, work of nonconservative dissipative forces is path dependent, and part of the mechanical energy is converted (dissipated) to the thermal energy. The nonconservative forces are also external or surface forces.

For example, during a free gravity fall (or free bounce) without air friction, the potential energy is being converted to kinetic energy of the falling body (or vice versa for free bounce), and at any time the total mechanical energy (sum of kinetic and potential mechanical energies) is conserved, that is, stays the same (Fig. 3). The mechanical energy is also conserved if a mass freely vibrates on an ideally elastic spring or if a pendulum oscillates around its pivot, both in the absence of dissipative effects such as friction and nonelastic deformation. In general, for work of conservative forces only, the mechanical energy (E_{mech}) for N isolated systems is conserved because there is no dissipative conversion in thermal energy and, thus, no heat transfer, that is,

$$\begin{aligned} E_{mech} &= E_K + E_{Pg} + E_{Ps} \\ &= \sum_{j=1}^{N}\left(\frac{1}{2}mv^2 + mgz + kx\right)_j = const. \end{aligned} \tag{7}$$

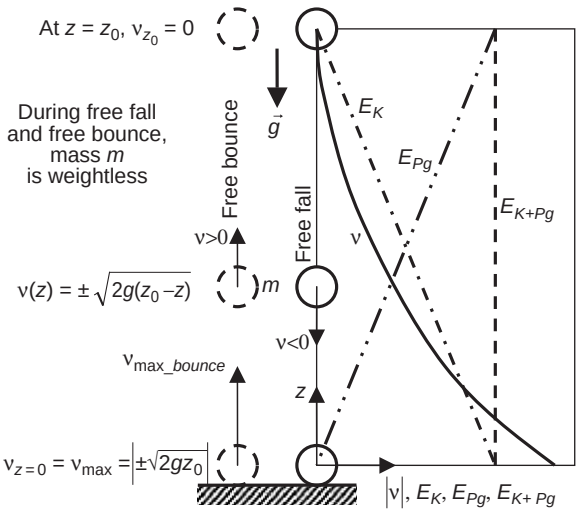

FIGURE 3 Energy and work due to conservative gravity force.

When work of nonconservative forces W_{nc} is exchanged among N isolated systems, from an initial state i to a final state f, the total mechanical energy of all systems is reduced by that work amount, that is,

$$W_{nc,i\to f} = \left(\sum_{j=1}^{N} E_{mech,j}\right)_i - \left(\sum_{j=1}^{N} E_{mech,j}\right)_f. \tag{8}$$

This correlation is known as the work–energy principle.

Regardless of the traveled path (or displacement), the work against conservative forces (e.g., gravity or elastic spring in the preceding cases) in the absence of any dissipative forces will depend on the final and initial positions (or states) only. However, the work of nonconservative dissipative forces W_{nc} will depend on the traveled path because the energy is dissipated during the force displacement, and mechanical energy will not be conserved but rather partly converted (via dissipation and heat transfer) into the thermal energy (see Eq. 8). This should not be confused with total energy conservation, which is always the case, and it must include both work and heat transfer (see Eqs. 5 and 6).

4. ENERGY, WORK, AND POWER OF ROTATING SYSTEMS

Motors and engines are important energy devices that convert other energy forms into their rotating shaft motion with a twisting action and, thus, into the mechanical work and kinetic energy. Also, many other devices, including parts of diverse machineries involving energy transfers in the form of work, are

mounted on rotating shafts or rotating bearings or pins (e.g., disks, gears, wheels, levers). Because shafts and bearings restrict motion to rotation around their axes, any mass at distance r from the axis of rotation, its circumferential velocity v, and the related twisting circumferential force F are related to the corresponding angular rotational speed ω and torque T with the simple correlations $v = \omega r$ and $T = rF$ (written in scalar form because rotational motion and twisting force action are restricted in a single, around-the-axis direction only). Then, the kinetic energy E_K and work rate dW/dt, or the power transfer of a rotating system, can be expressed as seen in Fig. 4, where J is the mass moment of inertia for a rotating system. For a cylinder (or disk) of radius R and mass m, or of density ρ and thickness b, the mass moment of inertia around its axis is $J = mR^2/2 = (\pi/2)\rho bR^4$.

5. ENERGY SOURCES, CONVERSION TO WORK, AND EFFICIENCY

Energy sources are those systems (substances or natural phenomena) that allow for abundant, convenient, and efficient (and thus economical) conversion of their energy into useful energy forms (for consumption needs), usually thermal for heating or mechanical and electrical for work, with the latter also being very convenient for transmission and very efficient for conversion into any other useful energy form. Because energy consumption needs are time and location dependent, energy conversion rate, energy density (per unit mass, volume, area, etc.), transportation (transmission), and storage are important.

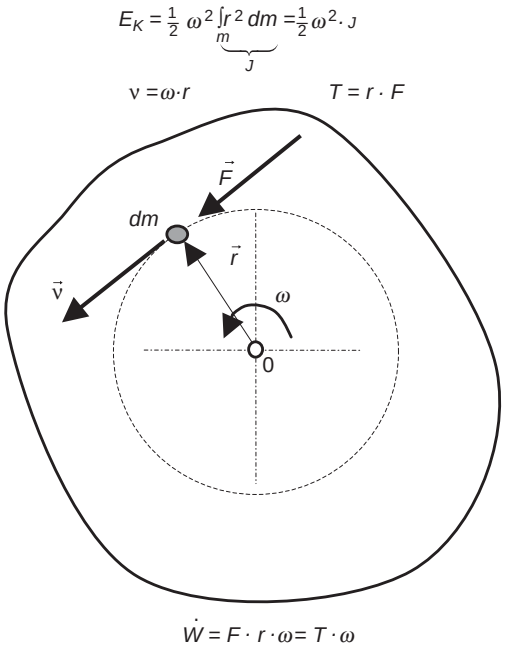

FIGURE 4 Energy and power of rotating system.

There are many sources of energy (Table III) for diverse needs of human activities and society in general. Energy consumption may be classified into four general sectors (see Table VI): (1) *residential*: for appliances and lighting, space heating, water heating, air conditioning, and so on; (2) *commercial*: for lighting, space heating, office equipment, water heating, air conditioning, ventilation, refrigeration, and so on; (3) *industrial*: for water and steam boilers, direct process energy, machine drive, and so on; and (4) *transportation*: for personal automobiles, light and heavy trucks, air transport, water transport, pipe transport, rail transport, and so on. In all four sectors, in addition to primary energy sources, electrical energy, as a secondary energy source produced from primary energy sources, is used extensively.

The primary energy sources for the world in the year 2000 and for the United States in the year 2001 are presented in Table IV. The primary energy sources for the production of electricity are presented in Table V. In addition, the U.S. energy supply by consumption sector, including electricity production, is given in Table VI. The world and U.S. populations, energy production, and energy consumption are summarized in Table IV as well. The total energy production, including losses, import, and export, is available as energy supply for consumption and storage. Also, most of the world's electricity ($\sim$64% vs $\sim$70% in the United States) is produced from fossil fuels, with an overall conversion efficiency of only approximately 30%. The conversion efficiency is similar in nuclear power plants, which contribute approximately 17% of world electricity production and approximately 21% of U.S. electricity production. When the global energy supply is given together with fossil fuels and is expressed in British thermal units, all electrical energy (including hydro, wind, etc.) is given in equivalent British thermal units, accounting for the conversion efficiency (the U.S. Energy Information Agency uses 31%). When electrical energy is accounted for separately, the actual electrical output is given in kilowatt-hours, as seen in Tables V and VI. Because of different forms and conversion efficiencies of primary energy sources, and because of complexities of energy production and losses, transportation and storage, and import and export, it is virtually impossible to account correctly for all energy paths and forms in

TABLE III

Primary Energy Sources and Conversion to Work

Primary energy source		Conversion
Nonrenewable		
Fossil fuels	Coal	Combustion (heat and heat engine H/HE/W[a])
	Peat	
	Oil/Crude petroleum	
	Natural gas	
Nuclear	Uranium	Fission (H/HE/W)
	Thorium	
	Deuterium	Fusion[b] (H/HE/W)
Renewable[c]		
Geothermal[d]	Hot steam/water	H/HE/W
	Ground soil/rock heat	
	Volcanic, etc[b]	
Ocean–gravitational	Tidal–ocean wave	Direct to work
Solar related		
Ocean	Ocean thermal	H/HE/W
	Ocean currents	Direct to work
	Ocean wave	
Biomass	Wood	Combustion (H/HE/W)
	Vegetation, etc[e]	
Direct solar	Solar–thermal	H/HE/W
	Photoelectric	Direct to work
	Photochemical	
Electrostatic	Lightning, etc[b]	
Wind	Wind–air streams	
Hydro	River/Accumulation	
Muscular	Human and animals	

Note. Secondary energy sources (e.g., electrical, synthetic fuels, hydrogen) with energy storage and distribution completes the energy supply domain, which with energy needs, consumption, and efficiency completes the global energy realm.

Energy related processes: Electromagnetic radiation; Photosynthesis cycle in nature; Biosyntheses cycle in nature; Electrical processes: electrodynamic, electromagnetic, electrochemical; Nuclear reactions: fission, fusion, radioactive radiation; Chemical reactions: combustion, oxidation, etc.; Heat transfer and frictional dissipative processes; Thermomechanical expansion and compression; Natural air streams driven by solar dissipation, gravitation, and buoyancy (evaporation, precipitations, water streams); Natural water streams (rivers and ocean streams); Mechanical expansion and compression.

[a] H/HE/W, conversion to heat and via heat engine to work.

[b] Not commercialized yet.

[c] All renewable sources, except tidal and geothermal, are due to solar radiation.

[d] Usually renewable but may be nonrenewable.

[e] Includes many types as well as waste/garbage.

the same units; therefore, the total figures (and percentages) usually do not add up exactly.

Fossil fuels share more than 85% of the total world and U.S. energy consumption (Table IV). Nearly 40% of the total world and U.S. energy is used for electricity production (Tables IV, V, and VI), mainly in thermal and nuclear power plants ($>80\%$ in the world and $>90\%$ in the United States), using heat engines undergoing thermomechanical conversion processes with relatively low conversion efficiencies (Table VII). The overall conversion efficiencies from chemical or nuclear fuel energy to thermal energy of combustion gases or steam, and to mechanical and electrical energy, is only approximately 30 to 35%.

5.1 Heat Engines

Heat engines are devices undergoing thermomechanical cycles, similar to the one in Fig. 5, with a mechanical expansion and compression net work ($W = Q_h - Q_c$), obtained as the difference between the heat transferred to the engine from a high-temperature heat reservoir (at T_h) and rejected to a low-temperature heat reservoir (at T_c), thereby converting part of thermal energy into mechanical work. The combustion process itself is an irreversible one, where chemical energy (electrochemical energy binding reactants' molecules) is chaotically released during combustion (i.e., converted in random thermal energy of products' molecules) and cannot be fully transferred into directional work energy. The second law of thermodynamics limits the maximum amount of work that could be obtained from thermal energy between two thermal reservoirs at different temperatures, hot T_h and cold T_c, by using the ideal reversible Carnot cycle (Fig. 5) with thermal efficiency:

$$\begin{aligned}\eta_{th,C_ad} &= \frac{W}{Q_h} = \frac{Q_h - Q_c}{Q_h} \\ &= 1 - \frac{T_c}{T_h}\bigg|_{T_h = T_{ad} = 2273\ K,\ T_c = 293\ K} \\ &= 1 - \frac{293}{2273} = 87.1\%, \end{aligned} \tag{9}$$

where $W = W_T - W_C$ is the net work of expansion, usually turbine W_T, and compression W_C. The maximum efficiency is achieved if heat is supplied at the highest possible temperature T_h and released at the lowest possible temperature T_c. However, both temperatures are limited by the fact that a fuel combustion is performed using oxygen with ambient air, resulting in maximum so-called adiabatic, stoichiometric combustion temperature T_{ad}, which

for most fuels is approximately 2000°C or $T_{ad} = 2273\,\text{K}$. A part of the heat supplied at hot temperature T_h must be released to the surroundings at a cold temperature of approximately $T_c = 20°\text{C} = 293\,\text{K}$, resulting in a Carnot efficiency of 87.1% (see Eq. 9 and Fig. 5). However, the fuel heating value energy ($Q_{HV} = Q_{ad_var}$) is not available entirely at the adiabatic temperature of the products but rather is distributed over their variable temperature range, from initial surrounding temperature before combustion T_c to final adiabatic temperature T_{ad} (Fig. 6). If a single Carnot cycle is used at constant temperature $T_h < T_{ad}$, only fraction $(T_{ad} - T_h)/(T_{ad} - T_c)$ of the fuel heating value will be used, resulting in a reduced Carnot efficiency:

$$\eta_{th,C} = \left(1 - \frac{T_c}{T_h}\right)\left(\frac{T_{ad} - T_h}{T_{ad} - T_c}\right)\Bigg|_{\text{max for } T_h = \sqrt{T_{ad}T_c}} = \frac{\sqrt{T_{ad}/T_c} - 1}{\sqrt{T_{ad}/T_c} + 1}\Bigg|_{T_{ad} = 2273\ K,\ T_c = 293\ K} = 47.2\%. \quad (10)$$

The efficiency may be increased further by employing a large number (infinite in limit) of ideal

TABLE VII

Energy-to-Work Conversion Efficiencies

Engine/Process	Efficiency Percentage
Otto (gasoline) engine	25–30
Diesel engine	30–40
Gas turbine	30–40
Steam turbine	30–40
Nuclear, steam turbine	30–35
Combined gas/steam turbines	40–55+
Fuel cell (hydrogen, etc.)	40–60+
Photovoltaic cell	10–20
Windmill	30–40 (59% limit)
Hydro turbine	80–85
Electromechanical motor/generator	80–95

Note. Thermal-to-mechanical work conversion is limited by stoichiometric combustion temperature and the Carnot cycle efficiency. Fuel cell efficiency is limited by Gibbs free energy values for process reactants and products and may be close to 100%. Because of material property limitations and process irreversibilities (dissipation of energy), practical efficiencies are much lower and there is room for substantial improvements. For example, existing hybrid cars have 80% improved efficiency (and mileage) over the same classical cars, from 25 to 45%, by using electromechanical engines/storage hybrid systems.

Carnot engines operating at various temperatures (with $dW = dQ$) or with variable hot temperature heat exchange (Fig. 6). Assuming constant specific heat of combustion products, and after integration, the variable hot temperature Carnot cycle yields the maximum possible combustion products-to-work conversion efficiency:

$$\eta_{th,C\ \text{var max}} = \left(1 - \frac{\ln(T_{ad}/T_c)}{(T_{ad}/T_c) - 1}\right)\Bigg|_{T_{ad}=2273\ K,\ T_c=293\ K} = 69.7\%. \quad (11)$$

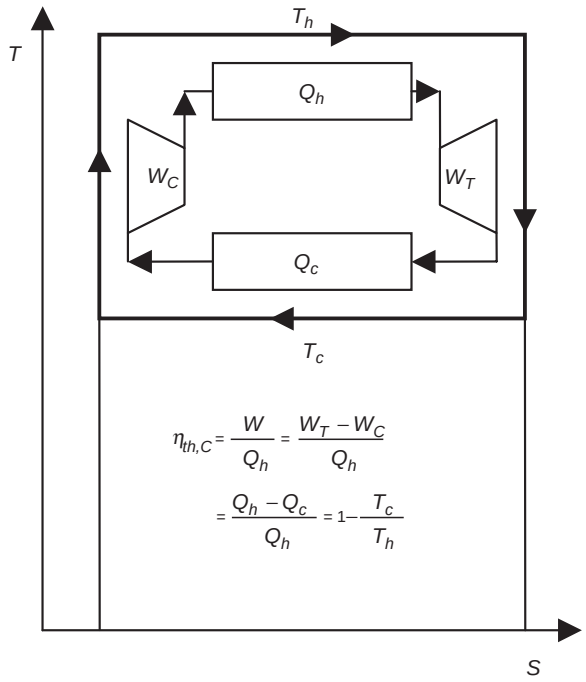

FIGURE 5 Heat engine, ideal Carnot cycle.

Because of engine material property limitations and other unavoidable irreversibilities, it is impossible to reach the ideal Carnot efficiency. Different actual heat engines undergo similar but different cycles, depending on the system design. For example, internal combustion engines undergo the Otto cycle with gasoline fuel and the Diesel cycle with diesel fuel, whereas steam and gas turbine power plants undergo the Rankine and Brayton cycles, respectively. However, with improvements in material properties, effective component cooling, and combining gas and steam turbine systems, more than 50% efficiencies are being achieved, a substantial improvement over current ones of approximately

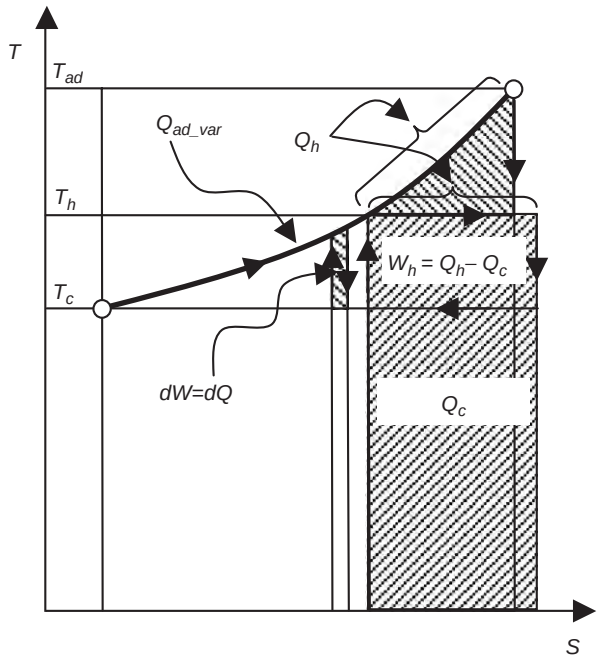

FIGURE 6 Heat engine, constant and variable temperature, ideal Carnot cycle.

35% (see Table VII). The ideal Carnot cycle is an important reference to guide researchers and engineers to better understand limits and possibilities for new concepts and performance improvements of real heat engines.

5.2 Fuel Cells

It is possible to convert fuel chemical energy to electrical work directly, without heating the reaction products as is done during combustion, by using an electrochemical cell, also known as a fuel cell. It is a very simple device, similar to a fueled battery. It consists of two porous metal electrodes with an electrolyte in between. The fuel (e.g., hydrogen), after diffusing through one electrode, will dissociate into positive ionic components by releasing electrons to that electrode. In the process, the positive fuel ions are transferred to another electrode that is in contact with oxygen. If an external load is connected to the electrodes, an electric current (and electrons) will be flowing and electrical work will be departed to the load, while hydrogen fuel's positive ions will be diffusing through the electrolyte and at another electrode will be reacting with oxygen, forming water as the reaction product. The high efficiency of the fuel cell results from the electrochemical process, whereby the energy of binding reactants' electrons, is converted directly into directional electrical work, departed by the electrons that move in the cell's external circuit. This is in contrast to conversion of the same energy during combustion to chaotic thermal motion (i.e., heating of combustion products' molecules), accompanied by substantial irreversibility and loss of work potential. The maximum efficiency and work from a fuel cell is limited, according to the second law of thermodynamics, to the decrease of the Gibbs free energy ($F = H - TS$) of the reactants (*re*) as they form products (*pr*) in the electrochemical reaction (i.e., $W_{max} = F_{re} - F_{pr}$), where $H = E_U + PV$ is a system and/or component enthalpy and E_U, P, V, T, and S are internal thermal energy, pressure, volume, temperature, and entropy, respectively. The difference between reactants' and products' Gibbs free energies is very close to the fuel heating value Q_{HV}, so that the fuel cell theoretical energy conversion efficiency, $\eta_{max} = W_{max}/Q_{HV}$, is close to 100% if the process is conducted at constant pressure and temperature and without dissipative heating of the products. In practice, with finite reaction rates accompanied by dissipative heating and the need for cooling to maintain reaction at as constant a temperature as possible, the efficiency is lower than the maximum possible but more than 40% or even 50%, which is still higher than the heat engine efficiencies given in Table VII along with efficiencies of other energy conversion processes to mechanical or electrical work.

6. ENERGY RESERVES AND OUTLOOK

Currently, most of the world's energy consumption is supplied by fossil fuels ($\sim$85%). However, proven fossil fuel reserves are limited, and it is estimated that if they continue to be used at the current rates (as used under current conditions), coal will be depleted in approximately 250 years, oil will be depleted in 60 years, and natural gas will be depleted in 80 years. One must keep in perspective the fact that "proven reserves" refers to the customary and economical "mining" and use of fuels, whereas new reserves and more efficient technologies are being discovered and make new fuel reserves economical. Currently, a substantial amount of the world's electricity is obtained from nuclear and hydro energy ($\sim$17 and 18%, respectively), use of other renewable energy resources is increasing (e.g., geothermal, wind, biomass, solar), and alternative synthetic fuels (e.g., hydrogen fuel cells) are being developed. It is worth

noting that some countries produce most or nearly all of their electricity from hydro energy (e.g., Norway, Brazil, New Zealand, Austria, Switzerland), whereas France produces most of its electricity from nuclear fuel (76%). The nuclear fuel reserves are orders of magnitude higher than fossil fuel reserves, and nuclear fuel does not contribute to CO_2 and greenhouse gas pollution.

Furthermore, advances in energy conversion and utilization technologies as well as increases in efficiency, including computerized control and management, contribute to energy conservation, increases in safety, and reduction of related environmental pollution. Actually, per capita energy use in the United States and other developed countries has decreased during recent years. However, the increase in world population and the development of many underdeveloped and highly populated countries, such as China and India, will continue to increase the world's energy consumption.

As an ultimate energy source for virtually all natural processes, solar energy is available for direct "harvest" if needed and is absorbed by vegetation and water surfaces on Earth. Thus, it is the driving force for natural photosynthesis, and in turn for biosynthesis processes as well as natural water cycle and all atmospheric processes (see the solar-related renewable energy sources in Table III). The solar radiation power density incident to Earth's atmosphere, known as the solar constant, is 2 cal/min/$(cm)^2$ or 1.4 kW/m^2, which after taking into account average day/night time (50%), varying incident angle (50%), and atmospheric/cloud scatter and absorption (53%), reduces to only $0.5 \cdot 0.5 \cdot 0.47 = 11.7\%$ of the solar constant, or approximately 165 W/m^2 at the Earth's surface, as an all-time average. This solar power per square meter corresponds to human metabolic energy consumption of 3400 kcal/day. The dietary energy reference value of 2000 kcal/day is equivalent to 97 W or 331 Btu/h. Furthermore, the world's total energy consumption is approximately 7500 Btu/h per capita or 2.2 kW per capita (or 11.8 kW per capita in the United States). (The total energy rate in kilowatts needs to be scaled by 31% efficiency to be compared with the electrical energy rate in kilowatts.) The corresponding per capita electricity consumption rates are 0.275 and 1.48 kW in the world and in the United States, respectively.

Therefore, the outlook for future energy needs is encouraging. There are many diverse and abundant energy sources with promising future potentials, so that humankind should be able to enhance its activities, standard of living, and quality of living by diversifying energy sources and by improving energy conversion and utilization efficiencies while at the same time increasing safety and reducing environmental pollution.

Glossary

human development The process of enlarging people's choices by expanding human capabilities and functionings. The three essential capabilities for human development are for people to lead long and healthy lives, to be knowledgeable, and to have a decent standard of living.

Millennium Development Goals Proposed by the United Nations Millennium Declaration of 2002. The declaration, adopted by 147 heads of state and 189 states of the United Nations, mainstreams eight mutually reinforcing development goals and 18 related targets into the global development agenda.

sustainable development Development that meets the needs of the present without compromising the ability of future generations to meet their own needs.

Type II agreements Partnerships between a combination of governments, nongovernmental organizations (NGOs), and the private sector for the implementation of sustainable development.

United Nations Conference on Environment and Development (UNCED) Also know as the Earth Summit, this was held at Rio de Janeiro, Brazil, from June 2 to 14, 1992. By far this was this largest and most prominent global environmental summit.

United Nations Conference on the Human Environment (UNCHE) Held in Stockholm, Sweden, from June 5 to 16, 1972, this was the first meeting to seek global policy consensus on issues related to the environment.

World Summit on Sustainable Development (WSSD) Held in Johannesburg, South Africa, from August 26 to September 4, 2002, this was the third major global environmental summit sponsored by the United Nations.

Energy is related to sustainable development as a source of environmental stress, as a principal motor of macroeconomic growth, and as a prerequisite for meeting basic human needs. These three dimensions correspond to the three dimensions of the often-used triangle of sustainable development: environmental, economic, and social factors. Using this framework, this article traces how successive environmental summits at Stockholm, Rio de Janeiro, and Johannesburg have dealt with energy issues. It identifies a slow, surprising, and important evolution of how energy issues have been treated at these global discussions. Energy has received increasing prominence at these meetings and it has become more firmly rooted in the framework of sustainable development. Stockholm was primarily concerned with the environmental dimension, Rio de Janeiro focused on both the environmental and economic dimensions, and the major headway made in Johannesburg was the meaningful addition of the social dimension and the linking of energy issues to the United Nations' Millennium Development Goals.

1. ENERGY AND SUSTAINABLE DEVELOPMENT: CONCEPTUAL CONNECTIONS

The efficient use of energy and supplies that are reliable, affordable, and less-polluting are widely acknowledged as indispensable components of sustainable development. Although perennial debates linger about precise definitions of sustainable development, there is increasing agreement among scholars and practitioners that sustainable development policy relates to three critical elements that need to be treated together: economic, social, and environmental factors. Energy is central to any discussion of sustainable development because it is central to all three dimensions. In terms of the economic dimension of sustainable development, energy is clearly an important motor of macroeconomic growth. In terms of the environmental dimension, conventional energy sources are major sources of environmental stress at global as well as local levels. In terms of the social dimension, energy is a prerequisite for the fulfillment of many basic human needs and services, and inequities in energy provision and quality often manifest themselves as issues of social justice. Figure 1 presents the now-familiar triangular diagram depicting the three essential elements of sustainable development, modified to show how the energy dimension maps on to each of these elements. The remainder of this section elaborates upon the conceptual linkages between energy and each of the three dimensions of sustainable development.

Having briefly defined a framework for examining the conceptual relationship between energy and sustainable development, let us now examine how the issue of energy has been dealt with at the three major global environmental conferences held at Stockholm (1972), Rio de Janeiro (1992), and Johannesburg (2002). While these are not the only events of importance to have taken place in this period, they are the three most important policy conferences that have been attended by government representatives at the highest level and that have focused on a wide range of issues related to what has come to be known as sustainable development. For this reason, we have not focused on a host of energy-specific conferences that have been held over this period or specific policy negotiations on energy-related issues such as global climate change. Our goal is not as much to focus on the development of energy policy but to concentrate on the development of sustainable development policy to highlight how energy issues have featured within these discussions. Our purpose is to chart the evolution of the policy response and, in particular, to examine whether a perceptible trend of moving from a purely environmental focus to a broader sustainable development focus is evident in how these summits have dealt with energy issues. We will do so by examining the key documents negotiated at each of the three summits in terms of the three dimensions of energy-sustainable development linkages as defined here.

2. THE UNITED NATIONS CONFERENCE ON THE HUMAN ENVIRONMENT

The United Nations Conference on the Human Environment (UNCHE), held in Stockholm, Sweden,

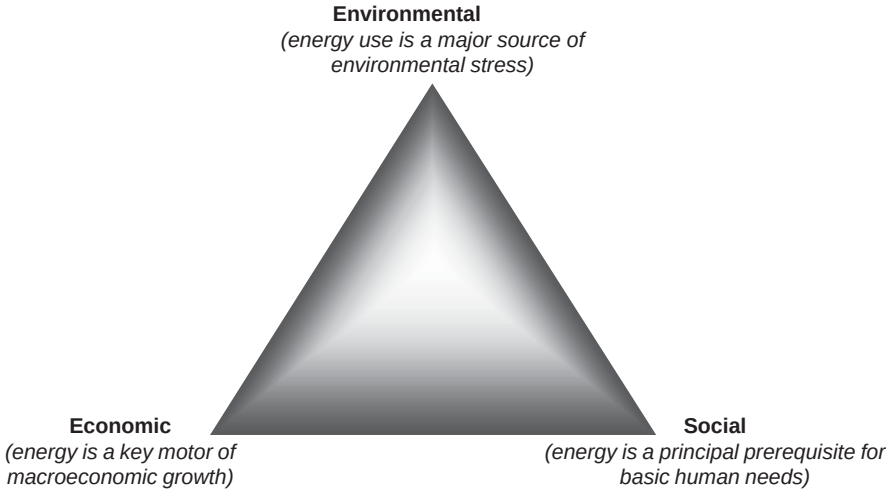

FIGURE 1 Energy and sustainable development: Deep linkages.

from June 5 to 16, 1972, was a first in many respects: it was the first meeting that brought the nations of the world (113 countries participated) together to discuss the environmental future of the planet; it was the first United Nations conference on a single global issue; it was the first global meeting that saw a large presence and influence of nonstate actors, including nongovernmental organizations and scholars; and it was the first meeting to seek global policy consensus on issues related to the environment.

Triggered by increasing scientific evidence of human-induced environmental degradation and a concurrent wave of growing environmental awareness in the industrialized nations of North America and Western Europe, the conference was an attempt to turn the environment into a more global issue, particularly by more meaningfully incorporating the developing countries of the South into the emerging global environmental discourse. The conference turned out to be unexpectedly contentious—with most Soviet bloc countries boycotting it due to the exclusion of then East Germany and with developing countries apprehensive of the North's newfound environmental concern. However, despite the intense North-South differences, and possibly because of them, the conference stumbled toward a more authentic global agenda: one that sought to merge the North's growing concern about environmental quality and the South's long-held interest in human development. Eventually, but much later, the desire to formulate the two interests into a single composite framework would lead to the concept of sustainable development.

The major institutional legacy of the conference was the creation of the United Nations Environmental Programme (UNEP). This was accompanied by two declaratory documents—The Stockholm Declaration and the Stockholm Action Plan—ideas from which have been carried forth by subsequent summits, including at Rio de Janeiro and Johannesburg. In addition to these, a few more ritualistic declarations were also adopted: one calling for a second UN Conference on the Human Environment (which was never actually held), another establishing an annual World Environment Day (which is now observed in most countries each June), and one calling for a stop to nuclear testing, particularly atmospheric nuclear testing (in fact, this was the single most hotly debated issue at the conference and inspired by the global politics of the time).

Surprisingly little was said or discussed at the conference or in any of its formal products regarding issues related to energy (see full text of Stockholm documents at www.unep.org). The conference declaration, which was the major political document emerging from Stockholm, has no direct reference to the energy issue. Of the 26 principles laid out in the declaration, the one that can be construed to be of most relevance to energy issues is Principle 5, which states: "The non-renewable resources of the earth must be employed in such a way as to guard against the danger of their future exhaustion and to ensure that benefits from such employment are shared by all mankind." A little more than one year later, energy was thrust on to the international agenda when the oil crisis nearly doubled real energy prices and plunged many national economies into recession.

The Stockholm Action Plan on the Human Environment is a more comprehensive document that includes a Framework for International Action accompanied by a list of 69 specific recommendations, three of which do, in fact, deal with energy (emphasis added):

- Recommendation 57 called upon the UN Secretary-General to "take steps to ensure proper collection, measurement and analysis of data relating to the *environmental effects* of energy use and production."
- Recommendation 58 called for better exchange of information on energy. The recommendation is motivated by the need for "the rationalization and integration of resource management for energy" and seeks mechanisms (such as exchange of national experiences, studies, seminars, meetings, and a "continually updated register of research") for accessing existing information and data, particularly on "the *environmental consequences* of different energy systems."
- Recommendation 59 called for a "comprehensive study to be promptly undertaken with the aim of submitting a first report, at the latest in 1975, on available energy sources, new technology, and consumption trends, in order to assist in providing a basis for the most effective development of the world's energy resources, with due regard to the *environmental effects* of energy production and use."

Even at Stockholm itself, none of these recommendations was particularly inspiring in its scope or aspiration. They are even less so with the hindsight we now enjoy. Indeed, between them they call merely for better data collection and analysis, and the mechanisms envisaged for doing so are not particularly innovative or exciting. More important, even the minimal level of action that the Action Plan envisaged on the energy issue never really materialized.

For example, the official documents make no mention of Stockholm's implementation of the comprehensive study that was sought by 1975 (Recommendation 59). The one issue related to energy that did gain wide political and policy prominence at Stockholm was atmospheric nuclear testing. This was a subject of great and heated debate at the conference, became the subject of a separate resolution, and made the International Atomic Energy Agency a frequently mentioned organization within the Stockholm Action Plan. This discussion was very much an artifact of the Cold War politics of the time and was at its root far more concerned with nuclear weapons than with energy and its role in the economy and as an agent of environmental change.

The lack of imagination or urgency on the energy issue should not be entirely surprising. Held in mid-1972, the Stockholm conference came before the great oil shock of the 1970s. State delegates attending Stockholm still lived in a relatively calm world of declining real oil prices, and the possibility of spiraling energy prices or oil scarcity could not have been high on their mental maps. Similarly, global climate concerns had not yet taken root in 1972 and environmentalists were more focused on the pollution outputs of industrialization than the energy inputs for economic production. While those attending UNCHE were well aware of the many environmental implications of energy issues, these were not their most pressing priorities at that time.

What is clear from the recommendations, however, is that to the extent that energy was considered an issue of any importance, that importance derived directly from the environmental effects of energy extraction, processing, and consumption. While the recommendations slightly hint at the importance of energy as a motor of economic growth, their principal preoccupation is with the potential for environmental stress from the chain of energy supply and use. The dimension of energy as a prerequisite for meeting basic human needs does not figure into the equation at this juncture.

3. THE UNITED NATIONS CONFERENCE ON ENVIRONMENT AND DEVELOPMENT

The United Nations Conference on Environment and Development (UNCED), popularly know as the Earth Summit, was the crowning moment not only of environmental summitry but of UN mega-summitry as a genre. Held at Rio de Janeiro, Brazil from June 2 to 14, 1992, it brought together more than 100 heads of state and government, 150 nations, more than 1400 nongovernmental organizations (NGOs), 8000 journalists, and nearly 35,000 participants. More than that, it caught the public imagination like no conference before or since. Some consider the summit to have failed its potential, if not its mandate in terms of the content of its substantive agreements. But most commentators and experts consider this summit to have been a success in terms of elevating the global profile of environmental issues and raising awareness regarding sustainable development.

Held to mark the 20th anniversary of the Stockholm conference, the Rio Earth Summit became everything that an earlier "Stockholm plus ten" conference, held in Nairobi in 1982, could not. Indeed, it became more than even its proponents had hoped for. Instead of being the second United Nations Conference on the Human Environment, Rio was the United Nations Conference on Environment *and* Development; putting those two terms together, which had been so much at odds at Stockholm, might itself have been Rio's most important achievement. In particular, it broadened the scope of global environmental diplomacy by adopting the notion of sustainable development, which had been advocated 5 years earlier in by the World Commission on Environment and Development as one of its key policy frameworks.

The world at Rio was, of course, very different from the world at Stockholm. In the intervening two decades, the Cold War (which was the defining political framework at UNCHE) had disappeared, the level of public interest in the environment was greatly increased, environmental issues such as stratospheric ozone depletion and global climate change were now squarely on the global policy map, and energy had become a major concern for economic security in the aftermath of the oil price shocks of 1973–1974 and 1980–1981.

The products coming out of UNCED included a political Declaration enunciating 27 principles of environment and development, a 700-page action program called Agenda 21, a nonbinding set of principles for sustainable forest management, and specific conventions on climate change and biodiversity. The institutional innovation resulting from the conference included an agreement on the operating rules for the Global Environmental Facility (GEF) and the establishment of a Commission on Sustainable Development (CSD) on the basis of an Agenda

21 recommendation. Technically, the official products of UNCED were only the Rio Declaration on Environment and Development, the Authoritative Statement of Forest Principles, and Agenda 21, all of which were adopted by consensus (without vote) by the conference. The conventions on climate change and biodiversity were products of independent, but concurrent, negotiating processes that were opened for signatures at UNCED.

The Rio Declaration on Environment and Development, like its predecessor at Stockholm, had nothing specific to say about energy. Indeed, the clause about the depletion of natural resources contained within the Stockholm Declaration was dropped. While a number of the principles articulated in the Declaration could be construed to have bearing on energy, none deals with the issue directly.

Although the climate and biodiversity conventions were not direct products of the Rio process, the former is of direct relevance to the energy issue. Indeed, the United Nations Framework Convention on Climate Change (UNFCCC) is the nearest thing we have to a global convention dealing directly with energy concerns. Since energy production and consumption is the biggest source of anthropogenic greenhouse emissions, climate policy in the UNFCCC, and subsequently in the 1997 Kyoto protocol, has been discussed mostly through the lens of energy policy in a wide variety of ways. Two examples, among many, of how climate policy becomes energy policy are the intense policy debates about the variable ability and responsibilities of different nations to change their energy consumption and production patterns and the role of energy taxation as a means of emissions control.

These debates during and after Rio have been defined principally by compulsions that lie at two distinct corners of the sustainable development triangle: the environmental compulsion emanating from the ecological stresses associated with specific energy production and consumption choices, and the economic compulsion derived from the central role of energy in economic growth. The saliency that the climate issue had assumed by 1992 meant that the discussion on energy at Rio was not only more intense than it had been at Stockholm but also broader. Whereas UNCHE had been principally concerned with the role of energy as a source of environmental stress, Rio's energy concerns related to both economic and environmental dimensions.

This evolution of the energy focus was quite evident in Agenda 21, the most comprehensive of the Rio documents. Interesting, Agenda 21 (which has a total of 40 chapters) does not have a chapter on energy. However, Chapter 9 of Agenda 21, which deals with protecting the atmosphere, serves as a *de facto* energy chapter since it focused on global climate change and related issues of fossil fuel use. In addition, the chapters on changing consumption patterns (Chapter 4), promoting sustainable human settlements (Chapter 7), and promoting sustainable agriculture and rural development (Chapter 14) also have significant discussions on the energy issue. The vast bulk of this discussion is contextualized in the need to balance the environmental and economic nodes of the sustainable development triangle. What is carried over from Stockholm is a clear emphasis on the environmental impacts of energy production and use (especially in terms of global climate change). New additions are the prescriptions contained in these various chapters—or the energy message of Agenda 21—which fall into familiar categories: decrease energy consumption (see Agenda 21 sections 4.24, 7.5), increase energy efficiency (see Agenda 21 sections 4.18, 7.49), and develop cleaner sources of energy (see Agenda 21 sections 9.12, 9.18).

The third dimension of the sustainable development triangle dealing with social concerns such as the role of energy as a human need do not figure as prominently in Agenda 21 as the environmental and economic dimensions. However, glimpses of such concerns do occasionally surface in the document. For example, the chapter on human settlements (Chapter 7) mentions energy as a human need at par with other needs such as water (see Agenda 21 sections 7.27, 7.40). Section 9.9 goes the furthest by defining energy as an essential component of economic as well as social development and as a prerequisite for an improved quality of life. Although these references are quite general and made in passing, with very little prescriptive policy content, they do signify an important evolution from the Stockholm texts where these issues were conspicuous only by their absence.

Overall, then, one finds that UNCED did treat the energy issue very differently from UNCHE. At Stockholm, energy was discussed in the most general, even cursory, fashion, and only in terms of its environmental impacts. In the years between Stockholm and Rio, concerns about the environmental stress imposed by energy production and use became more precise with the mounting evidence of global climate change. As a result, Rio was relatively more precise and prescriptive in terms of energy policy in that it went beyond simply calling for more

information collection and dissemination to highlighting the need for decreasing consumption, increasing efficiency and transitioning to cleaner sources. In doing so, Rio broadened the focus from merely environmental concerns to the balance between environmental and economic concerns. However, the third node of the sustainable development triangle, the social dimension signified by energy as a human need, still remained in the shadows and peeped through the Rio documents only infrequently and rather unimpressively.

4. THE WORLD SUMMIT ON SUSTAINABLE DEVELOPMENT (WSSD)

Few expected the 2002 World Summit on Sustainable Development (WSSD) to be as impressive as UNCED. Held to mark the 10th anniversary of the Rio Earth Summit and to take stock of progress on Agenda 21 in those 10 years, the run-up to Johannesburg was singularly dismal and uninspiring. The world had, once again, changed. The high hopes of a new era of global environmental cooperation that had been ignited by Rio soon proved false. The industrialized countries of the North had remained unwilling to provide the developing countries of the South with the resources or support that had been implied at Rio, meanwhile the promise of a post-Rio harvest of global environmental treaties and implementation proved unfounded as key states, particularly but not solely the United States, dragged their feet on key issues such as climate change. As a result, a malaise had set in well in advance of WSSD, which was only made worse by events at the geopolitical level, where the global mood had gone sour after the tragic terrorist attack on the United States and a growing sense of insecurity and violence around the world. Held in Johannesburg, South Africa, from August 26 to September 4, 2002, WSSD was different from both Stockholm and Rio in that it was not born within the optimism and high hopes that had accompanied earlier summits.

In terms of sustainable development, WSSD had the distinction of actually having those two magic words in its very title. However little had been achieved in the 10 years since Rio on other counts, Johannesburg was testimony to the fact that the term sustainable development had gained policy acceptance. Even though some argued that the term had lost its edge and was mostly being used rhetorically, the fact remained that it had also become a political necessity. For those who believed in the concept, this was a chance to put meaning into it. At best, Johannesburg was viewed as a chance to advance the agenda that had been set by Rio; at the very least, it was an attempt to keep the Rio agenda alive.

It became clear fairly early on in the Johannesburg process that WSSD would not be able to match the ambition or scope of UNCED, certainly not in terms of its products. Like Stockholm and Rio before it, the Johannesburg summit also sought a political declaration as its principal output. In addition, it also sough a plan of implementation; one that was much less ambitious in scope or scale than Agenda 21 but more extensive than the Stockholm plan of action. The major innovation at Johannesburg were the so-called Type 2 agreements. These were informal agreements involving nonstate parties, sometimes among themselves and sometimes with individual governments. On the one hand, Type 2 agreements were a reflection of the massive change in landscape that had occurred over the previous 10 years, with NGOs and business taking a far more important role in international environmental affairs. At the same time, however, they were a reflection of the WSSD organizer's desperation and desire to get something memorable out of the summit. According to the rough count by the summit organizers, more than 220 Type 2 agreements were reached at Johannesburg, signifying around US$235 million in pledged resources; 32 of these Type 2 agreements relate to energy, accounting for US$26 million in resources; the vast majority of these are programs of technical cooperation in energy generation and conservation (www.johannesburgsummit.org). It should be noted that a systematic accounting of these agreements has not yet been accomplished, and it is not yet clear how many of these agreements and how much of these resources are, in fact, new and unique. The other innovation at Johannesburg, in comparison to previous summits, relates to the fact that the Johannesburg plan of Implementation sought agreement on actual targets and timetables rather than simple statements of intent. While it is true that in many cases (including renewable energy) such targets and timetables were not forthcoming and in others they were merely restatements of targets that had already been set (such as in access to clean water), it is also true that in a few areas (such as sanitation) meaningful headway was made in terms of reaching agreement on targets and timetables where there had previously been none.

Looking carefully at the various products it does seem that amidst the many disappointments of Johannesburg, energy might be one of these few areas where progress was made. First, and quite strikingly, the Johannesburg declaration is different from its predecessors from Stockholm and Rio in that it actually does have a direct reference to energy. More important, the declaration (clause 18) clearly identifies energy as a human need at a par with needs such as clean water, sanitation, shelter, health care, food security, and biodiversity. Although this is a declaratory clause with no enforceability, it does signify a demonstrable shift from the previous summits. It clearly defines energy as a basic human need, thereby evoking the social dimension of the sustainable development triangle more clearly than either Stockholm or Rio had done.

The Johannesburg plan of implementation breaks similar new ground in terms of how it deals with the energy issue. While the focus on the environmental stress-economic growth axis that had emerged at Rio is not at all lost, the Johannesburg plan is strikingly different from its predecessors in two distinct and important ways. First, it clearly deals with energy as an issue in its own distinct right rather than as a facet of other issues. Second, it firmly adds the social dimension to the existing environmental and economic dimensions to begin dealing with the entirety of the sustainable development triangle for the very first time.

The concerns about energy in terms of environmental stress and economic growth show up similarly to how they had surfaced at Rio. The principal arena for these concerns remains climate change and the need for a balanced approach is once again reiterated, as are the preferred mechanisms for achieving such balance: decrease energy consumption, increase energy efficiency, and transition to cleaner energy systems. This discussion is most clear in article 19 of the Johannesburg plan whose 23 subclauses relate to various environmental and economic aspects of energy in relation to sustainable development. The environmental dimension of sustainable development is most clearly and persistently manifest in the many references to the need for enhanced energy efficiency, in particular the call for establishing domestic programs for energy efficiency (subclause h), the need to accelerate the development and dissemination of energy efficiency and energy conservation technologies (subclause i), and the call to promote and invest in research and development of such technologies (subclause k). The economic dimension is also strong in article 19, parts of which call for removing market distortions including the restructuring of taxes and the phasing out of harmful subsidies (subclause p) and the call to support efforts to improve the functioning, transparency, and information about energy markets with respect to both supply and demand (subclause o). One area in which Johannesburg tried, but failed, to make new headway within the environmental-economic axis relates to renewable energy. WSSD saw heated debates about setting up quantifiable targets and timetables for renewable energy use. These discussions eventually failed to yield actual timetables and targets (principally because of U.S. opposition to them), but they did succeed in introducing more detailed language regarding energy issues than had been present in Agenda 21. The subclause (e) of article 19 is, therefore, crafted in general language and calls for diversifying energy supply and substantially increasing the global share of renewable energy sources.

What is new and quite intense in the Johannesburg plan on implementation are the repeated references to energy and sustainable development. Here, the document goes beyond Agenda 21 by focusing more on the social dimension of energy and sustainable development and by concentrating on the role energy plays as a prerequisite for basic human needs including those defined in the United Nations' Millennium Development Goals (MDGs). The most significant of these references is made in article 8 of the plan of Implementation, which falls within the section on poverty eradication. New ground is covered here when the Johannesburg plan clearly and unambiguously calls for

> *access to reliable and affordable energy services for sustainable development sufficient to facilitate the achievement of the millennium development goals, including the goal of halving the proportion of people in poverty by 2015, and as a means to generate other important services that mitigate poverty, bearing in mind that access to energy facilitates the eradication of poverty.*

This is not only interesting but groundbreaking, because the original Millennium Development Goals—a set of quantitative targets proposed by the UN Secretary General to the 2000 Millennium Summit as the foundation of the United Nations' work program from the next decades and as a framework for measuring development progress (see www.developmentgoals.org)—do not mention energy at all. The case for energy as a prerequisite for basic human needs is made, instead, by the Johannesburg plan of implementation. Indeed, it is made

rather convincingly. Subclause (a) of article 8, for example, calls for improving

> *access to reliable, affordable, economically viable, socially acceptable and environmentally sound energy services and resources, taking into account national specificities and circumstances, through various means, such as enhanced rural electrification and decentralized energy systems, increased use of renewables, cleaner liquid and gaseous fuels and enhanced energy efficiency, by intensifying regional and international cooperation in support of national efforts, including through capacity-building, financial and technological assistance and innovative financing mechanisms, including at the micro and meso levels, recognizing the specific factors for providing access to the poor.*

Subclause (g) of the same article, elaborates the case further by calling for

> *access of the poor to reliable, affordable, economically viable, socially acceptable and environmentally sound energy services, taking into account the instrumental role of developing national policies on energy for sustainable development, bearing in mind that in developing countries sharp increases in energy services are required to improve the standards of living of their populations and that energy services have positive impacts on poverty eradication and improve standards of living.*

Here, then, is an example of all three dimensions of the sustainable development triangle being invoked together and in a way that was not seen in any of the Stockholm or Rio documents. Although this is still preliminary, it is nonetheless a novel and welcome attempt to deal with energy fully in the context of sustainable development by seeking policy that responds to the environmental, economic as well as the social impulses of the concept. Policy made under the guidelines set here would need to be evaluated not only in terms of the environmental stresses being imposed, or effects on economic growth, but also in terms of social justice and especially in terms of how it affects the poorest and the most vulnerable.

5. AN EVOLVING AGENDA

The process of evolution that seems to have taken place between the 1972, 1992, and 2002 environmental summits is depicted in Fig. 2, which builds on the three dimensions of sustainable development to illustrate how the documents emerging from each successive conference have dealt with energy issues. Figure 2 suggests that a rather neat evolution of the agenda has happened with the Stockholm summit of 1972 dealing with energy issues principally as a source of environmental stress, the 1992 Rio summit added a clear economic focus to its treatment of the subject, while the 2002 Johannesburg conference built on the existing environmental and economic focus and added the element of energy as a requisite for basic human needs to the equation for the first time. Of course, the fact that these summits have dealt with energy in a particular way does not imply that global energy policy has moved in that direction automatically. The purpose of such summits is principally declaratory. However, the value of these declaratory proclamations must not be underestimated. They serve not only to advance the conceptual agenda but also tend to eventually influence the actual policies, although usually with some time lag.

In terms of general conclusions, a number of surprises can be highlighted:

1. Although conventional wisdom maintains that Johannesburg is a pale comparison to conferences before it, on the specific issue of energy it has actually

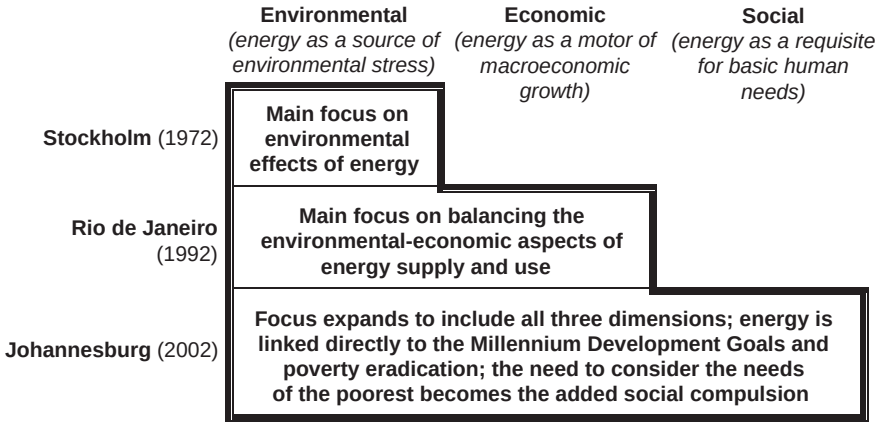

FIGURE 2 Energy and sustainable development: An evolving agenda.

made major conceptual headway by incorporating the energy issue more fully into a sustainable development framework. While the conference as a whole may not have been inspiring, on this one issue it has traversed into new and important territory.

2. It is rather surprising that the UN Millennium Development Goals fail to identify energy as a key human development and human needs theme. However, the Johannesburg plan of implementation has partially filled that gap and made the argument that would have better come from the Millennium Development Goals. That energy is a prerequisite for many human needs and for poverty alleviation merits explicit inclusion in the Millennium Development Goals. Because of Johannesburg, this notion now has the endorsement of the comity of nations, and there seems to be a strong case for incorporating energy issues explicitly within MDG programs.

3. There is a need for the practice of energy policy as well and the scholarship on energy policy to catch up with the realization imbedded in the Johannesburg plan on implementation regarding the importance of energy as a prerequisite for basic human needs.

4. A broader argument can now be made that megaconferences can advance global agendas in significant ways, as they have done with energy. The energy gives cause for more optimism than many scholars invest in these conferences. However, a corollary to be investigated further would be whether such impact is more likely to be noticeable on specific issues rather than on the general agenda as a whole.

6. CONCLUSIONS

In focusing on the actual text of the documents negotiated at various global environmental summits and using a framework of how energy policy relates to various aspects or dimensions of sustainable development, this article finds that there has been a slow but demonstrable evolution in how these conferences have dealt with energy. Not only has energy assumed a successively more prominent role in these global summits, but a noticeable evolution has occurred in the dimensions of energy policy that have been addressed. Moreover, this evolution has been along the trajectory of sustainable development. Although energy policy per se might not have made this transition as yet, these summits have given a clear signal to national and international policymakers to align energy policy more firmly to sustainable development, and to do so in more intricate ways.

In terms of evaluating the impact of the Johannesburg Earth Summit on the energy and sustainable development agenda, it seems that the one summit that had started with the worst prospects might well have achieved the most important advance in terms of conceptualizing energy policy within a framework rooted in all dimensions of sustainable development. Both the Johannesburg declaration and the Johannesburg plan of implementation are remarkable in that they highlight the human need aspect of energy, in addition to the environmental and economic dimensions that had already been incorporated at Stockholm and Rio.

Glossary

antiquity The era of ancient (from the Western perspective, mostly the Middle Eastern and Mediterranean) civilizations extant between prehistory and the Middle Ages.

determinism A doctrine claiming that human actions are determined by external factors; its prominent varieties include environmental and geographic determinism.

early modern world The period immediately following the Middle Ages, variously dated as 1493–1800, 1550–1850, or the 16th to 18th centuries.

energy transition A period of passing from one configuration of prime movers and dominant fuels to a new setup.

middle ages The period between antiquity and the modern era, often circumscribed by the years 500–1500 CE.

prehistory The period of human evolution predating recorded history.

A strict thermodynamic perspective must see energy—its overall use, quality, intensity, and conversion efficiency—as the key factor in the history of the human species. Energy flows and conversions sustain and delimit the lives of all organisms and hence also of superorganisms such as societies and civilizations. No action—be it a better crop harvest that ends a famine or the defeat of an aggressive neighbor—can take place without harnessing and transforming energies through management, innovation, or daring. Inevitably, the availability and quality of particular prime movers and sources of heat and the modes of their conversions must have left deep imprints on history. But no energetic perspective can explain why complex entities such as cultures and civilizations arise and no thermodynamic interpretation can reveal the reasons for either their remarkable history or their astounding diversity of beliefs, habits, and attitudes from which their actions spring. This article examines both of these contrasting views of energy and world history.

1. A DETERMINISTIC VIEW OF HISTORY

Countless energy imperatives—ranging from the solar flux reaching the earth to minimum temperatures required for the functioning of thousands of enzymes—have always shaped life on Earth by controlling the environment and by setting the limits on the performance of organisms. Deterministic interpretations of energy's role in world history seems to be a natural proposition, with history seen as a quest for increased complexity made possible by mastering higher energy flows. Periodization of this quest on the basis of prevailing prime movers and dominant sources of heat is another obvious proposition. This approach divides the evolution of the human species into distinct energy eras and brings out the importance of energy transitions that usher in more powerful, and more flexible, prime movers and more efficient ways of energy conversion. Perhaps the most intriguing conclusion arising from this grand view of history is the shrinking duration of successive energy eras and the accelerating pace of grand energy transitions.

The first energy era started more than 300,000 years ago when the human species, *Homo sapiens*, became differentiated from *Homo erectus*, and the era continued until the beginning of settled societies some 10,000 years ago. Throughout prehistory, all efforts to control greater energy flows were capped

by the limited power of human metabolism and by the inefficient use of fire. Domestication of draft animals and harnessing of fire for producing metals and other durable materials constituted the first great energy transition: reliance on these extrasomatic energies had raised energy throughput of preindustrial societies by more than an order of magnitude. The second transition got under way only several millennia later; it was not as universal as the first one and its effects made a profound, and relatively early, difference only in some places: it came as some traditional societies substituted large shares of their muscular exertions by waterwheels and windmills, simple but ingenious inanimate prime movers that were designed to convert the two common renewable energy flows with increasing power and efficiency.

The third great energy transition—substitution of animate prime movers by engines and of biomass energies by fossil fuels—began only several centuries ago in a few European countries and it was accomplished by all industrialized nations during the 20th century. That transition is yet to run its course in most low-income economies, particularly in Africa. The latest energy transition has been under way since 1882 when the world's first electricity-generating stations were commissioned in London and New York (both Edison's coal-fired plants) and in Appleton, Wisconsin (the first hydroelectric station). Since that time, all modernizing economies have been consuming increasing shares of their fossil fuels indirectly as electricity and introducing new modes of primary electricity generation—nuclear fission starting in the mid-1950s, and later also wind turbines and photovoltaic cells—to boost the overall output of this most flexible and most convenient form of energy. The second key attribute of this transition has been a steady relative retreat of coal mirrored by the rise of hydrocarbons, first crude oil and later natural gas.

Improving the quality of life has been the principal individual benefit of this quest for higher energy use that has brought increased food harvests, greater accumulation of personal possessions, abundance of educational and leisure opportunities, and vastly enhanced personal mobility. The growth of the world's population, the rising economic might of nations, the extension of empires and military capabilities, the expansion of world trade, and the globalization of human affairs have been the key collective consequences of the quest. These advances are discussed in this article and the limits of prime movers and heat sources that were available during the successive eras of energy use and the major accomplishments that were achieved through ingenuity and better organization are noted.

2. THE EARLIEST ENERGY ERAS

During the long span of prehistory, the human species relied only on its somatic energy, using muscles to secure a basic food supply and then to improve shelters and acquire meager material possessions. Organismic imperatives (above all, the basal metabolism scaling as the body mass raised to 0.75 power) and the mechanical efficiency of muscles (able to convert no more than 20–25% of ingested food to kinetic energy) governed these exertions: healthy adults of smaller statures cannot sustain useful work at rates of more than 50–90 W and can develop power of 10^2 W only during brief spells of concentrated exertion. The former performance sufficed for all but a few extreme forms of food gathering and the latter exertions were called on for some forms of hunting. Simple tools made some foraging and processing tasks more efficient and extended the reach of human muscles.

Energy returns in foraging (energy in food/energy spent in collecting and hunting) ranged from barely positive (particularly for some types of hunting) to seasonally fairly high (up to 40-fold for digging up tubers). The choice of the collected plants was determined above all by their accessibility, nutritional density, and palatability, with grasslands offering generally a better selection of such species than did dense forests. Collective hunting of large mammals brought the highest net energy returns (because of their high fat content) and it also contributed to the emergence of social complexity. Only a few coastal societies collecting and hunting marine species had sufficiently high and secure energy returns (due to seasonal migrations of fish or whales) such that they were able to live in permanent settlements and devote surplus energy to elaborate rituals and impressive artistic creations (for example, the tall ornate wooden totems of the Indian tribes of the Pacific Northwest).

The only extrasomatic energy conversion mastered by prehistoric societies was the use of fire for warmth and cooking, which can be indisputably dated to approximately 250,000 years ago. Eventual shifts from foraging to shifting cultivation and then to sedentary farming were gradual processes driven by a number of energy-related, nutritional, and social factors: there was no short and sharp agricultural revolution. These changes were accompanied by

declining net energy returns in food production, but these declines had a rewarding corollary as the higher investment of metabolic energy in clearing land and in planting, weeding, fertilizing, harvesting, and processing crops, as well as storing grains or tubers, made it possible to support much higher population densities. Whereas the most affluent coastal foraging societies had densities less than 1 person/km^2 (and most foraging societies had carrying capacities well below 0.1 person/km^2), shifting agricultures would easily support 20–30 people/km^2 and even the earliest extensive forms of settled farming (ancient Mesopotamia, Egypt and China's Huanghe Valley) could feed 100–200 people/km^2, that is, 1–2 people/ha of cultivated land (Fig. 1).

The increasing size of fields could not be managed by slow and laborious hoeing but plowing is either exceedingly taxing or, in heavy soils, outright impossible without draft animals. Farming intensification thus led to harnessing the first important extrasomatic source of mechanical energy by domesticating draft animals throughout the Old World (the pre-Colombian Americas had only pack animals). Continuous energy investment was then needed for animal breeding and feeding, as well as for producing more complex implements.

Small bovines would rate less than 200 W, stronger animals could sustain more than 300 W, and the best oxen and good early draft horses could surpass 500 W, equal to the labor of 6–8 adult men (Fig. 2). Draft animals thus speeded up field, transportation, and crop processing tasks and boosted agricultural productivity. Their numbers were governed by an obvious energetic imperative: no society could afford to cultivate feed crops where harvests were barely adequate to provide subsistence diets. Those agroecosystems where grazing land was also limited (the rice regions of Asia) could support only relatively small numbers of draft animals.

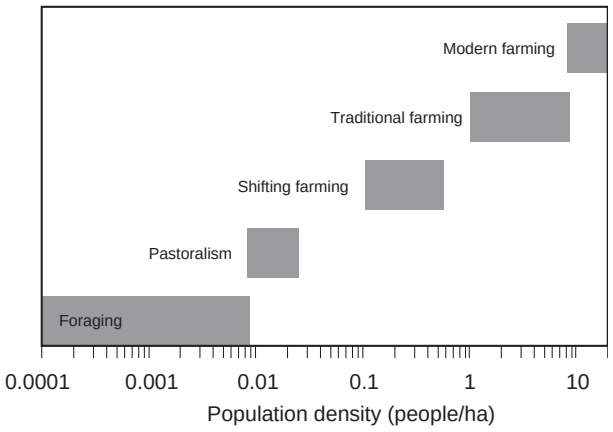

FIGURE 1 Successive stages of sedentary agricultures have required higher energy inputs but have been able to support 10^3 to 10^4 more people per unit of land than did foraging.

Limited unit power of muscles could be overcome by massing people, or draft animals, and the combination of tools and organized deployment of massed labor made it possible to build impressive structures solely with human labor. Massed forces of 20–100 adults could deliver sustained power of 1.5–8 kW and could support brief exertions of up to 100 kW, enough to transport and erect (with the help of simple devices) megaliths and to build impressive stone structures on all continents except Australia. In contrast to this massed deployment of human labor in construction, no Old High culture took steps to a truly large-scale manufacture of goods and the atomization of production remained the norm. In addition, violent conflict powered solely by an individual's muscles could take place only as hand-to-hand combat or by an attack with an arrow launched from less than a couple hundred meters away, a limit ordained by the maximum distance between one extended and one flexed arm when drawing a bow. Eventually catapults, tensioned by many hands, increased the mass of projectiles, but did not substantially lengthen the maximum distance of attack.

Shifting agriculturalists extended the use of fire to the regular removal of vegetation, and early settled societies also adopted fire to produce bricks and containers and to smelt metals, beginning with copper (before 4000 BCE) and progressing to iron (common in some parts of the Old World after 1400 BCE). Charcoaling was used to convert wood to a fuel of higher energy density (29 MJ/kg compared to no more than 20 MJ/kg for wood and less than 15 MJ/kg for crop residues) and superior quality (essentially smokeless and hence suitable for burning indoors in fixed or portable hearths). But open fireplaces and braziers converted less than 10% of the supplied energy into useful heat and traditional charcoaling turned less than one-fifth of the charged wood energy into the smokeless fuel. Primitive furnaces used for metal smelting were also very inefficient, requiring as much as 8–10 units of charcoal for a unit of pig iron. The resulting high demand for wood was a leading cause of extensive deforestation, but a nearly complete disappearance of forests from parts of the Mediterranean (Spain, Cyprus, and Syria) and the Near East (Iran, Afghanistan) was caused by smelting copper rather than iron.

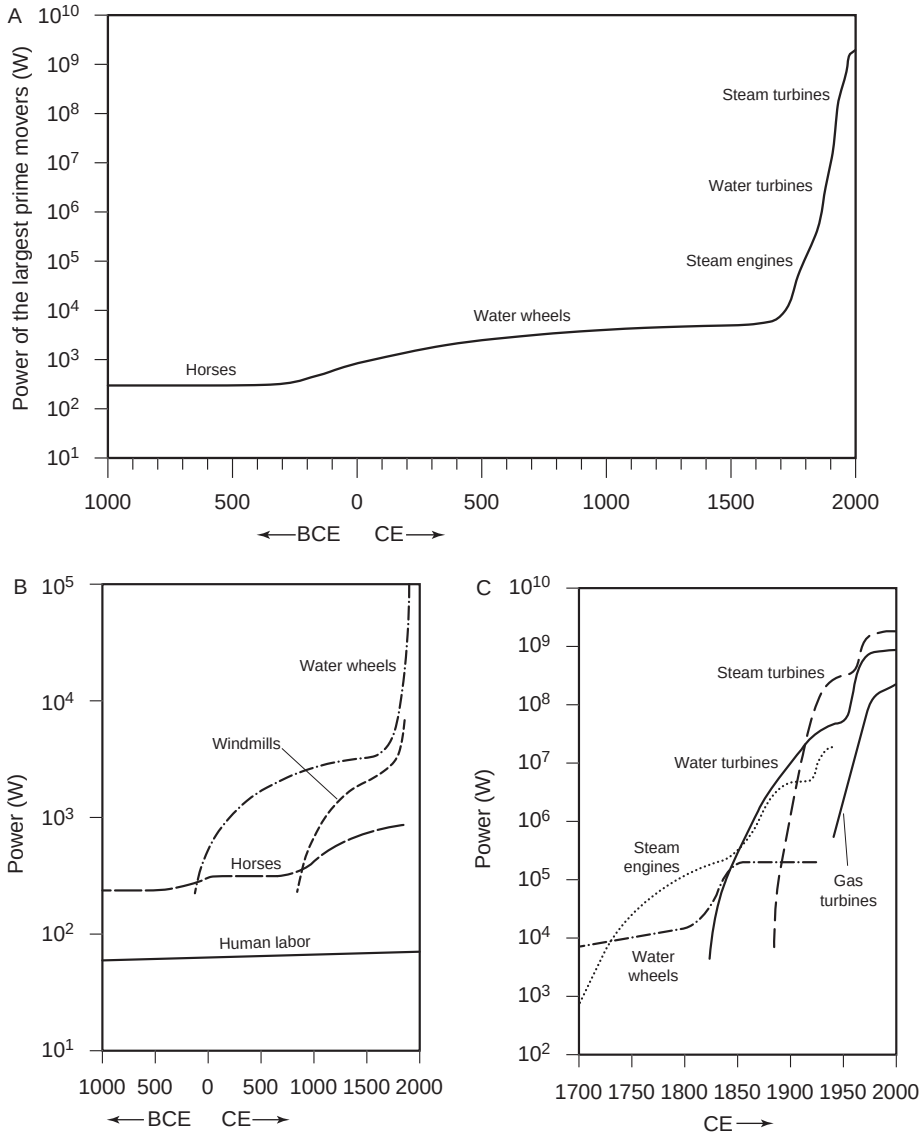

FIGURE 2 The maximum power of prime movers shown as the sequence of the highest capacity converters for the span of the past 3000 years (A) and shown in detail for the periods 1000 BCE to 1700 CE and 1700 CE to 2000 CE (B and C).

Small-scale and highly energy-intensive metallurgy meant that no early societies could smelt enough metal to make it the dominant material in daily use and simple machines, farming implements, and household utensils of the antiquity remained overwhelmingly wooden. This changed radically only when coke-based smelting began producing inexpensive iron after 1750. Similarly, the inherently limited power of oxen, the most affordable draft animals, which were rarely fed any concentrates, meant a ponderous pace of field operations: plowing a hectare of a loamy field with a pair of these animals was easily four times faster than hoeing the same land, but a pair of well-fed horses would have accomplished the same task in less than one-half the time required by oxen. And the combination of weak animals, inefficient harnessing, and poor (unpaved) roads greatly restricted the size of maximum loads and the greatest distance of daily travel.

European antiquity also saw the first uses of water-driven prime movers. Their origins are obscure, with the first reference to their existence, by Antipater of Thessalonica during the first century BCE, describing their use in grain milling. The earliest wheels were horizontal, with water directed

through a sloping wooden trough onto wooden paddles fitted to a shaft that was directly attached to a millstone above. More efficient vertical water wheels, first mentioned by Vitruvius in 27 BCE, turned the millstones by right–angle gears and operated with overhead, breast, or undershot flows. Although there were some multiple installations of Roman water wheels—perhaps most notably the set of 16 wheels at Barbegal near Arles amounting to over 30 kW of capacity—cheap slave labor clearly limited the adoption of these machines.

3. MEDIEVAL AND EARLY MODERN ADVANCES

The dominance of animate prime movers extended throughout the Middle Ages but their efficiency had improved and they were increasingly joined by gradually more powerful converters of flowing water and wind. Human statures did not show any notable growth during the medieval era but better designs of some man-powered machines were able to harness muscle power more efficiently. Man- and animal-powered tread-wheels were deployed in the construction of tall buildings and in loading and unloading ship cargoes. The combination of breeding, better feeds, more efficient harnessing, and shoeing eventually raised the performance of the best draft animals as much as 50% above the capacities that prevailed during antiquity.

The collar harness, optimizing the deployment of powerful breast and shoulder muscles, had its origins in China of the 5th century of the CE and its improved version became common in Europe five centuries later. Iron horseshoes, preventing excessive wear of hooves and improving traction, became common at approximately the same time. But it took centuries before the intensification of cropping, with more widespread rotation of food and feed (particularly leguminous) species, increased the availability of concentrate feeds and allowed for harder working draft animals. During the 18th century, a good horse was considered to be equivalent to 10 men, or at least 700 W, and the best horses would eventually surpass power equivalent to 1 kW. Whereas a pair of early medieval oxen could sustain no more than 600 W, a pair of good horses in early modern Europe delivered 1.2 kW and large horse teams (up to 40 animals) deployed in the United States after 1870 to pull gang plows or the first grain combines had draft power of at least 8 kW and up to 30 kW.

Some medieval societies began to rely on inanimate prime movers for a number of demanding tasks including grain milling, oil pressing, wood sawing, powering of furnace bellows and forge hammers, and the mechanization of manufacturing processes ranging from wire pulling to tile glazing. Waterwheels were the first machines to spread widely and the famous Domesday Book attests how common they were in England of the late 11th century: it lists 5624 water mills in southern and eastern England, one for every 350 people. A subsequent increase in the highest capacities of waterwheels was slow: it took nearly 800 years to boost the performance by an order of magnitude. Early modern Europe developed some relatively very large water-driven wheels, and although typical unit capacities of these wooden machines remained limited (by 1700 they averaged less than 4 kW), they were the most powerful prime movers of the early modern era (Fig. 2).

Ships with simple square sails were used by the earliest Old World civilizations, but the first written record of wind-driven machines comes only approximately 1000 years after the first mention of water wheels. In 947 CE, al-Masudi's report described their use to raise water for irrigating gardens in what is now eastern Iran, and the first European record dates only from the closing decades of the 12th century. Subsequently, inefficient windmills continued to be used infrequently throughout the Mediterranean and the Middle East, and even less so in India and in East Asia, and they had undergone a great deal of development in only a small number of European regions. The earliest European windmills pivoted on a massive central post that was supported usually by four diagonal quarter-bars, had to be turned to face the wind, and were unstable in high winds and their low height limited their efficiency.

However, they were widely used in grain milling and water pumping (the Dutch drainage mills being the best known example), as well as in some industrial operations. Post mills were gradually replaced by tower mills and smock mills, and during the early 17th century the Dutch millers introduced first relatively efficient blade designs (however, true airfoils, aerodynamically contoured blades with thick leading edges, originated only just before the end of the 19th century), and after 1745 the English invention of using a fantail to power a winding gear turned the sails into the wind automatically. Even with these innovations, the average power of the 18th century windmills remained below 5 kW.

The Late Middle Ages and the early modern era were also the time when wind energy was harnessed

more effectively for Europe's great seafaring voyages. The rise of the West clearly owes a great deal to an unprecedented combination of harnessing two different kinds of energy: better, and larger, sailships equipped with newly developed heavy guns. Once the medieval ships became rigged with a larger number of loftier and better adjustable sails, increased in size, and acquired stern-post rudders and magnetic compasses (both invented in China), they became much more efficient, and much more dirigible, converters of wind energy. These ships carried first the Portuguese and then other European sailors on increasingly more audacious voyages. The equator was crossed in 1472, Columbus led three Spanish ships to the Caribbean in 1492, Vasco da Gama rounded the Cape of Good Hope and crossed the Indian Ocean to India in 1497, and in 1519 Magellan's *Victoria* completed the first circumnavigation of the earth. The inexorable trend of globalization was launched with these sailings.

Gunpowder was another Chinese invention (during the 11th century) that was better exploited by the Europeans. The Chinese cast their first guns before the end of the 13th century, but Europeans were only a few decades behind. Within a century, superior European gun designs transformed the medieval art of war on land and gave an offensive superiority to large sailships. Better gun-making was obviously predicated on major medieval advances in ore-mining and metal-smelting techniques that are exhaustively described in such classics as Biringuccio's and Agricola's volumes from 1540 and 1556, respectively.

These innovations reduced the need for energy inputs, particularly in the iron-making blast furnaces that appeared first in the lower Rhine valley before the end of the 15th century. As these furnaces grew in volume, charcoal's fragility limited their height and the annual volume of individual smelting operations. Larger operations also required the use of waterpower (for blasting and subsequent metal forging) and this demand restricted the location to mountainous areas. But the main challenge was to keep them supplied with charcoal, and the English predicament is the best illustration.

By the early 18th century, a typical English furnace produced only approximately 300 tons of pig iron per year, but with at least 8 kg of charcoal per kilogram of iron and 5 kg of wood per kilogram of charcoal, its annual demand was approximately 12,000 tons of wood. With nearly all natural forests gone, the wood was cut in 10- to 20-year rotations from coppicing hardwoods yielding between 5 and 10 tons/ha. This means that approximately 2000 ha of coppicing hardwoods, a circle with a radius of 2.5 km, were needed for perpetual operation. Nationwide (with nearly 20,000 tons of pig iron produced annually during the 1720s), this translated (together with charcoal needed for forges) to at least 1100 km^2 of coppiced growth. To produce 1 million tons with the same process would have required putting at least one-quarter of the British Isles under coppiced wood, an obvious impossibility. Yet starting in the mid-1830s, Great Britain began smelting more than 1 million tons of iron per year and yet some the country's forests began regrowing; coke and steam engines made that possible.

4. TRANSITIONS TO MODERNITY

Millennia of dependence on animate power and biomass fuels came to an end only gradually and the great transition to fossil fuels and fuel-consuming engines had highly country-specific onsets and durations. Differences in accessibility and affordability explain why traditional energy sources were used for so long after the introduction of new fuels and prime movers. For example, four kinds of distinct prime movers, in addition to human labor, coexisted in parts of Europe for more than 150 years between the late 18th and the mid-20th centuries before internal combustion engines and electric motors became totally dominant: draft animals (both in agriculture and in city traffic), water wheels (and, since the 1830s, water turbines), windmills, and steam engines. In the wood-rich United States, coal surpassed fuelwood combustion and coke became more important than charcoal only during the 1880s.

Moreover, the epochal energy transition from animate to inanimate prime movers and from biomass to fossil fuels has yet to run its global course. By 1900, several European countries were almost completely energized by coal—but energy use in rural China during the last year of the Qing dynasty (1911) differed little from the state that prevailed in the Chinese countryside 100 or 500 years earlier. Even in the early 1950s, more than one-half of China's total primary energy supply was derived from woody biomass and crop residues. The share of these fuels had been reduced to 15% of China's total energy use by the year 2000, but it remains above 70%, or even 80%, for most of the countries of sub-Saharan Africa (in the year 2000, India's share of traditional biomass fuels was approximately 30% and that of Brazil was approximately 25%), and globally it still accounts for nearly 10%.

Industrialization of the British Isles is, of course, the best known case of an early transition from wood to coal and England was the first country to accomplish the shift from wood to coal during the 16th and 17th centuries. Much less known is the fact that the Dutch Republic completed a transition from wood to peat during its Golden Age of the 17th century when it also replaced a large share of its mechanical energy needs by sailships, which moved goods through inland canals and on the high seas, and by windmills. In England and Wales, the process started as a straightforward fuel substitution in a society where the combined demand for charcoaling, ship- and house-building, heating, and cooking led to extensive deforestation. The use of coal as the fuel for a new mechanical prime mover began only after 1700 with Newcomen's inefficient steam engine. James Watt's separate condenser and other improvements (patented in 1769) transformed the existing engine from a machine of limited utility (mostly water pumping in coal mines) into a prime mover of unprecedented power suitable for many different tasks.

Watt's improved machines still had low conversion efficiency (less than 5%) but his engines averaged approximately 20 kW, more than 5 times that of the typical contemporary watermills, nearly 3 times that of windmills, and 25 times the performance of a good horse. One hundred years later, the largest stationary steam engines were 10 times as efficient as Watt's machines and rated $\approx$1 MW. After the expiration of Watt's patent, the development of high-pressure steam engines progressed rapidly, radically transforming both land and maritime travel. For centuries, horse-drawn carriages averaged less than 10 km/h, but by 1900, trains (the first scheduled services began during the 1830s) could go easily 10 times faster and carry passengers in much greater comfort (Fig. 3). Railways had also drastically lowered the cost of moving voluminous loads in areas where inexpensive canal transport was not possible. Steamships cut the length of intercontinental travel and greatly expanded and speeded long-distance trade. For example, trans-Atlantic crossing, which took more than 1 week with the sailships of the 1830s, was cut to less than 6 days by 1890.

Steam engines will be always seen as the quintessential energizers of the Industrial Revolution, that great divide between the traditional and the modern world. But this notion is far from correct, and so is the very idea of the Industrial Revolution. Coal did power the expansion of iron-making, but the textile industry, the key component of that productive transformation, was commonly energized, both in

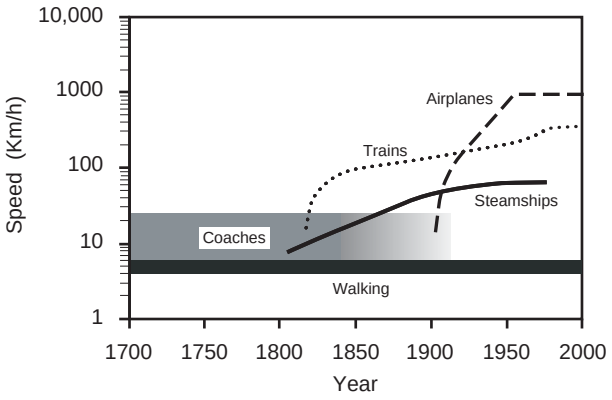

FIGURE 3 Maximum speeds of transportation during the years 1700–2000.

Europe and in North America, by water power rather than by coal combustion. Innovations to meet this demand included Benoit Fourneyron's reaction water turbine (in 1832) and an inward–flow turbine of James B. Francis (in 1847). Before the century's end, Francis' turbines and also Pelton machines (jet–driven turbines introduced in 1889) helped to launch modern water-powered electricity generation (only Viktor Kaplan's axial flow turbines are a 20th century innovation). As for the Industrial Revolution, the author sides with those historians who see it much more as a complex, multifaceted, and protracted process rather than as a clearly definable, intensive transformation powered by coal and coal-generated steam. After all, in 1850, England still had more shoemakers than coal miners and more blacksmiths than ironworkers, and in the United States, coal began providing more energy than wood only during the early 1880s.

Another little appreciated fact is that the harnessing of wind energy reached its peak at the same time that the steam engine did. America's westward territorial progression across the windy Great Plains created a demand for windmills to pump water for steam locomotives, households, and cattle. These machines were made generally of large numbers of fairly narrow slats that were fastened to solid or sectional wheels and usually equipped with either the centrifugal or the side–vane governor and independent rudders. Total sales of these relatively small (less than 1 kW) machines amounted to millions of units after 1860, whereas the capacity of approximately 30,000 larger windmills in countries around the North Sea peaked at approximately 100 MW by the year 1900.

From the vantage point of the early 21st century, it is clear that it was the next energy transition—the

process of electrification and the rising global dependence on hydrocarbons—that has left the greatest mark on individual lives as well as on the fortunes of economies and nations during the 20th century. The invention of a commercially viable system of electricity generation, transmission, and use (beginning only with incandescent lighting) by Thomas A. Edison and his associates was compressed into a remarkably short period during the early 1880s. This was followed by a no less intensive period of innovation with fundamental contributions by George Westinghouse [who correctly insisted on alternate current (AC) for transmission], Charles Parsons (who patented the first steam turbine in 1884), William Stanley (who introduced an efficient transformer in 1885), and Nikola Tesla (who invented the electric motor in 1888).

As a result, by the late 1890s, the entire electric system was basically perfected and standardized in the form that is still relied on today; the challenge ahead was to keep enlarging its unit sizes and improving efficiencies and this challenge has been met in many impressive ways. Since 1900, the maximum sizes of turbogenerators grew from 10 to $\approx$1.5 GW, AC transmission voltages rose from less than 30 kV to more than 700 kV, and in 2003, the best efficiencies of thermal generation surpassed 40% (and with cogeneration 60%), compared to as little as 5% in 1900. An inexpensive and reliable supply of electricity transformed every aspect of everyday activities by bringing bright and affordable light to both interiors and streets, by powering a still-growing array of time-saving and leisure-enhancing gadgets, and by energizing urban and intercity trains.

But the most revolutionary consequence of electrification was in industrial production. The reciprocating motion of steam engines had to be transmitted by rotating shafts and belts, resulting in friction and a great deal of lost time with accidents and allowing only limited control of power at individual workplaces. Inexpensive electric motors of all sizes changed all that: no shafts and belts, no noise and dangerous accidents, only precise and flexible individual power controls. American manufacturing was the first to make the transition in just three decades: by 1929, the capacities of industrial electrical motors accounted for over 80% of all installed mechanical power. Highly productive assembly lines (Ford pioneered them in 1913) were an obvious product of this transformation, as were many new specialized industries. And although the experimental beginnings of radio and television predate World War I, it was only after World War II that electricity began powering the new computer age with its immense flow of information and entertainment options.

Electricity has been also the principal means of easing the burden of female household labor as a growing variety of machines and gadgets took over common chores. Another great change brought about by inexpensive electricity has been the global spread of air conditioning (first patented by William Carrier in 1902). Its availability opened up the American Sunbelt to mass migration from the Snowbelt, and since the 1980s, room units have also spread rapidly among more affluent households of subtropical and tropical countries.

The age of crude oil was launched during the same decade as that of electricity, and the three key ingredients of a modern automobile—Gottlieb Daimler's gasoline-fueled engine, Karl Benz's electrical ignition, and Wilhelm Maybach's float-feed carburetor—came together during the 1890s when Rudolf Diesel also introduced a different type of internal combustion engine. Subsequent decades have seen a great deal of improvement but no fundamental change of the prime mover's essentials. Only in the United States and Canada did car ownership reach high levels before World War II; Western Europe and Japan became nearly saturated only during the 1980s. By 1904, the Wright brothers built their own four-cylinder engine with an aluminum body and a steel crankshaft to power the first flight of a machine heavier than air, and the first 50 years of commercial and military flight were dominated by airplanes powered by reciprocating engines. Jet engines powered the first warplanes by 1944; the age of commercial jet flights began during the 1950s and was elevated to a new level by the Boeing 747, introduced in 1969.

Transportation has been the principal reason for the higher demand for crude oil, but liquid fuels, and later natural gas, also became very important for heating, and both hydrocarbons are excellent feedstocks for many chemical syntheses. By 1950, crude oil and natural gas claimed approximately 35% of the world's primary energy supply, and by 2000, their combined share was just over 60% compared to coal's approximately 25% (Fig. 4). Fossil fuels thus provided approximately 90% of all commercial primary energy supply, with the rest coming from primary (hydro and nuclear) electricity. Despite a great deal of research and public interest, new renewable conversions (above all, wind turbines and photovoltaics) still have only a negligible role, as do fuel cells whose high conversion efficiencies

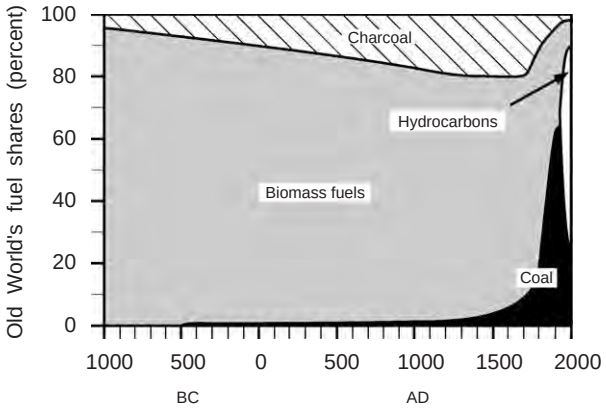

FIGURE 4 Approximate shares of global fuel consumption in the period from 1000 BCE to 2000 CE.

and pollution-free operation offer a much better way of converting gaseous and liquid fossil fuels to kinetic energy than does air-polluting combustion.

5. HIGH-ENERGY CIVILIZATION AND ITS ATTRIBUTES

Fossil fuels and electricity have helped to create the modern world by driving up farm productivity and hence drastically reducing agricultural populations, by mechanizing industrial production and letting the labor force move into the service sector, by making megacities and conurbations a reality, by globalizing trade and culture, and by imposing many structural uniformities onto the diverse world. Inevitably, all of these developments had enormous personal and collective consequences as they released hundreds of millions of people from hard physical labor, improved health and longevity, spread literacy, allowed for rising material affluence, broke traditional social and economic confines, and made the Western ideas of personal freedom and democracy into a powerfully appealing (as well as fanatically resented) global force.

But these benefits are fully, or largely, enjoyed only by a minority (only $\approx 15\%$) of the world's population. The great energy transitions of the past century raised standard of living everywhere but it has not been accompanied by any impressive decline of disparities between rich and poor societies. In the year 2000, the richest 10% of the world's population consumed more than 40% of all commercial primary energy (Fig. 5). In addition to being liberating and constructive, modern high-energy civilization is an enormous source of environmental pollution and degradation

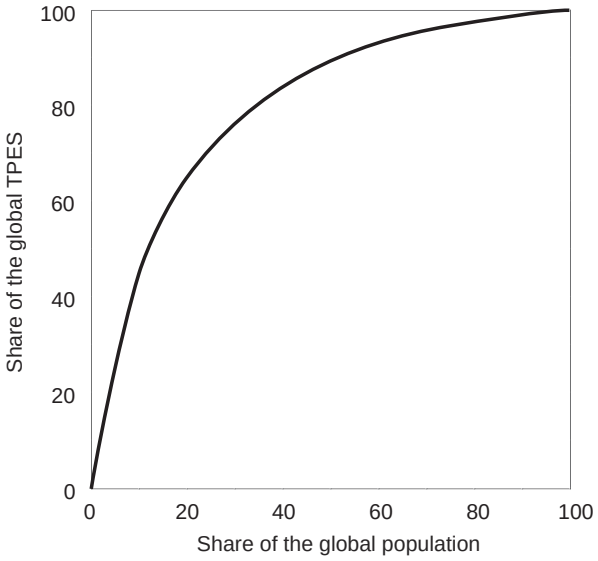

FIGURE 5 Inequality of global commercial energy use in the year 2000 is indicated by a highly convex shape of the Lorenz curve: the richest 10% of the world's population claimed approximately 45% of all energy, whereas the poorest 50% had access to just 10% of the total.

of ecosystems (perhaps even endangering the very maintenance of a habitable biosphere), is prone to many social ills accentuated by urban living, has acquired weapons of mass destruction, and is highly vulnerable to asymmetrical threats of terrorism.

People who live in affluent societies take the levels of energy that individuals and collectives control for granted, but the claims now made on energy resources are still astounding no matter if they are compared across the entire span of human evolution or just across the 20th century. Peak unit capacities of prime movers rose from less than 100 W of sustained human labor for the late Neolithic foragers to approximately 300 W for a draft ox of the early antiquity and to 2 kW for the largest Roman waterwheels. Improved versions of those machines rated approximately 5 kW by the end of the first millennium of the CE and still no more than 8 kW by 1700. A century later, Watt's steam engines pushed the peak ratings to 100 kW, by 1900 the largest steam and water turbines had capacities 100 times higher (10 MW), and steam turbines reached eventually their maximum at 1.5 GW (Fig. 2). Peak unit capacities of prime movers that deliver sustained power thus rose approximately 15 million times in 10,000 years, with more than 99% of the rise taking place during the 20th century. Increases in the destructive discharge of energies have been even more stunning: the largest tested thermonuclear

weapon (the Soviet Union's 100-megaton bomb in 1961) had power 16 orders of magnitude higher than the kinetic energy of a forager's arrow.

Because of the rapid growth of the global population, per capita comparisons yield naturally smaller multiples. Despite the near quadrupling of the global population—from 1.6 billion in 1900 to 6.1 billion in 2000—the average gross annual per capita supply of commercial energy more than quadrupled from just 14 GJ to approximately 60 GJ. In the United States, per capita energy use more than tripled to approximately 340 GJ/year, Japan's more than quadrupled to just over 170 GJ/year, and China's per capita fossil fuel use, exceptionally low in 1900, rose 13-fold between 1950 and 2000, from just over 2 to ≈30 GJ/year. These gains are far more impressive when expressed in more meaningful terms as useful energy services. Conservative calculations indicate that because of better conversion efficiencies, the world in the year 2000 had at its disposal at least 25 times more useful commercial energy than in 1900 and the corresponding multiples exceed 30 in some rapidly industrializing countries.

Perhaps the best way to compare the secular energy gains at a household level is to compare installed electric power. In 1900, a typical urban U.S. household had only a few low-power light bulbs, adding up to less than 500 W. In the year 2000, an all-electric, air-conditioned suburban house with some 400 m^2 of living area had more than 80 switches and outlets ready to power every imaginable household appliance and drawing upward of 30 kW, at least a 60-fold jump in one century. Three vehicles owned by that household would boost the total power under the household's control to close to half a megawatt! Equivalent power—though nothing like the convenience, versatility, flexibility, and reliability of delivered energy services—would have been available only to a Roman *latifundia* owner of ≈6000 strong slaves or to a 19th century landlord employing 3000 workers and 400 large draft horses.

Because the adoption of new energy sources and new prime movers needs substantial investment, it is not surprising that this process broadly correlates with the upswings of business cycles. The first wave, well documented by Schumpeter, corresponds to the rising extraction of coal and the introduction of stationary steam engines (1787–1814). The second wave (1843–1869) was stimulated by railroads, steamships, and iron metallurgy, and the third wave (1898–1924) was stimulated by the rise of electricity generation and the replacement of steam-driven machinery by electric motors in manufacturing (Fig. 6).

The initial stages of energy transitions also correlate significantly with the starts of major innovation waves that appear to be triggered by economic depressions. The first innovation cluster, peaking in 1828, was associated mainly with mobile

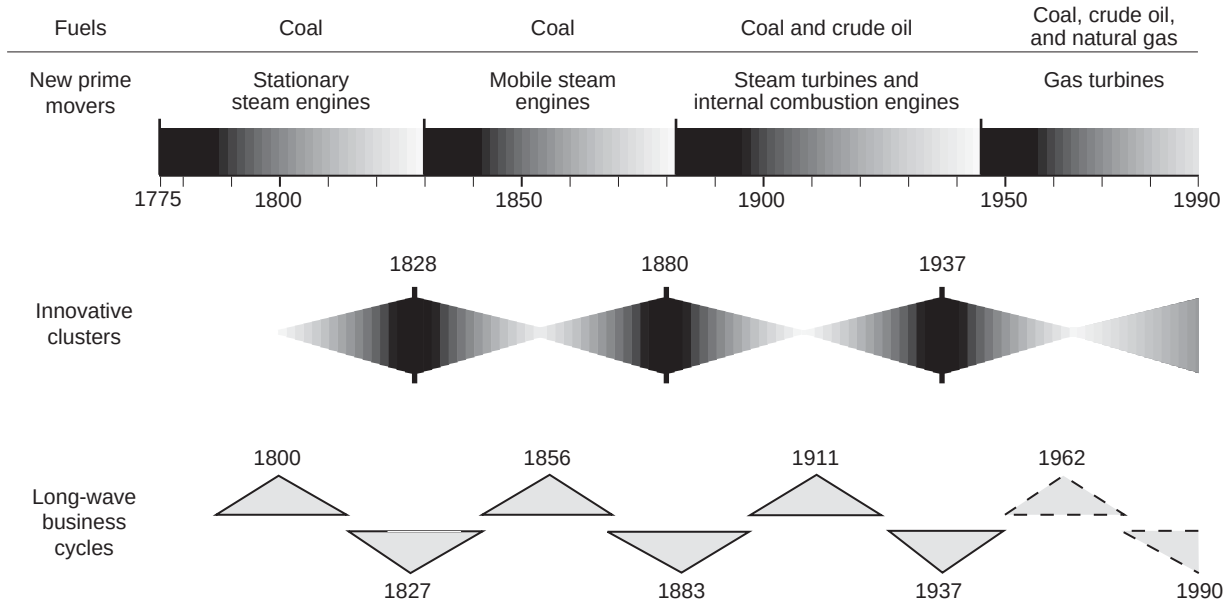

FIGURE 6 Timelines of major energy eras, innovative clusters (according to G. Mensch), and long-wave business cycles (according to J. A. Schumpeter) in the years 1775–1990.

steam engines; the second, peaking in 1880, was associated with the introduction of electricity generation and internal combustion engines, and the third cluster, peaking in 1937, included gas turbines, fluorescent lights, and nuclear energy. Post-World War II extension of these waves would include the global substitution of hydrocarbons for coal and mass car ownership; this wave was checked in 1973 by the sudden increase in the price of oil initiated by the Organization of Petroleum Exporting Countries.

6. LIMITS OF ENERGETIC DETERMINISM

When seen from a strictly biophysical point of view, energy may have an unchallenged primacy among the variables determining the course of history, but when it is considered from broader cultural and social perspectives, it may not even rank as *primus inter pares*. In addition to all of those indisputable energy imperatives, there are a multitude of none-nergy factors that initiate, control, shape, and direct human decisions to harness and use energies in a myriad of specific ways. Only if one were to equate the quality of life, or the accomplishments of a civilization, with the mindless accumulation of material possessions, would the rising consumption of energy be an inevitable precondition. But such a primitive perspective excludes the multitude of moral, intellectual, and esthetic values whose inculcation, pursuit, and upholding have no links to any particular level of energy use.

To begin with, timeless artistic expressions show no correlation with levels or kinds of energy consumption: the bison in the famous cave paintings of Altamira are not less elegant than Picasso's bulls drawn nearly 15,000 years later. It should also noted that all universal and durable ethical precepts, be they of freedom and democracy or compassion and charity, originated in antiquity, when an inadequate and inefficient energy supply was but a small fraction of today's usage. And to cite some more recent examples, the United States adopted a visionary constitution while the country was still a subsistence society running on wood; in contrast, before its collapse, the Soviet Union was the world's largest producer of crude oil and natural gas—yet all that country could offer its citizens was an impoverished life in fear, in a cage they were not allowed to leave. That political freedoms have little to do with energy use can be clearly seen by inspecting the list of the world's least free countries: it includes not only energy-poor Afghanistan, Vietnam, and Sudan, but also oil-rich Libya and Saudi Arabia.

Long-term trends in population growth are another key historic variable that is hard to relate to changes in the energy base and to levels of energy use. Improved nutrition could be seen as the principal cause of tripling the European population between 1750 and 1900, but such a claim cannot be reconciled with careful reconstructions of average food energy intakes. China's example is even more persuasive: between 1700 and 1900, the Qing dynasty did not see any major change in energy sources and prime movers, and no rise in the average per capita use of wood and straw, but the country's population tripled to approximately 475 million people.

Even the links between economic output and energy use are not that simple. When seen from a physical (thermodynamic) perspective, economies are complex systems that incessantly acquire and transform enormous quantities of fossil fuels and electricity, and some very high correlations between the rate of energy use and the level of economic performance suggest that the latter may be a direct function of the former. There is little doubt that the successive positions of economic preeminence and international influence wielded by the Dutch Republic in the 17th century, Great Britain in the 19th century, and the United States in the 20th century had their material genesis in the early exploitation of fuels that yielded higher net energy returns and allowed for higher conversion efficiencies (peat, coal, and crude oil, respectively).

A closer analysis, however, reveals that the link between energy use and economy cannot be encompassed by any easily quantifiable function as national specificities preclude any normative conclusions and invalidate many intuitive expectations. Possession of abundant energy resources has been no guarantee of national economic success and their virtual absence has been no obstacle to achieving enviable economic prosperity. A long list of energy-rich nations that have nevertheless mismanaged their fortunes must include, to name just the three most prominent cases, the Soviet Union, Iran, and Nigeria. The list of energy-poor nations that have done very well by any global standard must be headed by Japan, South Korea, and Taiwan. And countries do not have to attain specific levels of energy use in order to enjoy a comparably high quality of life.

Although it is obvious that a decent quality of life is predicated on certain minima of energy use, those countries that focus on correct public policies may realize fairly large rewards at levels not far above

such minima, whereas ostentatious overconsumption wastes energy without enhancing the real quality of life. A society concerned about equity and willing to channel its resources into the provision of adequate diets, availability of good health care, and accessibility to basic schooling could guarantee decent physical well-being, high life expectancy, varied nutrition, and fairly good educational opportunities with an annual per capita use of as little as 40–50 GJ of primary energy converted with efficiencies prevailing during the 1990s.

A better performance, pushing infant mortalities below 20/1000, raising female life expectancies above 75 years, and elevating the UNDP's Human Development Index (HDI) above 0.8 appears to require at least 1400–1500 kgoe (kilograms of oil equivalent) of energy per capita, and in the year 2000, the best global rates (infant mortalities below 10/1000, female life expectancies above 80 years, HDI above 0.9) needed no less than approximately 2600 kgoe/capita (Fig. 7). All of the quality-of-life variables relate to average per capita energy use in a nonlinear manner, with clear inflections evident at between 40 and 70 GJ/capita, with diminishing returns afterward and with basically *no* additional gains accompanying consumption above 110 GJ/capita or ≈2.6 metric tons of crude oil equivalent. The United States consumes exactly twice as much primary energy per capita as does Japan or the richest countries of the European Union (340 GJ/year versus 170 GJ/year), but it would be ludicrous to suggest that American lives are twice as good. In reality, the United States falls behind Europe and Japan in a broad range of quality-of-life variables, including higher infant mortality rates, more homicides, lower scientific literacy, and less leisure time.

Finally, energy use is of little help in explaining the demise of the established order. The long decline of the Western Roman Empire cannot be tied to any loss of energy supplies or a drastic weakening of energy conversion capabilities and neither can the fall of the French monarchy during the 1780s, the collapse of the Czarist empire in 1917, or the Nationalist retreat from mainland China during the late 1940s. Conversely, many historically far-reaching consolidations (including the gradual rise of

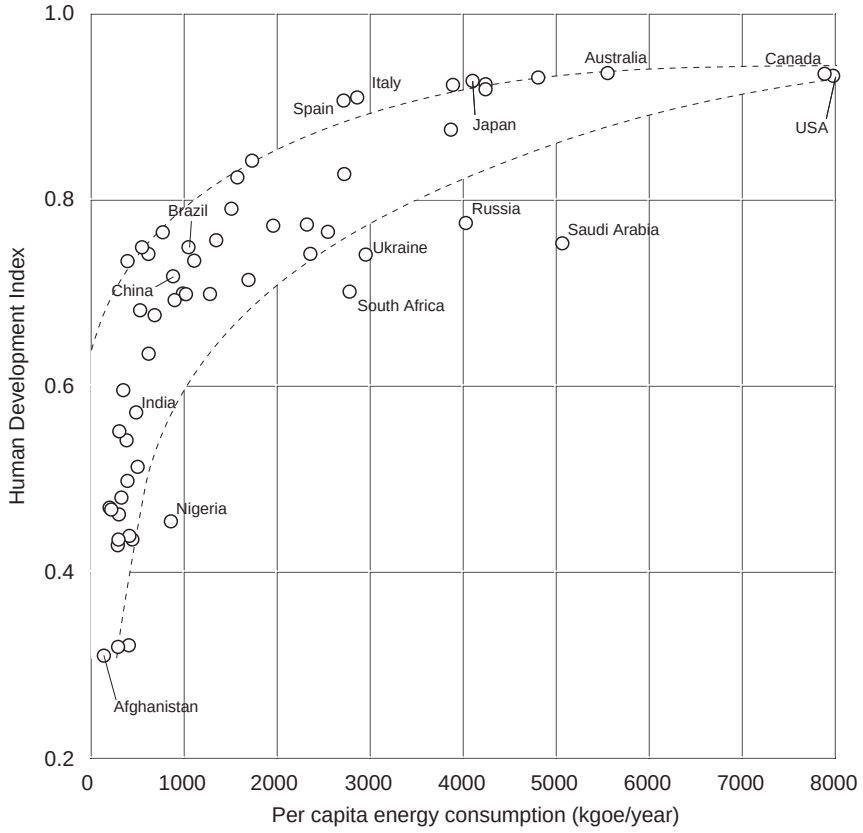

FIGURE 7 Plot of the Human Development Index against the average annual per capita use of commercial energy in the year 2000, which shows that virtually no quality-of-life gains accrue with consumption above 2.6 metric tons of oil equivalent.

Egypt's Old Kingdom, the rise of the Roman Republic, or the rise of the United States) and lightning expansions of power (including the spread of Islam during the 7th and 8th centuries or the Mongolian conquest of the 13th century) cannot be linked to any new prime movers or to better uses of prevailing fuel.

There is clearly an ambivalent link between energy and history. Energy sources and prime movers delimit the options of human history and determine the tempo of life, and, everything else being equal, thermodynamics requires that higher socioeconomic complexity must be supported by more intensive flows of energy. And yet, neither the possession of abundant energy sources nor a high rate of energy consumption guarantees the security of a nation, economic comfort, or personal happiness. Access to energies and the modes of their use constrain the options for human beings' actions but do not explain the sources of people's aspirations and the reasons for the choices they make and do not preordain the success or failure of individual societies at a particular time in history. Indeed, the only guaranteed outcome of higher energy use is greater environmental burdens whose global impacts may imperil the very habitability of the biosphere. To prevent this from happening, humanity's most important future choice may be to limit the use of energy and thus to embark on an entirely new chapter of history.

CHRONOLOGY OF ENERGY-RELATED DEVELOPMENTS

The following chronology presents a list of events that have had significant implications for the field of energy. This section has been compiled by chief editor Cutler Cleveland, in collaboration with Christopher Morris of the Academic Press/Elsevier publishing staff. The associate editors supplied material for a number of the entries that appear here, as well as providing other valuable advice. In addition, various encyclopedia authors furnished material for entries within their specific area of expertise. The chronology includes more than 1,500 entries in all.

Every effort has been made to establish the proper date for each entry in the chronology, but it must be acknowledged that certain dates here represent the best possible estimate. In general the earlier the date of an entry, the more likely it will be an approximation, or an expression of a range of possible dates. We also recognize that for some milestones of energy there are competing claims as to which individual, group, or nation deserves the credit for having been first, and we have tried to reflect this in the wording of the entries.

Earliest Times to 4500 BC

about 4.5 billion years ago Suggested time at which the Sun's fusion reactions begin, and solar energy reaches the Earth.

about 600 million years ago Proposed time at which the Earth's ozone layer forms; i.e., enough ozone is present in the stratosphere to sufficiently shield Earth from biologically lethal ultraviolet radiation. Prior to this period, life was restricted to the ocean; the presence of ozone is a fundamental prerequisite for organisms to develop and live on the land.

about 500 million years ago The organic precursors to fossil fuels are created. Marine and terrestrial plants absorb solar energy and use it to produce carbohydrates; these and other organic materials eventually settle on the ground and in stream, lake, and sea beds. As they become buried, they are transformed by heat and pressure into solid, liquid, or gaseous hydrocarbons (coal, oil, or natural gas).

about 350 million years ago Evidence for the first forest fires on Earth appear in the geological record.

2.5 to 1.5 million years ago Proposed time span for the Oldowan tradition of East Africa, the earliest known use of stone tools by the forerunners of modern humans.

1 million to 500,000 BC Proposed time span for the development of more sophisticated stone tool use at various sites.

500,000 BC Estimated time of the first controlled use of fire by humans. Various scholars have proposed dates ranging from 1.5 million to 150,000 years ago; the large range is due to debate over the archaeological and paleontological evidence, and in particular the problem of distinguishing natural fire events (as from lightning) from human-produced fire.

40,000 BC Estimated date for the first use of artificial light in lamps, which were probably in the form of a hollow rock, shell, or other such natural object, fueled with animal fats and using lichens, moss, or other plant fiber for a wick.

24,000 BC Pits dug at sites in the East European plain constitute the first evidence of storage of non-food items, such as fuel and other raw materials.

10,000 BC Estimated date for the earliest use of hot springs (e.g., North America, Anatolia, Japan) for cooking and bathing and as religious sites or sanctuaries.

8000 BC Estimated date for the first use of various forms of human transportation, such as sledges, skis, and primitive boats or rafts.

8000–7000 BC Estimated time span for the beginnings of agriculture worldwide, based on evidence such as wheat being grown in Mesopotamia and corn in the Oaxaca Valley of Mexico.

7000 BC Improved versions of lamps are in use, with oils derived from a variety of plant and animal fats as fuel. Wicks made from hemp, flax, wool, or cotton are used to control the rate of burning.

6000 BC Humans begin to utilize animal power as an energy source through the domestication of various animals such as the wild ox, the horse, the pack ass, and the camel.

6000 BC The Bible has numerous references to the use of pitch, which is asphalt or bitumen in its soft state. Noah follows God's instructions to cover the Ark with pitch. The reed basket that carries the infant Moses into the Nile River is waterproofed with pitch. The Tower of Babel is built with "bricks for stone and slime they had for mortar." (*Slime* is another word for pitch.)

5000 BC Evidence of ocean-going reed boats being used in the Persian Gulf. Other indications of early use of reed boats exist in sites such as the Sudan, coastal Peru, Lake Titicaca, New Zealand, and the marshes of southern Iraq.

4800 BC Residents of the Nabta Basin in Egypt construct stone calendar circles that target due north and the summer solstice.

4600 BC Farmers begin to use the plow rather than the hoe as a farm implement, in Mesopotamia or possibly Egypt.

4500–2000 BC

4241 BC The earliest known official recording of a date is registered in the calendar of ancient Egypt.

4000 BC Egyptians build boats made from planks joined together. Previously, boats were dug out from logs, or made of reeds bound together or skins stretched over a framework.

4000 BC The crafts of glassmaking, brickmaking, and copper smelting are in existence.

4000 BC The earliest proposed date for the use of the horse for riding, on the basis of excavations from Dereivka in the Ukrainian steppes that show possible signs of bit wear on horse teeth.

3800 BC Based on boat fragments found in southeast Turkey, suggested date for the earliest transport of trade goods by riverboat, including petroleum products.

3500 BC Earliest evidence of sailing ships, on the Nile river and in the Mediterranean.

3200 BC Earliest specific evidence of the use of wheeled vehicles, at the Uruk site in what is now Syria.

3100 BC The earliest known use of candles, as indicated by candle holders found in Crete and Egypt. Early fuels are derived from local materials, e.g., wax from insects molded in paper tubes, various forms of tallow (rendered animal fat).

3000 BC Coal is in use as a fuel, based on evidence found in various ancient sites such as China and Wales.

3000 BC Mesopotamians use "rock oil" (an early term for petroleum) in architectural adhesives, ship waterproofing, medicines, and roads.

3000 BC The Sumerians divide the day into 24 hours, the hour into 60 minutes, the minute into 60 seconds, and the circle into 360 degrees.

3000 BC The use of oars to power a boat is established in Egypt.

3000 BC Various Mideast peoples use deposits of bitumen (asphalt) in the form of natural seepage from sites such as the Dead Sea for a number of purposes including road building, bonding and waterproofing, and the making of artifacts.

2950–2900 BC The earliest complex is constructed at the Stonehenge site in southern England. Subsequent periods of construction (2900–2400 BC and 2550–1600 BC) culminate in the complicated setting of large stones that still exists today.

2900 BC Specialized oil lamps are in regular use in the Middle East, probably employing olive oil or possibly beeswax as fuel.

2800 BC Solar orientation is the basic principle of design for Egyptian temple construction, with pyramids positioned to show the change in the Earth's location relative to the Sun over the course of a year. A temple in Kamak, honoring the sun god Ra, is oriented so that sunlight penetrates the building in a precise beam.

2560 BC Construction begins for the Great Pyramid of Khufu (Cheops), one of the Seven Wonders of the World in ancient times and the only one still in existence.

2200 BC Crude oil is refined in China for use in lamps and in heating homes.

2000–600 BC

2000 BC Horse-drawn vehicles are in use in Egypt; also contemporaneously or subsequently in China.

2000 BC The Greeks use water power to turn waterwheels for grinding wheat into flour.

2000 BC Various peoples construct baths using geothermal hot springs.

1900 BC Spoked wheels have appeared in Egypt and Palestine. These wheels are significantly lighter than solid wheels, allowing a wheeled cart to carry a heavier load.

1900 BC The Greeks employ an early form of passive solar heating.

ca. 1810 BC King Amenemhet III of Egypt completes a system to regulate the inflow of water into the large Lake of Fayoum (Lake Moeris) depression, southwest of Cairo. This includes one of the world's earliest dams and provides both a flood control for the seasonal overflow of the Nile and a reservoir for irrigation.

1600 BC The *shadouf* (or *shaduf*) is used to raise water from a river or well. This is a form of lever consisting of a pole balanced on a pivot, with a weight at one end and a bucket at the other. This first appears in Egypt or possibly India; it is still in use today.

1500 BC Smelted iron tools come into in use. Armenia is traditionally thought of as the first site for this.

ca. 1380 BC A canal diverging from the Nile extends along the Wadi Tumilat to Heroopolis, a port at the head of the Bitter Lakes, providing a shipping passage between the Nile and the Red Sea. The path of this canal was frequently followed by the builders of the modern Suez Canal.

1000 BC Phoenician warships and merchant ships travel over the Mediterranean Sea, employing a large square sail and banks of oarsmen.

900 BC Hand-dug oil wells near the Gulf of Suez are used as a source to extract bitumen for use as a preservative in Egyptian mummies.

900 BC The first practical use of natural gas takes place when the Chinese use it for brine evaporation.

800 BC The Scythians, a unified group of nomadic tribes from the southern Russian steppes, display great skill and mobility as mounted archers.

ca. 692 BC Sennacherib, king of Assyria, constructs a highly advanced aqueduct at Jerwan, a portion of which still exists today.

600s BC The Greeks begin making terra cotta lamps to replace hand-held torches. The word "lamp" is derived from the Greek term *lampas,* meaning "torch."

600–300 BC

ca. 600 BC Ancient Assyrian writings tell of the "Eternal Fire," a continuously burning flame from a natural oil spring. In the modern era the Iraqi oil industry will come into being at this same site.

ca. 585 BC The Greek philosopher Thales of Miletus notes that an amber rod attracts to itself light materials, such as straw, when it is rubbed. Though not understood at the time, this is the first known observation of the phenomenon of static electricity.

500s BC One of the first industrial uses of pitch is in the Hanging Gardens of Babylon of King Nebuchadnezzar II, one of the Seven Wonders of the ancient world. The gardens are built of brick and asphalt protected by lead.

500s BC Ancient Chinese proverbs describe what will become known in the modern era as an ecological pyramid based on energy relations among trophic (feeding) levels: (1) "The large fish eat the small fish, the small fish eat the water insects, the water insects eat plants and mud"; (2) "Large fowl cannot eat small grain"; (3) "One hill cannot shelter two tigers."

500 BC Construction begins on China's Grand Canal; it is extended over the centuries by dredging new sections and by connecting existing canals and natural rivers until it eventually becomes the longest canal in the world.

480 BC The Persians use flaming arrows wrapped in oil-soaked fibers at the siege of Athens.

ca. 450 BC The Greek philosopher Empedocles refines the existing belief that the universe consists of four basic properties—earth, air, water, and fire—by stating that all types of matter are composed of varying proportions of these. This idea holds sway in the West for roughly the next 2,000 years.

ca. 420 BC The Greek philosopher Democritus postulates that all matter consists of tiny particles called atoms that cannot be divided, and that their constant motion explains the physical nature of the universe.

400s BC Spurred in part by wood fuel scarcity, classical Greek architecture develops widespread use of passive solar energy. Socrates states the basic principles of this practice: homes are oriented toward the south, and eaves are added to shade for south windows in summer; entire cities are designed to allow equitable access to the winter sun.

400–200 BC Greek thinkers such as Aristotle, Hippocrates, Euclid, and Pythagoras lay the foundations for modern science through their inquiries that emphasize evidence, logic, and and deduction.

ca. 380 BC Many parts of of Greece are completely bare of trees due to their harvest for fuel, smelting operations, and shipbuilding. The philosopher Plato laments, "The mere skeleton of the land remains." A tax is then placed on wood for home heating and cooking, and the supply of wood is regulated by public authorities in some localities.

ca. 350 BC Aristotle proposes the use of distillation as a means of desalinating sea water.

ca. 340 BC Aristotle describes how heat from the Sun's rays sets in motion the circulation of huge masses of air and moisture in the atmosphere. This concept remains unchallenged for nearly 2000 years.

ca. 340 BC Aristotle provides the first technical definition of *energeia*, a word formed by combining two root forms meaning "at" and "work." He uses this to describe the operation or activity of anything; the modern term "energy" ultimately will be derived from this concept of *energeia*.

325 BC The Greeks develop an accurate form of the clepsydra (water clock), improving on a technology that is thought to have originated in Egypt.

ca. 315 BC The Greek philosopher Theophrastus publishes *De Lapidus,* which uses the term *anthrax* to refer to a black stone that would burn (coal).

312 BC Rome's Via Appia (the Queen of Roads) is completed, as well as the Aqua Appia, the first aqueduct to serve the city; both are named for Roman censor Appius Claudius Cieco.

ca. 300 BC Syrian glassmakers invent the blowpipe to enable the production of glass in hollow shapes, followed by the invention of the two-part mold that enables multiple production of glass products.

3rd to 1st Century BC

ca. 270 BC Aristarchus of Samos, an early Greek astronomer, estimates the distance and size of the Sun, and proposes that the Earth goes around it.

ca. 270 BC The Great Lighthouse at Alexandria (Egypt) is constructed on the island of Pharos, using fire at night and reflecting the Sun's rays from a giant mirror during the day. It stands for some fifteen centuries until being destroyed by earthquakes in 1326.

ca. 250 BC Greek mathematician Archimedes states that a body immersed in a fluid is buoyed up by a force equal to the weight of the displaced fluid, which explains the buoyancy of ships. He is also credited with having discovered the principle of the lever and with providing a foundation for modern calculus.

240 BC The lift-and-force piston pump is used to raise water, an invention attributed to the Greek engineer Ctesibius of Alexandria. He is also said to have invented a pneumatic catapult that hurled stones by combining a spring device with a compressed air system.

212 BC Solar energy is reportedly employed to defend the harbor of Syracuse against a Roman siege. Archimedes uses a "burning glass" to set fire to the ships of the Roman fleet from shore. Possibly this was a parabolic mirror of polished metal combined with a large series of smaller mirrors; later experts disagree as to whether such a technique is possible.

ca. 211 BC The first known well is drilled for natural gas in China to a reported depth of 500 feet. The Chinese are said to drill their wells with primitive percussion and bamboo poles as pipelines. The gas is burned to dry rock salt.

ca. 210 BC The Archimedes screw (a helix-shaped screw in a tube) is employed to lift water from rivers for irrigation.

ca. 191 BC A temple in Rome contains an "eternal fire" that burns continuously in homage to Vesta, the goddess of the hearth; this is probably a natural gas flame.

150 BC The quern, a rotary hand mill used to grind grain, is developed, likely by the Romans. Over the next several centuries this comes into widespread use in Europe through Roman influence there.

mid 100s BC A decline in forest cover occurs in the environs of Rome because of demand for wood for industrial fuel, home and ship construction, central heating, and lavish baths.

ca. 130 BC Hipparchus of Rhodes, a Greek astronomer, applies mathematical principles to the determination of locations on the Earth's surface, expressed in terms of their specific longitude and latitude.

ca. 122 BC The Chinese writer Liu An refers to "ice-charcoal"; this is assumed to be the first written reference to the mineral coal, which is used in China by this time for home heating.

100s BC Chinese farmers use an iron plow with a moldboard (a curved plate above the plowshare that lifts and turns over the soil, creating a true furrow). Iron plows are also in use in Britain at this time, but moldboard technology is not reported in Europe until centuries later.

100s BC Waterwheels are in operation in Greece and Rome and probably elsewhere in southern Europe.

ca. 85 BC The earliest known mention of the specific use of water power to replace human labor is made by the poet Antipater of Thessalonica, who refers to maids having their hard work of hand milling relieved by the power of a water mill.

ca. 80 BC The Romans employ the technique of hypocaust heating in baths and other buildings, the first known system of central heating.

ca. 63 BC King Mithradates the Great of Pontus (Asia Minor) reportedly uses a hydraulic machine, presumably a water mill.

ca. 25 BC Glass melting, working, and forming technology flourishes in the Mediterranean region of the Roman Empire.

ca. 10 BC Vitruvius, a Roman engineer, publishes the earliest known description of a vertical water mill.

1st to 10th Century AD

ca. 20 AD Imperial orders in China reportedly set down the first environmental protection laws, including energy-related issues such as restrictions on wood burning and mining.

ca. 37 AD The first greenhouse is reportedly used to grow cucumbers for Tiberius Caesar, emperor of Rome.

47 AD Roman historian Tacitus reports on the digging of a 23-mile canal by Roman soldiers in Germany, linking the Rhine and Meuse rivers.

ca. 60 AD Hero (Heron) of Alexandria publishes *Pneumatica,* which describes over 100 different machines, including gears, a lever, and the aeolipile, the first working steam engine. The aeolipile is similar in operation to the modern jet engine.

77 AD Roman author Pliny the Elder describes people living near the Rhine River delta (now the Netherlands) who dig lumps of earth which they then dry and burn for cooking and heating. This is the first known mention of the use of peat as fuel.

100 AD The Romans construct a huge bridge near the city of Nesausas (modern-day Nimes, France), still standing and now known as Pont Du Gard. It features an aqueduct that is part of a system bringing water to the city from springs 50 km distant.

ca. 105 AD Paper manufacture is reported in China, with a man named Ts'ai Lun credited as the inventor. Over the next several centuries papermaking spreads to other parts of Asia.

ca. 110 AD The Roman occupiers of Britain use coal obtained from surface mines for heating and metalworking. The early peoples of Britain apparently mined coal long before this date; large quantities of burned coal fragments have been discovered at an Iron Age settlement near Edinburgh and, as even earlier evidence, flint axes have been found embedded in coal in Derbyshire.

150 AD An efficient reservoir and dam for irrigation is built at Saurashtra, India.

150 AD The Romans advance Greek solar technology by employing clear window coverings such as glass to enhance the capture of solar energy and using dark colors and pottery to store thermal energy. "Sun rights" guarantees are codified in Roman law.

300 AD A Roman flour mill at Barbegal, near Arles, in southern France, operates a large series of water wheels, each turning a pair of millstones; this complex is said to have a total capacity of 3 tons of grain per hour.

300s AD The Roman *Cursus Publicus* (imperial postal system) extends over more than 80,000 km.

300s AD Water mills appear in the Roman Empire.

ca. 320 AD Pappus of Alexandria identifies five elementary machines in use: the cogwheel, lever, pulley, screw, and wedge. This follows on a similar description by his predecessor Hero (ca. 60 AD).

500 AD The modern horse collar is in use in China, thus allowing a single draft animal to pull a much heavier load. This follows the earlier development of the stirrup (ca. 300 AD), also reportedly in China.

500s AD The heavy plow is in use in Slavic Europe. The earlier Roman light plow was suited to Mediterranean soil but not to the rich, heavy, often wet soils of Northern Europe. Over the next two centuries the heavy plow is introduced elsewhere in Europe, e.g., Northern Italy's Po Valley and the Rhineland.

600 AD Japanese excavators hand dig wells to depths of 600 to 900 feet.

600s AD Arab and Persian chemists discover that petroleum's lighter elements can be mixed with quicklime to make Greek fire, which was in effect the napalm of its day, used as an incendiary weapon in warfare.

600s AD Windmills are used in Persia to grind grain; also possibly in the same period or earlier in China. At this time rude vertical axis panemones (wind turbines) are used to grind grain in the Afghan highlands.

ca. 700 AD Scholars in the Arab world adopt the Indian system of numbering, which is more useful and sophisticated than the extant method of Roman numerals. Though some argue this system should be called Hindu numerals because of its likely origin, it becomes known in the West as Arabic numerals because Europe learns of it from the Arab world.

700s AD The Catalan forge comes into use in Andorra. This produces significantly higher temperatures than existing furnaces and allows larger amounts of ore to be smelted at one time.

ca. 750 AD Papermaking reaches the Islamic world from contact with China. The Arab world then improves this technology over the next two centuries by the use of linen fibers.

ca. 776 AD Works written by Geber (Jabir Ibn Haiyan), and by later Arab writers but attributed to him, introduce experimental investigation into alchemy and establish many of the principles of modern chemistry. In 1144 the Englishman Robert of Chester translated Geber's major works into Latin.

late 700s AD The earliest known tidal-powered mills of Europe are in operation on the northeast coast of Ireland.

800s AD The horse collar, stirrup, and moldboard plow appear in Europe.

ca. 830 AD The Muslim mathematician al-Khwarizmi describes various important concepts of modern mathematics; the current term *algorithm* derives from his name and *algebra* comes from the title of a book he wrote. He is considered the main source of European knowledge of the Arabic numeral system.

900 AD Sailing vessels have appeared in various waters with multiple masts and lateen (triangular) sails that make directional sailing possible, whereas earlier square-sail vessels were limited to sailing with the wind. The probable origin of this technology is Arab merchant ships on the Red Sea.

ca. 950 AD Gunpowder is developed, most likely in China, though claims have been made for several other cultures. Its use spreads to Europe at some point during the next two centuries, probably as a result of the Mongol invasion.

ca. 980 AD The pound lock for canals comes into use in China, thus allowing boats to move from a lower to significantly higher stretch of water.

late 900s AD Muslim chemists in Moorish Spain practice the technique of distillation to produce alcohol for use as a solvent and antiseptic (though not for alcoholic beverages, in accordance with Islamic law). The word *alcohol* comes from "Al-Kohl," an Arabic term for a cosmetic powder that was a product of the distillation process.

11th to 14th Century

1000–1400 The age of feudalism in Europe: castles, knights, religious fervor, only very rudimentary science and technology. The Vikings sail as far as Greenland and America. Mongol warriors overrun and subjugate southern Russia.

ca. 1000 The magnetic compass is discovered in China.

early 1000s The waterwheel is widely used in Western Europe; it remains the main source of large-scale power there until well into the 18th century.

1031 Waste paper is reportedly re-pulped into new paper in Japan; this is considered the earliest known example of recycling.

ca. 1050 The Anasazi peoples of southwestern North America build distinctive multistoried cliff dwellings with southern exposure, providing passive solar heating.

1066 The Norman Conquest alters the profile of energy use in England, as the subsequent growth of towns and trade leads to greater use of water power and water transportation.

1086 A total of 5,624 water-driven mills are in use by the manors of England south of the Trent River, or about one mill for each 400 people. This is according to the *Domesday Book,* a statistical survey that survives as a portrait of medieval life.

1100s Arabs in Spain introduce to Western Europe the practice of distilling petroleum products for illumination.

1100s The Chinese drill wells with primitive boring equipment to depths as great as 3,500 feet.

ca. 1130 Gunpowder is employed for weaponry in China, as primitive rockets, mortars, and cannons are in use. Similar weapons are reportedly in use by Moorish armies at around the same time.

ca. 1150 The first known paper mill in Europe is built by the Moors in Xativa, Spain. Papermaking then becomes established in Italy and gradually spreads across Christian Europe, though it does not become truly important until the invention of the printing press.

mid 1100s Monks and lay brothers of the Cistercian order display special talents in the use of water resources and water power, e.g., irrigation channels, dams, mills, and canals. In their agricultural practices they also exhibit an early awareness of modern ecological concepts such as reclamation, sustainable development, and food webs.

1180 Windmills are widely in use in France, England, and elsewhere in Europe. The first documented appearance of the familiar European or "Dutch" style of windmill is recorded in Normandy at around this time. A written record of a windmill in Yorkshire, England dates from 1185.

ca. 1187 Working in Toledo, Spain, Italian scholar Gerard of Cremona provides Latin translations of many important thinkers from the Greek and Arab world, such as Ptolemy, Euclid, Geber, and al-Khwarizmi, thus providing Europe with scientific knowledge that had become lost or obscured during the early Middle Ages.

ca. 1200 A treadmill hoisting machine powered by donkeys is installed at the Abbey of Mont St. Michel on the French seacoast.

ca. 1200 Reinier, a monk of the Priory of St. Jacques, Liège, Belgium, describes the use of coal for metalworking. At this time coal is being exported from northeastern England to other parts of Britain and elsewhere in Western Europe.

1202 Italian mathematician Fibonacci (Leonardo Pisano) of Pisa publishes *Liber Abaci,* a book that introduces the Arabic numeral system into Europe.

1230 The first importing of Scandinavian timber is recorded in England, indicating that wood as a domestic fuel supply was already experiencing shortages.

ca. 1230 Robert Grosseteste, chancellor of Oxford University, breaks with medieval thought to stipulate that science should be based on observation and experimentation. He also theorizes on the nature of light in a way that anticipates the work of Newton.

1232 The Chinese use rockets to defend the city of Kaifeng against Mongol invaders.

ca. 1264 The young Marco Polo visits Baku, a Persian city on the shores of the Caspian Sea in modern Azerbaijan. There he observes people collecting oil from seeps, a practice that is said to date back to the time of Alexander the Great.

1267–1268 English philosopher Roger Bacon prepares three large works for Pope Clement I, in which he lays a foundation for the development of modern science with his emphasis on the experimental method, rather than established tradition, as the proper means for acquiring knowledge about the world.

1269 The first experiments in magnetism are carried out by Petrus Peregrinus de Maricourt, a French engineer, who observes and describes some of the fundamental properties of magnets.

1270 An illustration of an English windmill appears in the *Windmill Psalter,* which has its origin in Canterbury.

1273 Pollution from coal smoke offends the citizens of London. An ordinance is then enacted prohibiting the use of coal because it is "prejudicial to health." This is the first recorded example in Britain of an explicit air-pollution control.

1291 A royal charter granted to the Abbot of Dunfermline gives him and his monks the rights to dig for coal. At this time in Britain coal is obtained from shallow underground mines known as bell pits or stair pits. Another form of soft coal called "sea coal" is gathered on beaches as it washes up on the shore.

1298 Marco Polo's *Description of the World* comments on many novel customs and practices of China, including the use of "stones that burn like logs" (coal). Some scholars now question whether Marco Polo actually observed China at first hand or simply reported on what others told him, but in either case his writings made the West aware of Chinese culture.

1300s The first geothermal district heating system is set up at the town of Chaudes-Aigues in France; it employs as the heat source a natural flow of hot water from springs at 82°C (it is still in use today).

early 1300s Serious wood shortages begin to be reported in England and elsewhere in Western Europe; these will become gradually more acute over the next 300 years.

1306 King Edward II of England prohibits artificers from burning sea coal while Parliament is in session, because of its offensive smoke.

1326 The first known drawing of a cannon in Europe appears in a Florentine manuscript. In the following year King Edward III of England is reported to have used cannon in battles with the Scots. Cannon were definitely used by the English in the Battle of Crecy in 1345.

1327 The Beijing-Hangzhou Grand Canal (1800 km long) is completed, the longest man-made canal in the world. It was begun in about 600 AD (though supposedly parts of it existed at least 1,000 years earlier) and it still exists today.

1340 A *flüssofen* (flow oven) is in operation at Marcheles-Dames, Belgium. This is the earliest form of a true blast furnace, which was developed in the Rhineland as an improvement on the earlier *stückofen,* in which malleable iron was produced directly from the ore.

1347 The Black Death (Plague) reaches Italy via merchant ships after having inexorably moved westward from Asia along the trade routes over the past two decades. Over the course of the next five years the Plague devastates Europe, killing about one-third of the entire population.

ca. 1350 Franciscan alchemist Joannes de Rupescissa characterizes ethanol as "*aqua vitae rectificata,*" and identifies it as the fifth essential form of matter, in addition to earth, air, fire, and water.

1379 The first tax on coal is enacted in England; in 1421 "a duty of twopence per chaldron (an old unit of measure) was to be paid to the Crown by all persons, not franchised in the port of Newcastle, who bought coals."

late 1300s Portable firearms are in use, including the first weapon referred to as a handgun, i.e., a weapon that can be held and fired by one person.

15th Century

ca. 1400 The Hopi people of southwestern North America burn coal for cooking and heating and to bake the pottery they make from clay.

1400s Huge draft horses, originally bred to carry heavily armored knights in battle, are now in use as work animals.

1400s Major advances are made in the use of candles, including the first use of candle molds and the use of beeswax instead of tallow (producing less smoke and odor).

1408 The drainage windmill is used in Holland, employing a large scoop wheel to carry inland waters out to sea, thus permitting the use of lowland areas for agriculture.

1427 Portuguese caravels in the service of Prince Henry the Navigator discover the Azores archipelago roughly 1,500 kilometers west of the European mainland. Over the next two decades Portuguese sailors also explore the west coast of Africa, a region previously little known to Europeans.

1450 The Dutch invent the *wipmolen,* a form of windmill in which the top portion, bearing the sails, can be turned to face the wind.

1454 After more than 20 years of experimentation, German inventor Johannes Gutenberg prints 300 copies of a 42-line, 1,282-page Latin Bible, known today as the Gutenberg Bible, and inaugurates the era of movable type. At the time, all of Europe had a total of only about 30,000 books. By the year 1500, there were an estimated 9 million.

1457 A new type of carriage is introduced into France from Hungary; it features light spoked wheels and a springed undercarriage. It becomes known in Europe as the "cart of Kocs," from the town where it was built, and this leads to the modern English word *coach*.

1474 William Caxton prints the first book in English, a translation of a popular French romance.

1482 King Edward IV of England establishes 42 gallons as the standard size for a barrel of herring, in order to end cheating in the packing of fish. This becomes a standard unit of measure for various goods and eventually (mid 19th century) barrels of oil will use this same standard.

1488 Portuguese explorer Bartolomeu Dias sails to the Cape of Good Hope at the southern tip of Africa.

1492 Genoese navigator Christopher Columbus sails across the Atlantic in the service of Spain, making Europeans aware of "new" lands lying to the west of Europe. Evidence exists of earlier European presence in North America, e.g., Vikings in Newfoundland ca. 1000 AD, but it is the voyage of Columbus that establishes a permanent link between Europe and the Americas.

ca. 1493 Leonardo da Vinci sketches an experimental flying machine. It is also reported that he created a design for a bicycle at around the same time; during his lifetime he designs or describes hundreds of other innovative machines and devices, such as a windmill, a parabolic mirror, and a parachute.

1497–1498 Portuguese explorer Vasco da Gama follows the route recently established by Bartolomeu Dias to sail around the southern coast of Africa, then proceeds across the Indian Ocean to Calicut, a port city on the Malabar Coast of India.

ca. 1498 The Inca empire of western South America establishes the Andes highway, a vast system of roads built of stone bricks, reportedly extending over more than 15,000 miles in total.

16th Century

ca. 1500 By this date, direct use of geothermal water for medical purposes is common practice at Xiaotangshan Sanitarium, northwest of Bejing. The 50°C water is still used today for the treatment of high blood pressure, rheumatism, and skin diseases, and for recuperation after surgery.

1502 Italian navigator Amerigo Vespucci asserts that the land discovered by Columbus is a "new world," completely separate from Asia. In 1507 German mapmaker Martin Waldseemuller publishes a map of the new continent discovered by Columbus and calls it "America" after Amerigo Vespucci.

1519 Ferdinand Magellan of Portugal sets sail from Spain on the first voyage around the world. Although he is killed in the Philippines midway through the journey, Magellan's voyage provides information on the size of the Earth and the independent structure of continents.

ca. 1520 The Saxon spinning wheel is introduced (named for its supposed origin in Saxony). This improves on the existing European spinning wheel by featuring a foot pedal, leaving both hands free to manipulate the fibers.

1536–1539 King Henry VIII rejects the authority of the Pope and dissolves the monasteries of England. Church lands thus pass into public hands, most significantly the coal mines of Newcastle and other areas, which can now be exploited by local merchants.

1543 Shortly before his death, Polish astronomer Copernicus publishes *De Revolutionibus Orbium Coelestium* (On the Revolutions of Celestial Bodies). He presents a heliocentric model of the solar system; i.e., the Earth and other planets orbit the Sun. This contradicts the prevailing geocentric (Earth-centered) system developed earlier by Ptolemy.

ca. 1550 King Gustaf I Vasa of Sweden (ruled 1523–1560) is one of the earliest rulers to recognize the importance of energy supply to national security (forests in this case).

ca. 1550 Miners in Germany use wooden rails and pushcarts with flanged wheels to move ore along a track from the mines. A simpler rail system was in use in Slovakia as early as 1513.

mid 1500s The first known production of hydrogen is made by the Swiss physician and alchemist Paracelsus,

probably through the combination of sulfuric acid and iron. Paracelsus notes that this reaction produces a gas or "air," and that the air is released with great pressure.

1551 Jerome Cardan (Girolamo Cardano), an Italian mathematician, distinguishes electricity from magnetism by observing that while amber will attract various light objects, a lodestone (magnetic stone) will attract only metals.

1560 The Swedish Baltic Empire dominates Northern Europe from this time until 1721, based in part on its rise as a producer and exporter of metals, while England's and mid-Europe's metal production declines due to a drop in charcoal production caused by deforestation and wood scarcity.

1561 Adam Lonicier of Germany writes of a solar heating technique used by alchemists to make perfume, in which flowers are heated by light reflected from a mirror to cause their essence to diffuse into water.

1568 Gerardus Mercator introduces cylindrical projection in maps, now known as Mercator projection. The cover of his book of maps shows the Greek Titan Atlas balancing the world on his shoulders, a picture which gave atlases their name.

1570–1630 England experiences a widespread shortage of firewood, especially in areas with ironworks, since large amounts of fuel are required for smelting iron. This depletion of the wood supply leads to a shift to coal as the chief energy source for smelting and other industrial purposes. As a result England becomes the first country to develop a full-scale coal industry.

late 1500s Oil from seeps in the Carpathian Mountains is burned in street lamps to provide light for the Polish town of Krosno.

1583 Mathematician Simon Stevin demonstrates the laws of hydrostatics, showing that the surface pressure of a liquid is related to the height of the liquid above the surface and the area of the surface, but not to the shape of the container holding the liquid.

1586 Stevin is said to have performed a key gravitational experiment, noting that weight does not affect the pull of gravity. (It is also said that Galileo reached this same conclusion after dropping two different weights from the top of the Leaning Tower of Pisa.)

1589 The Reverend William Lee of England invents the first knitting machine, which can knit faster than human hands, using a stocking frame.

1590 Dutch spectacle-maker Zacharias Janssen constructs the first microscope, using two convex lenses and a tube.

1592 Galileo develops the first primitive thermometer, known as a thermoscope, using air in a tube instead of liquid.

1592 The first wind-driven sawmill is built in the Netherlands by Cornelis Cornelisz. It is mounted on a raft to permit easy turning into the wind.

1594 An oil well 35 meters deep is reportedly dug in Azerbaijan.

1597 Andreas Libavius publishes *Alchemia,* the first European chemical textbook, in which he describes the preparation of hydrochloric acid, sulfuric acid, and tin tetrachloride.

1600–1649

1600 William Gilbert presents a model of the solar system based on magnetism, explaining gravity through electromagnetic terms and noting magnetic dip in a compass.

early 1600s Giovanfrancesco Sagredo, a disciple of Galileo, divides his thermometer into 360 divisions like a circle, after which the divisions on a thermometer are called "degrees."

1603 Hugh Platt describes coke, a charcoal-like residue left after the volatile components of coal have been driven off. This later becomes an important fuel. Ironically Platt at the same time complains about the damage being caused to London's buildings and vegetation by the burning of coal, the process that produces coke.

1603 Italian alchemist Vincenzo Cascariolo makes the first scientific investigation into the property of luminescence when he finds that a heated mixture of barium sulfate and coal glows in the dark and can be "recharged" through exposure to sunlight.

1603–1604 Huntingdon Beaumont of England constructs a wooden wagonway from the bell pits at Strelley down to Wollaton Lane, to carry coal (horse-drawn) to the Nottingham market.

1604 Robert Cawdrey publishes a dictionary of hard words; this is the first alphabetical reference work in English.

1606 Italian Giambattista della Porta designs a device capable of raising water, an improved version of "Hero's Fountain," with steam instead of air as the displacing fluid. He also describes the formation of a vacuum by condensation of steam.

1608 Hans Lippershey of the Netherlands builds the first practical telescope.

1609 German astronomer Johannes Kepler formulates his first two laws of planetary motion: the elliptical orbits of the planets and the alteration of planetary speed according to distance from the Sun.

1609–1611 Galileo improves the telescope and pioneers its use for astronomical observation, discovering mountains on the moon, many new stars, the four satellites of Jupiter, the phases of Venus, and the composition of the Milky Way.

1610 The English coal industry has grown to the point that nearly half of all the country's maritime trade consists of coal exports. The city of Newcastle upon Tyne in the northeast part of the country is the hub of this industry (giving rise to the expression "carrying coals to Newcastle" for an activity that is a waste of time because it supplies something which is already present in abundance).

1612 Jan Adriaanszoon Leeghwater (literally, "empty water") directs the drainage of Beemster and other polders (lowlands), beginning a long period of wind-driven polder drainage in the Netherlands.

1615 A royal proclamation in Britain prohibits the use of wood for glassmaking. Wood is in high demand for the crucial shipbuilding industry, so glass-making furnaces are changed to burn coal instead.

1615 French engineer Salomon de Caux (Caus) builds a solar-powered water pump, using glass lenses to heat a sealed vessel containing water and air. This is regarded as the first use of solar energy since classical times. He also describes the principles of a steam engine and advocates its use.

1619 Kepler formulates his third law of planetary motion, involving a calculation to determine the distance of a planet from the Sun. He also publishes a defense of the Copernican system.

1620 In his influential *Novum Organum Scientiarum,* Francis Bacon advocates observation and the inductive method over postulation and *a priori* reasoning, describing what is known today as the scientific method.

ca. 1620 Dutch inventor Cornelius Drebbel creates a thermostat which he uses to regulate the temperature of an oven by controlling the flow of air.

1621 The first ironworks in colonial North America is set up at Jamestown, Virginia.

1628 British physician William Harvey publishes *On the Motion of the Heart and Blood in Animals*, in which he describes the circulation of the blood and the pumping of the heart; this is often described as the foundation of modern medicine.

1629 Italian engineer Giovanni Branca invents a stamping mill whose power is generated by a steam-powered turbine.

ca. 1630 Jan Baptista van Helmont of Brussels coins the word *gas,* from the Flemish word for *chaos,* to describe what he calls the "wild spirit" component of oaken coal that has been burned, i.e., that does not remain as ashes. This is the first known description of an air-like substance, without fixed volume or shape, other than air itself.

1635 John Winthrop opens America's first chemical plant in Boston, producing saltpeter (potassium nitrate) for use in the manufacture of gunpowder.

1637 In *Discours de la Methode,* Rene Descartes champions deductive reasoning on the basis of mathematical laws; famous appendices to this influential work present important advances in physics, optics, meteorology, and mathematics.

1638 Galileo publishes his major work on mechanics, including experiments on acceleration, friction, inertia, and falling bodies that correct many of Aristotle's errors.

1640 Italian physicist Evangelista Torricelli applies Galileo's laws of motion of fluids, establishing the science of hydrodynamics. In 1643 he invents the mercury barometer and in the process makes an artificially created vacuum, the first known instance of this.

1641 Descartes argues in his *Principles of Philosophy* that the Universe is governed by simple laws and that natural processes might have shaped the Earth.

1645 German engineer Otto von Guericke (Gericke) demonstrates the effect of atmospheric pressure on evacuated bodies when he builds the first vacuum pump and takes the first measurement of the density of air.

1646 English physician Sir Thomas Browne publishes *Pseudodoxia Epidemica,* in which he discusses his experiments with static electricity and magnetism and introduces the words *electric* and *electricity* into the English language.

1648 From an experiment using barometers at different levels on a mountain, French mathematician Blaise Pascal establishes that air pressure decreases with altitude, leading him to conclude that the atmosphere has only a finite height. He also formulates the principle that pressure is uniform throughout a static fluid.

1650–1699

ca. 1650 The longwall coal mining technique is introduced in Shropshire, England. This becomes the most widely used method of coal extraction.

1652 The government of New Amsterdam (New York City) establishes the first traffic laws in the Americas, ruling that horse-drawn wagons, carts, and sleighs are not to be driven at a gallop in the city.

1654 Ferdinand II of Italy develops the first sealed liquid thermometer.

1654 Otto von Guericke begins a series of public demonstrations of the power of air pressure in a vacuum, including experiments in which teams of horses are unable to separate a sphere held together by a vacuum.

1656 Dutch scientist Christiaan Huygens builds the first pendulum clock based on the cycloid, much like a modern grandfather clock. It is the first clock to keep highly accurate time.

1659 Thomas Shirley describes an inflammable gas seeping from coal deposits near Wigan, England. This is the first known discovery of natural gas in Europe.

1661 John Evelyn publishes "Fumifugium, or the Inconvenience of the Aer and Smoake of London Dissipated," one of the earliest tracts on air pollution. He describes the poor air quality of London and suggests remedies to deal with this, such as relocating certain industries (e.g., ironmaking, brewing) outside the city, and then planting gardens and orchards in their place.

1662 Anglo-Irish chemist Robert Boyle discovers that air can be compressed and formulates Boyle's law, which states that in an ideal gas of constant temperature, pressure and volume vary inversely.

1662 John Graunt compiles a study of London death records, in what is considered the first statistically based public health study. He notes that roughly one out of every four deaths results from lung-related diseases. This contrasts with lower death rates in rural areas, away from London's smoke-filled air.

1662 King Charles II of England grants a charter to the Royal Society of London, an organization formed to encourage scientific research and communication.

1663 Guericke develops the first electric generator, which consists of a revolving ball of sulfur inside a glass globe, mounted on a wooden frame. This produces a static electric spark when a pad is held against the ball as it rotates.

1665 Denis de Sallo of Paris publishes the initial volume of the *Journal des Scavans,* the first Western scholarly journal.

1665–1666 Isaac Newton conducts a series of experiments, discovering that white light is composed of different colors that can be separated by a prism, formulating his first law of universal gravitation, and inventing the first form of calculus.

1666 The Great Fire of London sweeps through this metropolis of wooden buildings, destroying virtually all of the city north of the Thames River. The fire does have one positive effect in that it "sanitizes" areas that had just been devastated by an outbreak of plague, and England never again has a major epidemic of the disease.

1668 John Wallis suggests the law of conservation of momentum, according to which the total momentum of a closed system does not change.

1669 In his quest to create gold from another material, German chemist Hennig Brand identifies a faintly glowing element that he names "phosphorus." The discovery of this element is the first attributable to a specific person and time.

1669 Nicolaus Steno of Denmark lays the foundation for the science of crystallography with his statement that the angles are constant between equivalent faces of crystals of the same substance, when measured at the same temperature.

1671 Hydrogen is isolated by Robert Boyle. Earlier in the century, hydrogen was discovered to be flammable by Turquet de Mayerne.

1671 Wagonways from Ravensworth Colliery deliver coal to the Team-staith at Dunston, England.

1672 Giovanni Cassini calculates the distance from the Earth to the Sun to be 87 million miles, within 6 million miles of modern estimates. Scientists begin to realize just how large the solar system must be.

1672 Guericke recognizes that the static electricity produced by his sulfur ball device (see 1663) will cause the surface of the sulfur to glow, thus identifying the phenomenon of electroluminescence. Guericke also notes that like charges repel each other.

1673 Huygens produces what is regarded as the first heat engine, although the lack of a reliable fuel hampers its development.

1673 The first record of coal in the United States is shown in a map prepared by the French explorer Louis Joliet. The map shows "*charbon de terra*" seen by Joliet and Jacques Marquette along the Illinois River, near present-day Utica, Illinois.

1675 Gottfried Leibniz of Saxony (now Germany), working independently of Newton, develops differential and integral calculus. His notations, including the integral sign and derivative notation, are still in use today.

1675 In the course of his study of Jupiter's moons, the Danish mathematician Olaus Roemer estimates the speed of light to be about 141,000 miles per second. Before Roemer, many scientists believed that light had infinite speed.

1676–1677 Looking at pond water through a microscope of his own construction, Anton van Leeuwenhoek is the first to view what he called "animalcules," known today as microorganisms.

1678 A patent application is made by Clement Clerke of Bristol, England for a lead smelting reverberatory furnace using pit coal.

1678 Abbé Hautefeuille of Orleans, France is one of the first to propose the use of explosive powder for motive energy when he suggests the construction of a powder motor to raise water.

1679 French engineer Denis Papin builds the first atmospheric engine called the "Digester" (pressure cooker).

1680 Boyle discovers the match by rubbing phosphorus and sulfur together.

1680 Newton proposes that a jet of steam can be used to power a carriage, an idea now considered to be a precursor to the development of the jet engine.

ca. 1684 The experiments of English minister John Clayton of Yorkshire, an amateur chemist, reveal the presence of a clear, flammable "spirit of coal" as a byproduct of distillation, though he does not recognize a practical use for this coal gas.

1686 English astronomer Edmond Halley shows that low latitudes receive more solar radiation than higher ones and proposes that this gradient provides forcing for the atmosphere's general circulation. For this, and his work on tides, Halley is considered a founder of geophysics (though he is better known for his study of what is now called Halley's Comet).

1686 Leibniz posits an early version of the law of conservation of energy. He argues that the true measure of the effect of force is *vis viva* or "living force" as exhibited in motion and not "dead force" as exhibited in statics.

1687 Isaac Newton publishes *Philosophiae Naturalis Principia Mathematica,* often regarded as the most important book of science ever written. He establishes three laws of motion, the law of universal gravitation, and other fundamental principles. Newton thus provides the basic description of the natural laws governing the universe (later modified by the work of Einstein).

1688 The Royal Society of London officially notes that gas can be extracted from coal and oil, and then burned as a source of heat and light.

1690 Denis Papin develops the idea of using steam to pump water out of mines. He also describes an atmospheric steam engine operating with piston and cylinder.

1690 William Rittenhouse establishes the first paper mill in the American colonies, on a creek near Philadelphia. This has been described as America's first example of recycling, since the mill's fiber for papermaking was obtained from discarded rags and cotton.

1695 Italian academicians Averoni and Targioni conduct experiments on the combustibility of diamonds, including the use of solar heat by means of a large burning-glass.

1698 Captain Thomas Savery, an English military engineer and inventor, receives the first patent for a crude steam engine, based on Papin's Digester of 1679. Savery is motivated by the challenge of pumping water out of coal mines. He names his engine "The Miner's Friend."

1700–1749

early 1700s Settlers in New England utilize solar energy by "saltbox" houses that face toward the winter sun. Many feature a lattice overhang on the south facade, supporting deciduous vines that afford shade in summer but drop their leaves in winter, allowing sunlight through.

1701 Coal deposits are found by Huguenot settlers in Manakin on the James River, near present-day Richmond.

1701 English agriculturist Jethro Tull invents an efficient mechanical seed drill, which allows seed to be sown in evenly in neatly spaced rows.

1702 Czar Peter the First establishes Russia's first regular newspaper, *Vedomosti.* The paper's first issue carries a story about the discovery of oil on the surface of the river Sok in central Russia.

1705 Neon light is born when Francis Hauksbee of England creates electrical effects by putting mercury into a glass globe, pumping out the air, and then turning it with a crank. When he does this in the dark, and then rubs the globe with his bare hand, it glows.

1709 Abraham Darby, iron-maker at Coalbrookedale in the West Midlands of England, develops the use of coke in iron smelting, enabling factories to produce iron at a much faster rate. Before that, iron furnaces could only be located at a site with both sufficient water power and an extensive wood supply, to provide the fuel source for charcoal.

1709 Sir Isaac Newton builds an electric generator consisting of a rotating glass sphere.

1711–1712 English engineer Thomas Newcomen devises a new kind of steam engine with a piston and cylinder construction that utilizes ordinary low-pressure steam to pump water out of coal mines. This is the culmination of efforts he began in 1705 and it becomes the first successful atmospheric steam engine.

1714 Gabriel Fahrenheit develops a mercury thermometer and the Fahrenheit scale of measurement based on the temperature of ice, water, and ammonium chloride (0 degrees), ice and water (32 degrees), and boiling water (212 degrees).

1716 Swedish engineer Martin Triewald uses a hot water system to heat a greenhouse in Newcastle upon Tyne, in

northern England. This is considered the first modern instance of central heating.

1723 Jacob Leupold of Germany publishes a nine-volume work that is the first detailed and systematic exposition of mechanical engineering, including a design for a noncondensing, high-pressure steam engine similar to the ones that would be built much later.

1728 James Bradley notes the periodic shift of the stars' positions during a year and explains it by the aberration of light caused by the Earth's orbit. He uses his findings to recalculate the speed of light, which he places within 5% of what it is now stated to be.

1729 Through a series of experiments, Stephen Gray establishes that some materials conduct electricity better than others and that static electricity travels on the surface of objects rather than through the interior. This is considered the first discovery of the principle that electricity can flow.

1733 Charles-Francois de Cisternay du Fay states a "two-fluid" theory of electricity, dividing electrical charges into vitreous (positive) fluid and resinous (negative) fluid, and noting that like charges attract and differing charges repel. Benjamin Franklin also distinguishes between positive and negative charges, though he favors a one-fluid theory.

1733 Englishman John Kay patents the flying shuttle loom, enabling one person to do much more work with relatively less effort.

1735 George Hadley, an English meteorologist, introduces the importance of Earth's rotation in the features of major winds, including the easterly trades and the midlatitude westerlies.

1735 Swedish naturalist Carolus Linnaeus publishes *Systema Naturae* (Systems of Nature), introducing a method of classification for plants still in use today, which he later extends to include animals.

1736 Swiss scientist Leonhard Euler writes the first book of mechanics based on differential equations.

1738 Swiss scientist Daniel Bernoulli develops his kinetic theory of gases, according to which pressure within a closed container of gas increases as temperature rises and decreases as temperature goes down.

1742 Anders Celsius suggests replacing the Fahrenheit scale with the Centigrade scale, which places the freezing point of water at 0 degrees and the boiling point at 100 degrees. In 1948 the name of this scale is changed to Celsius scale by international agreement.

1743 Jean le Rond d'Alembert expands on Newton's laws of motion, proposing that actions and reactions in a closed system of moving bodies are balanced. He applies this principle to several mechanical problems.

1743 King Louis XV of France has a "flying chair" installed in his palace to allow him to ride from the first to the second floor; this is considered the earliest form of passenger elevator.

1745 Edmund Lee introduces the fantail mechanism for windmills; it automatically rotates the blades of the windmill into the wind, as opposed to having a person manually do this.

1745 Shafts are dug into the hillsides of Pechelbronn, France to extract petroleum; these are the first known wells specifically sunk to search for oil.

1745–1746 Pieter van Musschenbroek and Ewald Georg von Kleist independently invent the capacitor, an electricity-storage device that is the first practical way to store static electricity. It comes to be called the Leiden (Leyden) jar after Musschenbroek's employer, the University of Leiden.

ca. 1746 Euler determines the mathematics of light refraction, based on Huygens' theory of 1690 that light is composed of different colors of varying wavelengths.

1747 Benjamin Franklin describes his discovery that a pointed conductor can draw off electric charge from a charge body. This is the basis for his lightning rod, even before he proves the connection between electricity and lightning.

1748 The first commercial coal production in colonial America is recorded near Richmond, Virginia. By the end of the 1750s other coal deposits are reported in Pennsylvania, Ohio, Kentucky, and West Virginia.

1749 Benjamin Franklin installs a lightning rod on his home.

1749 George-Louis Leclerc de Buffon publishes the first of his 44 volumes of *Historie Naturelle* (Natural History), in which he anticipates Charles Darwin's theory of evolution by presenting arguments for descent with modification and species extinctions. He also suggests that existing estimates of the age of the Earth are much too low.

1750–1775

1750 A French military officer notes that Indians living near Fort Duquesne (now the site of the city of Pittsburgh) set fire to an oil-slicked creek as part of a religious ceremony.

mid-1700s An extensive system of canals is established in various countries of Western Europe. At the same time the quality of surface roads in these countries is generally poor.

mid-1700s England and Holland make advances in greenhouse technology.

1752 Benjamin Franklin conducts his famous experiment with a kite in a lightning storm, showing that lightning is a form of electricity.

1754 Joseph Black discovers "fixed air," or carbon dioxide, when he heats limestone. He determines that carbonates are compounds of a gas and a base.

1755 The first known instance of artificial refrigeration is demonstrated by William Cullen at the University of Glasgow.

1757 Captain John Campbell of the Royal Navy develops a nautical sextant for precise measurements of longitude and latitude.

1758 Coal is "exported" from the James River district of the colony of Virginia to New York.

1758 Swedish chemist Axel Fredrik Cronstedt divides minerals into four classes: earths, bitumens, salts, and metals. This establishes the classification of minerals by chemical structure.

1759 English civil engineer John Smeaton determines that the overshot waterwheel is much more efficient than the traditional undershot wheel. He also makes advances in the design of many other devices and structures, e.g., an improvement on the Newcomen steam engine.

1759 Franz Aepinus rejects mechanical theories of electricity and suggests that ordinary matter repels itself in the absence of electricity, a theory of electrostatics similar to Newton's law of gravity and supporting Benjamin Franklin's one-fluid theory of electricity.

1760 John Mitchell proposes that earthquakes are caused by the build-up of pressure within the earth and that they produce waves which travel at measurable speeds.

1761 Joseph Black discovers that ice absorbs heat without changing temperature when melting. He calls this property "latent heat," a quality later important in the improvement of the steam engine.

1762 An act of the New York City assembly gives the authority to provide funds for lighting the city, and in that year the first street lamps and posts are purchased.

1762 Deposits of anthracite coal are discovered in Pennsylvania.

1764 James Hargreaves introduces a new device, called a "spinning Jenny," which can spin eight threads at once and thus provide much greater efficiency than the traditional spinning wheel.

ca. 1765 Burmese excavators hand dig hundreds of oil wells.

1766 Henry Cavendish identifies and outlines the properties of a highly flammable substance which he calls "fire air," now known as hydrogen.

1766 Swiss physicist Horace-Benedict de Saussure develops an electrometer, a device for measuring electric potential by means of the attraction or repulsion of charged bodies. He also constructs the first known solar flat plate collector.

1766 The brothers Thomas and George Cranege receive a patent for a reverberatory or air furnace, for use in iron-making. This is later improved upon by Peter Onions (1783) and Henry Cort (1784).

ca. 1766 The opulent Paris townhouse of François de Monville features a central heating system; this is the first time that buildings in France have had central heat since the era of the ancient Romans.

1767 Joseph Priestley offers an explanation for rings formed by an electrical charge on metal (now known as Priestley's rings) and proposes that electrical forces follow the same inverse square law that gravity does.

1769 French army engineer Nicholas-Joseph Cugnot builds a three-wheeled wagon powered by a steam engine, the first example of a "horseless carriage." However, it can only operate for a few minutes without stopping to get up steam, and it is soon retired after overturning in what is described as the world's first motor vehicle accident.

1769 Richard Arkwright invents a spinning frame that produces cotton threads for textile manufacture, one of the key developments leading to Britain's Industrial Revolution.

1769 Scottish inventor James Watt receives the patent for an improved version of the Newcomen steam engine. It uses a condenser, separate from the cylinder, to improve efficiency. A unit of power called the *watt* is eventually named after him.

ca. 1769 Spanish missionary Juan Crespi writes of "extensive swamps of bitumen" that he has seen while traveling on an expedition to the region that is now the city of Los Angeles, California. These swamps are the La Brea Tar Pits, and more than 200 years later the oil industry of Southern California will begin in this same area.

1770 George Washington observes a "burning spring" on the Kanawha River in West Virginia.

1771 In experiments with plants in carbon dioxide-filled chambers, Joseph Priestley discovers that plants somehow convert the gas breathed out by animals and created by fire back into oxygen; this lays the foundation for an understanding of photosynthesis.

1772 Daniel Rutherford, Joseph Priestley, Carl Scheele, and Henry Cavendish independently discover nitrogen, although Rutherford is usually given credit for being the first.

1774 Priestley publishes his discovery of oxygen. Scheele had previously discovered it in 1772 but did not publish his findings until 1777, and Antoine Lavoisier actually named the element. The identification of oxygen overturns an idea that had dominated science for more than

2,000 years, namely that air is a singular, elementary substance.

ca. 1775 Lavoisier builds a solar furnace that can generate enough heat to melt platinum.

1775 James Watt patents a new steam engine that he had developed in 1765, which is six times as efficient as the old Newcomen engine. Its condenser is separated from the cylinder, allowing the steam to act directly on the piston.

1775 Pierre-Simon Girard invents a water turbine.

1775 The first chemical extraction from geothermal waters (mainly borate products) is undertaken in Lardarello, Italy.

1776–1799

1776 *An Inquiry into the Nature and Causes of the Wealth of Nations* is published by Scottish philosopher Adam Smith. It establishes economics as a distinct field of study and provides the basis for laissez-faire economics, in particular the idea that "the invisible hand" of the free market, and not government, is the proper controlling force for a nation's use of resources.

1776 The American colonies declare independence from Britain. From this time the industrialization of the United States will proceed separately from that of Britain; prior to this one-third of all British ships were being built in America and the colonies were also a center for British iron manufacturing.

1776 The Watt steam engine is put into practical use, to drain water from coal mines.

1778 Scheele and Lavoisier independently conclude that air is composed mainly of oxygen and nitrogen.

ca. 1778 The first industrial blast furnace is created by ironmaster John Wilkinson, using a steam engine rather than water power.

late 1770s Factories are sited along rivers to utilize the power of waterwheels.

1779 Dutch scientist Jan Ingen-Housz identifies principles of photosynthesis when he notes that plants convert carbon dioxide into oxygen, which animals convert back into carbon dioxide. He also discovers that only the green parts of plants release oxygen, and that oxygen is only given off when plants are in the presence of light.

1779 The earliest versions of the modern bicycle appear on the streets of Paris.

1780 During experiments with oxidation of organic gases, Johann Wolfgang Döberreiner discovers that there are certain similarities of reaction among elements. This forms the basis of the periodic table.

ca. 1780 Luigi Galvani of Italy discovers that when he touches a dead frog's leg with a knife, it twitches violently. Alessandro Volta will later show this is because electricity is created when moisture (from the frog) comes between two different types of metal (the steel knife and a tin plate); this phenomenon will become known as *galvanism*.

ca. 1780 M. Bonnemain of France creates a hot water boiler that uses a gravity system to circulate the heated water.

1780s Watt continues to adapt his steam engine invention. He creates a mechanical attachment with a rotary movement, enabling the engine to power a wider variety of machines, and he develops the first governor and flywheel. Flywheels will later be the focus of extensive research as power storage devices.

1781 Priestley "creates" water by igniting hydrogen in oxygen.

1781 Richard Arkwright builds the first modern factory to house his water frame for spinning.

1783 Joseph and Etienne Montgolfier launch the first hot air balloon, the earliest successful air flight in history. The second flight carries a cargo of animals, and the third flight carries two men. The same year, Jacques Charles creates and flies in the first hydrogen balloon.

1783 Lavoisier, with Pierre Laplace, uses a calorimeter to estimate the amount of heat evolved per unit of carbon dioxide produced. The ratio is the same for a flame and an animal, indicating that animals produce energy by a type of combustion, and also demonstrating the role of oxygen in the respiration of animals and plants.

1783 William Herschel explains the apparent movement of stars together and apart from each other by arguing that the Sun itself is moving toward some stars and away from others, changing their relative positions.

1784 Benjamin Franklin notes that the substitution of coal for wood as a fuel has helped to preserve England's remaining forests, and he urges France and Germany to do the same.

1784 Franklin suggests that a great eruption of the Laki volcano in Iceland is responsible for the unusually severe winter that follows, thus showing an awareness of the effect of volcanism on global climate.

1784 For the first time a flour mill in England successfully substitutes a steam engine for wind power.

1784 Ironmaster Henry Cort develops both the puddling method of manufacturing wrought iron from coke-smelted iron and the rolling mill with grooved rollers.

1784 Jean Pierre Minkelers describes the production of gas from coal, and uses such gas to illuminate his

classroom at Leuven, Belgium. This is sometimes considered the origin of gas lighting.

1784 Swiss scientist Aimé Argand patents a new type of lamp that burns much brighter than candles, produces less smoke, and reduces the danger of fire. It features an oil receptacle, a round wick lamp with a chimney, and a glass cylinder in which the flame burns. This becomes the prototype for many subsequent oil lamps.

1785 French physicist Charles-Augustin de Coulomb is the first to measure accurately the forces exerted between electric charges.

1785 Henry Cavendish establishes that water is composed of hydrogen and oxygen.

1785 The theory of uniformitarianism, or the very gradual and regular evolution of the earth's structure, is introduced by James Hutton. According to his ideas, the earth is so old that it is almost impossible to determine when it began.

1787 Jacques Charles demonstrates that different gases expand at the same rate for a given temperature. This principle, known as Charles's Law, had actually been discovered by Guillaume Amontons as early as 1699.

1787 John Fitch builds and launches the first steamboat on the Delaware River. Although a technological success, it is a commercial failure.

1787 John Wilkinson launches an iron boat, believed to be the world's first such vessel for commercial use. Reportedly it is intended as a canal barge for freight.

1788 The fur trader Peter Pond is the first European to describe the vast oil sands (tar sands) of Atahabasca, Canada. He writes of "bituminous fountains" and describes how the local Indians mix this fluid with gum from fir trees to waterproof their canoes.

1789 French engineer Philippe Lebon distills gas from heated wood and suggests that it can heat and illuminate interiors and inflate balloons. This is an important contribution to the subsequent development of the manufactured gas industry.

1789 German chemist Martin Heinrich Klaproth discovers uranium in the mineral pitchblende. It is not until 1841, however, that this element is isolated by Eugene Péligot.

1789 In *Traite Elementaire de Chimie* (Elementary Treatise on Chemistry), Lavoisier introduces the law of conservation of mass that he had developed some years before, and establishes a new system of chemical nomenclature.

late 1700s Spermaceti, an oil found in the head of sperm whales, is highly sought after for various industrial uses. It is especially prized for candlemaking; the term candlepower is based on a measurement of the light produced by a spermaceti candle.

1790 England builds its first steam-driven rolling mill.

1790 Samuel Slater builds the first American factory, constructed entirely from his memory of blueprints he had seen earlier in England, and ushers in the Industrial Revolution in the United States.

ca. 1790 Claude Berthollet and Joseph Priestley determine the molecular formula for ammonia.

ca. 1790 Friendly Societies, forerunners of modern trade unions, are organized in Britain.

1791 John Barber receives the first patent for a basic turbine engine, which he intends to use to power a "horseless carriage." Though he does not achieve practical success, this is the first engine to use the thermodynamic cycle of a modern gas turbine.

1792 William Murdock discovers that by heating coal in a closed container, the gas given off will yield a steady flame. Murdock produces "coal gas," or "manufactured gas" and conveys it through metal pipes, lighting his Redruth, Cornwall cottage and offices.

1793 Benjamin Thompson (Count Rumford) challenges the prevailing caloric theory that heat is an elastic fluid. From his work boring cannon barrels, he notes that the cannon stay hot as long as the friction of boring continues, and he associates heat with mechanical energy. By defining heat as a form of motion rather than matter, he anticipates the kinetic theory of heat.

1793 Eli Whitney invents the cotton gin to pull the cotton threads off the seeds in cotton bolls. The machine is so successful that it completely changes the economy of the southern United States, where cotton becomes the main crop.

1794 Inventor Philip Vaughn obtains the first patent for a modern type of ball bearing while working on carriage axles. Leonardo da Vinci is said to have developed a model for ball bearings some 300 years earlier but none were actually produced from this.

1795 Count Rumford invents the Rumford stove, an innovative version that provides greater heat with less smoke.

1795 Joseph Bramah patents a hydrostatic machine (hydraulic press), one of many inventions with which he is credited.

1796 M. Ambroise & Company, Italian fireworks manufacturers, reportedly exhibit a form of gas lighting in Philadelphia.

1796 Pierre-Simon Laplace advances his "nebular hypothesis" of the origin of the world, which states that our solar system was formed by the condensation of a nebula of dust and gas, a theory still widely accepted today.

1797 Edmund Cartwright invents an engine that runs on alcohol. He also makes significant contributions to weaving loom technology.

1798 Eli Whitney is awarded a government contract for 10,000 muskets. In manufacturing these weapons, he

develops methods to produce standardized interchangeable parts, a procedure important to the Industrial Revolution.

1798 Henry Cavendish accurately determines the mass of the Earth by determining the gravitational constant, the unknown *G* in Newton's equations.

1798 Thomas Robert Malthus publishes *An Essay on the Principle of Population,* arguing that poverty and famine are inevitable because the world's population is bound to grow at a faster rate than the food supply. This leads to many subsequent analyses of the relationship between population and available resources, in particular Darwin's ideas about natural selection.

1799 Alessandro Volta creates the first electric battery (known as Volta's pile). It consists of alternating zinc and silver disks separated by felt soaked in brine. It is the first source of a steady electric current. Volta announces this invention in 1800.

1799 Philippe Lebon receives a patent for his Thermolamp, which is illuminated by coal gas. By 1801 he lights his own home in this manner and he also conducts a light demonstration at the Hotel Seignelay in Paris. Lebon also conceives of a gas-powered engine.

1799 The first patent for a wave energy system is granted in Paris to a father and son named Girard; they envision a system that would harness the power of heavy ships rocking back and forth on the waves in a harbor.

1800–1809

1800 Less than two months after Alessandro Volta's battery was publicized, English scientists William Nicholson and Anthony Carlisle build a battery and use it to perform electrolysis on water, separating it for the first time into hydrogen and oxygen.

1800 While investigating the heat of different colors in a spectrum, William Herschel discovers that there is an invisible light beyond the red that produces the most heat, now known as infrared radiation.

1800–1870 The level of carbon dioxide gas (CO_2) in the atmosphere, as later measured in ancient ice, is about 290 parts per million. Fossil fuel use and land clearing associated with the Industrial Revolution, population growth, and rising affluence will produce a steady rise in CO_2 concentrations over the next two centuries.

1801 Building on Herschel's discovery of radiation beyond the red end of a spectrum, Johann Ritter experiments with silver chloride and detects radiation beyond the violet end as well, now known as ultraviolet radiation.

1801 Thomas Young discovers that light passing through two narrow slits produces an interference pattern, providing further support for the wave theory of light.

1801 William Symington launches the *Charlotte Dundas* on the Forth and Clyde canal in Scotland. This is the first vessel built for the specific pusrpose of being propelled by a steam engine. Symington builds more than 30 different steam engines in the period 1790–1808.

1801–1802 Jean-Baptiste Lamarck provides the first classification scheme for invertebrates, and also presents ideas about a relationship between physical energy and morphological changes in organisms over generations.

1802 Applications of manufactured gas lighting take place in Britain and the United States; e.g., William Murdock installs gas lighting at the Watt and Boulton Birmingham works; a gas lighting system is patented in London by Frederick Winsor; Benjamin Henfrey demonstrates his "thermo-lamp" coal gas lighting method in Pennsylvania.

1803 Claude Berthollet applies physics to chemistry to show that reaction rates depend on the amounts of reacting substances as well as on affinities.

1803 John Buddle develops an air pump to provide ventilation for coal mines in Britain.

1803 John Dalton is the first to formally propose the atomic theory of matter, claiming that atoms (a word he took from Democritus's writings of ca. 440 BC) explain why chemicals combine only in specific proportions.

1803 William Henry proposes the law that will be named after him, which states that the mass of a gas dissolved in a liquid is proportional to the pressure.

1804 Cornish engineer Richard Trevithick develops the *Penydarren,* the world's first steam locomotive to run on iron rails. However, the weight of the engine proves too heavy for the rails. Shortly before this Trevithick also developed a steam-powered road carriage to carry passengers.

1804 Sir George Cayley designs a glider that is regarded as the first successful heavier-than-air vehicle, one of several such vehicles he develops. In a long career (1799–1850s) studying the principles of aviation, Cayley describes many of the concepts and elements of the modern airplane.

1805 British manufacturer George Medhurst receives a patent to use compressed air to drive a motor.

1805 Commander William Beaufort develops a wind force scale consisting of 13 degrees of wind strength, from calm to hurricane. He bases this on the observed effect of various wind strengths on the sails of a British frigate.

1805 Frederick Tudor and Nathaniel Wyeth of Cambridge, Massachusetts devise new methods to cut, store,

and transport ice blocks from nearby Fresh Pond. They ship the ice as far as India and Cuba, with production reaching 65,000 tons by 1846.

1806 David and Joseph Ruffner drill a well on the banks of the Great Kanawha River within the present city of Charleston, West Virginia. The well is drilled in search of brine, which can be evaporated to make salt. This is the first well known to have been drilled, rather than dug, in the Western Hemisphere.

1806 David Melville lights his house in Newport, Rhode Island using coal gas. In 1810 he receives the first U.S. patent for this.

1807 Great Britain, the principal slave-trading nation of the time, abolishes the Atlantic slave trade. The United States enacts similar legislation in the same year and other nations follow suit. (Denmark had already done so, in 1803.)

1807 Isaac de Rivaz of Switzerland designs an an internal combustion engine, believed to be the first of its kind. He subsequently uses this to build a gas-powered car, using a mixture of hydrogen and oxygen for fuel.

1807 Sir Humphrey Davy of Britain isolates a new metal, sodium, using electrolysis.

1807 The *Clermont,* a 133-foot-long steam-powered paddleboat built by Robert Fulton, makes its maiden voyage up the Hudson River in New York. It proves to be a great commercial success.

1807 The resort city of Hot Springs, Arkansas is founded, and shortly thereafter visitors begin arriving to enjoy the heated waters. The area is made a national park in 1921.

1807 Thomas Young begins to use the term *energy* in the modern sense. He states, "The term *energy* may be applied, with great propriety, to the product of the mass or weight of a body, into the square of the number expressing its velocity." This refers to what is now known as kinetic energy.

1808 French chemist Joseph Louis Gay-Lussac publishes his discovery that gases combine in definite proportions, just as elements do, when forming compounds.

1808 Judge Jesse Fell burns anthracite coal on an open grate in his Wilkes-Barre, Pennsylvania home. At the time most people thought that this type of coal was of little value.

1809 Chilean nitrates are discovered. These will serve as the chief source of nitrogen for explosives and for the chemical industry over the next 100 years.

1809 Humphrey Davy uses a high-powered battery to induce a bright light between two strips of charcoal 10 centimeters (4 in.) apart, creating the first arc light.

1809 Lamarck states that animals evolved from simpler forms and that unused body parts will degenerate or new parts develop as needed for survival. Though scientists now reject Lamarck's idea that acquired characteristics can be inherited, he was credited by Darwin as a major influence on his own theory of evolution.

early 1800s A new era in illumination has begun, with gas producing a much higher quality flame than the oil lamp, the dominant lighting technology for many previous centuries. However, the new technology leaves vast pools of toxic coal tar as a byproduct in many European and American towns, a serious public health legacy.

1810–1819

1810 The first reported U.S. coal mine explosion occurs in Virginia.

1811 Amedeo Avogadro suggests that at a given temperature and pressure, equal volumes of any gas will always contain equal numbers of molecules. This comes to be known as Avogadro's Hypothesis.

1812 German promoter Frederick Albert Winsor receives a charter from Parliament to establish the London and Westminster Gas Light and Coke Company. This is the origin of public gas lighting in Britain. The following year, Winsor lights Westminster (London) Bridge.

1813–1816 The first miner's safety lamps are developed independently by Sir Humphrey Davy, William Clanny, and George Stephenson. They reduce the risk of igniting the gas mixtures that are common in mines. Davy's design is particularly effective in that it prevents the lamp temperature from rising above the ignition point of mine gases such as methane.

1814 George Stephenson builds the *Blucher* (or *Blutcher*), the first practical steam locomotive in England. It is capable of pulling 30 tons up a grade at 4 miles per hour, a vast improvement over horse-drawn wagons.

1815 Samuel Clegg, chief engineer for Frederick Winsor's gas company, develops an efficient gas meter and also installs a gas works at the Royal Mint.

1815 From his work digging canals, William Smith discovers that each layer (stratum) of earth contains a unique assemblage of fossils, and that he can distinguish one formation from another by the characteristic fossils in each. He then publishes what his biographer Simon Winchester called "the map that changed the world," a geological survey of England and Wales.

1816 Karl von Drais of Germany builds a steerable two-wheeled vehicle that is propelled by pushing with the feet against the ground. In the same year his country-

man Karl D. Sauerbronn develops the first prototype for the modern bicycle.

1816 Scottish minister Robert Stirling receives a patent for a new type of engine, the forerunner to the modern Stirling engine. This features the "Heat Economiser" (a refrigerator) and represents an advance in safety. Unlike existing steam engines, Stirling's engine would not explode because it operated at lower pressures.

1816 The artist Rembrandt Peale receives permission from the city of Baltimore, Maryland to supply the city with coal gas for street lights. Peale and his associates then charter the Gas Light Company of Baltimore, the first energy utility in the United States.

1818 The first commercial oil well in North America is drilled by Marcus Huling on land leased from Martin Beatty in McCreary County, Kentucky. The well is drilled in search of brine, but when drilled to about 200 feet, it produces large quantities of oil.

1819 English chemist John Kidd demonstrates that distilled coal tar can be used to produce naphthalene, an industrial chemical with a variety of uses, thus beginning the use of coal as a source of chemicals.

1819 Frederick Christian Accum publishes *A Description of the Process of Manufacture of Coal Gas,* which serves to bring greater recognition to the technique of gas lighting. He also publishes the first systematic study of food technology (1820).

1819 The American coastal packet *Savannah* sails across the Atlantic Ocean, becoming the first vessel to make an ocean crossing with steam-assisted power.

1820–1829

1820 Danish physicist Hans Christian Oersted is the first to note the magnetic effect of electric currents when, by accident, he observes that an electric current in a wire can deflect a nearby compass needle.

1820 Expanding on the work of Oersted, Andre Marie Ampere finds that two wires carrying current in the same direction attract each other, while wires carrying current in opposite directions repel.

1820 Johann Schweigger also expands on Oersted's experiments and invents the galvanometer to measure the strength of a current.

1820 The Rev. W. Cecil of Magadelen College, Cambridge writes a paper on how to use the energy of hydrogen to power an engine, and provides a description of how such a hydrogen engine could be built.

1820 Warren De la Rue of Guernsey encloses a platinum coil in an evacuated glass tube and passes electricity through it, in the first recorded attempt to produce an incandescent lamp.

early 1820s Gas companies in Baltimore, Boston, and New York City provide commercial gas service to light streets and buildings.

1821 French engineer Gaspard de Prony invents a brake to measure the power of engines.

1821 Michael Faraday publishes the results of his research into electromagnetic rotation, providing the basis for his efforts to create an electricity-powered motor.

1821 The first natural gas well in the United States is drilled in the village of Fredonia, New York by William Hart. By 1825, the gas is being used to light buildings in Fredonia and also reportedly for cooking in the local hotel.

1821 The Lehigh Navigation Company and the Lehigh Coal Company merge, forming a single company for the purpose of transporting coal on the canals of eastern Pennsylvania. By 1825 this new company is shipping over 30,000 tons of anthracite coal to Philadelphia.

1821 Thomas Johann Seebeck observes that if two dissimilar metals are joined with a heat difference between the juncture points, this will produce an electric current. This phenomenon is called thermoelectricity or the Seebeck effect; it will later be used in the development of the semiconductor.

1822 Friedrich Mohs sets up a scale of mineral hardness, now known as the Mohs scale, and presents a mineral classification system.

1823 French engineer Benoit Fourneyron invents the first practical water turbine. He goes on to produce various improved versions of this (1832–1855).

1823 Michael Faraday is able to liquefy chlorine by a systematic use of cold and pressure. Later he uses the same technique to liquefy other gases.

1823 Samuel Brown constructs a gas engine that runs a road carriage successfully on the streets of London and a boat on the Thames River.

1823 William Sturgeon invents the electromagnet, which is improved by Joseph Henry eight years later to the point where it can hold suspended a ton of iron.

1824 Hans Christian Oersted discovers aluminum. German chemist Friedrich Wohler then devises a method for isolating the pure form of this element (1827).

1824 Joseph Aspin, an English bricklayer, receives the first patent for Portland cement, which will become a fundamental material of industrial society as a basic ingredient in concrete and mortar. Cement production is among the most energy-intensive of material processes.

1824 Nicolas Léonard (Sadi) Carnot of France publishes a seminal analysis of the steam engine, showing that work is done as heat passes from a reservoir of higher

temperature to a lower one. He defines work and provides the basis for the second law of thermodynamics.

1825 Employing a locomotive developed by George Stephenson, the Stockton and Darlington Railway opens in northern England, operating the first public passenger train. Its original purpose is to carry coal from the collieries of West Durham to the port of Stockton.

1825 The Chatham Garden and Theatre in New York City is illuminated by gas lighting.

1825 The Cheshunt Railway is in operation in Hertfordshire, England, the first known monorail (horse-drawn). It is based on a patent obtained in 1821 by Henry Robinson Palmer.

1826 Samuel Morey of Connecticut receives a U.S. patent for his "vapor engine," which is regarded as the first successfully designed forerunner to the modern internal combustion engine.

1826 Swedish-born inventor John Ericsson constructs a heat engine that runs on hot air rather than steam.

1827 German physicist Georg Simon Ohm states that an electrical current is equal to the ratio of the voltage to the resistance (Ohm's law).

1827 Robert Brown discovers the constant motion of microscopic particles (Brownian motion). This will provide a foundation for proof of the existence of atoms.

1828 James Beaumont Neilson of Glasgow introduces the "hot blast" oven, an advance in ironmaking. This involves a stream of heated air rather than the previous technique of cold air, thus requiring a smaller amount of coal and allowing the use of lesser grades of coal.

1829 The *Rocket* locomotive of Robert Stephenson and Company wins a competition held by the new Liverpool and Manchester Railway to choose between competing engines. The basic design principles of the *Rocket* are utilized until the end of British steam locomotive building in the mid 20th century.

1830–1839

1830 A railroad boom begins in Europe and North America. The first locomotive in the United States to power a passenger train, the *Tom Thumb,* carries 26 people 13 miles over the tracks of the Baltimore and Ohio Railroad. The Liverpool to Manchester railway opens in England.

1830 Andrew Ure patents a thermostat based on the principle of differential expansion of two different metals. He also publishes a widely read dictionary in which he introduces the word *thermostat* to describe devices for controlling temperature automatically.

1830 Charles Lyell publishes the first volume of his landmark *Principles of Geology,* advancing the uniformitarian theory that becomes generally accepted, i.e., the principle that the same physical processes which can be observed today were responsible for the geological changes of the past.

early 1830s English mathematician Charles Babbage designs a mechanical calculating device he calls an "analytical engine"; this is regarded as the earliest prototype for the modern electronic computer.

1831 Charles Sauria develops the first practical friction match, using phosphorus on the tip. This improves on earlier versions of the late 1820s from John Walker and Samuel Jones.

1831 Cyrus Hall McCormick carries out the first successful demonstration of his mechanical reaper during the harvest of 1831. He further refines it and takes out a patent in 1834. (Obed Hussey had announced the construction of a mechanical reaper of his own in 1833.)

1831–33 Michael Faraday and Joseph Henry independently discover the principle of electromagnetic induction, which becomes the basis for the development of the electric generator and electric motor.

1832 Antoine-Hippolyte Pixii of France builds the first practical mechanical generator of electrical current, using concepts demonstrated by Faraday.

1832 Joseph Henry is the first to produce high-frequency electrical oscillations for communication purposes, and the first to detect them at a distance, using what becomes known as a magnetic detector. This is a key precursor to the development of radio technology.

1833 Faraday derives the laws of electrical separation of compounds (electrolysis), and suggests that atoms contain electrical charges.

1833 John Lane uses a saw blade to produce the first steel-bladed plow in the United States. This becomes known as the "prairie plow" because it is much more efficient in plowing the thick prairie sod of the American Midwest than existing wooden plows.

1833 Karl Friedrich Gauss and Wilhelm Eduard Weber collaborate to produce an electromagnetic telegraph, the signals being given by the deflection of a galvanometer needle.

1834 American inventor Jacob Perkins receives the first U.S. patent for a practical refrigerating machine; it uses ether in a vapor compression cycle. In his long career as an inventor, Perkins also makes improvements to the steam engine and hot air furnace.

1834 Benoit Paul Emile Clapeyron provides a graphical representation of Sadi Carnot's ideas on heat, which were largely unknown before Clapeyron's analysis. Clapeyron thus provides the link between Carnot's study of heat engines and Clausius's expression of the second law of thermodynamics (1850).

1834 James Bogardus of the United States patents the "gasometer," which is regarded as the first gas meter; it operates on the principle of a bellows, alternately being filled and emptied of gas, the pulsations being counted on a register.

1834 London officials bring nuisance charges against a coal gas manufacturing firm for polluting the Thames River with coal tar.

1834 Vermont blacksmith and inventor Thomas Davenport establishes the first commercially successful electric streetcar (horse-drawn streetcars are the dominant type in this era).

1834 Walter Hancock operates a regular service for the London and Paddington Steam Carriage Company, using a "steam bus" called the *Enterprise* to carry passengers between London Wall and Paddington via Islington.

mid-1830s The island city of Nantucket, Massachusetts reigns as the "Whaling Capital of the World." Whale oil is in great demand as a lighting fuel, and about 100 whaling ships from the port of Nantucket search the oceans in quest of whales, especially the sperm whale (the prototype for Herman Melville's Moby-Dick in the novel of the same name).

1835 Gaspard Gustave de Coriolis of France publishes the laws of mechanics in a rotating frame, including an apparent force (Coriolis force) exerted on moving objects by the rotation of the Earth.

ca. 1835 Robert Anderson of Scotland invents a form of electric-powered carriage.

1836 John Frederic Daniell invents the Daniell cell, the first reliable source of electric current; it represents a great improvement over the voltaic cell.

1837 Scottish inventor Robert Davidson constructs a prototype for an electric car.

ca. 1837 Astronomer Sir John Herschel (son of William Herschel) uses a solar collector box to cook food while exploring in Africa.

1838 A commercial shale oil industry is established in Autun, in central France, to produce lamp fuel.

1838 William Cooke and Charles Wheatstone put the first electric telegraph into commercial service. It uses visual signaling in which two needles at a time, out of a total of five, rotate on the receiving device to point to letters on a display.

late 1830s Steamships begin to replace sailing ships as the preferred vessel for Atlantic Ocean crossings. I. K. Brunel's steamship *Great Western* (1837) is launched at Bristol, England, the largest such ship in the world at the time and the first steamship in regular transatlantic service. This is followed by Brunel's *Great Britain* (1843), an iron-hulled vessel with a screw propeller, and *Great Eastern* (1858), the largest of all and not equaled in size for another 50 years.

1839 Charles Goodyear develops vulcanized rubber, a stabler and much more useful substance than plain rubber. He supposedly invents this after he accidentally drops rubber mixed with sulfur on a hot stove and notices that this strengthens the mixture.

1839 Kirkpatrick MacMillan of Scotland develops a new form of bicycle, identified as the first version of the two-wheeled pedal-driven bicycle that is the standard form today.

1839 Nineteen-year-old Edmund Becquerel, a French experimental physicist, discovers the photovoltaic effect while experimenting with an electrolytic cell made up of two metal electrodes.

1839 Sir William Robert Grove builds a device that will combine hydrogen and oxygen to produce electricity; this is the world's first gas battery, later renamed the fuel cell.

1840–1849

1840 G. H. Hess observes that the sum of the enthalpies of the steps of a reaction will equal the enthalpy of the overall reaction. "Hess's Law" allows the enthalpy change for an entire chemical reaction to be calculated without any direct measurements through calorimetry.

1840 German botanist Justus von Leibig formulates his Law of the Minimum, which states that if any one essential material is absent or only minimally available, then the growth and functioning of an organism is adversely affected. Later scholars will apply this concept of the limiting factor to larger contexts, e.g., ecosystems.

1840 James Prescott Joule states that heat is produced in an electrical conductor; this becomes known as "Joule's Law."

1841 The first incandescent lamp is patented in England by Frederick de Moleyns. It has a design using powdered charcoal heated between two platinum wires.

1842 In England, the Royal Commission on Employment of Children in the Mines reports "cruel slaving revolting to humanity," such as women and children chained to carts and working 15-hour days in the nation's coal

mines. The subsequent Mines Act prohibits women and boys under age 10 from working in the mines.

1842 Julius Robert von Mayer of Germany presents a numerical value for the mechanical equivalent of heat, based on a horse stirring paper pulp in a cauldron. This is the original statement of the first law of thermodynamics (law of the conservation of energy), a fundamental principle of modern physics.

1842 Sir John Bennet Lawes patents the first artificial fertilizer, "superphosphate," a combination of rock phosphate with sulfuric acid. This frees farmers from dependence on animals to produce manure to nourish crops and proves that agriculture can be a technical process, rather than an entirely natural one.

1842 Justus von Liebig is among the first to argue that body heat and muscular action are derived from the oxidation of foodstuffs. He proposes that the energy source for muscular exertion in animals and humans comes principally from protein, and not carbohydrates and fats.

1843 James Joule determines the mechanical equivalent of heat by measuring the change in temperature produced by the friction of a paddlewheel attached to a falling weight. The *joule* becomes a common unit of heat measurement. He also shows that heat is a form of energy.

1844 Englishman Robert Beart is issued the first patent for rotary well drilling, so named for the rotary table through which a drill pipe with a bit at the end is inserted and rotated. Rotary drilling rigs can drill faster, deeper, and more effectively than cable tool rigs that rely on pulverizing rock formations.

1844 Jean Foucault brings electric light to Paris, the City of Light, when he illuminates the Place de la Concorde, the largest public square in the city.

1844 Samuel F. B. Morse demonstrates his telegraph by sending the message "What hath God wrought?" from Baltimore to Washington, D.C., using a system that imprints dots and dashes on paper. Operators soon learn to read the dots and dashes directly, by listening to the click of the receiver.

1844 Stuart Perry of New York City develops an effective internal combustion engine. It is a two-cycle engine using turpentine as a fuel.

1845 Scottish inventor Robert William Thomson patents the first pneumatic (air-filled) tire of vulcanized rubber. However, this is not economically practical, and it will be more than 40 years before pneumatic tires come into use through the efforts of fellow Scot John Boyd Dunlop.

1845 William Robert Grove publishes an article describing and illustrating the principles of the modern gas-filled incandescent lamp. His actual work on this may have been done as early as 1840, thus predating the 1841 patent of Frederick de Moleyns.

1846 Wilhelm Eduard Weber develops a force law that is dependent on velocity and acceleration, which will be crucial to James Clerk Maxwell in his electromagnetic theory of light. He also invents the electrodynamometer, an instrument for measuring small currents.

ca. 1846 Italian chemist Ascanio Sobrero is the first to prepare the highly explosive compound nitroglycerine.

1847 Hermann Helmholtz of Germany publishes *On the Conservation of Force,* in which he is the first to extended James Joule's work to a general principle. He expresses the relationship among mechanics, heat, light, electricity, and magnetism by treating them all as forms of a single force, i.e., energy.

1847 The Siemens and Halske Telegraph Company is founded in Berlin with Werner von Siemens as principal. His younger brother William (Wilhelm) will establish a London branch in 1850. The company becomes a leader in telegraphy, telephony, and electrical engineering.

1847 William Bell Elliot discovers a geothermal steam field north of San Francisco which he names "The Geysers." In the 1850s the area becomes a tourist attraction for its steam baths, and in the 20th century it will become an important source of geothermal energy.

1848 Lord Kelvin (William Thomson) proposes a temperature of –273°C as the "absolute zero" point, or least possible temperature, since at that point the energy of molecules in a gas would be at a theoretical minimum. He proposes a new temperature scale (now known as the Kelvin scale) based on this principle of absolute zero.

1848 President James K. Polk turns on the first gas light at the White House, one year after James Crutchett had lit the U.S. Capitol building with gas.

1848 William Staite uses his arc lamp technology to light the portico of the National Gallery museum in London. Staite makes various improvements in arc lamp technology during the 1830s and 1840s, though the original patent is awarded to Thomas Wright (1845).

ca. 1848 A commercial oil well is drilled in Baku, Azerbaijan under the direction of a Russian engineer, F. N. Semenov. This is described as the world's first modern oil well.

ca. 1848 James B. Francis develops an improved inward-flow water turbine in Lowell, Massachusetts, one of several important steps made by Francis in the use of water power. Uriah Boyden of Lowell also improves on the existing Fourneyron turbine at around the same time.

1849 Abraham Gesner, a Canadian geologist, devises a method to distill kerosene from petroleum. Kerosene (also known as "coal oil" or "paraffin oil") is cheap, easy to produce, relatively odorless, and can be stored indefinitely, and it rapidly replaces whale oil and other oils in illumination applications.

1849 Joseph J. Couch of Massachusetts receives the first U.S. patent for a steam-powered percussion rock drill. Later versions of the drill, along with dynamite, will make it possible to excavate large amounts of earth and rock in tunneling, mining, and quarrying.

1849 The California Gold Rush begins, setting off a process that will eventually make California the most populous U.S. state, with huge requirements for energy and water.

1849 The speed of light is accurately calculated by Armand Fizeau, using a turning disk and a mirror placed five miles away. His assistant, Jean Foucault, improves the technique in 1850 and determines the speed of light to be 185,000 miles per second, within 1% of the true figure.

1850–1859

1850 Rudolf Clausius, a German mathematical physicist, makes the first formal expression of the second law of thermodynamics, which becomes a cornerstone of modern science. This states that heat cannot of its own accord pass from a colder body to a hotter one.

1850 Scottish chemist James "Paraffin" Young patents a process of extracting oil from cannel coal.

1850 The first absorption refrigeration machine is developed by Edmond Carré, using water and sulfuric acid. His brother Ferdinand demonstrates an ammonia/water refrigeration machine in 1859. Most early refrigerants are flammable and/or toxic, and some are also highly reactive. These disadvantages are not overcome until fluorocarbon refrigerants appear in the 1930s.

1850s Swift-sailing, graceful clipper ships carry passengers and freight on long ocean voyages, especially trips to California and China.

1850s The New England whaling industry is in steep decline because of massive depletion of whale stocks and the rise of petroleum and other fuels that are used in place of whale oil.

ca. 1850 Simple distillation of seep and salt well oil is carried out in Pittsburgh, Pennsylvania by Samuel Kier. He builds a one-barrel still to treat crude oil, which he buys by the gallon. This is regarded as the first commercial refinery in North America.

1851 In his work treating tropical diseases, Florida physician John Gorrie becomes convinced that cooler sickrooms will reduce fever and make patients more comfortable. He goes on to patent a cooling machine that produces artificial ice, thus laying the groundwork for modern refrigeration and air-conditioning.

1851 William Thomson (Lord Kelvin) is the first to describe a heat pump, a device in which heat is absorbed by the expansion of a working gas and given off at a higher temperature in a condenser.

1852 Henri Giffard, a French engineer, builds and flies the first full-sized airship, a hot air balloon powered by steam and steered by a rudder. This can be considered the first powered and controlled aircraft flight.

1852 Irish scientist George Gabriel Stokes names and explains the phenomenon of fluorescence based on the absorption of ultraviolet light and then emission of blue light.

1852 James Prescott Joule and Lord Kelvin demonstrate that an expanding gas with no outside energy source will become cooler; this is now known as the Joule-Thomson effect.

1853 Employees of the Russian-American Company document oil seeps in Alaska, on the western shore of Cook Inlet. The native peoples of Alaska had traditionally used oil-soaked tundra as heating fuel.

1853 Ignacy Lukasiewicz, a Polish druggist in the city of Lvov (then part of the Austro-Hungarian Empire, now in Ukraine), invents an improved kerosene lamp, using the distillation techniques recently developed by Abraham Gesner in Canada.

1854 Abraham Gesner opens a plant in New York to convert coal into kerosene, using his patented process of fractional distillation.

1854 Daniel Halladay invents the first commercially successful self-governing windmill in Connecticut. Halladay's machine has four wooden blades; it automatically turns to face changing wind directions and controls its own speed of operation.

1854 German-American watchmaker Heinrich Gobel of New York develops an incandescent electric lamp in which a carbonized bamboo filament is secured in a glass vessel. This predates the work of Thomas Edison and Joseph Swan by two decades.

1854 Hermann von Helmholtz proposes that the Sun derives its energy from gravitational shrinkage.

1854 In order to provide oil for his kerosene lamp business, Ignacy Lukasiewicz establishes an "oil mine" near Bobrka, a town in the Gorlice region of Poland. High-quality crude oil is pumped from wells as deep as 150 meters. This is often described as the beginning of the modern oil industry, though various competing claims have been made.

1854 New York lawyer George H. Bissell and others, most notably financier James Townsend, form the Pennsylvania Rock Oil Company to search for oil in western Pennsylvania. This is the first U.S. company created explicitly as an oil business.

1855 Abraham Gesner receives a patent for his process of extracting kerosene from bituminous shale and coal.

1855 An 800-horsepower water turbine is installed at the Pont Neuf waterworks in Paris.

1855 At the request of the Pennsylvania Rock Oil Company, chemist Benjamin Silliman of Yale University applies fractional distillation to Pennsylvania rock oil and discovers that it produces high-quality lamp oil.

1855 Heinrich Geissler designs a mercury-powered air pump which he uses to create the most effective vacuum tubes to date. The Geissler tube will eventually lead to the discovery of electrons.

1856 Following a series of cholera outbreaks in London in the late 1840s, the Metropolitan Board of Works is created and charged with providing a cleaner water supply for the city, with particular attention to the condition of the Thames River. Measures to control air pollution are also taken at this same time.

1856 Henry Bessemer develops a new way to remove carbon from cast iron in steel-making by sending a blast of air through molten iron in special furnaces. This is now known as the Bessemer process.

1856 The Siemens brothers, William and Friedrich, introduce a regenerative gas furnace. This is an improvement on existing furnaces in which much of the heat of combustion is lost by being carried off in the hot gases that pass up the chimney.

1856 Workers near the Neander River in Germany discover the first known skeleton of a Neanderthal (Neandertal) man in a limestone cave. This becomes an important step in studying human evolution.

1857 A system of oil wells in Romania begins to produce a sizeable output. Some authorities describe this operation as the origin of the oil industry, rather than the efforts of Ignacy Lukasiewicz (see 1854).

1857 George Pullman develops the first successful railroad sleeping car, making longer trips more comfortable. The "Pullman Car" becomes widely known in 1865 when one is used to carry the body of President Abraham Lincoln from Washington for burial in Illinois.

1857 Oil is found at a site in Canada near Lake Erie; this is considered to be North America's earliest commercial petroleum discovery, predating the better-known Drake field in Pennsylvania by two years.

1857 The first elevator for public use is installed in New York City by Otis Brothers, a steam-driven type installed in a five-story department store on Broadway.

1858 A telegraph cable is laid across the Atlantic Ocean between Newfoundland, Canada and Ireland, the first such connection between the United States and Europe. This cable line fails after three months but a successful one is eventually established in 1866.

1858 Brothers C. W. and W. W. Marsh of De Kalb, Illinois develop a harvesting machine that improves on the McCormick reaper by reducing the amount of labor needed to bind the grain.

1858 James Miller Williams of Hamilton, Ontario mines "gum beds" (surface oil seeps that have congealed), planning to sell the material for caulking in ships. He soon sees the greater potential for oil as an illuminating fuel and builds a small refinery.

1858 William Hart, originator of natural gas drilling in the United States in 1821, forms the Fredonia Gas Light and Water Works Company; this is described as the first incorporated natural gas company in the United States.

1859 Charles Darwin publishes *On the Origin of Species,* a book outlining his theory of evolution by natural selection. It becomes the foundation of a completely new approach to biology.

1859 Edwin Drake drills an oil well near Titusville, Pennsylvania, with a depth of about 70 feet. This is considered to be the first commercially successful U.S. oil well and is regarded as the origin of the U.S. petroleum industry.

1859 Gaston Plante of France invents the first rechargeable lead-acid storage battery (alkaline battery).

1859 George B. Simpson of Washington, D.C., patents an electric cooking device using the same principle as modern electric ranges.

1859 Jean Lenoir of France builds the first practical and operative internal combustion engine, fueled by coal gas. The following year he incorporates it in a "horseless carriage."

1859 John Tyndall, a self-taught Irish scientist, suggests that water vapor, carbon dioxide, and any other radiatively active ingredient of the atmosphere could produce "all of the mutations of climate which the researches of geologists reveal." This will become a basic component of climate science.

1859 Scottish physicist William John Rankine proposes a temperature scale having an absolute zero value, below which temperatures do not exist, and using a degree of the same size as the Fahrenheit scale. Absolute zero, or 0°R, is the temperature at which molecular energy is at a minimum.

1859 The first volume of the *American Gas-Light Journal* is published.

1860–1869

1860 A proposal to transport oil by pipeline is made by 17-year-old Samuel Duncan Karns of Parkersburg, West

Virginia. A salt well in the region is beset by an influx of oil; Karns suggests that the oil be shipped to a refinery on the Ohio River via a wooden pipeline along a route that would allow the oil to flow by gravity.

1860 Concerned about France's dependence on coal, Auguste Mouchout begins the first research on the direct conversion of solar radiation into mechanical power. He goes on to develop a solar-powered steam engine, the first successful example of a motor running on solar energy.

1860s American railroads provide the best means of transporting oil to coastal cities, where it is used in refineries or shipped overseas. The first method involves transporting the oil in wooden barrels stacked on flat cars or in layers on specially built racks.

1860s The clipper ship era ends as these classic vessels are supplanted by the steamship, which has proven to be a much more profitable method for carrying large freight cargoes.

1861 The first bulk transportation of oil in America is accomplished by wooden barges known as "bulk boats" on Oil Creek and the Allegheny River in Pennsylvania. These boats carry 400-barrel loads down river to refineries at Pittsburgh.

1861 The first shipment of oil to be exported from the United States (Philadelphia) to Europe (London) is carried aboard the sailing ship *Elizabeth Watts*.

1861 The U.S. Civil War begins. Steam-powered railroads will play a key role in the war for the transportation of troops and supplies, especially through the U.S. Military Railroads system organized by the Union government.

1862 Louis Pasteur's experiments with bacteria conclusively disprove the theory of spontaneous generation and advance the germ theory of disease, revolutionizing medical research and treatment.

ca. 1862 Werner von Siemens proposes the measurement of electrical conductance; later the name *siemens* will be used for a basic unit of conductance.

1863 Because of the damage caused by harmful emissions from alkali works, Great Britain enacts its first environmental protection law, the Alkali Act. This requires a reduction by 95% in the discharge of all noxious and offensive gases by alkali manufacturers. It also establishes an official regulator, the Alkali Inspectorate, to enforce the legislation.

1863 French engineer Rodolphe Leschot invents the diamond core drill and uses it to drill blast holes for tunneling Mount Cenis on the France-Italy border. Eventually, diamond drill bits will produce a major advance in oil and gas exploration because their extreme hardness improves drilling efficiency.

1863 London opens the first route of its subway (underground) system, linking Paddington railway station to Farringdon Street, near the King's Cross rail station. The line is built on the "cut and cover" method in which a large trench is dug under a street and then roofed over so that surface traffic can use the street.

1863 Pierre and Ernst Michaux of Paris produce the Michaux Velocipede, a new form of bicycle in which the pedals are directly connected, via crankshafts, to the front wheel.

1864 George Perkins Marsh of Vermont publishes *Man and Nature: The Earth as Modified by Human Action,* often considered one of the first modern treatments of environmental problems, and in particular the role of humans as agents of environmental change.

1864 Scottish physicist James Clerk Maxwell proposes his equations of electromagnetism and is the first to suggest that light is an electromagnetic wave.

1864 Siegfried Marcus of Vienna, Austria builds a one-cylinder engine with a crude carburetor, and attaches it to a cart for a 500-foot drive. This is described as the world's first successful gasoline-powered vehicle.

1864 The construction of the Hot Lake Hotel near La Grande, Oregon marks the first time that geothermal energy from hot springs is used for the direct heating of a large building.

ca. 1864 Natural gas deposits are found near Stockton, California, the first such discovery in the western United States.

1865 After years of research with pea plants, Gregor Mendel publishes his theories of heredity in an obscure publication. These ideas establish the science of genetics but are generally unknown for over 30 years.

1865 America's Civil War ends, and with it the use of human slave power as an energy source in the United States.

1865 Amos Densmore, an oil buyer and shipper at Oil Creek, Pennsylvania, invents the first railroad oil tank car. The Densmore tank car is a major breakthrough in bulk transportation compared to the earlier method of stacking barrels on a flat car.

1865 British inventor George Law devises a rock drill in which an air-driven piston operates a hammer tool. This is considered to be the first practical application of compressed air to drive a motor.

1865 Colonel E. A. L. Roberts uses eight pounds of black powder to make the first successful oil well "shot" on the Ladies Well along Oil Creek, Pennsylvania. "Shooting" a well refers to the detonation of an explosive device in the well bore so as to allow oil to flow to the surface.

1865 Friedrich August Kekule recognizes that benzene is made up of carbon and hydrogen atoms in a stable

hexagonal ring, not a chain. This discovery changes the way chemists view molecular structure.

1865 Rudolf Clausius introduces the concept of entropy (disorder) to explain the directionality of physical processes. He establishes that entropy can never decrease in a physical process and can only remain constant in a reversible process. This becomes formalized as the second law of thermodynamics, which Clausius had first proposed in 1850.

1865 Samuel Calthrop of the United States develops a streamlined railroad train.

1865 Samuel Van Syckel builds the first major oil pipeline in the Oil Creek area of Pennsylvania. At the time teamsters charged extremely high prices to haul barrels of oil by wagon, and Van Syckel underprices them with his line of wrought iron pipes, laid partly underground and partly on the surface.

1865 The British economist W. Stanley Jevons publishes *The Coal Question,* in which he argues that coal is essential for the industry of Britain and that this resource will one day be exhausted, causing the collapse of British society. The prediction proves wrong because Jevons did not foresee improvements in mining technology and the use of oil as a substitute for coal.

1865 W. Stanley Jevons formulates Jevons' paradox, a concept now employed by modern scholars. It states that increased efficiency in the use of a natural resource, such as coal, will actually result in greater consumption, not less. This is because improvement in efficiency will lead to higher demand; e.g., U.S. gas consumption increased after fuel-efficient cars were introduced in the 1970s.

1866 Alfred Nobel tames the volatility of nitroglycerin by enclosing it in kieselguhr, a packing material, making a much safer explosive that he names *dynamite*. He goes on to produce other new explosive substances in the 1870s.

1866 Early Pennsylvania oil producers adopt the 42-gallon barrel as their standard. It is still the standard unit of measurement today.

1866 German scientists Adolph Fick and Johannes Wislicenus test von Liebig's theory that protein alone powers muscle activity. They eliminate protein from their diet, climb Mt. Faulhorn in the Swiss Alps, and calculate their energy expenditure. Urine analysis indicates that protein catabolism could not have supplied the requisite energy.

1866 Lyne Taliaferro Barret and his partners in the Melrose Petroleum Oil Company drill the first oil well in Texas, in Nacogdoches County. Though this well produces only a modest flow of oil, other efforts at the same site in 1887 have much greater success and set off the state's first oil boom.

1866 Strip mining begins near Danville, Illinois, when horse-drawn plows and scrapers are used to remove overburden so that the coal can be dug and hauled away in wheelbarrows and carts.

1866 Werner von Siemens discovers the dynamo-electric principle. This solves the problem of needing direct current batteries to generate continuous current and high voltage, and provides the crucial advance needed to supply electric power at commercially reasonable prices.

1867 German engineer Nikolaus August Otto and his partner Eugen Langen demonstrate an improved version of Jean Lenoir's engine, theirs operating on liquid fuel instead of coal gas. This engine is the forerunner of Otto's major breakthrough in 1876 (see below).

1867 The Reverend Leonard Wheeler, a missionary to the Ojibwa Indians of Wisconsin, invents a classic American farm windmill that is a departure from the earlier Dutch style.

1868 A refrigerated railroad car is patented by J. B. Sutherland of Detroit, Michigan, for use in transporting perishable foods such as meats and dairy products. In the 1870s and 1880s Gustavus Franklin Swift will build a huge meat-packing firm using refrigerated cars to ship meat from Chicago to markets in the East.

1868 American engineer George Westinghouse patents the air brake, which benefits the railroad industry by making braking a safer venture and thus permitting trains to travel at higher speeds. To manufacture his invention he establishes the Westinghouse Air Brake Company, a predecessor to the huge Westinghouse Electric Company.

ca. 1868 Georges Leclanche of France invents a precursor to the modern dry cell battery, now widely used in consumer products such as flashlights, toys, and other electronic devices.

late 1860s Enclosed cast iron stoves are common in America. Stoves had been resisted at first on the grounds that they hid the fire, but gradually they replace the open fireplace because of their greater efficiency.

1869 Belgian Zenobe-Theophile Gramme builds the first efficient direct-current dynamo, two years after building an efficient alternating-current dynamo. In 1873 it is demonstrated that the Gramme type dynamo can function as an electric motor, a major step in the development of electric power.

1869 Dmitri Ivanovich Mendeleev is the first of several scientists to publish a periodic table of the elements, with elements arranged in order of increasing atomic weight.

1869 German biologist Ernst Haeckel introduces the term *ecology* in his work *Generelle Morphologie der Organismen.*

1869 In the French Alps, Aristide Berges sets up a pipeline to transport a pressurized stream of water to his wood pulp factory. He then uses a dynamo to transform the water power into electricity. This is regarded as the first systematic use of hydroelectric power.

1869 Norman Lockyer suggests that a yellow spectral line observed in the Sun's spectrum during an 1868 eclipse must belong to a new element. Lockyer has discovered helium (from the Greek *helios,* or Sun), which is identified in terrestrial material by William Ramsay in 1895 and later isolated by him.

1869 The first transcontinental railroad line in the United States is completed when a symbolic golden spike is driven into the ground at Promontory Point, Utah. The Union Pacific line from the East meets the Central Pacific line from the West at this spot.

1869 The Pennsylvania Railroad introduces the horizontal boiler-type metal tank car for oil shipments, which is still the basic design in use today. The metal tanks are safer and more reliable than the earlier wooden Densmore tank car.

1869 The Red Sea is joined to the Mediterranean as the Suez Canal opens, construction having begun 10 years earlier under the direction of the French promoter Ferdinand de Lesseps. The canal will come under the control of Great Britain in 1875 and will serve as the crucial link to India and other British interests in the Far East.

1869 The ship *Charles* of Antwerp, Belgium becomes the forerunner of the modern oil tanker, carrying oil from the United States to Europe in iron tanks.

1869 Thomas Andrews of Belfast, Ireland suggests that there is a "critical temperature" for every gas at which it can no longer be liquefied by pressure alone.

1870–1879

1870 Briquetting of coal is introduced in the United States. This provides greater thermal stability and cleaner combustion.

1870 Drawing upon the earlier work of George Medhurst, American inventor Alfred Ely Beach constructs New York City's first subway, a pneumatically powered system operating along a line one block long in lower Manhattan. Though the route closes three years later for lack of riders, it represents the beginning of underground transport in the United States.

1870 John D. Rockefeller and his associates form the Standard Oil Company in Cleveland, Ohio. Cleveland had become the leading site for the U.S. oil refining industry in the 1860s.

ca. 1870 Julius Hock of Vienna develops the first internal combustion engine operating on modern principles.

1870s Edward Frankland, a British chemist, is among the first to apply the conservation of energy principle to human energetics. Building on the work of Fick and Wislicenus, Frankland shows that the energy intake of the body equals the heat expelled. He also is among the first to measure the caloric value of food.

1871 Andrew Smith Hallidie in San Francisco, California patents the first cable (street) car. In 1873 the first passengers travel along 2,800 feet of track to the crest of a hill 300 feet above the starting point. This is the first successful attempt to replace horses with a machine in the U.S. streetcar system.

1871 Charles Darwin publishes *The Descent of Man,* in which he specifically applies his principles of evolution in the animal kingdom to the human race.

1871 Italian-American Antonio Meucci declares the intent to patent his "Talking Telegraph," a predecessor to the comparable device patented five years later by Alexander Graham Bell. Meucci is forced to let his application lapse because of lack of funding, and Bell becomes recognized as the inventor of the telephone.

1872 Abraham Brower opens the first mass transportation system in America along Broadway in New York City. The vehicle is an omnibus, which looks like a stagecoach and is pulled by horses.

1872 George B. Brayton, a British-trained engineer of Boston, Massachusetts, receives a patent for a gas-powered streetcar. This goes into operation the following year, though electric-powered streetcars will become the dominant form.

1872 L. C. Marcy of Philadelphia develops an improved oil lamp using two flat and parallel cotton wicks.

1872 The first long-distance pipeline for natural gas goes into operation in Pennsylvania, extending from the Newton gas well to the town of Titusville.

1872 The first wireless telegraphy patent in the United States is issued to Mahlon Loomis. In 1866, Loomis had set up a demonstration experiment on two mountain peaks in the Blue Ridge Mountains of Virginia, 22 kilometers apart.

1872 Thomas Edison develops an automatic telegraph machine, one of many improvements in telegraphy for which he is responsible.

ca. 1872 Swedish-American engineer John Ericsson develops an improved form of the Stirling engine; this is intended for use as means of pumping water to provide irrigation for arid lands of the American West. Ericsson is also noted as the designer of the Civil War ironclad battleship *Monitor.*

1873 Entrepreneurs Robert and Ludwig Nobel (brothers of the better-known Alfred) establish a company to exploit the oil riches of Baku, Azerbaijan. They become the most successful oil producers in the area and help to make Baku's oil industry the largest in the world in the late 19th century.

1873 Johannes van der Waals refines Boyle's and Charles's laws of gases, introducing modified equations that allow for a wider range of molecular behavior.

1873 Joseph Henry proposes that the physical drudgery of human labor can be ameliorated only by more inanimate sources of energy and more powerful energy convertors. This is an early application of the new science of thermodynamics to socioeconomic concerns.

1873 London experiences the first of a series of "killer fogs." A thick winter fog settles over the city, darkening the sky to the point that visibility is nearly zero. An estimated 500 deaths occur both from respiratory illnesses and from accidents caused by the lack of visibility. Two similar events in 1880 and 1892 are each responsible for about 1,000 deaths.

1873 Thaddeus S. C. Lowe of the United States develops a new gas manufacturing process, carbureted water gas. This is cheaper and more efficient than the existing coal gas process and soon comes to dominate the manufactured gas industry.

1873 Willoughby Smith of England and his assistant Joseph May note that when selenium is exposed to light, its electrical resistance decreases. This discovery provides the means to transform images into electric signals, and leads to the manufacture of photoelectric cells and other light sensors. It also lays the foundation for the development of television.

1874 Joseph F. Glidden of DeKalb, Illinois develops a successful form of barbed wire, improving on the version patented in 1868 by Michael Kelly. Barbed wire will change the face of the American West, as it provides a means of confining cattle and of separating them from crop fields.

1874 Jules Verne publishes *The Mysterious Island,* set during the U.S. Civil War. The book's main characters speculate on how the depletion of coal will affect the future. Cyrus Harding, one of the characters, asserts "I believe that one day hydrogen and oxygen, which together form water, will be used either alone or together as an inexhaustible source of heat and light."

1874 Siegfried Marcus produces a true four-cycle, four-wheeled vehicle with electrical ignition, jet carburetion, and a throttle. This is accepted by many historians as the true forerunner of the modern automobile, though many competing claims exist.

1874 The "Destructor" goes into operation in Nottingham, England. This is the first known example of a systematic incineration of urban solid wastes. The Destructor burns mixed waste and produces steam to generate electricity. Several hundred similar facilities are built in the coming decades.

ca. 1874 Swedish engineer Charles Wilson builds the first solar distillation plant, in the mining area of Las Salinas in what is now northern Chile. This provides fresh water to the mining community; it remains in operation for about 40 years.

1876 Alexander Graham Bell transforms the world of communication when he patents the first telephone. Bell's patent precedes a similar application just two hours later on the same day by rival inventor Elisha Gray. Bell's device is improved almost immediately by Thomas Edison, who adds carbon powder to the mouthpiece, allowing it to carry more current.

1876 German engineer Carl von Linden patents a process of liquefying gas (ammonia) that marks a major advance in basic refrigeration technology.

1876 Nikolaus August Otto of Germany invents a successful four-stroke internal combustion engine, known as the "Otto cycle." This engine represents the first true advance over the steam engine and is almost universally adopted for all liquid-fueled automobiles from that point on.

1876 Thomas Edison establishes a laboratory at Menlo Park, New Jersey that will become the site of many of his famous inventions and innovations.

1876–1878 After a wave of violence in the coal mining region of Pennsylvania, a sensational murder trial results in the execution of 20 members of the Molly Maguires, a secret society of Irish-American miners. The historical record is unclear as to what extent the violence was incited, or even committed, by private detectives hired by mine owners to infiltrate the miners' union.

1877 A steam-powered shovel excavates some 10 feet of overburden from a 3-foot-thick coal bed near Pittsburg, Kansas.

1877 Austrian physicist Ernst Mach publishes a paper that accurately describes the relationship between the speed of a fast-moving object and the local speed of sound (Mach number).

1877 Louis Paul Cailletet and Raoul-Pierre Pictet independently liquefy oxygen.

1877 Oakland Gas Light establishes what is said to be the first high-pressure gas transmission in the United States; two years later the company introduces gas cooking stoves into California.

1878 American inventor Charles F. Brush develops an efficient dynamo and goes on to produce a commercially viable arc light, which is used to illuminate a private home in Cincinnati and a public square in Cleveland. He then founds Brush Electric Company, which will eventually join Edison's General Electric Company.

1878 Marie Alfred Cornu, a French physicist, measures the spectrum of solar radiation reaching Earth's surface and suggests that the absence of short-wave ultraviolet radiation is due to an atmospheric absorber. Two years later, Walter Hartley concludes that Cornu's absorber is ozone in the upper atmosphere (the ozone layer).

1878 Samuel Pierpont Langley of the United States invents the bolometer, a radiant-heat detector that is sensitive to differences in temperature of one hundred-thousandth of a degree Celsius (0.00001°C). The device is still used to provide accurate regional and global measurements of the components of the Earth's radiation budget.

1878 Thomas Edison founds the Edison Electric Light Company to finance his efforts to invent a practical incandescent electric lamp. This and various other electric companies established by Edison will later be combined in what becomes the General Electric Company.

1879 Attorney George Selden of Rochester, New York applies for a patent for his "road engine," a vehicle powered by an internal-combustion engine. This is the first automobile patent in the United States, though it is not granted until 1895. Later Selden will sue Henry Ford for producing his own automobiles, and the courts then declare the Selden patent too vague to be enforced.

1879 English physicist William Crookes identifies a fourth state of matter in addition to solid, liquid, and gas, one in which a collection of electrons and ions move freely within a given space. Irving Langmuir later applies the name *plasma* to this state. Plasmas make up about 99% of the visible matter in the universe and offer the potential for a large-scale energy source.

1879 Thomas Edison in America and Joseph Swan in England independently produce carbon-thread electric lamps. Edison's first bulb burns for 40 continuous hours, and only a year later he opens the first electric generation station in London used primarily for lighting.

1879 The Siemens Company builds the world's first electric train in which power for the train is supplied through the tracks rather than from overhead wires.

1879 William Adams, a British colonial official in India, constructs a heating system with a series of large mirrors to concentrate the Sun's radiation. He demonstrates it by placing a piece of wood in the focus of the mirrors where, he notes, "it ignited immediately." This system is similar to the one reportedly used by Archimedes 2,000 years earlier.

1880–1889

1880 Charles Brush's Electric Light and Power Company successfully demonstrates an arc lighting system along New York City's famous avenue Broadway, and soon thereafter builds New York's first central power station. Broadway will later become known as the "Great White Way" because of its dazzling array of electric lights.

1880 John Milne of England invents the first modern seismograph.

1880 Lester Allan Pelton of California obtains a patent for a new type of water turbine with a more effective jet of water. In 1883 the Pelton turbine wins a competition for the most efficient water wheel turbine, and it will serve as the standard design for the next 40 years.

1880 Michigan's Grand Rapids Electric Light and Power Company, generating electricity by means of a Brush dynamo belted to a water turbine, lights up a set of Brush arc lamps to provide theater and storefront illumination.

1880 Pierre and Jacque Curie discover that some crystalline materials, when compressed, produce a voltage proportional to the applied pressure and that when an electric field is applied across the material, there is a corresponding change of shape. This is called piezoelectricity or pressure electricity.

1880 The Bradford Gas Company of Rixford, Pennsylvania begins using the first natural gas compressor.

1880 Wabash, Indiana becomes the first city to be lit entirely by electric light, using the Brush dynamo and arc light system.

early 1880s A "current war" is underway over the choice between DC current, promoted by Thomas Edison, and AC current, promoted by George Westinghouse. An intense battle for public opinion and political support ensues.

1880s John D. Rockefeller and Standard Oil base the first decades of their business producing kerosene and shipping it around the world on ships called "kerosene clippers." Today kerosene is used primarily as a heating and aviation fuel, and as a solvent and thinner.

1880s Oil tanker barges are a major form of transportation for refined products in the Low Countries and Germany, which have extensive networks of rivers and canals.

1881 A hydroelectric generating station is operated on the Niagara River. An 85-foot cascade of water generates electricity to run the machinery of local mills and to light some of the village streets.

1881 German naturalist Karl Semper publishes the *Natural Conditions of Existence as They Affect Animal Life*. This is regarded as one of the earliest studies of energy flows in nature.

1881 Jacques D'Arsonval of France describes a method for using the temperature difference between the warm surface sea water and cold deep ocean water to generate

electricity (later known as ocean thermal energy conversion, or OTEC).

1881 Scottish engineer Sir Dugald Clerk patents his two-stroke internal combustion engine (in contrast with the four-stroke engine developed at around the same time by Nikolaus Otto). It will become widely used for motorcycles and other light engines.

1882 Augustin Mouchout and his associate Abel Pifre demonstrate a solar power system in Paris in which solar energy is used to make steam to operate a printing press.

1882 The first commercial hydroelectric power plant goes into operation on the Fox River in Appleton, Wisconsin. It is used to power two paper mills and eventually the town's streetcar system as well.

1882 The Standard Oil Trust is formed by John D. Rockefeller, largely to shield himself against legal challenges to his control of oil production and refining, and against public outcry over this perceived monopoly.

1882 The United States Electric Illuminating Company establishes an electric power station in Charleston, South Carolina.

1882 Thomas Edison's power generating company in New York City produces electricity for lighting. Three 125-horsepower "Jumbo" generators at the Pearl Street station provide power to 5,000 lamps in 225 homes.

1883 Charles Fritts, an American inventor, describes the first solar cells made from selenium wafers.

1883 John Ericsson designs and demonstrates his "Sun motor," a working solar heat engine.

1883 S. Podolinsky, a Ukrainian socialist, is the first to explicitly describe the economic process from an energy perspective, and in particular agricultural energetics. His biophysical analysis leads him to conclude that limits to growth are imposed not by constraints on production, but by physical and ecological laws.

1883 Swedish engineer Carl Gustaf de Laval develops a high-speed steam turbine. His innovative use of special reduction gearing allows a turbine rotating at high speed to drive a propeller at comparatively slow speed, a principle having great value in marine engineering.

1883 The Chartiers Valley Gas Company is formed to produce, gather, and transport gas to Pittsburgh's industrial plants.

1884 English engineer Charles Parsons invents the compound steam turbine, which converts the power of steam directly into electricity; it ultimately becomes the preferred power plant of electric power stations and ships.

1884 Paul Nipkow patents the world's first electromechanical image scanning system, consisting of a rapidly rotating disc with a pattern of holes. This is an important early step in the development of television; in the 1920s John Logie Baird will use the Nipkow disc to transmit the first true television pictures.

1884 The French military officers Charles Renard and Arthur Krebs make a flight of five miles in their airship *La France,* in which they are able to guide the ship so that it lands at the point from which they begun the flight.

1884 The Serbian-American electrical engineer Nikola Tesla designs practical methods for generating alternating current, a prerequisite for long-distance transmission of electricity. Called the "Master of Lighting," Tesla will receive more than 100 patents relating to electricity generation and transmission and radiocommunications.

mid 1880s Steam-driven plows and threshing machines are in use on the prairies of North America, though oxen and horses will remain the principal source of power for some time to come.

1885 A high-pressure manufactured gas transmission line is installed between Oakland and Alameda under the San Francisco Bay.

1885 A Westinghouse Company employee, William Stanley, invents the transformer for shifting the voltage and amperage of alternating current, enabling electricity to be transported over long distances with relatively little loss.

1885 Carl Auer von Welsbach at the Bunsen laboratory in Germany develops the Welsbach mantle, which becomes a key technology for the utilization of manufactured gas.

1885 Gottlieb Daimler extends Otto's work and invents what is recognized as the prototype of the modern gas engine, with a vertical cylinder and with gasoline injected through a carburetor (patented 1887). Daimler uses the engine in a two-wheeled vehicle he calls the *Reitwagen* (Riding Carriage). One year later he builds the world's first four-wheeled motor vehicle.

1885 John Kemp Starley of England introduces the Rover Safety Bicycle, a vehicle with essentially the same design as the modern bicycle. It is an immediate success and is marketed by Starley and fellow bicycle innovator William Sutton through their Rover Company.

1885 Sylvanus F. Bowser of Fort Wayne, Indiana develops a workable gasoline pump and then founds a company to manufacture the device.

1885 The German mechanical engineer Karl Benz designs and builds the world's first practical automobile to be powered by a gasoline-burning internal combustion, engine. The following year, Benz offers this vehicle for sale to the public.

1885 The Massachusetts Gas Commission becomes the first government agency to regulate the energy industry, including the setting of prices.

1886 Charles Hall of the United States and Paul Hêroult of France independently develop a molten electrolysis

process for the production of aluminum. The Hall–Héroult process is still the basic method of aluminum production.

1886 The first alternating current power plant in the United States goes into operation in Great Barrington, Massachusetts.

1886 The first oil tanker of modern design, *Gluckauf,* is built at Newcastle, England for a Bremen, Germany shipping company. The ship differs from previous versions in that the liquid cargo is contained directly in tankage integral with the hull, rather than in individual barrels.

1887 Geographer and climatologist Eduard Bruckner makes pioneering studies of climate change and in particular of the effect of human activity on climate.

1887 German physicist Heinrich Rudolf Hertz proves that energy is transmitted through a vacuum by electromagnetic waves. He detects and produces radio waves for the first time, with enormous implications for future technologies in radio, television, and radar.

1887 High Grove Station in San Bernardino, California becomes the first hydroelectric plant in the western United States.

1887 In his studies of air and sound, Ernst Mach notes that air molecules behave irregularly when pushed faster than the speed of sound.

1887 Scottish veterinarian John Boyd Dunlop experiments with his son's bicycle in an effort to improve upon the existing technology of solid rubber tires. He develops the first practical pneumatic tire, which becomes an essential component of the automobile industry.

1887 Solomon R. Dresser of Bradford, Pennsylvania develops a new type of coupling for pipe joints that makes it possible to provide a leakproof pipeline over extended distances. The company he founds becomes a leader in the oil and gas industry.

1888 Andrew Lawrence Riker founds the Riker Electric Vehicle Company in Elizabethport, New Jersey, which becomes one of the country's largest manufacturers of electric cars and trucks. Riker produces his first electric car in 1894, using a pair of bicycles as a base.

1888 Austrian botanist Friedrich Reinitzer observes that a substance called cholesteryl benzoate appears to have two different melting points, one in which the solid changes to a cloudy liquid and a higher one in which it becomes a clear liquid. German physicist Otto Lehmann confirms this and coins the term "liquid crystal" to describe this distinct phase of matter.

1888 Carl Gassner of Germany develops the first dry cell battery, using a carbon rod as the positive electrode and zinc as the outer container and negative electrode. This cell is easy to use and portable and it becomes the prototype for the dry battery industry.

1888 Charles F. Brush begins operation of an efficient wind dynamo in Cleveland, Ohio, modifying existing windmill technology to produce what is considered the world's first wind power plant.

1888 Granville T. Woods develops and patents a system for overhead electrical conducting lines for railroads, which is adopted for the railway system of various large cities. Through this and other innovations in electricity and telegraphy, the African-American inventor Woods becomes known as "the Black Thomas Edison."

1888 In Richmond, Virginia, Frank Julian Sprague establishes what is regarded as the first large-scale, successful streetcar system powered by electricity. Similar systems are soon established in many other American cities and the streetcar becomes the preferred mode of urban mass transit.

1888 Oliver B. Shallenberger, an electrician at the Westinghouse Electric Manufacturing Company, receives a U.S. patent for an ampere-hour meter, which accurately measures the amount of electricity used.

1888 Wilhelm Hallwachs extends Hertz's work on the photoelectric effect, noting that when illuminated with ultraviolet light, a neutral or negatively charged body (a zinc plate) becomes slightly positively charged.

late 1880s Electric vehicles begin to appear on the streets of the United States and Britain, including an electric bus company making regular trips in London.

1889 Norwegian-American engineer Edwin Ruud invents the first device to store and automatically heat water. Ruud founds a company (still in operation) to produce water heaters for commercial and residential use.

1889 Paris becomes known as "The City of Light" during the 1889 World's Fair, since it is the first large city to switch to all electric lighting.

1889 Willamette Falls, Oregon provides the first commercial, long-distance transmission of electric power in the United States with a direct-current line to the city of Portland.

1890–1899

1890 French Engineer Clement Ader reports that his *Eole*, a steam-powered, bat-winged flying machine, is the first full-sized aircraft to make a powered flight. Witnesses describe a liftoff covering 50 meters at a height of about 20 centimeters off the ground. Historians differ as to whether this was truly an airplane flight, or merely a "running hop."

1890 The United Mine Workers of America is established in Columbus, Ohio through the merger of two earlier groups.

1890s Approximately 1,000 manufactured gas plants are in operation in the United States.

1890s Ludwig Boltzman, an Austrian physicist, founds the field of statistical mechanics. His interpretation of the second law of thermodynamics introduces the theory of probability into a fundamental law of physics and thus breaks with the classical precept that fundamental laws have to be strictly deterministic.

1890s U.S. chemist W. O. Atwater constructs a calorimeter and uses it to identify the energy content of different foods, using subjects who eat either a high fat or high carbohydrate diet while riding a stationary bicycle many hours per day. His "Atwater general factors" provide a good estimate of the energy content of the daily diet.

ca. 1890 Coal takes the place of wood as the dominant fuel in the U.S. economy, as industry has replaced human labor and draft animals with steam engines and other inanimate energy converters.

1891 Clarence Kemp of Baltimore, Maryland patents the first commercially successful solar water heater. His invention is later marketed in California and becomes popular enough to heat one-third of the homes in the city of Pasadena.

1891 German engineer Otto Lilienthal makes the first in a long series of successful glider flights. Lilienthal is a pioneer in aerodynamics, especially wing design, and his work will greatly influence the Wright Brothers.

1891 German-American chemical engineer Herman Frasch patents a process (Frasch process) to extract sulfur compounds from oil using copper oxide powder; until then, the foul smell of sulfur had prevented oil from being widely used as a fuel.

1891 Inventor Poul la Cour, the "Danish Edison," begins a series of experiments with wind turbines. His work will establish a foundation for modern use of wind energy.

1891 Nikola Tesla invents the Tesla coil, an air-core resonant transformer that can generate extremely high voltages at high frequency. Tesla coils can produce spectacular lightning-like discharges and have often been used in the film industry for special effects.

1891 The first extended natural gas pipeline in the United States is built. It carries gas from wells in Indiana over a distance of 120 miles to Chicago.

1891 The first long-distance high-voltage electricity line is established between Lauffen and Frankfurt am Main, Germany, a distance of over 100 miles.

1892 Edward L. Doheny begins the oil industry in Los Angeles, California, supposedly after he notices oil sticking to the wheels of a wagon and asks the driver where it had come from. Doheny becomes one of the wealthiest men in the United States and a major figure in the creation of modern Los Angeles. Later he will be at the center of the Teapot Dome Scandal (see 1921).

1892 Electrical winders are in use in British coal mines.

1892 Inventor Aubrey Eneas founds the Solar Motor Company of Boston to build solar-powered motors as a replacement for steam engines powered by coal or wood.

1892 John Froelich develops a tractor running on an internal combustion engine; this will eventually supplant the steam-powered tractor, which is less practical because of its large size.

1892 R. E. Bell Crompton and H. J. Dowsing of England patent the first electric radiator.

1892 The first steel barges for oil transportation are put into use by Standard Oil of New York. Steel barges are larger, stronger and safer than their wood predecessors.

1892 The first U.S. geothermal district heating system is in operation in Boise, Idaho.

1892 The *Murex* is the first tanker to pass through the Suez Canal, with a load of kerosene to be delivered from Batum, a Russian port on the Mediterranean, to Singapore. Marcus Samuel, the owner of *Murex,* forms Shell Trading and Transport, which eventually merges with Royal Dutch to form one of the world's largest oil companies.

1892 The Sierra Club is founded in San Francisco "to do something for the wilderness and make the mountains glad." John Muir is the club's first president.

1893 Julius Elster and Hans Geitel of Germany develop the first photoelectric cell. This is sensitive to both visible light and ultraviolet rays.

1893 Nikola Tesla begins a series of lectures and articles presenting his ideas for the fundamental methods of practical radio communication. Tesla thus precedes Guglielmo Marconi, popularly known as the "Father of Radio," though Marconi will state that he carried out his own work without knowing of Tesla's earlier efforts.

1893 Rudolf Diesel publishes a paper describing a new type of internal-combustion engine that will be named after him. Its distinctive feature is that it operates on the principle of self-combustion; i.e., rather than relying on a separate energy source such as a spark plug, it heats and compresses the fuel mixture to the point where it ignites itself.

1893 With the idea that his three-wheeled motor vehicle is unstable and uncomfortable, Karl Benz modifies the design to produce a four-wheeled vehicle. This is considered the world's first inexpensive, mass-produced car.

1894 Drilling begins at Alberta's Athabasca tar sand site, the world's largest accumulation of tar sands. Crews strike a reservoir of natural gas that will blow wild for 21 years.

1895 Conventional wisdom holds that the radio is born at this time, when Guglielmo Marconi of Italy demonstrates that it is possible to send signals by using electromagnetic waves to connect a transmitter and a receiving antenna. However, the U.S. courts will later conclude that Marconi relied upon the earlier work of Nikola Tesla (see 1893).

1895 Colonel George E. Waring is appointed as New York City's commissioner of street cleaning. Waring is a noted expert on drainage, sanitation, and urban public health. Public sanitation becomes a major issue, and the first curbside pickups of garbage begin.

1895 The Baltimore and Ohio Railroad becomes the first U.S. railway line to make regular use of an electric locomotive.

1895 The Metropolitan West Side Elevated Railway begins service in Chicago; it is described as the nation's first electric elevated rail line.

1895 Wilhelm Roentgen of Germany discovers X rays, and their medical implications are immediately recognized. Roentgen's discovery will lead to the year 1895 being referred to as the beginning of the Nuclear Age in human history.

mid-1890s A period of great popularity begins for electric cars in the United States. Over the next 20 years about 35,000 electric vehicles will come into use. Popular makes include the Riker, the Columbia, and the Baker.

1896 "Permitted" explosives are introduced to British coal mining. These are industrial explosives that are specially produced and tested for use in mines where firedamp and/or dangerous coal dust occur.

1896 A Santa Barbara, California group headed by Henry L. Williams drills wells from piers extending out into the sea. This leads to the 1898 discovery of the Summerland field, which is considered to be the first productive offshore oil facility in the world. (Similar offshore wells are reported in the Caspian Sea about five years later.)

1896 An electrical battery is developed by William W. Jacques that produces electricity directly from coal.

1896 Henri Becquerel of France discovers radioactivity when his experiments indicate that uranium emits radiation without an external source of energy such as the Sun, as observed when the invisible rays darken a photographic plate.

1896 Henry Ford's automotive experiments culminate with the completion of his own self-propelled car, the Quadricycle (so named because it runs on four bicycle type wheels). It is a four-wheeled vehicle built on a steel frame with no body; it is steered by a tiller, like a boat.

1896 Svante August Arrhenius of Sweden presents a paper to the Stockholm Physical Society entitled, "On the Influence of Carbonic Acid in the Air upon the Temperature of the Ground." This establishes the role of carbon dioxide as a greenhouse gas.

1896 The first subway on the European continent is opened in Budapest.

1896 William Hadaway of the United States receives a patent for an electric stove.

ca. 1896 A Niagara Falls hydroelectric plant is in operation, including a one-mile tunnel under the town of Niagara Falls and the use by George Westinghouse of Nikola Tesla's alternating current for long-distance transmission of power to Buffalo, 26 miles away.

1897 Encouraged by reports of the successful 1892 flight of Clement Ader's *Eole* flying machine, the French government provides funding for a new craft, named the *Avion*. Ader arranges a demonstration at a military base near Versailles, but *Avion* never succeeds in becoming airborne and the experiments are abandoned.

1897 Ferdinand Braun of Germany invents the cathode-ray oscilloscope, the precursor of the television picture tube. Braun does not patent this because he wishes it to be available to all scientists for research. Braun also makes important contributions to wireless telegraphy, for which he shares the Nobel Prize with Marconi.

1897 Henry Morris and Pedro Salom form the Electric Carriage and Wagon Company to operate electric cabs on the streets of New York City. This is described as the first motor vehicle service in the United States. Prior to this Morris and Salom had developed an electric car known as the Electrobat.

1897 Joseph John Thomson shows that cathode rays are particles with a negative electric charge, thus identifying the electron, the first subatomic particle known. This leads to much greater understanding of electric and electronic processes.

1897 Justus B. Entz, chief engineer of the Electric Storage Battery Company of Philadelphia, develops what is considered to be the first hybrid-electric vehicle (actually called the petro-electric car). It uses a gasoline engine as the primary drive and an electric motor to assist when more power is required.

1897 New York and other large cities have established garbage "picking yards" to separate out materials that have value for reuse, such as paper, metal, rubber, and twine.

1897 Nikola Tesla files his first U.S. patent application for basic radio communication. The patent is granted in 1900, the same year that Guglielmo Marconi's application is turned down. However, a 1904 ruling will overturn this and award the radio patent to Marconi.

1898 Energy recovery from garbage incineration begins in New York City; this is the first known example of a waste-to-energy system.

1898 Pierre and Marie Curie of France isolate and analyze radium and polonium, the elements that constitute most of the radioactivity in uranium ore.

1898 The Sulzer Brothers firm of Switzerland builds its first diesel engine. (Years earlier Rudolph Diesel had begun his career as an apprentice in Sulzer's engine works.) The company will become a world leader in the production of diesel engines.

1898 The Winton Motor Carriage Company of Cleveland, Ohio produces the first American truck, a gas-powered delivery wagon with a single-cylinder, six-horsepower engine.

1898–1900 Phillip Lenard, a German physicist, is the first to cause cathode rays to pass from the interior of a vacuum tube through a thin metal window into the air, where they produce luminosity.

ca. 1898 Albert Champion opens the Champion Ignition Company to manufacture spark plugs for the developing automobile industry. Champion later joins forces with General Motors and becomes the leader in the field. (Various others have been credited with inventing the spark plug, such as Edmond Burger, Oliver Lodge, and Robert Bosch.)

late 1890s A vital solar hot water heater industry emerges in Southern California; it later collapses due to the availability of cheap fossil fuels.

late 1890s The manufacture of automobiles is in full swing in western Europe and North America, led by industry pioneers such as Rene Panhard and Emile Levassor, Armand Peugot, Charles and Frank Duryea, and Ransome Eli Olds. This creates a great demand for gasoline. (Prior to this, kerosene for heating had been the main oil product.)

late 1890s The United States takes over the lead in coal production. Britain now ranks second, after having been the world leader since the beginnings of the industry in the 1500s. Germany is third, an indication of her growing industrial power relative to continental rival France.

1899 A leading American magazine, the *Literary Digest,* analyzes the future of the automobile and declares that "the ordinary horseless carriage is at present a luxury for the wealthy; and although its price will probably fall in the future, it will never, of course, come into (such) common use as a bicycle."

1899 Waldmar Jungner of Sweden invents the nickel-cadmium battery, which uses nickel for the positive electrode and cadmium for the negative. Two years later, Edison produces an alternative design by replacing cadmium with iron.

1900–1909

1900 Electric cars outsell gasoline and steam-powered cars in the United States Electric vehicles do not require a hand starter or gearshift, and they are quieter and operate with less vibration. Gas-powered cars take over in the 1920s due to cheap gasoline, the elimination of the hand crank, mass production, and the relatively limited range and speed of electric vehicles.

1900 German physicist Max Planck is the first to describe photons when he tries to explain the "black body" distribution of wavelengths in the light emitted by a solid hot object. "Planck's constant" becomes a universal constant that is fundamental to all quantum theory.

1900 Gregor Mendel's work on heredity is rediscovered by three different biologists working independently in separate countries. They finally give publicity and credence to Mendel's theories, establishing the field of genetics.

1900 Paul Ulrich Villard observes gamma rays, proving them to be a form of radiation more powerful than X rays.

1900 Standard Oil of New Jersey dominates in the United States with more than 80% of the market share in crude oil supplies, refining capacity, and kerosene and gasoline sold. In the following decade independent Texas oil companies will emerge to make inroads into this market share, and in 1911 Standard Oil is broken up by the government.

1900 The first dirigible to make a successful flight is built by Count Ferdinand von Zeppelin of Germany. The name *zeppelin* will come to be a synonym for aircraft of this type.

1900 The first transmission of a human voice over radio is made by Reginald Aubrey Fessenden, who transmits "words without wires" over a distance of 1,600 meters between two aerial systems on an island in the Potomac River. Fessenden will make the world's first radio broadcast on Christmas Eve in 1906.

ca. 1900 Charles Seeberger of the Otis Elevator Company develops a working escalator, improving upon an earlier design by Jesse Reno.

1901 At an oil field near Beaumont, Texas, a drilling crew supervised by Austrian engineer Anthony Lucas unexpectedly exposes a huge gusher of oil shooting 250 feet in the air. This becomes the site of the famous "Spindletop" well which will reportedly produce as much as 100,000 barrels of oil per day, a rate thousands of times greater than existing wells.

1901 Azerbaijan ranks as the world's most productive oil region, thanks to an oil boom in the area around the city

of Baku. A large refining industry also exists to turn crude oil into kerosene.

1901 The first Federal Water Power Act is enacted in the United States, beginning an era of large hydropower projects in the West.

1901 The *King Edward,* the first merchant vessel fitted with steam turbines, is launched in Scotland.

1901 Using an antenna he invented in 1895, Marconi broadcasts the first radio signals across the Atlantic Ocean from Cornwall, England to Newfoundland, Canada, a distance of more than 2,000 miles.

1901 What is now known as the Centennial Light Bulb is first lit at a firehouse in Livermore, California. It is a hand-blown bulb with a carbon filament, using approximately 4 watts of electricity. The bulb has now been burning continuously for over 100 years.

1902 A large gusher of oil spews forth in the Cotella (Katalla) region along the Gulf of Alaska. This is the first successful oil well in Alaska and provides evidence of the area's potential as an energy source.

1902 An anthracite coal strike in the United States severely disrupts the national economy. The power of the United Mine Workers union grows as its membership goes from less than 10,000 members before the strike to over 100,000 members afterward. The UMW becomes the nation's largest trade union.

1902 Arthur Korn of Germany develops a photoelectric scanning system for the transmission and reproduction of photographs. He goes on to establish a commercial picture transmission system linking Berlin, London, and Paris; this is the world's first fax (facsimile) network.

1902 Ernest Rutherford of New Zealand and Frederick Soddy of England publish their theory of radioactive decay, stating that atoms of a radioactive element emit charged particles (alpha or beta) and in doing so change into atoms of a different element.

1902 Marie and Pierre Curie measure the atomic weight of radium.

1902 Philipp Lenard studies the photoelectric effect, showing that electrons are emitted from certain metals when illuminated by ultraviolet light. He observes that the number of electrons released is proportional to the intensity of the light, while their speed is independent of this and is determined by the wavelength of the light.

1902 The first municipal oil-gas plant in the western United States is erected in Oakland, California for lighting purposes.

1902 The U.S. Congress establishes the Bureau of Reclamation to administer money from the sale of public lands to build dams and irrigation projects for western states. By 2000 the Bureau operates 60 dams with a total capacity of 14,757,668 kilowatts.

1902 Willis Haviland Carrier designs the first industrial air-conditioning system; in the following decades he and the Carrier Air Conditioning Corporation carry out various other innovations, culminating with the first air-conditioned stores and theaters in 1924 and a practical home air-conditioner in 1928.

ca. 1902 French auto pioneer Louis Renault is credited with the invention of the internal expanding drum brake, a great improvement in stopping power for motor vehicles.

1903 Brothers Wilbur and Orville Wright make the first successful flight of a controlled, powered, heavier-than-air machine, for 59 seconds over a distance of 850 feet at Kitty Hawk, North Carolina.

1903 Henry Ford and a group of financial backers found the Ford Motor Company in Detroit, Michigan.

1903 Konstantin Tsiolkovsky of Russia publishes *The Investigation of Outer Space by Means of Reactive Devices,* which suggests the use of liquid propellants for rockets to achieve greater range. This is one of many writings by Tsiolkovsky on space flight, in which he puts forth ideas such as multistage rockets, artificial satellites, and manned space stations.

1903 The 1903 Nobel Prize for Physics is jointly awarded to Pierre and Marie Sklodowska Curie and Henri Becquerel for their pioneering work on radioactivity. Marie Curie is the first woman to win a Nobel Prize.

1904 Beltram Borden Boldwood proves that uranium changes into radium through the process of radioactive decay. He later expands his theory, showing that radium decays into lead and that, in general, radioactive substances eventually decay into non-radioactive ones.

1904 English electrical engineer John Ambrose Fleming patents the thermionic valve, which is the first electronic rectifier of radio waves. Along with the amplifier grid of Lee de Forest (see 1906), Fleming's invention is the forerunner of the triode and other vacuum tubes and thus a foundation of the modern electronics industry.

1904 Prince Piero Ginori Conti of Italy successfully produces electricity from geothermal energy in an experimental "indirect cycle," using pure steam produced from a heat exchanger.

1904 Swedish-American electrical engineer Ernst Alexanderson develops a high-frequency alternator that provides the means for effective long-distance radio communication.

1904 The earliest large-scale U.S. aluminum recycling operations begin in Chicago and Cleveland.

1904 The first official New York City subway system opens in Manhattan, the Interborough Rapid Transit (IRT). It consists of 28 stations from City Hall to 145th Street, along 9 miles of track. The IRT extends to the Bronx in 1905, Brooklyn in 1908, and Queens in 1915.

1904 The Kern River oil field in Bakersfield, California reaches a peak production level of 17.2 million barrels per year, roughly equivalent to the output of the entire state of Texas.

1905 Albert Einstein proposes that light can be described as a stream of separate particles of energy. This explains the photoelectric effect, which had been extensively studied by his predecessors such as Hertz, Hallwachs, and Lenard, but which could not be accounted for by Newtonian physics, with its assumption that light is a continuous wave.

1905 In a second major paper, Einstein presents his special theory of relativity. He proposes that the laws of nature have the same application in all frames of reference. This applies to the speed of light, which is said to be constant, independent of any relative motion between the light source and the observer. Einstein describes mass and energy as equivalent ($E = mc^2$).

1905 In a third landmark paper of 1905, Einstein calculates how molecular movement causes Brownian motion (the irregular movement of microscopic particles suspended in a fluid). This confirms the validity of the atomic theory of matter.

1905 New York's Long Island Railroad is the first major rail carrier to install extensive main line electrification.

1905 The concept of a limiting factor in photosynthesis is shown by Frederick Frost Blackman. Photosynthesis is limited by the supply of carbon dioxide, temperature, and light intensity. The rate of photosynthesis is controlled by the factor in the shortest supply.

1905 The gas pump innovator Sylvanus F. Bowser develops a self-measuring pump that dispenses precise amounts of fuel.

1906 In his statement of the third law of thermodynamics, Walther Nernst proposes that absolute zero is a point that can be closely approached, but never actually reached.

1906 Lee de Forest of the United States invents the triode, a vacuum-tube device that amplifies weak electric signals. It is first used as a detector of radio waves, then as an amplifier for long-distance telephone calls, and eventually as a major technology of the radio transmitter, sound films, loudspeakers, and many other electronic devices.

1906 The British battleship *Dreadnought* is launched, the best-armed and fastest battleship in the world. Its presence in the Royal Navy sets off a competition among rival nations to build other ships of this class in the years leading up to World War I.

1907 American chemist Bertram Borden Boltwood is the first to use radiometric dating to estimate the age of the Earth. Using the half-life of uranium as a standard, he estimates the Earth's age at 2.2 billion years. This is a dramatic increase over previous estimates of Earth's age.

1907 An explosion in a coal mine in Monongah, West Virginia results in the death of 362 miners, virtually the entire work force in the mine at that time. This is the worst coal mine disaster in American history and consequently Congress is impelled to create the Bureau of Mines to study mine safety and conduct inspections.

1907 Coal reaches the historic high point (78%) of its share of the U.S. energy supply.

ca. 1907 Russian scientist Boris Rosing succeeds in transmitting and reproducing black-and-white silhouettes of simple shapes, using a mechanical mirror-drum apparatus as a camera and a cathode-ray tube as a receiver. In the 1920s, Rosing's student Vladimir Zworykin will become a key figure in the development of television technology in the United States.

ca. 1907 The first electric-powered washing machine is developed by Alva J. Fisher and marketed by the Hurley Machine Company of Chicago.

1908 A. A. Campbell-Swinton proposes a television system in which images are stored in the form of electric charge in a camera tube and reproduced on a picture tube, in the manner now employed in modern television broadcasting.

1908 Ernest Rutherford and his assistant Hans Geiger develop the Geiger counter to detect radiation levels.

1908 With a commission from the Shah of Persia (Iran) to explore for oil in the region, Englishman William Knox D'Arcy and his team make the first major commercial oil discovery in the Middle East at Masjid-i-Suleiman. D'Arcy then forms the Anglo-Persian Oil Company (later British Petroleum) to exploit this discovery.

1908 Henry Ford revolutionizes the manufacturing process when he sets up the first assembly line in his Model T factory. The inexpensive Model T makes automobile ownership possible for the average American and it becomes the largest-selling car model of its era.

1908 Hermann Minkowski publishes *Space and Time,* proposing time as a fourth dimension for the study of the universe.

1908 The history of superconductors begins with the successful liquefication of helium by the Dutch scientist Keike Kamerlingh Onnes at a temperature of just 4 K.

1908 The Wisconsin Railroad Commission orders gas companies to use British Thermal Units (BTUs) as the new heating measurement standard.

1909 "England's isolation has ended once and for all" is the judgment of one English newspaper after French aviator Louis Bleriot becomes the first to fly across the English Channel. Bleriot will later found an aircraft company that produces thousands of the famous SPAD warplane for the Allies in World War I.

1909 Leo Hendrik Baekeland of Belgium invents bakelite, a dense synthetic polymer (a plastic) that is used to make jewelry, game pieces, engine parts, radio boxes, switches, and many other objects. Bakelite is the first industrial thermoset plastic, i.e., a material that does not change its shape after being mixed and heated.

1909 The Hughes Tool Company makes the first rotary rock bit, which makes it possible to drill through hard rock formations with a rotary rig.

1910–1919

1910 A California gusher shoots forth a huge column of oil. The well, between the towns of Taft and Maricopa, will eventually reach an uncontrolled rate of 100,000 barrels and destroy its derrick. Its estimated output of 9 million barrels of oil is a record for the time, though reportedly less than half of this could be saved.

1910 American engineer Elmer A. Sperry establishes the Sperry Gyroscope Company (with himself as the lone employee) to market the innovative ballistic gyrocompass he had created two years earlier.

1910 Georges Claude displays the first neon lamp in Paris.

ca. 1910 Farms in North America are home to about 25 million horses and mules. These animals supply the power for general transportation and for essential farm tasks such as plowing, seeding, cultivating, and harvesting. Following World War I, the mechanized tractor will take over this role, and on today's farms animal power is a rarity.

1911 Austrian physicist Victor F. Hess discovers cosmic radiation. He is not certain what this phenomenon is, and it is poorly understood even today.

1911 Dissolution of the Standard Oil trust is ordered by the U.S. Supreme Court. John D. Rockefeller's empire is broken up into many smaller companies, including Standard Oil of New Jersey, Standard Oil of New York, Standard Oil of California, Standard Oil of Ohio (later part of BP), Standard of Indiana (later Amoco), Continental Oil (Conoco), and Atlantic Oil (Arco).

1911 Dutch physicist Heike Kamerlingh Onnes discovers superconductivity—the loss of electrical resistance in mercury near absolute zero temperatures. It is soon determined that other metals and alloys become superconductors at very low temperatures.

1911 Ernest Rutherford conducts experiments with the scattering of alpha particles off atoms, from which he concludes that the atom's mass and positive charge are concentrated in a tiny nucleus. The nuclear model of the atom is born.

1911 Famed photojournalist Lewis W. Hine produces his classic "Breaker Boys" series of photos depicting harsh child labor conditions in the United States. Breaker boys are employed in coal mines to separate coal from unwanted stone and slate, a grueling task that requires them to spend the day sitting suspended above a conveyer belt as the coal rushes by.

1911 George von Hevesy of Hungary conceives the idea of using radioactive tracers, which will have great applications in medical and ecological research. He first applies this method to a biological problem in 1923, when he traces lead absorbed by plants.

1911 The U.S. output of kerosene is eclipsed for the first time by a formerly discarded byproduct—gasoline.

1912 C. V. Boys and Frank Shuman's solar-powered steam boiler begins pumping irrigation water from the Nile River. This is the world's largest solar plant and Shuman envisions one even larger, a gigantic facility covering thousands of square miles in the Sahara Desert. World War I intervenes and Shuman's dream is never realized.

1912 George Sarton, a Belgian-born professor at Harvard University, founds *Isis,* which will evolve into the premier international journal dedicated to the history of science. Sarton will edit *Isis* until 1952, and he is widely considered to be the father of the history of science.

1912 The General Motors Company approves the installation of Charles Kettering's automatic self-starter in its Cadillac line of automobiles. This is one of many innovations in auto starting, ignition, and lighting accomplished by Kettering, first with his Delco company and then with General Motors after it acquires Delco.

1912 The world's largest ocean liner, *Titanic,* sinks on her maiden voyage.

ca. 1912 Robert Bosch of Germany develops what is considered to be the first successful fuel injection system.

1912–1914 First Lord of the Admiralty Winston Churchill, fearing conflict with Germany, hastens the conversion of British battleships from coal to oil. Oil-powered ships are faster, they can be refueled at sea, and they require less on-board labor. The Royal Navy eventually overcomes the largely coal-based German fleet in World War I.

1913 Austrian Victor Kaplan invents an improved turbine. The Kaplan turbine features movable blades that rotate, or "feather," to handle different conditions; this allows hydroelectric power stations to operate with greater efficiency.

1913 Canadian engineer Sidney Ells advocates the hot water flotation method of separating bitumen from the tar sands of Athabasca. His is one of several unsuccessful attempts to develop the Athabasca sands. Decades later, oil sands will re-emerge as a viable energy source.

1913 Electric refrigerators for home use begin to appear on the market in the United States.

1913 Frederick Soddy formulates the concept of isotopes, stating that certain radioactive elements may exist in two or more forms which have different atomic weights but which are indistinguishable chemically.

1913 French physicist Charles Fabry discovers the ozone layer, the thin shield in the upper atmosphere that acts as a screen to protect life on the surface of Earth from the ultraviolet rays of the Sun.

1913 Friedrich Bergius, a German chemist, invents a process he calls "destructive hydrogenation" of coal, which later comes to be known as direct liquefaction. Bergius liquefies coal by reacting it with hydrogen at high temperature and pressure.

1913 In the famous "oil drop experiment," Robert Andrews Millikan measures the charge of a single electron to be sixteen-quintillionths of a coulomb.

1913 Irving Langmuir develops an improved incandescent lamp by filling the lamp with an inert gas so that the atoms of tungsten evaporate more slowly. This is the first major advance in the incandescent lamp since the days of Edison, and it remains a standard technology today.

1913 Niels Bohr applies the quantum theory to the atom and concludes that electrons have fixed orbits around the nucleus and that they emit or absorb specific amounts of energy, or quanta, when they jump into another orbit.

1913 The first geothermal power plant is built at Larderello in Tuscany, Italy, employing heat from a dry steam field to generate a constant flow of electricity.

1913 The percentage of the world's energy consumption coming from coal peaks at 61%.

1913 *U.S.S. Jupiter,* a transport and coal carrying vessel, is commissioned in California. This is the first surface ship in the U.S. Navy to be propelled by electric motors.

1913 Using radiometric dating, the English geologist Arthur Holmes proposes the first geological time scale. He estimates the Earth's age at 4 billion years, far older than prevailing wisdom.

1913 William Burton of the Standard Oil Company receives a patent for a thermal cracking process (the application of steady heat and pressure to crack, or break down, heavier hydrocarbons into lighter ones). This greatly increases the proportion of gasoline obtainable from crude petroleum.

ca. 1913 Fritz Haber and Carl Bosch of Germany devise an industrial process in which nitrogen from the atmosphere and hydrogen under high temperature and pressure react to form ammonia. The Haber-Bosch process becomes an effective way to produce ammonia-based fertilizers.

1913–1914 Ford Motor Company installs the first moving assembly line for the manufacture of automobiles. Once the system is in full operation, Henry Ford announces that his workers will be paid $5 per day, more than double the usual wage at the time, while also having their work day reduced. This makes Ford a hero to the American work force.

1914–1918 World War I engulfs Europe. Newer forms of warfare are employed, such as tanks, airplanes, submarines, machine guns, and poison gas. Railroads and motor vehicles transport troops and war matériel. However, military tactics lag behind technology, and in the slaughterhouse of trench warfare millions of lives are lost in fruitless assaults on heavily defended positions.

1914 A version of the modern traffic light is put into operation in Cleveland, Ohio, with red and green lights and a warning sound to indicate when the light is changing. Three-color lights with yellow as the warning will be introduced in 1920.

1914 Acid mine drainage from abandoned coal mines in the United States receives considerable attention when the Army Corps of Engineers begins an extensive investigation of the problem in the Ohio River basin. Municipalities are concerned about the increased costs of water filtration and pipe corrosion.

1914 Data compiled from annual mine inspector reports leads to the conclusion that about 90,000 people have died or suffered injury in the mines of Great Britain in the period from 1850 to 1914. Most of the deaths are in coal mines.

1914 Ernest Rutherford suggests that the positive nucleus of atoms contains protons that balance the charge of electrons but have a much greater mass.

1914 Professor Robert Hutchings Goddard of Worcester, Massachusetts receives two U.S. patents, one for a rocket that uses liquid fuel, the other for a two- or three-stage rocket using solid fuel. This is considered the first step in the era of rocket propulsion.

1914 The first regularly scheduled airline in the United States begins operation. The Benoist Company, using a flying boat, carries passengers across Florida's Tampa Bay, between St. Petersburg and Tampa. The flights will last for only about six months.

1914 The Panama Canal opens, linking the Atlantic and Pacific Oceans and drastically reducing the sailing time from Europe or eastern North America to the West Coast.

1914 Through studies of earthquake waves, Beno Gutenberg determines that there is an inner and outer core at the center of the earth measuring about 4,200 miles in diameter, with a sharp dividing line between the mantle and the outer core (now known as the Gutenberg discontinuity).

1915 German-American blacksmith August Fruehauf builds the first semi-trailer type of truck, in which the load-carrying vehicle has wheels only at the rear and is towed and supported by a powered vehicle in front.

1916 Edward Ardern and William Lockett, workers at a wastewater treatment plant in Manchester, England, demonstrate the activated sludge process, which will become the most widespread technology for wastewater purification.

1916 Einstein publishes his General Theory of Relativity, or Theory of Gravitation, equating gravitational and inertial mass and showing space to be curved.

1916 Gilbert Newton Lewis and Irving Langmuir independently formulate a system of chemical bonding based on the number of electrons in each shell of an atom.

1916 The Goose Creek oil field on Galveston Bay becomes the first offshore drilling operation in Texas and the second in the United States. The Goose Creek area will soon become the site of one of the largest oil refineries in the United States.

1916 Using Einstein's general theory of relativity, Karl Schwarzschild postulates on the existence of what are later named black holes.

1917–1921 Russian oil production and exports drop sharply as a result of the Russian revolution in 1917, and the nationalization of the oil fields by the Communists in 1920. Production strengthens by the mid-1920s due to an infusion of foreign investment from the West.

1918 A U.S. Revenue Act restores the depletion allowance for minerals and fossil fuels, reducing taxes for owners of such resources to compensate for the exhaustion of an irreplaceable capital asset. Critics argue that the allowance is a huge subsidy because these resources are valuable enough to justify high levels of investment without tax incentives.

1918 The American Gas Association is formed through the consolidation of smaller gas organizations. It represents companies involved in all areas of the transmission and distribution of natural gas in the United States.

1918 The first major U.S. gasoline pipeline is established to transport gasoline over a 40-mile distance in Wyoming.

1918 The first well of the Panhandle field north of Amarillo, Texas goes into operation. This will become one of the most productive oil and gas fields in the world, and within a few years Amarillo and other nearby towns of the Panhandle region will double and even triple in size.

1918 U.S. production of anthracite coal peaks at 100 million tons per year. Located primarily in the state of Pennsylvania, anthracite is a relatively clean burning form of coal that enjoys extensive use in home heating. By 2000 production drops to about 4 million tons, due largely to the depletion of the resource base.

ca. 1918 Summing up the role of energy supply in World War I, British Foreign Secretary Lord Curzon is said to remark that "The Allies floated to victory on a sea of oil." (Other versions of this comment are reported, and it has also been attributed to Winston Churchill.)

1918–1920 The air-cooled radial engine comes into widespread use in military aircraft, with cylinders arranged to extend radially outward from its hub, like spokes of a wheel.

1919 Captain John Alcock and Lieutenant Arthur Whitten Brown of Great Britain make the first aircraft flight across the Atlantic, flying from Newfoundland, Canada to Ireland in about sixteen and a half hours. Their plane is a Vickers Vimy, a two-engine biplane.

1919 Less than one month after the transatlantic flight of Alcock and Brown, the British airship *R-34* makes the first two-way trip across the Atlantic, going from Scotland to New York and then back to England.

1919 Observations of a total eclipse of the Sun show a gravitational deflection of light that supports Einstein's general theory of relativity.

1919 The American Petroleum Institute (API) is organized in Chicago, Illinois, for the purpose of standardizing engineering specifications for drilling and production equipment.

1919 The first U.S. tax on gasoline is adopted by the Oregon state legislature to raise money for the maintenance of state highways. By 1929, all states impose a tax on gasoline, and three years later a Federal tax of one cent per gallon is enacted.

1919 The German scientist W. Schroeder makes the first estimate of global net primary production of carbon: 36.2 gigatons (10^{15}). Subsequent estimates are in the range of 100 gigatons.

1920–1929

1920 Isopropyl alcohol becomes the first commercial petrochemical, initially produced at Standard Oil's Bayway, New Jersey, plant.

1920 Radio station KDKA of Pittsburgh receives a broadcasting license and goes on the air with news reports on the U.S. Presidential election. This is the nation's first commercial radio broadcast; by 1925 there are more than 600 commercial stations in the United States and Canada.

1920 The Federal Power Act is enacted in the United States. It creates the Federal Power Commission (FPC) and empowers it to regulate the electric power and natural gas industries, including the licensing of non-Federal hydroelectric projects, the regulation of interstate transmission of electrical energy, and the rates for that electricity's sale.

1920 The number of automobiles in the United States exceeds nine million as gas stations open everywhere. Because of this increased use of gasoline, oil now provides almost one-fourth of the total U.S. energy consumption.

1920s Henry Ford and others promote the use of ethanol-blended gasoline, which they call gasohol. A fermentation plant to manufacture ethanol specifically for motor fuels is built in Atchison, Kansas, and in the 1930s, more than 2,000 service stations in the Midwest sell gasohol. Low oil prices in the 1940s end gasohol use until the 1970s.

1920s The technique of pulverizing coal into a fine powder for burning comes into use. This process brings advantages such as a higher combustion temperature, improved thermal efficiency, and a lower air requirement for combustion.

ca. 1920 From his studies of the chemical composition of gasoline, British engineer Harry Ricardo establishes a measurement system that is the basis of today's standard classification of fuels according to octane rating. Ricardo also makes important improvements to diesel and airplane engines.

early 1920s French engineer Eugene Jules Houdry discovers a revolutionary method for cracking low-grade crude oil into high-test gasoline. In the 1930s he moves to the United States and works with American oil companies to develop the Houdry process as a large-scale commercial enterprise. Later he will also be credited with the invention of the catalytic converter.

1921 A 4,500 metric ton stockpile of ammonium nitrate and ammonium sulfate explodes at a chemical plant in Oppau, Germany. The blast and subsequent fire kill 600 people, injure 1,500, and leave 7,000 homeless.

1921 Albert Einstein is awarded the Nobel Prize in Physics for "his services to theoretical physics, and especially for his discovery of the law of the photoelectric effect." (The citation does not specifically mention Einstein's theory of relativity, though today this is often described as the most important advance in physics since Newton.)

1921 Charles F. Kettering and his assistant Thomas A. Midgley discover that the addition of a slight quantity of tetraethyl lead will reduce "knock" (imperfect burning), which is a common drawback of the gasoline engines of this era.

1921 John D. Grant begins drilling in Geyser Canyon north of San Francisco with the dream of harnessing the steam power there. Grant builds a power plant that is one of the first U.S. facilities to generate electricity from geothermal power.

1921 Regularly scheduled passenger airline service is underway on various routes, such as Paris to London (by several French and British companies), Amsterdam to London (by KLM), Berlin to Weimar, Germany (by a forerunner of Lufthansa) and Los Angeles to San Diego, California (by a company owned by famous film director Cecil B. DeMille).

1921 Without competitive bidding, oil barons Edward Doheny and Harry Sinclair receive exclusive rights to valuable Federal oil reserves at Elk Hills, California and Teapot Dome, Wyoming. The Teapot Dome Scandal ensues, and U.S. Interior Secretary Albert B. Fall is convicted of bribery for getting "loans" from Doheny and Sinclair prior to granting them the rights.

1922 Frederick Soddy, a Nobel laureate in chemistry, publishes a critique of standard economic thought for its lack of consideration of how thermodynamics and other biophysical laws constrain human economic aspirations.

1922 The aircraft carrier *Hosho* enters service in Japan. This is the first ship to be launched specifically as an aircraft carrier (as opposed to a flight deck being grafted on another type of vessel).

1922 The first peer-reviewed, continuously running journal pertaining exclusively to energy is published: *Fuel, The Science and Technology of Fuel and Energy.*

1922 The first well of the Hugoton gas field is discovered in southwestern Kansas. This massive field now includes acreage in Kansas, Texas, and Oklahoma and is defined as the largest natural gas field in North America and the second largest in the world.

1923 Arthur Holly Compton illustrates the dual wave and particle nature of X rays and gamma rays by showing how their wavelengths increase when they collide with electrons.

1923 California ranks as the leading oil-producing state in the United States. The foremost site is Signal Hill (Long Beach), which is the richest field in the world based on output per area. Signal Hill will eventually produce over 1 billion barrels of oil and continues pumping at a rate of 1 million barrels per year into the 1990s.

1923 German chemist Matthias Pier of the BASF corporation develops a process to produce synthetic

methanol. By 1926 U.S. companies such as DuPont will also begin synthetic methanol production.

1923 German coal researchers Franz Fischer and Hans Tropsch discover a method of producing synthetic liquid fuel from coal gas. The Fisher–Tropsch process has significant contemporary applications, such as to convert biomass into fuel or to utilize associated gas at oil fields.

1923 Hermann Oberth writes *The Rocket into Interplanetary Space*, a book that has been described as the first accurate prediction of the events that would unfold in the Space Age. Later, Oberth's pupil Wernher Von Braun will lead the rocket program of Germany, and that of the United States as well.

1923 Russian-American engineer Vladimir Zworykin applies for a patent for his iconoscope, a camera tube for television broadcasting. Based on this and his subsequent kinescope, Zworykin is often described as the originator of U.S. television, but it is not definitely established that he constructed a working system prior to his viewing the work of Philo T. Farnsworth (see 1927).

1923 The first ethyl gasoline in the United States goes on sale at a gas station in Dayton, Ohio. Leaded gasoline becomes the dominant fuel for cars, although it is eventually shown to be a major health hazard, leading to laws that prohibit its manufacture.

1923 The first oil field in Iraq is discovered in the Naft Khana area.

1923 The number of coal miners in the United States reaches a historic high of 705,000. U.S. coal production will reach higher levels in the future but with a reduced labor force, due to mechanization.

1924 A conveyor belt is successfully installed in a Pennsylvania anthracite mine to carry coal to a string of cars at the mine entry.

1924 Dr. H. S. Hele-Shaw and T. E. Beacham of Great Britain develop a variable-pitch propeller; this allows the angle of the propeller blades to be adjusted to suit different flight conditions while the engine speed remains the same.

1924 Scotsman Daniel Dunlop leads the organization of the First World Power Conference in London, among the first international meetings on energy. The name is changed to the World Energy Council (WEC) in 1968. The WEC remains an important global energy organization, with member committees in over 90 countries.

1924 The first seismic discovery of an oil-producing salt dome is made at the Orchard field in Fort Bend County, Texas, using the refraction method.

1924 The first successful oil drilling platform over water is erected by the Lago Petroleum Company in Lake Maracaibo, Venezuela.

1924 U.S. biologist Alfred Lotka describes evolution in energy terms, stating that the advantage goes to organisms whose energy-capturing devices are more efficient in directing available energies into favorable conditions for the preservation of the species.

1925 Robert Millikan coins the term "cosmic rays" to describe the phenomenon discovered in 1913 by Victor Hess. Millikan, Hess, and others will confirm the extraterrestrial origins of this radiation.

1925 Scottish inventor John Logie Baird provides the first true television picture when he transmits live images to a screen in an adjoining room. He uses a mechanical scanning system based on Nipkow's disc of 1884. Baird's first image is the head of a dummy; he then televises the face of his young office assistant.

1925 The Magnolia Gas Company builds the first all-welded pipeline, over 200 miles in length, from northern Louisiana to Beaumont, Texas.

1925 Wolfgang Pauli proposes a fourth quantum number for energy levels of atomic electrons and theorizes that no two electrons with the same quantum number can occupy the same atom. This theory accounts for the chemical properties of elements.

1925–1927 Werner Heisenberg, Max Born, and later Erwin Schrödinger formulate quantum mechanics, a branch of physics that deals with matter at the atomic level. In 1927 Heisenberg states his famous uncertainty principle, i.e., that it is impossible to measure both energy and time (or position and momentum) with completely accuracy at the same time.

mid 1920s The practice of filling in wetland areas near cities with garbage, ash, and dirt becomes a popular disposal method in Europe and North America.

1926 Arthur Wood and David Gray of the Corning, New York Glass Works develop the "Ribbon" machine to make light bulbs. Bulbs can be made at speeds of one thousand per minute.

1926 Britain is paralyzed when, in support of a strike by coal miners over threatened wage cuts, the Trades Union Congress calls a general strike. The strike ends after nine days due to government emergency measures and lack of public support. The miners eventually return to work, accepting lower wages and longer hours.

1926 Fritz Winkler introduces a process for commercial fluidized-bed coal gasification at a BASF plant in Leuna, Germany.

1926 Robert Goddard launches the first rocket propelled by liquid fuel.

1926 The Federal Oil Conservation Board of the United States estimates that the nation has only enough oil to last for another six years.

1926 Georg Ebert of Germany produces a synthetic rubber from butadiene. During the following decade

this evolves into various types of "buna" rubber, so named from the two materials used to make them, butadiene and natrium (sodium).

1927 A huge flow of oil begins at the Baba Gurgur oil fields near Kirkuk, about 140 miles north of Baghdad, marking the beginning of the oil industry in Iraq. Peak flow rates are estimated at 95,000 barrels per day. This is at the ancient site where a natural oil spring known as the Eternal Fire burned for centuries.

1927 British ecologist Charles Elton publishes *Animal Ecology,* in which he outlines the importance of feeding (energy) relationships among organisms as the basis for understanding nature. Elton's perspective is a precursor to modern ecological theory.

1927 Brothers Conrad and Marcel Schlumberger of France develop the technique of wireline logging as a method of obtaining downhole data in oil and gas wells. They commercialize this process and the Schlumberger company becomes a leading provider of petroleum technology services.

1927 Charles A. Lindbergh flies from New York, United States to Paris, France to complete the first solo non-stop flight across the Atlantic Ocean.

1927 George Lemaitre proposes the earliest version of what is now known (and generally accepted) as the "Big Bang" theory of the origin of the Universe.

1927 U.S. inventor Philo T. Farnsworth produces the first successful transmission of a television image by wholly electronic means at his San Francisco laboratory. His "Image Dissector" system differs from John Logie Baird's earlier mechanical transmission system, which by the early 1930s will be supplanted by electronic transmission.

late 1920s The U.S. natural gas industry expands greatly as large new fields are developed in the Southwest and California. Eventually natural gas will completely replace the older technology of manufactured gas in the United States.

1928 A patent is assigned to Marvin Pipkin for an electric light bulb coated on the inside, which is stronger and has less glare than existing outside-coated bulbs. He goes on to develop an improved version of this in 1947.

1928 Station WGY of Schenectady, New York begins the first regularly scheduled television broadcasting. A half hour program is broadcast three days a week.

1928 The first diesel-electric passenger locomotive in the United States is built by the American Locomotive Co. for use on the New York Central Railroad.

1928 The U.S. Federal Trade Commission commences a massive four-year investigation of the nation's private electric companies. The FTC's report runs to 84 volumes and documents a vast number of financial abuses. Utility ownership becomes an issue in the 1932 Presidential election, with Franklin D. Roosevelt arguing for consumer-controlled systems.

1929 Manufactured gas suppliers in the United States annually distribute about 450 billion cubic feet of gas, more than twice the amount delivered per year prior to World War I. Over 50% of this is water gas, about 40% coal gas, and about 6% oil gas.

1929 The first ocean thermal energy conversion (OTEC) facility is built by Georges Claude of France in Mantanzas Bay, Cuba. The plant produces 22 kilowatts of electricity but requires about 80 kilowatts to run its equipment.

1929 The first particle accelerator, originally known as an "atom-smasher," is devised by John Douglas Cockcroft and Thomas Sinton Walton. The following year Ernest Lawrence expands on their idea to create the cyclotron. This leads to studies of the atomic nucleus and the forces holding it together.

1929–1931 The Panhandle Eastern, Northern Natural, and Natural Gas Pipeline Company of America are organized to deliver Southwestern gas to Midwestern markets.

1930–1939

ca. 1930 The human population reaches 2 billion.

1930 British engineer Frank Whittle registers the first patent for a jet propulsion engine. In 1934 Hans von Ohain of Germany, working independently of Whittle, patents a jet engine design similar in concept but different in internal arrangement. Both inventors go on to test their engines successfully in 1937.

1930 German engineer Rudolf Erren presents data on a hydrogen engine at the World Power Conference in Berlin. In the mid-1930s Erren will convert hundreds of gasoline vehicles to run on hydrogen or hydrogen/gasoline mixtures. Apparently none of these engines survived World War II.

1930 The first analog computer is invented by Vannevar Bush to solve differential equations.

1930 The giant East Texas oil field is discovered. It is larger than the next 20 fields in the United States combined and will become the largest oil-producing site in the contiguous United States. The first productive wells in the area are drilled by promoter Columbus Marion "Dad" Joiner.

1930 The Royal Institute of British Architects develops the heliodon to help architects determine the potential effects of the Sun on new buildings.

1930s Edward A. Birge and Chauncey Juday, American aquatic scientists, carry out studies to measure the energy budget of lakes. They develop the idea of primary production, i.e., the rate at which food energy is generated, or fixed, by photosynthesis.

1930s German architects lead a renaissance in solar building during the 1930s that spreads throughout Europe; many of these architects later flee to the United States when the Nazis condemn functional architecture as Jewish.

1930s The DuPont Company begins the manufacture of Freon (chlorofluorocarbon or CFC), a substance that does not carry the hazards of earlier refrigerants. Freon leads to much greater consumer use of refrigerators and air-conditioners. In the 1990s Freon will be banned because of concerns over its role in the depletion of the ozone layer.

1930s The first windowless buildings are built, reflecting the growing dependence on electric lighting in architecture.

1930s The Texas Railroad Commission begins to regulate oil drilling, production, and prices in Texas, in an effort to damp the boom-and-bust nature of the industry. The TRC will restrain production and thus establish a price floor. Other states follow the TRC's lead. The power of TRC wanes in the 1970s as production begins to decline.

1931 André Clavier demonstrates the potential value of microwaves when he uses them for a radio transmission across the English Channel.

1931 Auguste Piccard and his associate Paul Kipfer set an altitude record by ascending to almost 52,000 feet in a balloon. This can be considered the first successful flight into the stratosphere; it is one of several flights above 50,000 feet made in the 1930s by Auguste Piccard and his twin brother Jean.

1931 Ernst Ruska of Germany designs the first electron microscope; he then builds a working model of this in collaboration with his mentor Dr. Max Knoll.

1931 French engineer Georges J. M. Darrieus patents a new type of wind turbine with a distinctive "eggbeater" or "skipping rope" design. This becomes known as a vertical axis wind turbine (VAWT).

1931 Harold Hotelling of the United States publishes the economic theory of the optimal depletion of nonrenewable resources, which is still the dominant paridigm today in economics.

1931 U.S. chemist Harold Clayton Urey devises a method for the concentration of any possible heavy hydrogen isotopes by the fractional distillation of liquid hydrogen; this leads to the discovery of deuterium.

ca. 1931 English geologist Arthur Holmes provides the energetic explanation of continental drift. Currents of heat and thermal expansion in the Earth's mantle, he suggests, drive the continents toward or away from one another, creating new ocean floors and building mountain ranges.

ca. 1931 The Lurgi process for coal gasification is developed in Germany.

ca. 1931 U.S. physicist Robert Jemison Van de Graaff introduces his electrostatic generator, which is capable of producing extremely high voltages. It is a more efficient particle accelerator than the earlier Cockroft-Walton machine. Van de Graaff's "atom smasher" will play an important role in the early years of nuclear and particle physics.

1932 After years of speculation, the existence of the neutron in an atom is demonstrated by James Chadwick. Based on this discovery, Werner Heisenberg proposes that an atom nucleus is composed of protons and neutrons, explaining the existence of isotopes.

1932 British engineer Francis Thomas Bacon develops the first practical modern fuel cell. Bacon (a descendant of scientific pioneer Sir Francis Bacon) continues working on this device and eventually produces an effective working model in 1959.

1932 Hermann Honnef of Germany proposes a multiturbine wind generator 160 meters wide that would be capable of 20 megawatt output. He urges the Nazi regime to adopt it, but the device is never built.

1932 John Cockcroft and E. T. S. Walton of Great Britain split the atom on their linear accelerator in Ernest Rutherford's Cavendish Laboratory at Cambridge University. Their experiment substantiates Einstein's theory of relativity.

1932 The positron, a positively charged electron and the first form of antimatter to be discovered, is detected in cosmic-ray tracks by Carl David Anderson.

1933 A team led by Reginald Gibson and Eric William Fawcett discover polyethylene, one of the earliest plastics to come into common use.

1933 Edwin Armstrong demonstrates his frequency modulation (FM) system for the almost static-free transmission of radio waves; FM is one of many fundamental advances in radio broadcasting credited to Armstrong.

1933 King Abdel Aziz ibn Saud of Saudi Arabia establishes an agreement with Standard Oil of California (Chevron) to develop the oil resources of the country's Eastern Province. In 1936 Texas Oil (Texaco) joins the venture and it is named the Arabian-American Oil Company, or Aramco. It grows to become the largest oil company in the world.

1933 The Texas Company introduces the submersible drilling barge for oil exploration on the Gulf Coast of Louisiana; this allows drilling to be done on the bottom

of coastal marshes without the need to sink pilings and build a platform.

1933 The U.S. Congress passes legislation to create the Tennessee Valley Authority (TVA), beginning a period of large hydropower projects in the eastern United States. Electricity provided by the TVA will be crucial to the U.S. industrial effort in World War II.

1934 Enrico Fermi of Italy irradiates uranium with neutrons and believes he has produced the first transuranic element. Later it will be recognized that the reaction produced by this neutron bombardment actually is atomic fission.

1934 Husband and wife team Frederic and Irene Joliot-Curie develop the first artificially radioactive element, an isotope of phosphorus.

1934 The Technocracy Movement in the United States argues that the antidote to the Great Depression is to replace politicians with scientists and engineers who have the technical expertise to manage the nation's economy and natural resources. Technocrats use growth and decline curves to predict a wide range of societal trends.

1935 British scientist A. G. Tansley proposes the word *ecosystem* as a descriptive term for the fundamental ecological unit.

1935 Charles Richter invents a scale to measure the strength of earthquakes.

1935 Scottish engineer Robert Alexander Watson-Watt (a descendant of James Watt) uses microwaves to devise a radio detection and ranging system, better known as radar. By the outbreak of World War II Britain has a chain of radar stations along the east and south coast of England.

1935 The first era of electric vehicles in the United States ends when Detroit Electric, the best known company in the field, stops production after 30 years in business (though orders will still be taken into the early 1940s). Reportedly Clara Ford, wife of Henry Ford, drove a Detroit Electric car rather than a Ford because she disliked gasoline-powered cars.

1935 The first isotope of uranium, U-235, is discovered by Arthur Jeffrey Dempster.

1935 The General Electric Company introduces the first fluorescent lamp.

1935 The U.S. Bureau of Reclamation authorizes funding for California's Central Valley Project, a long-term plan for use of the water of the Sacramento River basin.

1935 Wallace Carothers of DuPont discovers a strong polyamide fiber that resists both heat and solvents; this is named Nylon and it quickly comes into widespread use, most notably for women's stockings and then later in many military applications.

1936 American astrophysicist Charles Greeley Abbott invents an efficient solar boiler.

1936 British mathematician Alan Turing publishes a paper describing an abstract device (Turing machine), which "can be made to do the work of any special-purpose machine, that is to say to carry out any piece of computing, if a tape bearing suitable 'instructions' is inserted into it." This is often described as a prediction of the modern computer.

1936 Hoover Dam (Boulder Dam) is completed at Black Canyon on the Colorado River between Arizona and Nevada, one of the major engineering feats of modern times and the source of much of the electric power consumed in the Southwest.

1936 Japanese television pioneer Kenjiro Takayanagi builds an all-electronic television set with 245 scanning lines. Earlier Takayanagi had transmitted an image on a Braun electric tube (1926) and had demonstrated a cathode ray tube system (1928).

1936 The airship *Hindenburg* becomes the largest aircraft ever to fly, at more than 800 feet long and 135 feet in diameter. After making several transatlantic trips, the *Hindenburg* catches fire on May 6, 1937 while making a landing at Lakehurst, New Jersey. Thirty-five people are killed and this tragedy effectively ends the use of airships for passenger transportation.

1936 The Rural Electrification Act is signed into law by President Franklin D. Roosevelt to address the fact that rural America is still largely without electricity. Within two years cooperative projects financed by the REA will provide electricity to 1.5 million farms, and by the mid-1950s virtually all American farms will be electrified.

1937 Carl David Anderson discovers the muon, a subatomic particle larger than an electron but smaller than a proton.

1937 Lockheed Aircraft produces the first airplane with a fully pressurized cabin, a modified version of its *Electra* model.

1937 Theodor Dobzhansky publishes *Genetics and the Origin of the Species,* providing the link between Darwin's evolutionism and Mendel's theory of mutation in genetics.

1938 Commercial quantities of oil are discovered at the Burqan field in southern Kuwait. In the same year Aramco makes a major discovery at the Dammam field in Saudi Arabia.

1938 Congress enacts the Natural Gas Act, giving the Federal Power Commission the authority to regulate commercial activity in the U.S. natural gas industry.

1938 G. S. Callendar publishes *The Artificial Production of Carbon Dioxide and Its Influence on Climate,* in which he directly implicates fossil fuel combustion as an agent of climate change. He is largely ignored or derided for this claim, but history proves him to be prophetic.

1938 Otto Hahn and his associates Lise Meitner and Fritz Strassman of Germany are the first to split a uranium atom, although they hesitate to call their success nuclear fission.

1938 The Bonneville Dam is completed on the Columbia River about 40 miles of Portland, Oregon, and begins supplying power to the Pacific Northwest.

1938 The British steam locomotive *Mallard* reaches a speed of 126 miles per hour (201 kph) running on a downward grade in Lincolnshire, England. This still stands as the world speed record for a steam locomotive.

1939 Franklin D. Roosevelt receives a letter from Albert Einstein (written with Leo Szilard) that describes the possibility of an extremely powerful uranium bomb. Einstein calls for "watchfulness, and if necessary, quick action on the part of the Administration." He urges FDR to provide government support for Fermi and colleagues in their work on chain reactions.

1939 Hans Bethe recognizes that the fusion of hydrogen nuclei to form deuterium releases energy. He suggests that much of the energy output of the Sun results from nuclear fusion reactions.

1939 John Randall and Henry Boot develop a resonant-cavity magnetron, providing a microwave transmission system for radar that is a significant advance on the existing meter-wave system.

1939 The first jet airplane takes flight with a turbojet engine developed by Hans von Ohain of Germany. This is followed by a 1941 flight by a British jet developed by Frank Whittle.

1939 The first practical gas turbine used to generate electricity operates at Neuchatel, Switzerland, developed by the Brown Boveri Company.

1939 The Packard Motor Car Company of Detroit engineers the first air-conditioned automobile.

1939 The *VS-300,* the first workable single-rotor helicopter, is produced by Russian-American aeronautical engineer Igor Sikorsky, following other important advances made by French aviation pioneers Louis Breguet and Rene Dorand (1935) and by Germans Heinrich Focke and Gerd Achgelis (1936). Sikorsky's craft makes its first free flight in 1940.

1939–1942 John Vincent Atanasoff of Iowa State University collaborates with his graduate student Clifford E. Berry to develop the first digital electronic computer. Though the better-known ENIAC machine (see 1946) is often given this honor, a 1973 court decision found that the design of ENIAC was based on the earlier work of Atanasoff.

1939–1942 World War II rages around the globe. As in World War I, new forms of warfare come into use, such as large-scale bombing of cities, combined aerial and ground assaults (blitzkreig), aircraft carriers, rocket bombs, jet planes, and most notably, nuclear weapons. New technologies include radar, sonar, battlefield radios, and electronic coding/codebreaking devices.

1940–1949

1940 Martin Kamen and Samuel Ruben, chemists at the University of California, Berkeley, use a cyclotron to bombard a graphite target with a beam of deuterium nuclei. The result is carbon-14, which, with a half-life of 5,000 years, becomes a powerful tool to trace carbon's movement through photosynthesis and many other biochemical processes.

1940 The American Association of Oilwell Drilling Contractors is founded in Dallas, Texas; it is now known as the International Association of Drilling Contractors (IADC).

1940 The first residential use of geothermal energy for space heating begins in the Moana area of Reno, Nevada.

1940 W. G. Templeman observes the effects of naphthalacetic acid, a highly selective compound that is toxic to broad-leafed plants but less harmful to grasses. This leads to the development of the herbicide 2,4-D in 1944, which revolutionizes weed control in cereal plants.

1940s Important new industrial materials are developed, such as polyethylene (electrical insulation and food packaging), silicones (lubricants, protective coatings, and high-temperature electronic insulation), and epoxy (a very strong adhesive).

1941 After Japan seizes part of Indochina, the United States responds by freezing Japanese assets. This leads to sanctions against the sale of American oil to Japan (at the time about 75% of Japan's oil supply came from the United States). Following this the Dutch government in exile in London bars the sale of oil to Japan from the Dutch East Indies (Indonesia).

1941 Having been denied access to oil supplies from the United States and the Dutch East Indies, the Japanese government concludes that if existing conditions continue they will run out of oil within a short time. This is cited by historians as probably the chief reason for Japan's decision to launch a surprise attack on the U.S. naval base at Pearl Harbor (December 7th).

1941 Nazi Germany surprisingly invades the Soviet Union, after having formed a nonaggression pact with the Soviets just two years earlier. The primary military objective of this operation is to capture the valuable Caucasus oil fields, since Germany's own supply is relatively meager and dependent on synthetic oil.

1941 On a hilltop in Rutland, Vermont known as "Grandpa's Knob," a 1.25 megawatt wind generator provides power to the local grid during the World War II era. This is considered the first use of wind energy to supply public power on a large scale.

1941 Plutonium, a new element, is identified by chemist Glenn Seaborg and his team at the University of California, Berkeley. Seaborg will discover 10 atomic elements in all, including one that now bears his name. Forms of plutonium become the main explosive ingredient of nuclear bombs and an important energy source for nuclear power reactors.

1941 Russell Ohl of the Bell Laboratories (United States) discovers that semiconductors can be "doped" with small amounts of foreign atoms to create interesting new properties. He develops the first silicon solar cell that converts available light into electrical energy.

1941 The first commercial plant for liquefied natural gas (LNG) is built in Cleveland, Ohio.

1942 A team of inventors at Exxon's Research and Engineering Company develop the technique known as fluid catalytic cracking, a process that now produces over half of the world's gasoline.

1942 Aquatic scientist Raymond Lindeman studies Cedar Creek Bog, a senescent lake in Minnesota, and describes the area in a classic paper titled "The Trophic-Dynamic Aspect of Ecology" (published after his death at the age of 27). Lindeman's analysis establishes trophic dynamics as the energetic basis of modern ecology.

1942 General Leslie R. Groves is appointed to head what becomes known as the Manhattan Project, the top-secret effort by the United States to build an atomic bomb before the Germans can do so.

1942 On the Baltic coast of Germany at Peenemunde, Wernher von Braun launches the A-4 rocket. Breaking the sound barrier, it reaches an altitude of 60 miles. This is the world's first launch of a ballistic missile and the first rocket to ascend to the fringes of space.

1942 Swedish physicist Hannes Alfven argues that an electromagnetic wave can propagate through a highly conducting medium. This discovery eventually forms the basis of magnetohydrodynamics (MHD), which studies the motions of electrically conducting fluids, such as plasmas and liquid metals, and their interactions with magnetic fields.

1942 The Grand Coulee Dam is completed in Washington, United States to harness the power of the great Columbia River. It is the largest hydroelectric dam in the world at this time (in fact the largest concrete structure of any kind), and still remains the largest dam in North America.

1942 The Petroleum Administration for War (PAW) is established to assure "the most effective development and utilization of petroleum in the United States and its territories and possessions." The PAW rations civilian petroleum use to insure adequate military supplies. The PAW is terminated in 1946.

1942 Ulrich Hütter of Germany writes a graduate thesis in which he provides the first statement of the theoretical basis for modern wind turbines.

1942 Under the football stands of Stagg Field at the University of Chicago, Enrico Fermi leads a team of scientists in successfully creating the first controlled nuclear chain reaction. This development will lead directly to the assembly and detonation of an atomic bomb.

1942–1944 Because transporting oil by sea is endangered by German submarines, the United States constructs the Big Inch and Little Big Inch pipelines to carry oil from East Texas to the northeastern United States, a distance of about 1,500 miles.

1943 A patent dispute stretching over a half century is finally resolved when the U.S. Supreme Court strikes down the Guglielmo Marconi patent of 1904 for the invention of radio in favor of Nikola Tesla's 1897 patent.

1943 DDT, a powerful and effective pesticide, comes into widespread use. At first DDT is hailed as a miraculous advance and its developer, Paul Müller of Switzerland, wins the Nobel Prize in 1948. However, DDT later is targeted as harmful to wildlife (see 1962), and eventually its use will be widely banned.

1943 Los Angeles, California experiences its first recognized episode of smog as visibility is reduced to three blocks and people suffer from eye irritation, breathing difficulty, and nausea. Fearful citizens at first believe the city is undergoing a gas attack, but eventually a wartime synthetic rubber plant is identified as the pollution source.

1943 The Rockefeller Foundation establishes the precursor to the International Maize and Wheat Improvement Center in Mexico, providing the research thrust on high-yield variety crops that will eventually launch the Green Revolution.

1943 The Soviet Union sets up a nuclear research program under the direction of physicist Igor Kurchatov, with the goal of building an atomic bomb.

1943 The U.S. Army Air Force begins a series of large-scale raids on Ploesti, Romania, a city that Sir Winston Churchill calls "the taproot of German might" because it is where the Nazi war machine obtains much of its oil. When the Ploesti refineries are finally rendered inoperative in late 1944, there is virtually no fuel left for the German military.

1943 U.S. anthropologist Leslie White proposes that like biological systems, cultures evolve around the strategies that they use to exploit energy.

1944 Based on experiments with pneumococci, Oswald T. Avery determines that DNA is the material carrying genetic properties in nearly all living organisms.

1944 In *FPC v. Hope Natural Gas Co.,* the U.S. Supreme Court rules that a regulatory body may fix rates, provided the return to the utility company is "just and reasonable" to allow it to operate successfully and compensate investors for the risks they assume. *FPC v. Hope* becomes the basis for most U.S. court decisions on energy pricing regulation.

1944 Massachusetts Institute of Technology professor Maria Telkes designs a portable, solar-powered seawater distiller for the life rafts of pilots shot down over the ocean. Telkes will develop many solar-powered devices, including the first residential solar heating system in 1948.

1944 President Franklin D. Roosevelt writes to Winston Churchill that the U.S. concern with maintaining a sufficient oil supply is not a sign that he is "making sheep's eyes (looking with envy) at your oil fields in Iraq or Iran." Churchill responds in kind, "We have not thought of trying to horn in upon your interests and property in Saudi Arabia."

1944 Tennessee Gas and Transmission Company completes a pipeline to bring natural gas from Texas to Appalachia to fuel wartime industry.

1944 The first full-scale nuclear reactor begins operation at the U.S. Army's Camp Hanford (Richland, Washington). Hanford is part of the Manhattan Project and produces plutonium for use in an atomic bomb.

1944 The Shasta Dam is completed in northern California after six years of construction. The waters of the Sacramento, McCloud, and Pit rivers, plus dozens of smaller streams, back up to create Lake Shasta.

1944 Wernher von Braun's A-4 rocket is renamed the V-2 and converted to a combat weapon. The V is for "*Vergeltung*" (revenge), since this is Hitler's retaliation against Allied bombing of German cities. When the first V-2 hits London, von Braun is said to have remarked, "The rocket worked perfectly, except for landing on the wrong planet."

1945 The Atomic Age begins, and the U.S. Manhattan Project reaches its goal, on July 16th at a test site at Alamogordo, New Mexico. A team of scientists headed by J. Robert Oppenheimer detonate the world's first nuclear explosive.

1945 The atomic bomb nicknamed Little Boy is dropped on Hiroshima, Japan on August 6th. Three days later, another bomb, Fat Man, is dropped on Nagasaki, Japan. The first bomb is uranium-235 based and the other is plutonium-based. Japan surrenders on August 15, ending World War II.

1945 The end of gasoline rationing in the United States is announced after the surrender of Japan; this had been in place since 1942. In Britain fuel rationing will not end until 1950.

1945 The Food and Agriculture Organization (FAO) is formed by the United Nations, with a mandate to raise levels of nutrition and standards of living, improve agricultural productivity, and better the condition of rural populations.

1946 Architect Arthur Brown designs the world's first solar-heated public building, the Rose Elementary School in Tucson, Arizona. It obtains over 80% of its heat from solar energy for the next decade.

1946 In return for the withdrawal of Soviet troops occupying its northwestern provinces, Iran makes a long-term agreement to provide oil to the Soviet Union. However, the following year the Iranian parliament nullifies this agreement.

1946 John W. Mauchly and J. Presper Eckert demonstrate an electronic digital computer at the University of Pennsylvania. ENIAC (Electronic Numerical Integrator and Computer) uses punched cards for input and output data, contains 17,000 vacuum tubes, weighs over 30 tons, and occupies 1,500 square feet of space.

1946 The Magnolia Petroleum Company (later part of Mobil) builds an oil drilling platform in the Gulf of Mexico off the coast of Louisiana, considered the first oil exploration effort in open ocean waters. It is a dry hole, but the following year Kerr-McGee brings in a producing well in the same area.

1946 The U.S. Atomic Energy Act is signed into law by President Harry Truman. It establishes the Atomic Energy Commission (AEC), a civilian body to control nuclear weapons development and explore peaceful uses of nuclear energy.

1946 The United States carries out the first subsurface detonation of a nuclear weapon at Bikini Atoll in the Pacific, followed by demonstrations in Times Square, New York against nuclear testing.

1947 Barium titanate is the first piezoelectric (electricity produced by mechanical pressure) ceramic to be used commercially, in its application as a phonograph needle.

1947 Cecil Frank Powell discovers the pion, a particle with mass between that of electrons and protons that interacts with neutrons and protons in the atomic nucleus. It is believed to be the meson-particle predicted by Hideki Yukawa 12 years earlier.

1947 The coal industry of Great Britain is completely nationalized under the auspices of the National Coal Board.

1947 The *Grandcamp,* a barge loaded with fertilizer grade ammonium nitrate, catches fire and explodes, destroying a nearby city and killing an estimated 570 people in what would later become known as the "Texas City Disaster."

1947 The microwave oven is introduced by Raytheon, which developed the device after one of the company's engineers, Dr. Percy Spencer, accidentally discovered that the candy bar in his pocket had melted due to microwave energy. Microwave ovens for the home are introduced in the early 1950s and by the mid-1970s their sale will surpass that of gas ranges.

1947 The Texas Eastern Transmission Corporation purchases the Big Inch and Little Big Inch and begins the process of converting them from oil to natural gas.

1947 The U.S. Atomic Energy Commission establishes the Brookhaven National Laboratory, a major research facility on eastern Long Island, New York.

1947 U.S. Air Force test pilot Charles E. "Chuck" Yeager flies the Bell X-1 rocket plane faster than the speed of sound, becoming the first pilot to break the sound barrier.

1947 Willard Frank Libby introduces a method of dating archaeological objects by determining the concentration of radioactive carbon-14 in the item of interest.

1948 Carl Nielsen of Ohio State University is credited with building the first ground-source heat pump.

1948 George Gamow, Ralph Alpher, and Robert Herman formulate the Big Bang theory, explaining the origin of the universe in terms of a huge explosion producing a burst of energy.

1948 John Bardeen, William Shockley, and Walter Brattain, scientists at the Bell Telephone Laboratories in Murray Hill, New Jersey, demonstrate the first transistor, a device composed of semiconductor material that can both conduct and insulate. By 1952, transistors are being used in radios and hearing aids.

1948 Norbert Weiner publishes *Cybernetics,* a detailed account of the mathematics of communication and a forerunner of computer science.

1948 The basic-oxygen steelmaking process comes into use in Switzerland (Linz-Donawitz process).

1948 The first nuclear reactor in France, the Zoe, begins operation at Fontenay-aux-Roses, using uranium from the Belgian Congo.

1948 The first successful continuous miners are introduced in U.S. underground coal mining. These machines break up the coal with huge bits or teeth, eliminating the need for blasting, and then load the broken coal directly into shuttle cars.

1948 The Ghawar Field is discovered in Saudi Arabia; it is the largest conventional oil field in the world (about 80 billion barrels).

1948 Twenty people die when a "killer fog" hovers over Donora, Pennsylvania. About 7,000 others are hospitalized or become ill, about half the population of the entire town. This is described as the first incident to make Americans generally aware of the health hazards of air pollution.

1949 A major advance is made in the measurement of time with the development of the first atomic clock, designed by Dr. Harold Lyons of the National Bureau of Standards in 1949, using a molecule of ammonium.

1949 The first natural gas deliveries to the New York City area arrive at Staten Island through the New York and Richmond Gas Company.

1949 The Soviet Union's first atomic bomb (known as Joe-1) is detonated at Semipalatinsk, Kazakhstan. It is a copy of the Fat Man bomb that the United States dropped on Nagasaki, Japan, with a yield of 21 kilotons. The nuclear arms race between the United States and the Soviets is now underway.

1950–1959

1950 Alan Turing proposes the Turing Test as a means of determining whether a machine can be described as intelligent. He suggests that computers should be able "learn" from experience and then modify their activity accordingly; this provides the basis for the field of artificial intelligence.

1950 Great Britain's first plutonium production reactor, Windscale's Number 1 Pile, begins operation.

1950 Oil begins to flow through the Trans-Arabian Pipeline (Tapline). Oil fields in Saudi Arabia are now linked with the Mediterranean Sea at Sidon, Lebanon, over 1,000 miles away. The pipeline greatly reduces the number of tankers required to transport oil around the Arabian Peninsula through the Suez Canal to the Mediterranean.

1950 Russian scientists Andrei Sakharov and Igor Tamm present an idea for a controlled thermonuclear fusion reactor, the Tokamak (abbreviated from the Russian term for Toroidal Chamber with Magnetic Coil). The Tokamak design becomes one of the most popular in subsequent fusion energy research.

1950 The first European offshore oil well is drilled 1.5 miles from land in the North Sea at the mouth of the Elbe River in Cuxhaven, Germany.

ca. 1950 Oil has replaced coal as the dominant fuel in the U.S. economy, as the discovery of cheap, abundant oil and the development of the internal combustion engine cause the coal-fired steam engine to be abandoned. Coal thereafter is used almost exclusively in power generation and steel production.

early 1950s Home ownership of a television set becomes commonplace in the United States.

1951 At the National Reactor Testing Station in Arco, Idaho, the Experimental Breeder Reactor I (EBR-1) becomes the first nuclear reactor in the world to produce useable quantities of electric power, lighting four 100-watt light bulbs.

1951 Mauchly and Eckert follow up on their ENIAC computer by creating UNIVAC I, the first electronic computer to store data on magnetic tape and to be mass-produced.

1951 Philip Edwin Ohmart of Cincinnati, Ohio invents the radioactive cell, a battery that converts nuclear energy to electrical energy.

1951 The first full-fledged offshore drilling in the Persian Gulf is carried out in 19 feet of water, 3 miles from shore, and 20 miles south of Ras del Misha'ab.

1951 The first mechanized U.S. longwall mining system is in use; longwall is a high-extraction method in which a large rectangular block of coal is isolated and then extracted in a single continuous operation by an automated cutting head moving parallel to the coal face.

1951 The Iranian parliament votes to nationalize Iran's oil industry; oil production then comes to a virtual standstill as British technicians leave the country. In response to Iran's action, Britain imposes a worldwide embargo on the purchase of Iranian oil, freezes Iran's sterling assets, and bans the export of goods to Iran.

1952 A group led by Edward Teller develops and explodes a hydrogen bomb at the Eniwetok atoll, in the Marshall Islands of the Pacific. This is the first thermonuclear device to employ the enormous power of nuclear fusion. It is described as 700 times more powerful than the atomic bomb dropped on Hiroshima in 1945.

1952 Britain's De Havilland Comet becomes the first commercial jetliner, with a flight from London to South Africa. However, crashes due to metal fatigue then cause the plane to be grounded for several years, and by the late 1950s two U.S. rivals, the Boeing 707 and Douglas DC-8, take over the lead in commercial jet service.

1952 Canada's Chalk River nuclear reactor experiences a potential calamity when human error causes an unintended reaction. The resulting explosion blows the four-ton lid off the reactor, spurting radioactive water and setting off warnings of lethal radiation levels. Fortunately the building is evacuated and there are no casualties.

1952 The first offshore well in California with no connection to land is drilled, in 45 feet of water 1.5 miles offshore from Seal Beach.

1952 The Great Smog of London occurs after an exceptionally cold winter forces homes and factories to burn large quantities of coal. A temperature inversion forms, trapping pollutants above the ground. More than 4,000 people die from respiratory ailments within the following week. This leads to major reforms in air quality controls for Britain.

1952 The keel for the U.S. Navy's first nuclear submarine, *Nautilus,* is laid at Groton, Connecticut. *Nautilus* is launched in 1954 and will set many records for submerged speed and distance traveled.

1953 Britain and the United States take part in Operation Ajax, a plan to oust nationalistic Iranian Premier Mohammed Mossadegh. The coup succeeds and the pro-Western Reza Shah Pahlavi establishes a new oil consortium that restores Iran's oil to the West. The United States then replaces Britain as the major foreign player in the Iranian oil industry.

1953 Discovery of the Great Global Rift in the Atlantic Ocean by Maurice Ewing and Bruce Charles Heezen establishes the study of plate tectonics and revolutionizes geology.

1953 Eugene P. Odum of the University of Georgia publishes *Fundamentals of Ecology,* with the aid of his brother Howard. This is the first textbook in the field; it employs a "top-down" approach starting at the ecosystem level and describes energy as a currency shared among the Earth's various life forms.

1953 James Watson of the United States and Francis Crick of Britain describe the double-helical structure of DNA, leading to a revolution in the science of biology.

1953 President Dwight D. Eisenhower, in a famous "Atoms for Peace" speech, proposes to the General Assembly of the United Nations the creation of an organization to promote the peaceful use of nuclear energy; this eventually leads to creation of the International Atomic Energy Agency.

1953 Prime Minister Winston Churchill authorizes the development of Calder Hall in West Cumbria, a complex of four reactors that is the world's first commercial nuclear power facility. Queen Elizabeth officially opens the first of these in 1956.

1953 The British begin nuclear testing at the Maralinga nuclear test site, a tract of Aboriginal land in the state of South Australia. The area will later be the target of a massive clean up campaign.

1953 The deepest known well dug by means of cable tool drilling, normally used for wells a few hundred feet deep, is completed when the New York Natural Gas Corporation drills a well to a depth of 11,145 feet.

1953 The EBR-I reactor demonstrates the feasibility of the breeder reactor concept; a team led by Walter Zinn shows that uranium can be "bred," or transformed, into plutonium, thus making it possible to use virtually all of the energy in natural uranium.

1953 The first gas-turbine, propane-fueled locomotive is placed in service by the Union Pacific Railroad.

ca. 1953 Architect Frank Bridgers designs the Bridgers-Paxton Building in Albuquerque, New Mexico; this is the first office building to use passive solar heating.

1954 Charles Townes and Arthur Schawlow invent a highly precise timing device called the maser (microwave amplification by stimulated emission of radiation). This is a forerunner of the laser, which Townes and Schawlow describe in theory in 1958 but do not actually produce (see 1960).

1954 Gerald Pearson, Calvin Fuller, and Daryl Chapin, researchers at New Jersey's Bell Laboratories, develop a method of producing electricity directly from sunlight, using an array of silicon-based solar cells.

1954 President Dwight Eisenhower signs the first major amendment of the original Atomic Energy Act, giving the civilian nuclear power program further access to nuclear technology.

1954 Researchers at RCA describe the photovoltaic effect in cadmium sulfide; eventually a large segment of the solar energy industry will use cadmium in its photovoltaic modules.

1954 South African Synthetic Oil Limited begins operation of SASOL One, the first civilian coal-to-fuel plant in the world.

1954 The Association for Applied Solar Energy (AFSE) is founded in the United States to encourage the use of renewable energy. The organization later becomes known as the American Solar Energy Society (ASES).

1954 The first purpose-built submersible drilling unit is used in the Gulf of Mexico by Odeco (Offshore Drilling and Exploration Company).

1954 The Soviet Union begins operation of the first nuclear reactor built for the peacetime production of power at the Obninsk plant. It is known as AM-1, with the letters being a Russian-language acronym for "peaceful atom."

1954 The U.S. Supreme Court rules that interstate natural gas producers are subject to regulation by the Federal Power Commission. An era of regulated gas prices is established, based on the cost of providing gas rather than its market value. This keeps prices low, encouraging demand, but it discourages exploration and thus contributes to shortages in the 1970s.

1954 UNESCO (United Nations Educational, Scientific and Cultural Organization) and the government of India sponsor a symposium on solar and wind power in New Delhi.

1955 Arco, Idaho, population about 1,300, becomes the first town in the United States to receive its entire supply of power from a nuclear source. The experimental boiling water reactor BORAX-III produces approximately 2,000 kilowatts of electrical power for about two hours.

1955 Geneva, Switzerland hosts the first United Nations International Conference on the Peaceful Uses of Atomic Energy. About 1,500 delegates attend, representing 73 countries.

1955 Lewis Strauss, chairman of the U.S. Atomic Energy Commission, predicts that electricity produced by nuclear power will soon be so abundant that "It is not too much to expect that our children will enjoy in their homes electrical energy too cheap to meter."

1955 The Atomic Energy Basic Law is passed in Japan, limiting the use of nuclear technology to peaceful purposes. Japan imports its first commercial nuclear power reactor from the United Kingdom and begins power production in 1966. By 2000, Japan gets about one-third of its power from nuclear plants.

1955 The first World Symposium on Solar Energy is held in Phoenix, Arizona, where engineers and scientists from around the world assemble to review the current state of the field. Accompanying this meeting is an exhibition, "The Sun at Work," attended by about 30,000 people.

1955 W. Fred Cottrell, a sociologist at Miami (Ohio) University, is the first to comprehensively apply the concept of net energy and energy surplus to the analysis of economic and social development.

mid-1950s Many factories now employ electrostatic precipitators to filter out some pollutants from smokestack emissions before they reach the atmosphere.

mid-1950s Various workers in the United States and Europe report that bundles of glass fiber can be used for image transmission. One of them, Indian-born researcher Narinder Singh Kapany, reportedly coins the phrase "fiber optics" to describe this technology.

1956 At the urging of President Eisenhower, the U.S. Congress enacts the Federal Aid Highway Act, a program of interstate highway construction that greatly expands the U.S. network of modern roadways. Originally conceived as a system of military transport, its eventual effect will be to ensure the demise of the railroad as a major form of interstate transportation.

1956 British engineer Christopher Cockerell invents the Hovercraft, a vessel that travels over water on a cushion of air.

1956 Celilo Falls, a traditional Indian salmon fishing site, is flooded by the waters of The Dalles Dam on the Columbia River. This leads to controversy over the conflict between tribal rights and hydropower development.

1956 French engineer Felix Trombe develops the Trombe wall, a solar collector consisting of a south-facing glass wall with an air space between it and a blackened concrete wall. The blackened wall is heated by sunlight passing through the glass, and it then releases heat,

causing warm air to rise in the space between the glass and the concrete.

1956 The Atomic Energy Commission (AEC) authorizes construction of the world's first two large, privately owned nuclear power plants, one at Indian Point, New York and the other in Grundy County, Ilinois.

1956 The first transatlantic telephone cable is laid between Newfoundland and Scotland; this links the phone networks of Canada and the United States with the United Kingdom, and, via London, with various nations on the European continent.

1956 The National Academy of Sciences in the United States recommends deep geologic disposal of the long-lived, highly radioactive wastes from nuclear reactors, suggesting that buried salt deposits and other rock types be investigated for permanent repositories.

1956 The Suez Crisis erupts as Israel, supported by Britain and France, attacks Egypt after that country nationalizes the Suez Canal. The crisis ends when the United States and the Soviet Union force a cease-fire. The resulting loss of prestige and influence for Britain is often described as the final step in her decline as a colonial power.

1956 To retaliate for the actions of Britain and France against Egypt in the Suez War (see above), King Saud of Saudi Arabia cuts off oil supplies to Britain and France. This marks the first time such a step is taken by an Arab state.

1956 U.S. geologist Marion King Hubbert predicts that oil production in the lower 48 states will peak in around 1970, which in fact it does. Hubbert's work becomes a lightning rod for debate about oil supplies for decades to come.

1956–1957 Engineer Johannes Juul develops the first alternating current windmill for the electricity company SEAS at the Gedser coast in southern Denmark. For many years the Gedser turbine remains the largest in the world.

1957 A converted version of the U.S. B-57 military aircraft flies with power from a liquid hydrogen fuel system.

1957 A reactor fire at England's Windscale (Sellafield) nuclear power plant burns out of control for about 24 hours. An estimated 20,000 curies of radioactive iodine escapes along with other isotopes such as plutonium, caesium, and the highly toxic polonium. Prime Minister Macmillan orders news of the accident to be suppressed for fear of alarming the public (see also 1982).

1957 Felix Wankel operates his rotary engine, an idea he first conceived in the mid-1920s. This is a four-cycle internal combustion engine that does not use pistons. Though the Wankel engine has great simplicity of operation and an excellent power-to-weight ratio, it does not come into use until the 1970s and to date it has not had a major commercial impact.

1957 IBM introduces the Model 608 computer, the first solid-state computer for the commercial market.

1957 Japanese physicist Leo Esaki discovers the tunnel diode, a high-speed current-switching device that is the first semiconductor quantum electron structure.

1957 Melvin Calvin, a U.S. chemist, uses radioactive carbon-14 to map the complete route that carbon travels through a plant during photosynthesis, starting from its absorption as atmospheric carbon dioxide to its conversion into carbohydrates and other organic compounds. This becomes known as the Calvin Cycle.

1957 Nobel laureate Linus Pauling writes and lectures on the dangers posed by nuclear fallout for human life and the environment. In the following year he presents a petition to the United Nations opposing further nuclear weapon testing, signed by more than 11,000 scientists from 49 different countries.

1957 Novelist Jack Kerouac publishes *On the Road;* it becomes a best seller and eventually will be known as the "Bible of the Beat Generation." The author's memorable descriptions of marathon car trips across the American continent epitomize the love affair between mid-century Americans and their automobiles.

1957 Oil is discovered at Alaska's Kenai Peninsula near the Swanson River, the first significant oil discovery in the state.

1957 Power from a civilian nuclear unit is generated for the first time by the Sodium Reactor Experiment at Santa Susana, California. The unit provides power until 1966.

1957 Roger Revelle of the United States and Hans Suess of Austria demonstrate that carbon dioxide has increased in the atmosphere as a result of the use of fossil fuels. Revelle concludes that "Human beings are now carrying out a large scale geophysical experiment of a kind that could not have happened in the past nor be reproduced in the future."

1957 The cooling system of a radioactive waste containment unit malfunctions and explodes at a nuclear facility in Chelyabinsk province of the Soviet Union. About two million curies are released, exposing a quarter of a million people to radiation. The facility also is responsible for decades of dumping that release large amounts of radiation.

1957 The first long-distance coal pipeline goes into commercial service. It moves coal slurry (a mixture of water, fine coal particles, and other wastes from washing coal) from a mine in Ohio to a power station over 100 miles away.

1957 The Price-Anderson Act provides financial protection to the American public and Atomic Energy

Corporation licensees and contractors if a major accident occurs at a nuclear power plant.

1957 The Space Age begins on October 4th with the launching of the first artificial satellite, *Sputnik 1,* by the Soviet Union. In the following month *Sputnik 2* is launched with the first animal to go into in space, a dog named Laika.

1957 The United Nations creates the International Atomic Energy Agency (IAEA) in Vienna, Austria, to promote the peaceful use of nuclear energy and prevent the spread of nuclear weapons around the world.

1957 The world's first large-scale nuclear power plant begins operation in Shippingport, Pennsylvania. The plant reaches full power three weeks later and supplies electricity to the Pittsburgh area.

1957 Three physicists at the University of Illinois, John Bardeen, Leon Cooper, and J. Robert Schrieffer, develop the "BCS" model of why superconductors behave as they do. They show that electrons in a superconductor condense into a quantum ground state and travel together collectively and coherently.

1957 U.S. ecologist Howard T. Odum publishes a landmark paper that quantifies the energy flow among the trophic levels in the ecosystem of Silver Springs, Florida.

1958 A geothermal power station begins operation at Wairakei, New Zealand; this is the second commercial geothermal plant in the world (after Larderello, Italy) and the first to exploit a wet geothermal resource.

1958 After years of unsuccessfully trying to harness fusion, scientists from the United States, Britain, and the Soviet Union declassify their fusion research at the second United Nations Conference on the Peaceful Use of Atomic Energy, held in Geneva.

1958 Based on the work of Willard Thomas Grubb and Leonard Niedrach, the General Electric Company develops the first commercially successful fuel cell, which will be used by NASA in the Gemini Earth-orbit space program.

1958 Chrysler introduces the first mass-produced electronic fuel injection system, designed by Bosch. It is not welcomed by consumers and in the 1960s the Bendix patents are sold to Bosch; that company then develops an improved version that becomes successful.

1958 Construction begins on the world's first nuclear-powered merchant ship, the *N.S. Savannah,* in Camden, New Jersey. The ship is launched the following year

1958 In response to the 1957 launch of *Sputnik,* the United States forms the Advanced Research Projects Agency (ARPA) within the Defense Department to promote the development of new technologies with military application. ARPA will be a catalyst for the development of the modern computer, the Internet, and other information technology.

1958 Sam Cohen, formerly of the Manhattan Project, develops the concept for a neutron bomb, a "smart" type of nuclear weapon modified to have a smaller overall blast effect but to release high-energy neutrons that will take lives far beyond the blast area.

1958 The U.S. Army Ballistic Missile Agency launches *Explorer I,* the first artificial satellite placed into orbit by the United States. In the same year the United States will launch five more *Explorer* satellites (some of which reach orbit and others not), as well as *Vanguard I,* which is now the oldest satellite still in orbit.

1958–1959 Engineers Jack Kilby and Robert Noyce of the United States separately invent the integrated circuit, a miniaturized electronic circuit that will make possible the development of much smaller, cheaper, and more powerful computers and other modern electronic devices.

1959 An oil well drilling platform is constructed in over 200 feet of water offshore from Louisiana.

1959 British scientist Francis Bacon demonstrates a fuel cell device that can produce 5 kilowatts of power, enough to run a welding machine. This is the culmination of nearly 30 years of effort by Bacon to produce a workable fuel cell. Later that same year, Harry K. Ihrig of Allis-Chalmers displays the first fuel cell vehicle, a 20-horsepower tractor.

1959 The Dresden-1 Nuclear Power Station in Illinois, the first U.S. nuclear plant built entirely without government funding, achieves a self-sustaining nuclear reaction.

1959 The first man-made object lands on the moon, the Soviet *Lunik II* rocket.

1959 U.S. brewing company Coors sells beer in aluminum cans for the first time, and other beverage companies soon follow suit. By the 1970s aluminum cans will replace bottles as the leading type of drink container, giving rise to a huge recycling program to recover the used cans.

1959 Verner Suomi, a U.S. meteorologist, uses data from the *Explorer VII* satellite to estimate the global radiation heat budget of the Earth–atmosphere system. This is the first use of a satellite to characterize the Earth's energy balance.

1960–1969

ca. 1960 The human population reaches 3 billion.

1960 Physicist Theodore Harold Maiman designs the first working laser (light amplification by stimulated emission of radiation), using a pink ruby medium. Within two years, the laser is being employed in eye surgeries. The term "laser" was reportedly coined earlier

by Gordon Gould, and he will eventually win several key laser patents.

1960 President Eisenhower establishes the Arctic National Wildlife Refuge in Alaska, which will eventually consist of more than 19 million acres. Later this area will become the focus of an intense debate between environmentalists and developers over whether to allow oil drilling in the coastal plain of the Refuge (see 1980).

1960 The final steam locomotive is built by British Railways, the *Evening Star.*

1960 The first large-scale geothermal power plant in the United States begins operation at The Geysers geothermal field in northern California. The Geysers soon becomes the world's largest steamfield, reaching its peak production in 1987, when it produces enough electricity to supply 1.8 million people.

1960 The Organization of Petroleum Exporting Countries (OPEC) is announced in Baghdad with five original members: Iraq, Iran, Kuwait, Saudi Arabia, and Venezuela. Qatar joins OPEC in 1961, followed by Indonesia and Libya (1963), the Emirates of Abu Dhabi (1968), Algeria (1969), Nigeria (1971), Ecuador (1973), and Gabon (1975). The latter two leave OPEC in the 1990s.

1960 The transition in the United States from manufactured gas to natural gas is virtually complete. However, environmental concerns still exist because of toxic byproducts remaining in soil and groundwater at the sites of former manufactured gas plants.

1960 The Yankee Atomic Electric Company plant (Yankee Rowe) begins operation on the Deerfield River at Rowe, Massachusetts. The company is formed by 12 New England utilities to supply electrical power. Yankee Rowe operates for more than 30 years until being shut down due to reactor vessel embrittlement.

1960 West Germany builds its first industrial nuclear reactor, the Kahl am Obermain experimental nuclear power plant. It will operate until 1985.

1961 Self-advancing hydraulic longwall supports are introduced to U.S. coal mining. These provide greater support for the roof of the mine and also reduce deformation, fracture, and movement around the coal face.

1961 The first use of a radioisotope thermoelectric generator for space applications is on the U.S. Navy Transit 4A spacecraft. These generators provide electrical power for spacecraft by direct conversion of the heat generated by the decay of plutonium-238.

1961 The Soviet Union sends the first human into space, Yuri Gagarin, who orbits Earth in a 108-minute mission aboard the *Vostok I*. The following month, Alan Shepherd becomes the first American in space when he makes a suborbital flight of 15 minutes.

1961 The U.S. Navy commissions the world's largest ship, the *U.S.S. Enterprise*. It is a nuclear-powered aircraft carrier with the ability to operate for distances up to 400,000 miles without refueling.

1961 U.S. physicist Murray Gell-Mann and others propose a system for classifying subatomic particles which Gell-Mann terms "the eightfold way." The system is the foundation of the quark theory.

1961 U.S. President Kennedy says that citizens can survive a nuclear attack if they take refuge in a fallout shelter. A national survey identifies large buildings and other sites such as mines, caves, and tunnels that could protect people from fallout radiation; these areas are designated as public shelters.

ca. 1961 Small nuclear-power generators are first used in remote areas to power weather stations and to light buoys for sea navigation.

early 1960s Regulations to limit harmful emissions from motor vehicles are introduced in the United States and other nations. Emission control devices are then installed in new vehicles.

early 1960s The Pratt and Whitney Division of United Aircraft (now United Technologies) takes out a license on the fuel cell patents of Francis Bacon (see 1932) and uses the concept of the Bacon cell to provide electrical power for the *Apollo* spacecraft.

1962 A trash fire in an open-pit anthracite coal mine in Centralia, Pennsylvania ignites an exposed vein of coal. This in turn burns through old coal mines under the town, and fire, smoke, and toxic gases reach the surface and eventually force the abandonment of most of the town's buildings. As of this writing, the fire still burns.

1962 General Electric scientist Nick Holonyak creates the first light-emitting diode (LED). LED displays will become a universally used light source in consumer electronics, traffic signals, public information messages, and many other applications.

1962 In Natick, Massachusetts, a solar furnace is built by the U.S. Army to simulate radiation burns and to experiment with pigs wearing sunscreen lotions that might protect soldiers from nuclear radiation.

1962 Rachel Carson publishes *Silent Spring,* the first widely read work to describe the effect on health and the environment of human-produced toxic chemicals, such as the insecticide DDT. This book is often given credit for launching the modern environmental movement at the popular level.

1962 The U.S. Congress creates the Communications Satellite Corporation (COMSAT). Agencies from 17 other countries join with COMSAT in 1964, forming an international consortium to establish a satellite communications network. By this time the United States has launched a series of satellites, beginning with *Echo I* in 1960.

1962 The U.S. Navy constructs a nuclear power plant at McMurdo Sound, Antarctica, to supply power for the American research installations there.

1963 Ffestiniog Power Station in Wales goes into operation, the United Kingdom's first major pumped storage power facility. Pumped storage involves two reservoirs at different levels. Water is pumped to the higher of the two, then released to flow downward through high-pressure shafts linked to turbines, thus generating power for electricity.

1963 Harold Barnett and Chandler Morse publish the first empirical analysis of the supply of natural resources in the United States. It shows that the cost of timber, fish, minerals, and fuels generally declined from 1870 to 1957 due to what they call "self-generating technological change." This is used by some to argue that human ingenuity can overcome natural resource constraints.

1963 Japan installs a 242-watt photovoltaic array on a lighthouse, the world's largest array at that time.

1963 The Jersey Central Power and Light Company announces its commitment for the Oyster Creek nuclear power plant, the first time a nuclear plant is ordered as an economic alternative to a fossil-fuel plant.

1963 Semisubmersible platforms are in use for offshore oil drilling. In semisubmersible technology, ballasted, watertight pontoons below the sea surface and its wave action provide a base for columns that penetrate the water surface and support the operating deck.

1963 The U.S. Congress passes the first Clean Air Act, legislation intended to "improve, strengthen, and accelerate programs for the prevention and abatement of air pollution." Various other Clean Air Acts will follow in the 1960s and after.

1964 George Heilmeier heads a research group at RCA that produces the first liquid crystal display (LCD). This becomes a widely used technology for various electronic applications, such as watches and clocks, computer displays, and eventually television screens (the original use envisioned by the RCA team).

1964 Japan's *Shinkansen* (also known as the Bullet Train) becomes the world's first high-speed railway system. It runs between Tokyo and Shin-Osaka at a maximum business speed of over 200 kilometers per hour (130–160 mph).

1964 Murray Gell-Mann and George Zweig independently introduce the three-quark model of elementary particles.

1964 The Baltimore Light Station on the Chesapeake Bay in Maryland becomes the first nuclear powered lighthouse in the United States.

1964 The General Electric PEM fuel cell represents the first successful application of a fuel cell in space.

1964 Three U.S. nuclear-powered surface ships, the *Enterprise, Long Beach,* and *Bainbridge,* complete "Operation Sea Orbit," an around-the-world cruise.

1964 U.S. President Lyndon Johnson signs the Private Ownership of Special Nuclear Materials Act, which allows the nuclear power industry to own the fuel for its units.

1965 A year of major advances in space technology, with the Soviets making the first space walk, the United States launching the first nuclear reactor in space (SNAP, or systems for nuclear auxiliary power), the Americans completing the first space rendezvous between two satellites, and the Soviets sending out a space probe that lands on Venus.

1965 Geologists discover oil and natural gas in the West Sole Field of the North Sea, off the coast of Great Britain. Eventually North Sea oil will make Britain roughly self-sufficient in energy and also bring great prosperity to Norway, which will become one of the world's leading oil exporters.

1965 The Great Blackout of 1965 covers 80,000 square miles of the northeastern United States and Canada. The failure affects four million homes in the New York City area, and leaves between 600,000 and 800,000 people stranded in the city's subway system. The events of the blackout become the subject of a Hollywood film, *Where Were You When The Lights Went Out?*

mid-1960s Both the United States and the Soviet Union have deployed a full-scale system of intercontinental ballistic missiles (ICBMs).

mid-1960s The era of the supertanker is underway as ultra-large vessels are used to transport oil around the globe, especially from the Middle East to western Europe and the United States.

mid-1960s U.S. ecologist Eugene E. Likens describes the phenomenon of acid rain in North America, based on observations at Hubbard Brook, New Hampshire, a leading research site he co-founded for studies in ecosystem science and biogeochemistry. Acid rain will be tied directly to pollutants from the combustion of fossil fuels.

1966 The world's largest tidal power plant goes into operation at the mouth of the La Rance river in northern France. The tide is channeled through the narrow entrance to the river, across which is a dam with turbines and generators.

1966 U.S. economist Kenneth Boulding publishes *The Economics of the Coming Spaceship Earth,* the first explicit application of the law of conservation of matter to describe the physical limits to economic growth.

1967 Egypt, Syria, and Jordan oppose Israel in the third Arab–Israeli War. This becomes known as the "Six-Day War" because of the swift Israeli victory. The war results

in territorial gains for Israel and increased tensions between the Arab World and the West (see next).

1967 Saudi Arabia leads an Arab oil embargo against the United States and Britain, who were accused of aiding Israel against Arab countries in the Six-Day War. The boycott, however, lasts for only two months and does not significantly affect the Western economies.

1967 The first barrel is shipped from the Great Canadian Oil Sands Project, the first commercially successful operation to tap the rich Athabasca oil sands in the province of Alberta. The project ushers in an era of rapid development of this oil sand resource base.

1967 The Oroville Dam on the Feather River in northern California is completed; it is the tallest dam in the United States.

1967 The supertanker *Torrey Canyon* runs aground on a reef near the coast of Cornwall in southwestern England. The ship spills an estimated 30 million gallons of oil into the sea, producing environmental damage on a scale not even imagined before that time and blighting the entire region for years to come.

1968 A coal mine explosion in Farmington, West Virginia results in the death of 78 miners. This mine is just a few miles away from Monongah, the site of the worst mine disaster in U.S. history (see 1907).

1968 Large oil deposits are discovered in Alaska at Prudhoe Bay, but it is not until 1977 that the first oil is shipped via the Trans-Alaska Pipeline.

1968 Lev Asimovich, director of the Soviet controlled-fusion program, announces that the Soviet T-3 tokamak has confined a plasma at a temperature of more than 10 million degrees centigrade for more than 10 thousandths of a second. Europe, Japan, and the United States all strive to develop tokamak designs.

1968 OPEC Resolution XVI.90 sets forth major new demands; this signals an era of stronger national control of Mideast oil, and the declining ability of Western multinational oil companies to control the global oil supply.

1968 The Odeillo solar furnace, the most powerful in the world, is built at Font-Romeu in the Eastern Pyrenees region of France. It has 10,000 small mirrors that concentrate the Sun's energy into useable power.

1968 The Soviet Union operates an experimental tidal power station near Murmansk.

1968 The Soviet Union's Tupolev Tu-144 becomes the first supersonic transport plane (SST) to take flight, preceding the Concorde by two months (see 1969). The TU-144 begins service in 1975 and makes its last commercial flight in 1978. The United States funds its own SST project in the 1960s, but the program is dropped in 1971 without any aircraft ever being flown.

1968 The U.S. Congress creates the Wild and Scenic Rivers System, which will "preserve selected rivers or sections thereof in their free-flowing condition to protect the water quality of such rivers and to fulfill other vital national conservation purposes."

1968 U.S. space scientist Peter Glaser presents the concept for the Solar Power Satellite system, to supply power from space for use on the Earth. The SPS system would have a huge array of solar cells, perhaps tens of square miles, that would generate electrical power to be beamed to Earth in the form of microwave energy.

late 1960s The advent of more powerful digital electronic computers make it possible to model the global general atmospheric circulation for the first time. By the 1970s, general circulation models (GCMs) are the central tool of climate scientists such as Syukuro Manabe and Kirk Bryan, and they will play a key role in describing climate change.

late 1960s The agricultural movement known as the Green Revolution is underway, featuring the widespread use of new, high-yielding crop varieties and new technologies such as increased use of irrigation, fertilizer, and pesticides. This increases harvests for millions of farmers, although with some negative social and environmental impacts.

1969 An offshore oil drilling platform at Santa Barbara, California, suffers a natural gas blowout, releasing about 200,000 gallons of crude oil. The spill mars 35 miles of coastline and causes extensive environmental damage, especially to the local populations of marine mammals and seabirds.

1969 ARPANET, the technological forerunner of today's Internet, is established. It links four nodes: the University of California at Los Angeles, University of California at Santa Barbara, University of Utah, and Stanford Research Institute. Its basic services of remote log-in, file transfer protocol, and electronic mail continue as functions of the Internet.

1969 Big Muskie, described as the world's largest earth-moving machine at over 200 feet in height and weighing some 13,500 tons, is put into use in Cumberland, Ohio. Big Muskie is what is known as a walking dragline, a machine designed to expose deeply buried coal seams that smaller machines could not reach.

1969 Boeing's 747, the first "jumbo jet," goes into commercial service. Jumbo jets such as the 747, the Lockheed L-1011, and the McDonnell Douglas DC-10 will be the stars of air travel in the coming decade, but rising fuel costs later cause the airlines to turn to smaller planes. Today only a single model of the 747 is a holdover from the jumbo jet era.

1969 Ted Hoff of Intel proposes the microprocessor, a new type of computer architecture based on a single-chip general-purpose central processing unit (CPU).

Intel will release the first working CPU in 1971; this single chip has as much computing power as the ENIAC computer, which filled an entire room.

1969 The British-French supersonic aircraft Concorde makes its first flight. It will begin transcontinental commercial passenger flights in 1976. The Concorde ceases flying in 2003 because of safety concerns and the high cost of operation relative to passenger revenue.

1969 The Cuyahoga River, flowing through Cleveland, Ohio, catches fire from oil and chemical pollution. The paradoxical image of a burning body of water becomes a rallying point for passage of the Clean Water Act.

1969 The first person to step on the moon is Neil A. Armstrong of the United States, followed by Buzz Aldrin, with Michael Collins orbiting the moon in the *Apollo 11* spacecraft.

1969 The *S.S. Manhattan,* an ice-breaking tanker, becomes the first commercial ship to sail the fabled Northwest Passage, a dream of navigators for 500 years. The purpose of the expedition is to test the feasibility of using the Northwest Passage to transport oil from Alaska's North Slope to the markets of the eastern United States and Europe.

1970–1979

1970 At California's Geysers project, the injection of spent geothermal fluids back into the production zone begins, as a means to dispose of waste water and maintain reservoir life

1970 Earth Day is celebrated for the first time in the United States as a nationwide demonstration advocating environmental protection and preservation. This demonstration is conceived by Gaylord Nelson, U.S. Senator from Wisconsin, and organized by Denis Hayes.

1970 IBM introduces an eight-inch "floppy disk" as a medium for data storage in its 370 computer.

1970 Premier Zhou-Enlai of China delivers a speech emphasizing the necessity for exploring the peaceful use of nuclear energy. The first nuclear reactor in China will not come on line until the 1990s.

1970 The Environmental Protection Agency (EPA) is formed in the United States, with the mission to "protect human health and to safeguard the natural environment—air, water, and land—upon which life depends."

1970 The first silica fiber optical cable is produced at the Corning Glass Works (New York), using chemical vapor deposition techniques to reduce attenuation and improve signal transmission.

1970 The Geothermal Steam Act is enacted by Congress; it authorizes and governs the lease of geothermal steam and related resources on public lands. The Geothermal Resources Council is formed to encourage the development of geothermal resources worldwide.

1970 The level of production of crude oil in the United States reaches its all-time high.

1970 The U.S. Congress adopts a law requiring federal agencies, including the Atomic Energy Agency, to consider thermal pollution in their licensing process. This is the first time that environmental issues are seriously raised in the context of nuclear power, and is a harbinger of more intense scrutiny of nuclear power's potential impact.

1970 The United States, Great Britain, the Soviet Union, and 45 other nations sign the Treaty for the Nonproliferation of Nuclear Weapons.

1970–1974 Paul Crutzen and Harold Johnston identify an ozone-destroying catalytic cycle involving oxides of nitrogen. Richard Stolarski and Ralph Cicerone propose another such cycle involving chlorine, and Mario Molina and F. Sherwood Rowland link this cycle to ozone depletion by chlorofluorocarbon (CFC) emissions.

1971 For the first time, surface mined coal production in the United States exceeds the amount of coal mined underground.

1971 Howard T. Odum publishes *Environment, Power, and Society,* a classic and comprehensive application of thermodynamics and ecological energetics to the analysis of human economic and social systems.

1971 Nicholas Georgescu-Roegen, a Hungarian-born mathematician and economist, publishes *The Entropy Law and the Economic Process,* in which the second law of thermodynamics plays a central role in production theory. This work becomes a cornerstone of the fields of ecological and evolutionary economics.

1971 Ray Tomlinson of Bolt Beranek and Newman, Inc. sends the first e-mail message across the ARPANET system. The content of the message is chosen at random, probably something like "qwertyuiop" or "Testing 1-2-3."

1971 Twenty-two commercial nuclear power plants are in full operation in the United States. They produce 2.4% of U.S. electricity at this time.

early 1970s Ecologists Robert Whitaker, Eugene Likens, H. Leith, and other biologists quantify the net primary production and plant biomass for the Earth's major biomes.

early 1970s Kalundborg, Denmark, a small coastal town, begins a web of energy and material exchanges among several firms seeking income-producing uses for waste products. Eventually, the firm managers and town

residents realize they are generating environmental benefits as well. The term "industrial symbiosis" is used to describe this system.

early 1970s Russian-born chemist Ilya Prigogine extends the second law of thermodynamics to systems that are far from equilibrium, and shows that stable, coherent patterns could emerge under such conditions. He calls these "dissipative structures"; this concept is used to describe phenomena such as the growth of cities and the physics of car traffic.

1972 Ford Motor Company develops a sodium-sulfur battery for use as a power source in electric vehicles.

1972 The Clean Water Act is passed, establishing the basic structure for regulating the discharge of pollutants into the waters of the United States.

1972 The Club of Rome publishes T*he Neo-Malthusian Limits to Growth,* warning that if the world's consumption patterns and population growth continue at the same high rates of the time, various calamities will befall the Earth and humankind.

1972 The first large-scale commercial waste-to-energy facility is used by the Union Electric Company's Meramec Plant in St. Louis, Missouri. Refuse is shredded and burned with coal to generate electricity.

1972 The U.S. Environmental Protection Agency announces a ban on the pesticide DDT. This is part of a trend in which DDT is generally banned worldwide. In recent years, however, critics have argued that the ban should be lifted because of the huge numbers of deaths in the developing world from the mosquito-borne disease malaria.

1972 The United Nations Conference on the Human Environment (UNCHE), is held in Stockholm, Sweden, with 113 countries represented; this is the first global environmental summit. Treatment of energy is largely limited to the environmental effects of energy extraction, processing, and consumption.

1972 U.S. scientist Paul Berg assembles the first DNA molecules that combine genes from different organisms. In the following year Herbert Boyer and Stanley Cohen report the construction of functional organisms that combine and replicate genetic information from different species.

ca. 1972 The U.S. Atomic Energy Commission announces that a salt mine at Lyons, Kansas, will be developed as a high-level radioactive waste repository. The decision is reversed in 1972 after geologists learn that the site is riddled with abandoned oil and gas exploration boreholes.

1972–1982 More than 100 orders for nuclear power plants in the United States are canceled, due mainly to cost overruns, a decline in the demand for power, and public concerns about safety. The number of cancellations grows to 124 by 2000.

1973 A huge pumped-storage facility goes into operation on Lake Michigan. The Ludington power plant pumps water uphill from the lake to a storage reservoir when demand is low, then releases the water to flow back downhill and generate electricity as needed by turning giant turbines.

1973 A total of 109 nuclear power plants operating in the United States generates 610 billion kilowatt-hours of net electricity, providing about one-fifth of the nation's electricity.

1973 America's public and private utilities form the Electric Power Research Institute (EPRI) in Palo Alto, California. EPRI will grow to be one of the world's most influential electric power research and development organizations.

1973 An international journal known as *Energy Policy* begins publication. This is the first social science journal pertaining to the study of energy.

1973 Chemist Nathaniel Wyeth receives a patent for PET (polyethylene terephthalate) beverage bottles. This is the first practical plastic that is strong enough to hold carbonated beverages without bursting, and it soon becomes a recyclable material.

1973 Conventional natural gas production peaks in the United States. Abundant quantities of unconventional gas (deep gas, coalbed methane, tight gas) still remain today, but their economic, technological, and environmental viability are the subject of considerable debate.

1973 Egypt and Syria launch a surprise attack against Israel (October 6th) in what will become known as the Yom Kippur War. Many other Arab states, including Iraq and Saudi Arabia, also provide troops and supplies.

1973 Members of the Organization of Arab Petroleum Exporting Countries (OAPEC) meet in Kuwait as the Yom Kippur War goes on. They reach agreement on a coordinated policy of cuts in oil production coupled with price increases.

1973 The Arab oil-producing states impose a complete embargo on oil shipments to the United States in retaliation for American support of Israel in the Yom Kippur War. The embargo will later be extended to The Netherlands. Japan and other nations in Europe will also be hard hit by the combination of price increases and production cuts.

1973 The Black Mesa coal pipeline becomes operational, transporting coal slurry 273 miles from a mine on Navajo Indian land in northern Arizona to the Mojave Generating Station at Laughlin, Nevada. This is currently the only coal slurry pipeline in operation in the United States.

1973 The first major energy crisis in the United States occurs as a result of the Arab oil embargo. By the following year the price of crude oil will be four times its level of 1972. The oil embargo will be lifted in

March of 1974, but the United States and other Western nations will continue to feel its effects for years to come.

1973 U.S. President Richard Nixon announces a series of measures to cope with fuel shortages, such as a national 55 miles per hour speed limit, year-round daylight saving time, and a ban on Sunday sale of gasoline. Various states will also impose forms of rationing, e.g., sale of gas to motorists on alternate days depending on a car's license number.

1974 A well that bottoms out at 31,441 feet is drilled in Oklahoma, the deepest well ever drilled in the United States at the time. It is a dry well.

1974 Entrepreneur Robert Beaumont revives the consumer electric vehicle market with his CitiCar. Several thousand of these will be produced, due to interest in alternative vehicles spurred by the oil crisis of 1973. However, the CitiCar is essentially a glorified golf cart, and by the late 1970s it is no longer produced.

1974 Faced with rising oil prices and a heavy dependence on imported oil, the French government embarks on an ambitious plan to develop nuclear power. By 2000, France has built 58 reactors that supply nearly three-quarters of its power.

1974 Howard Georgi and Sheldon Glashow develop the first Grand Unified Theory (GUT) to unite strong, weak, and electromagnetic forces. The attempt to develop a unified field theory was the focus of Einstien's work for many years.

1974 The American Wind Energy Association (AWEA) is founded to advocate the development of wind energy as a reliable, environmentally superior form of alternative energy in the United States and around the world.

1974 The Energy and Resources Institute (TERI) is formed in New Delhi, India. TERI will grow to be one of the world's leading organizations focusing on all forms of natural and human resources, with a special interest in sustainable energy and the environment.

1974 The first International Conference on Hydrogen Energy and the Hydrogen Economy is held in Miami Beach, Florida. From this meeting springs the International Association for Hydrogen Energy (IAHE), the first professional society dedicated to hydrogen energy.

1974 The first known use of the term "Internet" appears in a paper on Transmission Control Protocol (TCP) by Vinton Cerf and Robert Kahn.

1974 The International Energy Agency is created, a forum for 26 member countries who are committed to taking joint measures to meet oil supply emergencies. IEA collects and publishes a wide array of energy and environmental data and research reports.

1974 The U.S. Atomic Energy Commission is dissolved. The Energy Reorganization Act divides its functions between two new agencies: the Energy Research and Development Administration (ERDA), to carry out research and development, and the Nuclear Regulatory Commission (NRC), to regulate nuclear power.

1975 As a result of the oil crisis of 1973–1974, the U.S. Congress enacts the Energy Policy and Conservation Act (EPCA). EPCA sets minimum fuel economy standards for cars and light trucks, and also establishes the Strategic Petroleum Reserve, an emergency oil store intended to counteract a severe supply interruption.

1975 EPCA also requires that home appliances such as refrigerators, air-conditioners, and washing machines be sold with a label to indicate their energy usage. West Germany introduces a similar voluntary energy labeling program in the same year.

1975 Opinion polls in the United States show that about 20% of the public is opposed to the construction of more nuclear power plants. On the eve of the accident at the Three Mile Island nuclear plant in 1978, that number had risen to nearly 40%. By the time of the Chernobyl disaster in 1986, opposition had grown to about 80%.

1975 The development of microchips makes possible the first personal computer to have a significant public impact, the Altair, with 256 bytes of memory. It is sold by MITS, Inc. of Albuquerque, New Mexico. Bill Gates and Paul Allen then develop a BASIC software program for the Altair.

1975 The U.S. Geological Survey releases the first national estimate and inventory of geothermal resources.

ca. 1975 The human population reaches 4 billion.

1976 A U.S. Federal court rules that the Environmental Protection Agency has the authority to regulate leaded gasoline. The lead phase-out begins, and by June 1979, nearly half of all U.S. gasoline is unleaded.

1976 An Energy Modeling Forum is established at Stanford University to provide a structured forum within which energy experts from government, industry, universities, and other research organizations can meet to study important issues of common interest.

1976 British journalist Anthony Sampson publishes *The Seven Sisters: The Great Oil Companies and the World They Made*, a history of the large multinational firms that have historically dominated the oil industry. Sampson's "Seven Sisters" are Exxon, Mobil, Socal (Chevron), Texaco, Gulf, British Petroleum, and Royal Dutch/Shell.

1976 In a watershed year for the personal computer, Steve Wozniak and Steve Jobs form the Apple Computer Company and introduce their first Apple computer. The trade name "Microsoft" is registered, and Bill Gates and Paul Allen begin to work full time for the company.

1976 U.S. President Jimmy Carter enacts legislation which authorizes the U.S. Department of Energy to conduct an Electric and Hybrid Vehicle (EHV) program.

1976 The Alaska Natural Transportation Act calls for a pipeline to transport natural gas from deposits in Alaska through Canada to the lower 48 United States. The plan remains stalled for decades due to opposition from environmental groups, cost considerations, uncertainty about future gas prices, and Canada's proposal for a different route.

1976 The U.S. Resource Conservation and Recovery Act gives the Environmental Protection Agency (EPA) the authority to control hazardous waste from "cradle-to-grave." This includes the generation, transportation, treatment, storage, and disposal of hazardous waste.

1977 Congress abolishes the Joint Committee on Atomic Energy, which was established in 1946 to oversee the Atomic Energy Agency. With the demise of the JCAE, supporters of nuclear power lose control of strategic junctures of policy-making that had been favorable to the industry. Jurisdiction is now spread over many agencies.

1977 New York City and neighboring Westchester County are plunged into darkness as lightning downs major transmission power lines. Looting and violence erupt, and within a span of two days, police arrest nearly 4,000 looters and the city suffers an economic loss estimated at $300 million.

1977 President Carter installs solar panels on the White House and promotes incentives for solar energy systems. President Ronald Reagan removes these panels in 1980 and eliminates many of the policy incentives for renewable energy.

1977 Scientists develop the first hot dry rock reservoir at Fenton Hill, New Mexico to "mine" geothermal energy from beneath the earth.

1977 The Apple II becomes the first highly successful mass-produced personal computer.

1977 The Department of Energy (DOE) is established as a cabinet-level agency in the United States; the DOE takes over the activities of the Energy Research and Development Administration and the Federal Energy Administration.

1977 The Federal Energy Regulatory Commission (FERC) is established in the United States, succeeding the Federal Power Commission. FERC is a quasi-independent agency within the DOE with jurisdiction over such issues as interstate electricity sales, wholesale electric rates, hydroelectric licensing, natural gas pricing, and oil pipeline rates.

1977 The first oil flows through the Trans-Alaska Pipeline (TAPS). Actual construction began in 1974 and it ultimately will cost $8 billion, at the time the largest privately funded construction project in history. Throughout the 1980s and 1990s, TAPS carries as much as 20% of total U.S. oil production.

1977 The first shipment of oil, approximately 412,000 barrels of Saudi Arabian light crude, is delivered to the U.S. Strategic Petroleum Reserve, an emergency oil supply stored in huge underground salt caverns along the coastline of the Gulf of Mexico.

1977 The International Association for Energy Economics (IAEE) is founded. IAEE is the largest non-profit professional organization devoted exclusively to energy, with members in 70 countries. IAEE publishes one of the most respected academic journals on energy.

1977 The non-governmental organization Alliance to Save Energy is founded in the United States. The Alliance will play a major role in the education, communication, and political aspects of energy efficiency in the United States.

1977 The Solar Energy Research Institute (SERI), later to become the National Renewable Energy Laboratory (NREL), begins operation in Golden, Colorado.

1977 The U.S. Surface Mining Control and Reclamation Act is enacted. It sets federal mining standards for coal, as well as standards for the reclamation of mining sites.

1977 The *Voyager* spacecraft is launched; it is powered by thermoelectric generators that produce energy from the radioactive decay of plutonium.

1978 A 15% energy tax credit is added to an existing 10% investment tax credit, providing incentive for capital investment in solar thermal generation facilities for independent power producers.

1978 CFCs (chlorofluorocarbons, or Freons) are banned in the United States as spray propellants because of fears over their role in the depletion of the ozone layer.

1978 In the same vein as the first Earth Day earlier in the decade, people around the world celebrate "Sun Day" to focus on the use of solar energy as a replacement for fossil fuel sources.

1978 President Carter signs the National Energy Conservation and Policy Act, which includes various specific acts to promote conservation and develop greater energy efficiency.

1978 Shortages of natural gas prompt the U.S. Congress to pass the Natural Gas Policy Act, which effectively ends decades of natural gas price controls by the federal government. The goal of the legislation is to deregulate natural gas prices over time, to encourage exploration, and to reduce the price differentials between interstate and intrastate markets.

1978 The last two orders for new nuclear power plants in the United States are placed during this year.

1978 The U.S. Department of Transportation issues CAFE (Corporate Average Fuel Economy) standards for passenger cars, with an original standard of 18 miles

per gallon and an increase to 27.5 miles per gallon within seven years. DOT also establishes standards for light trucks, starting with the following model year.

1978 The U.S. Public Utility Regulatory Policies Act (PURPA) mandates the purchase of electricity from qualifying facilities (QFs) meeting certain technical standards regarding energy source and efficiency; this especially favors independent sources that are not fossil fuel-based, helping wind and other renewables.

late 1970s German automobile makers Daimler-Benz and BMW begin the experimental development of hydrogen-powered internal-combustion engine vehicles.

late 1970s Japanese automobile brands such as Toyota, Honda, and Datsun (Nissan) now play a major role in the U.S. market; these vehicles appeal to American buyers looking for greater fuel efficiency in an era of rapidly increasing gas prices.

1979 A blowout of the experimental Ixtoc-1 well off the coast of Mexico releases about 140 million gallons of crude oil. This is the largest non-war related oil spill to date (though its environmental impact is relatively small).

1979 At the Papago Indian Reservation in Schuchuli, Arizona, NASA's Lewis Research Center completes a 3.5-kilowatt photovoltaic system; this is the world's first village PV system.

1979 In a time of rising energy prices and fuel shortages, President Carter gives a speech in which he speaks of a crisis in the American spirit. He calls for import quotas, a tax on oil profits, development of synthetic fuels, and individual energy conservation. Now known as the "malaise" speech, it is poorly received by the public and contributes to Carter's loss in the next election.

1979 Iran's pro-Western ruler Reza Shah Pahlavi is driven from power and replaced by exiled Islamic leader Ayatollah Ruhollah Khomeini. Iranian militants seize the U.S. embassy in Tehran, holding more than 60 staff members hostage. In response, President Carter places an embargo on importing Iranian oil into the United States.

1979 Oil prices rise sharply following the revolution in Iran, largely because of fears that overall supplies from the Persian Gulf will be disrupted. By 1981 they will reach an all-time high of $36.47 per barrel or nearly triple the price prior to the revolt. Once again political events of the Middle East cause an energy crisis in the United States.

1979 Seventy-two licensed nuclear reactors generate 12% of the electricity produced commercially in the United States.

1979 *T.T. Jahre Viking,* the world's largest oil supertanker (in fact the largest floating object on Earth) returns to the high seas after extensive repair work; she had been sunk by Iraqi jets during the Iran–Iraq war. This ship is over 1,500 feet long and can carry more than 4 million barrels of crude oil.

1979 The worst accident in U.S. commercial reactor history occurs on March 28th at the Three Mile Island nuclear power station near Harrisburg, Pennsylvania. It is caused by a loss of coolant from the reactor core due to a combination of mechanical malfunction and human error. No one is injured, and no overexposure to radiation results from the accident.

1980–1989

1980 A solar power system is installed at Natural Bridges National Monument (NBNM) in Utah by a partnership of the Massachusetts Institute of Technology, the U.S. Department of Energy, and the National Park Service. The system provides uninterrupted electricity to NBNM for 10 years until being retired (restored in the 1990s).

1980 Heating oil is the first energy product sold on the New York Mercantile Exchange (NYMEX) futures market. This is followed by crude oil (1983), natural gas (1990), and electricity (1996).

1980 In a public referendum in Sweden, voters choose to build no new nuclear power plants, which at the time provide about 50% of their power. However, in 2003 the Swedish government admits that it cannot close the first few reactors on schedule because it has not find a suitable alternative source of power.

1980 Southern California Edison begins operation of a 10-megawatt experimental power plant at the Brawley, California geothermal field, with steam produced by Unocal (Union Oil Company of California). This is the first geothermal flash plant in the United States.

1980 The Alaska National Interest Lands Conservation Act greatly expands the Arctic National Wildlife Refuge (ANWR). However, the act leaves future lawmakers the option of authorizing oil and gas exploration in the area. ANWR becomes the focus of an intense debate over the balance between environmental protection and energy security.

1980 The U.S. Department of Energy initiates the Three Mile Island research and development program to develop technology for disassembling and de-fueling the damaged reactor. The program will continue for 10 years and make significant advances in nuclear safety technology.

1980 The drama series *Dallas* begins a five-year run as the most popular show on U.S. television, and also wins large audiences abroad. It features a family of Texas oil millionaires, and it continues the image established by Hollywood films such as *Boom Town* (1940) and *Giant*

(1956) of the American oil business as a world of dynamic, risk-taking individualists.

1980 The Energy Security Act is signed by President Carter, with provisions for energy conservation, solar and geothermal energy, and biomass and alcohol fuels. The act also creates the Synthetic Fuels Corporation (see next), with an initial authorization of $20 billion to be allocated for joint projects with private industry.

1980 The Synthetic Fuels Corporation is established to develop tar sands and shale oils so as to reduce the nation's dependence on imported oil. It enjoys little commercial success due to low energy prices, lack of interest from the private sector, and the high cost of synfuel production. Congress ends the Corporation in 1985.

1980–1983 The Greens establish a political party in West Germany and gradually develop into an important faction. They attract support with their anti-nuclear campaign slogan: "*Atomkraft? Nein, Danke*" (Nuclear Power? No, Thanks). Eventually they will form part of a coalition that wins the German popular vote.

1980s Bicycle production in China reaches 40 million units per year, which at the time is greater than the total world output of automobiles.

1980s High efficiency (greater than 50%) is achieved for combined cycle gas/steam turbine power plants.

1981 An aircraft known as the *Solar Challenger* flies across the English Channel powered entirely by energy from the Sun.

1981 An explosive growth of wind farms in California begins as a result of favorable government support.

1981 French president François Miterrand inaugurates service for the high-speed French railway program known as TGV (*Train à Grande Vitesse*). The first TGV train with paying passengers leaves Paris five days later.

1981 Ormat Technologies successfully demonstrates the technical feasibility of larger-scale commercial binary power plants for geothermal energy, in the Imperial Valley of California.

1981 The Chinese government approves a proposal to build a pressurized light water reactor at Haiyan in Zhejiang province. The Qinshan 1 nuclear reactor will take a decade to complete.

1981 The *Columbia,* a manned, reusable space shuttle, is successfully launched into space and then returned to earth.

1981 U.S. President Ronald Reagan signs an executive order effectively ending price controls on crude oil and refined petroleum products. These controls on energy prices were the last legacy of the comprehensive wage and price controls that President Richard Nixon had enacted in 1971.

early 1980s The Energy Research Group at the University of Illinois (Urbana) pioneers the use of input–output analysis to study energy flow in economic and ecological systems. The group publishes more than 300 studies on the subject.

1982 The Shippingport, Pennsylvania Power Station is shut down after 25 years of service. Decommissioning will be completed in 1989; this is the first U.S. nuclear power plant to be decommissioned.

1982 Solar One, the first commercial solar-thermal power plant in the United States, opens near Daggett, California.

1982 The British National Radiological Protection Board issues an official estimate of the health impact of the 1957 fire at the Windscale nuclear plant. This indicates that 32 deaths and at least 260 cases of cancer could be attributed to the radiation released by the fire. However, other analysts claim that the fire actually caused more than 1,000 deaths.

1982 The Tokamak Fusion Test Reactor at the Princeton Plasma Physics Laboratory produces power from nuclear fusion. Tokamak will set records for high plasma temperatures and make other advances in fusion technology; the reactor is decommissioned in 1997 in the wake of cutbacks in funding for fusion research.

1983 A fire aboard the tanker *Castillo de Bellver,* off South Africa, releases 78.5 million gallons of crude oil, the largest tanker-related oil spill to date.

1983 Eastman Chemicals of Rochester, New York is the first coal-to-chemicals facility to produce acetyl chemicals from coal rather than petroleum. The use of domestic high-sulfur coal displaces oil previously used to produce acetyl chemicals.

1983 Kary Mullis conceives and helps develop polymerase chain reaction (PCR), a technology for rapidly multiplying fragments of DNA. This technique will have application in a wide range of scientific fields, such as molecular biology, gene analysis, biomedical research, clinical diagnosis, paleontology, and forensic science.

1983 Microsoft announces Windows, an extension of the MS-DOS operating system that will provide a graphical operating environment for PC users.

1983 President Reagan signs the Nuclear Waste Policy Act (NWPA), the first comprehensive U.S. nuclear waste legislation. NWPA establishes a program for the disposal of high-level radioactive waste, including spent fuel from nuclear power plants.

1983 The Itaipu Dam, a joint project of Brazil and Paraguay on the Parana river, begins operation of its first unit. When completed Itaipu will become the largest hydroelectric power facility in the world and will eventually supply about one-fourth of Brazil's electrical power and nearly all of Paraguay's.

1983 The U.S. Congress cuts off funding for the Clinch River Breeder Reactor Project, an ambitious but highly controversial plutonium-based breeder reactor program near Oak Ridge, Tennessee.

1983–1986 Faced with reduced demand for its oil and increased oil production from non-member nations, OPEC oil production is cut by more than one-half; a "free-for-all" situation prevails with a rapid rise in Saudi Arabia's production, culminating in an oil price collapse in July, 1986 with Arab Light selling at less than $8 per barrel.

1984 Advanco Corporation and McDonnell Douglas demonstrate the potential for a high-efficiency 25-kilowatt solar dish.

1984 Nuclear power overtakes hydropower to become the second largest source of electricity in the United States, after coal. Eighty-three nuclear power reactors provide about 14% of the electricity produced in the nation.

1984 The Annapolis Royal power station is established on the Bay of Fundy coastline of Nova Scotia, the first tidal power plant in North America. The Bay of Fundy is known for the largest tidal changes in the world (a difference between high and low tides of as much as 50 feet).

1984 The first in a series of commercial solar thermal electricity generation plants is established in California, based on parabolic trough technology.

1984 The Great Plains Synfuels Plant goes into operation in Beulah, North Dakota, the first commercial coal gasification plant in the United States. The plant converts North Dakota's abundant lignite coal to methane.

1984 The Macintosh computer is introduced by Apple, the first affordable personal computer with a graphical user interface and a 3.5-inch floppy disk drive. It has a CPU speed of 8 Mhz and initially sells for $2,495.

1984 The University of Wisconsin introduces the Domain Name System. In 1985 Symbolics Technology, Inc. registers the first domain name: symbolics.com. The second registration is made by BBN Corporation, followed by several universities (Carnegie-Mellon, Purdue, Rice, and University of California, Berkeley).

mid-1980s Many passenger cars are now available with diesel engines, as a fuel economy strategy in response to price shocks of the preceding decade. For the most part consumers will decide that the saving in fuel cost is not enough to compensate for other disadvantages of the diesel engine, and today a relatively small percentage of passenger cars are diesel-powered.

1990s Scholars use the term "rebound effect" to describe the relationship between an increase in energy efficiency and the ensuing rate of consumption. They argue that the rebound effect can exceed 100%; i.e., improved efficiency will produce greater consumption, not less. This supports Jevon's paradox (see 1865).

1985 Richard Smalley and others at Rice University in Texas identify a new form of pure carbon (in addition to graphite and diamonds), a large molecule of 60 carbon atoms resembling a soccer ball. This is called a "bucky ball" for architect Buckminister Fuller, who designed a geodesic dome with the same shape.

1985 Scientific concerns about damage to the ozone layer prompt various governments to adopt the Vienna Convention on the Protection of the Ozone Layer, which establishes an international legal framework for action.

1985 The U.S. Institute of Nuclear Power Operations forms a national academy to accredit every nuclear power plant's training program.

1985 Wind energy facilities totaling more than 1,000 megawatts are installed in California on the Tehachapi Pass between Barstow and Bakersfield and on the Altamont Pass east of Oakland.

mid-1980s A policy is introduced to set fixed subsidy tariffs for the purchase by utilities of electricity from renewable electricity providers (especially in North America and Europe).

1986 Ahmed Zaki Yamani, the flamboyant oil minister for Saudi Arabia, is fired by King Faud. Sheik Yamani was a powerful figure within OPEC who steered Saudi policy—and, indeed, much of OPEC policy—through the roller-coaster period of price increases and decreases of the 1970s and early 1980s.

1986 At the University of California's Lawrence Livermore Laboratory, the world's most powerful laser, Nova, creates a one-billionth of a second fusion reaction with temperatures and pressures greater than the Sun.

1986 Britain announces that canaries in coal mines will be replaced by electronic sensors. For centuries caged canaries had been brought into mines to signal the presence of dangerous gases, the idea being that a canary would succumb quickly to the gas and thus warn the miners to get out. "Canary in a coal mine" is a metaphor for an early warning of oncoming danger.

1986 Human error causes a core meltdown at the Chernobyl nuclear power plant in the Ukraine (former Soviet Union), the world's most severe nuclear accident. Thirty-one people die in the accident or soon after, and another 134 are treated for acute radiation syndrome. Total related deaths probably number in the thousands.

1986 Karl Alex Muller and Johannes Georg Bednorz discover a superconductor that operates at about 35 K. This sets off a flurry of research on "higher" temperature superconductors.

1986 Leaded gasoline is banned in the United States due to its health effects. By 2000 many other countries have also banned leaded gasoline, though it continues in use in the developing world.

1986 The International Thermonuclear Experimental Reactor (ITER) group is formed, an international collaborative aimed at demonstrating the scientific and technological feasibility of commercial fusion energy.

1986–1988 OPEC abandons the practice of fixed oil prices and switches to netback pricing, a market-based system that guarantees purchasers a certain refining margin. This enables Saudi Arabia to recapture a significant market share from the rest of OPEC; it also contributes to a collapse in oil prices. The netback system lasts just two years.

1986–1992 The Deep Gas Project in Sweden drills experimental wells in the Siljan Ring, a crater formed by a meteor impact, to test a theory that methane migrates upward from the inner regions of the Earth. Two wells are drilled, one to a depth of nearly five miles, but they encounter no commercial amounts of hydrocarbons.

1987 OPEC changes its pricing system of using Saudi Arabian Light as the reference price for other OPEC crudes and replaces it with a "basket" of seven crudes as reference: Sahara Blend of Algeria; Dubai Crude; Saudi Arabia's Arab Light; Minas of Indonesia; Bonny Light of Nigeria; Tia Inana of Venezuela; Isthmus of Mexico.

1987 The Montreal Protocol on Substances That Deplete the Ozone Layer is signed, requiring industrialized countries to reduce their consumption of chemicals harming the ozone layer; requirements are strengthened through later amendments (1990–1999).

1987 The U.S. Department of Energy announces President Reagan's approval of the construction of the Superconducting Super Collider (SSC), planned as the world's largest and most advanced particle accelerator. Congress decides to halt the project in 1993 after two billion dollars had been spent.

1987 The U.S. Nuclear Waste Policy Act (NWPA) is amended. Congress directs the Department of Energy to study only the potential of the Yucca Mountain, Nevada, site for the disposal of high-level radioactive waste.

ca. 1987 The human population reaches 5 billion.

1988 Alaska's oil production at Prudhoe Bay peaks at 2 million barrels per day.

1988 In the midst of record heat and drought in the United States, NASA scientist James Hansen tells a Congressional hearing he can say "with 99% confidence" that a long-term warming trend is underway, and that the greenhouse effect is to blame. The news media publicize Hansen's statements, bringing about a new level of public awareness of climate change.

1988 OPEC abandons a fixed-price system, replacing it with an agreement on "target prices."

1988 The government of Saudi Arabia officially establishes the Saudi Arabian Oil Company (Saudi Aramco). This is the successor to the Arabian American Oil Company (Aramco), the original developer of oil in the country, which the Saudi government had gradually taken over beginning in the early 1970s.

1988 The Intergovernmental Panel on Climate Change (IPCC) is formed; it becomes the leading scientific authority on climate change.

late 1980s A flowering of modern European wind technology takes place; wind energy also experiences dramatic growth worldwide.

1989 New York State Governor Mario Cuomo announces that the Shoreham Nuclear Power Plant, although already completed, will not go into service, due to intense opposition from local citizens.

1989 The Berlin Wall falls, as East Germany opens its borders with West Germany.

1989 The Long Valley Exploratory Well project commences near Mammoth Lakes, California. Theoretically, wells completed to depths near a magma body could bring that heat to the surface, and thus provide a new source of geothermal energy.

1989 The oil tanker *Exxon Valdez* runs aground on Alaska's Bligh Reef and spills an estimated 10.8 million gallons of crude oil, fouling the waters of Prince William Sound and eventually more than 1,000 miles of beach in south-central Alaska. This causes widespread environmental damage, which according to a December 2003 study continues even to this day.

1989 The world's first hybrid (organic Rankine/gas engine) geopressure-geothermal power plant begins operation at Pleasant Bayou, Louisiana, using both the heat and the methane of a geopressured resource.

1990–1999

1990 Iraq's Oil Minister demands that OPEC curb supplies until petroleum prices have risen to $25 a barrel (from the existing $15 level). Iraq President Saddam Hussein wants a price increase to help pay off the country's debt, and charges that Kuwait had conspired with the United States to depress world oil prices through overproduction

1990 Kuwait is invaded by Iraqi forces and Saddam Hussein declares the country to be a province of Iraq. Crude oil prices rise to above $30 a barrel amid great uncertainty in world markets. The United Nations then

embargoes the export of oil from Iraq in response to the invasion.

1990 Results of a Gallup poll indicate that about 75% of Americans consider themselves to be "environmentalists."

1990 The annual production of coal in the United States tops 1 billion tons for the first time.

1990 The city of Tokyo has approximately 1.5 million buildings with solar water heaters (more than in the entire United States); Israel uses solar water heating for approximately 30% of its buildings and all new homes there are required to install solar water heating systems.

1990 The number of vehicle-miles per year traveled by Americans exceeds 2 trillion for the first time.

1990 The U.S. Clean Air Act Amendments require many changes to gasoline and diesel fuels to make them pollute less, including mandated sale of oxygenated fuels in areas with unhealthy levels of carbon monoxide. This helps resurrect production of gasohol, an ethanol-blended gasoline, which had been used in the early days of the auto industry.

1990 The unified German government closes the last of eight nuclear power plants in the formerly Communist East Germany (DDR).

1990 Tim Berners-Lee, working with Robert Cailliau at CERN (European Organization for Nuclear Research), proposes a distributed information system, based on hypertext, a way of linking related pieces of information stored on computers. The name "World-Wide Web" is chosen for this system.

1990 With natural gas prices decontrolled, the New York Mercantile Exchange (NYMEX) launches its first natural gas futures contracts. Natural gas can now be bought and sold by consumers and producers at a predetermined time in the future. This leads to short-run volatility, but in principle, greater long-term price stability.

1990s Russia, after having become the world's largest oil producer in the late 1980s, experiences a decade-long slide in production. The causes are resource depletion, poor management, reduced maintenance, and curtailed exploration, all of which are exacerbated by the economic crisis following the collapse of the Soviet Union.

1991 In what will become known as the Persian Gulf War, the United States and allied countries launch Operation Desert Storm against Iraq to end its invasion of Kuwait. After about six weeks of fighting Iraqi forces are expelled from Kuwait and a cease-fire is declared.

1991 More than 600 oil wells are set ablaze in Iraq and Kuwait by retreating Iraqi forces. The fires burn for more than nine months, creating giant oil lakes in the desert and massive regional air and water pollution. In addition, 240 million gallons of crude oil are released to the marine environment from oil terminals and tankers, the largest oil spill ever.

1991 Operation Desert Storm causes the U.S. government to make a decision to withdraw oil from the SPR (Strategic Petroleum Reserve). This is the only occasion to date when the United States has made use of this emergency supply.

1991 Sony offers the first commercial version of the lithium ion (Li-Ion) battery. Li-Ion and its contemporary the NiMH (nickel metal hydride) battery offer greater capacity and will largely replace the earlier nickel cadmium version.

1991 Sweden introduces the first tax aimed specifically at reducing emissions of the greenhouse gas carbon dioxide. Consumers pay a tax of 0.25 SEK/kg (about $100 per ton) on the use of oil, coal, natural gas, liquefied petroleum gas, petrol, and aviation fuel. Renewable fuels are largely excluded, and industry pays a substantially lower rate.

1991 The European Energy Charter is adopted by 51 nations. Its objectives are to facilitate energy cooperation between countries, to improve the security of energy supplies, and to provide greater efficiency in the production, conversion, transport, distribution, and use of energy, as well as technology transfer.

1991 The first commercial nuclear reactor in China, Qinshan 1, is connected to the power grid.

1991 The First National People of Color Environmental Leadership Summit is held in Washington, D.C., with a focus on environmental justice (the principle that underrepresented groups are disproportionately impacted by the negative effects of power plant siting, uranium mining, and other energy-related facilities).

1991 The United States operates 111 nuclear power plants with a combined capacity of 99,673 megawatts. These plants produce almost 22% of the electricity generated commercially in the country.

1991 U.S. oceanographer John Martin stirs debate when he suggests that by sprinkling a relatively small amount of iron into certain areas of the ocean, one can create large algal blooms that could take in so much carbon from the atmosphere that they could reverse the greenhouse effect and cool the Earth.

early 1990s China passes the United States and becomes the world's largest producer of coal. Coal production has doubled in just 10 years due to the expansion of power generation and steel production to drive China's rapidly expanding economy.

early 1990s Vaclav Smil of Canada and Peter Vitousek of the United States independently show that nitrogen fixation from human activity (fossil fuels and fertilizer production/use) is greater than that from natural nitrogen fixation (terrestrial systems plus lightning). In

doing so, they document the extent of human alteration of global biogeochemistry.

1992 A National Energy Policy Act is signed into law under the Clinton administration. It makes several important changes in the licensing process for nuclear power plants.

1992 CERN releases the World-Wide Web. By the beginning of 2004 there are an estimated 50 million web sites.

1992 Daniel Yergin receives the Pulitzer Prize for general nonfiction for his work *The Prize: The Epic Quest for Oil, Money and Power,* which traces the history of oil and its social, political, strategic, and economic importance.

1992 The U.S. Environmental Protection Agency introduces Energy Star, a government-backed labeling program that helps businesses and individuals adopt technologies with greater energy efficiency.

1992 The United Nations Conference on Environment and Development (UNCED), popularly known as the Earth Summit, is held at Rio de Janeiro, Brazil, bringing together nearly 35,000 participants. Treatment of energy expands from environmental effects to economic importance as well.

1992 The University of South Florida fabricates a 15.89% efficient thin-film PV (photovoltaic) cell, exceeding the 15% efficiency level for the first time.

1993 A new tax on fuels is proposed by U.S. President Bill Clinton, based on the heat content of oil, gas, and coal. The tax would raise the price of gasoline by about 7.5 cents per gallon (gas price then about $1.05 per gallon). Congress rejects the tax in the face of opposition from special interest groups and from some segments of the public.

1993 NEMS (National Energy Modeling System) is released by the Energy Information Administration. It is the first computer-based, energy-economy modeling system of national energy markets for the express purpose of answering policy questions.

1993 President Clinton pledges that the United States will reduce its output of greenhouse gases to 1990 levels by the year 2000. Vice President Al Gore reaffirms this two years later.

1993 The 33M-VS, developed by Kenetech Windpower (U.S. Windpower), becomes one of the first commercially available, variable-speed wind turbines.

1993–1994 U.S. oil imports exceed domestic oil production for the first time; import dependence will continue to grow in the coming years.

1994 California Energy becomes the world's largest geothermal company through its acquisition of Magma Power. Near-term international markets gain the interest of U.S. geothermal developers.

1994 The Energy Charter Treaty is signed; the signatories include various nations of Europe, as well as the European Union itself, Japan, and Australia. The treaty's objective is to facilitate Western investment in the development of energy resources in Eastern Europe and the former Soviet Union.

1995 A United Nations resolution allows partial resumption of Iraq oil exports in "oil for food" deal; an embargo on Iraqi oil had been in effect since 1990 as a result of Iraq's invasion of Kuwait.

1995 An Intergovernmental Panel on Climate Change (IPCC) concludes that "the balance of evidence suggests a discernible human influence on global climate." By 2001 the IPCC states "there is new and stronger evidence that most of the warming observed over the last 50 years is attributable to human activities."

1995 The European Union enacts energy labeling standards for household refrigerators and freezers, followed by energy efficiency standards (MEPS) in 1999.

1995 The nongovernmental organization ENERGIA (the International Network on Gender and Sustainable Energy) is founded after the Fourth World Conference on Women in Beijing. ENERGIA coordinates diverse initiatives, individuals, and organizations to strengthen the role of women in sustainable energy development.

1996 The U.S. Department of Energy announces the National Center for Photovoltaics, headquartered in Golden, Colorado.

1997 Qatar installs the world's first significant liquid natural gas (LNG) exporting facility.

1997 Ridership in the Moscow subway system, the world's largest, reaches a total of 3.2 billion riders per year (followed by Tokyo, Seoul, Mexico City, and New York). The system, built in 1935, also is one of the world's longest, with 340 kilometers of track.

1997 The first modern hybrid-electric vehicle is marketed in Japan, the Toyota Prius.

1997 The so-called Kyoto Protocol is adopted by the United Nations Framework Convention on Climate Change at a convention in Kyoto, Japan; this commits the signing nations to binding cuts in greenhouse gas emissions.

1997 Widespread protests against shipments of high-level nuclear waste take place in Germany; in 1998 the government temporarily halts the transport of nuclear waste. Waste shipments, and protests in response, will begin again in 2000.

1997–1999 Registered lobbyists for the oil and gas industry report expenditures averaging $60 million per year to influence the energy policies of the U.S. government.

1998 Based on annual growth rings in trees and chemical evidence contained in marine fossils, corals, and ancient ice, scientists at the University of Massachusetts conclude that the 20th century was the warmest one in 600 years, and that 1990, 1995, and 1997 were the warmest years in all of the 600-year period.

1998 The Protocol on Environmental Protection (Madrid Protocol) is approved by a body of nations; it imposes a moratorium on mining and oil exploration in Antarctica for a minimum of 50 years.

1998 The World Commission on Dams is formed with initial funding from the World Bank and IUCN, and subsequent support from many other organizations around the world. The Commission's mandate includes evaluating the effectiveness of dams and developing standards for construction, operation, and decommissioning of dams.

1998–1999 In a wave of oil company mergers, BP announces plans to acquire Amoco for $48.2 billion; BPAmoco then acquires Atlantic Richfield (Arco). Chevron Corporation acquires Texaco for about $36 billion, and Exxon acquires Mobil for about $80 billion to create the world's largest oil company. Total Fina and Elf Aquitaine agree to merge, as do Conoco and Phillips.

late 1990s After increasing steadily for nearly two decades, improvements in new vehicle fuel efficiency in the United States, level off at about 28 miles per gallon. This is due to the expiration of government regulations (corporate average fuel economy standards) that mandated efficiency improvements, and consumer demand for vehicles.

late 1990s Green certificate trading is introduced in Europe, the United States, and Australia. Generators of electricity from renewable resources receive a certificate for a predetermined unit of energy produced. These certificates have a market value, thus providing a financial incentive for the use of renewable energy.

1999 A severe accident at the uranium processing plant at Tokaimura, Japan exposes 55 workers to radiation.

1999 An ice core two miles long, drilled out of an Antarctic ice sheet, shows that levels of greenhouse gases are higher now than at any time in the past 420,000 years.

1999 Azerbaijan, Georgia, and Turkey agree to the Baku-Ceyhan route for a major new pipeline for Azeri oil exports. It will run a total of 1,038 miles (1,730 km) and cost up to 4 billion dollars. Oil is set to flow in 2005.

1999 Japan announces "Top Runner," a new set of energy efficiency standards for improved performance of cars, appliances, and other products.

1999 The first modern hybrid-electric vehicle is marketed in the United States, the Honda Insight.

1999 The United States withdraws from the International Thermonuclear Experimental Reactor, an international collaborative aimed at demonstrating the scientific and technological feasibility of commercial fusion energy, after Congress eliminates the funding required for U.S. participation.

21st Century

2000 The year 2000 (Y2K) begins and with it the possible onset of the "Y2K Problem," a widely publicized potential disaster caused by failure of the world's computer systems to accommodate dates beyond 1999. In fact Y2K produces no significant negative effects; analysts disagree as to whether this is because of adjustments made beforehand or because the problem was exaggerated.

2000 The Chernobyl nuclear facility is permanently shut down.

2000 The world's first commercial wave power station on the Scottish island of Islay is connected to the electrical grid. Devices are placed on the shoreline or at sea, using wave motion to drive turbines or hydraulic pumps by means of compressed air.

2000–2001 Millions of people in California experience a new energy phenomenon known as a "rolling blackout"; this is a planned series of temporary, controlled power outages intended to prevent heavy demand from crashing the state's electrical grid. Californians are faced with a combination of increased energy prices and reduced, uncertain supply.

ca. 2000 The human population reaches 6 billion.

2001 Enron, an energy services corporation, goes bankrupt. It had become the seventh-largest U.S. company by buying electricity from generators and selling it to consumers, and was praised in the business media as the model for a new type of energy company. In reality Enron had been losing vast amounts of money and disguising the losses by false reports and accounting tricks.

2001 In the wake of the September 11th attacks on New York's World Trade Center and the Pentagon, the city of Boston bars the liquefied natural gas (LNG) carrier *Matthew* from Boston Harbor because of fear of a terrorist attack. The event highlights the heightened concerns in the United States about the vulnerability of energy facilities.

2001 The Center for Disease Control in the United States lists 15,196 deaths in 717 disasters since the 1830s in the nation's mines, most of them in coal mines.

2001 The Ecuadorean tanker *Jessica* runs aground on rocks off the Galapagos Islands, releasing about two-thirds of its cargo of 240,000 gallons of oil. The accident occurs in the prophetically named Shipwreck Bay, outside the tiny harbor of San Cristobal Island.

2001 The first oil flows through the Caspian Pipeline Consortium (CPC) pipeline, a 1,700-kilometer pipeline originating in Tennis, Kazakhstan, and terminating near the port of Novorossiysk, Russia, on the Black Sea. The CPC pipeline is the first to connect the oil-rich region of central Asia with significant export terminals.

2001 The U.S. Office of Scientific and Technical Information (OSTI) releases the Energy Citations Database, which provides 2 million citations to bibliographic records for energy and energy-related scientific and technical information.

2002 A general strike occurs in Venezuela against President Hugo Chavez. Oil production and exports drop to nearly zero, sending a shudder through world oil markets and helping oil prices to rise sharply.

2002 At a time when more than 50% of its electricity comes from nuclear power, Belgium makes a decision to completely phase out nuclear power over the next 25 years.

2002 President George W. Bush "un-signs" the United States from the Kyoto Protocol, the treaty aimed at reducing greenhouse gas emissions. President Bill Clinton had originally signed the Protocol in 1998, although it was never ratified by the Senate. President Bush says that it would cause undue economic harm to the U.S. economy.

2002 The Japanese government announces that it will expand its nuclear power generation by 30% by the year 2010, in order to achieve the reduction goals for greenhouse gas emission set by the Kyoto Protocol.

2002 The *Prestige*, a crippled oil tanker carrying nearly 20 million gallons of heavy fuel oil, breaks in half and sinks off Spain's northwest coast. The tanker's slow demise releases thousands of tons of oil into the waters of the Atlantic, causing one of Europe's worst environmental disasters.

2002 The World Summit on Sustainable Development (WSSD) is held in Johannesburg, South Africa. Treatment of energy extends to its overarching role in sustainable development, i.e., the integration of environmental stewardship, economic development, and human well-being.

2002–2003 Oil prices increase by 50% between November and March due to strikes in the Venezuelan oil sector, a shortage of home heating oil in a cold winter, and fears of what a U.S.–Iraq war will do to oil production and prices. Oil prices drop sharply in the opening days of the war when Iraq does not sabotage production facilities at home or in Kuwait.

2003 A massive power outage cuts electricity from New York north to Toronto and west to Detroit, an area in which some 50 million people reside.

2003 Hybrid-electric urban buses are delivered to the New York City Transit Authority by Orion Bus Industries, the first production models of such vehicles.

2003 In a historic recall election, California voters remove Governor Gray Davis from office. Dissatisfaction with his handling of the state's energy policy is cited as the leading factor in his defeat.

2003 Mandatory energy labeling programs are in place in 35 different countries, covering as many as 25 product types.

2003 The Calder Hall nuclear power station in West Cumbria is closed down by BNFL (British Nuclear Fuel). This marks the end of an era for the British nuclear industry; Calder Hall was the world's first commercial nuclear power facility when it opened in 1956.

ANNOTATED BIBLIOGRAPHY OF ENERGY SOURCES

Adams, R. N. (1988). *The Eighth Day: Social Evolution as the Self Organization of Energy.* Austin: University of Texas Press.

An anthropologist's view of the role of energy in shaping human institutions and culture.

Adelman, M. A. (1990). Mineral depletion, with special reference to petroleum. *The Review of Economics and Statistics* 72, 1–10.

A renowned resource economist studies the economics of petroleum supply.

Alexander, R. M. (1999). *Energy for Animal Life*. Oxford: Oxford University Press.

A good overview of the ways in which animals capture and allocate energy.

Arntzen, C. J., Dale, B. E. *et al*. (2000). *Biobased Industrial Products*. Washington, D.C.: National Academy Press.

A thorough overview of chemicals and other products produced from biomass.

Ayres, R. U. (1978). *Resources, Environment, and Economics: Applications of the Materials/Energy Balance Principle*. New York: John Wiley and Sons.

A thermodynamic analysis of economic production, substitution, technical change, resource depletion and pollution.

Barnett, H. J., and Morse, C. (1963). *Scarcity and Growth: The Economics of Natural Resource Availability, Resources for the Future*. Baltimore and London: The Johns Hopkins Press.

The first empirical analysis of the scarcity of energy and other natural resources in the United States from 1870 to 1957.

Berndt, E. R. (1978). Aggregate energy, efficiency, and productivity measurement. *Annual Review of Energy* 3, 225–273.

An insight into the issue of energy quality and its implications for understanding energy efficiency.

Blem, C. R. (2000). Energy balance. In *Sturkie's Avian Physiology* (G. C. Whittow, ed.), pp. 327–343. New York: Academic Press.

An authoritative description of bird energetics, with an emphasis on the energy costs and benefits of migration.

Bormann, F. H. (1976). An inseparable linkage: Conservation of natural ecosystems and the conservation of fossil energy. *BioScience* 26, 754–760.

A classic analysis of the link between fossil fuel use and the degradation of essential ecosystem services.

Brady, R. N. (1996). *Modern Diesel Technology.* Englewood Cliffs, New Jersey: Prentice Hall.

A good technical introduction to the subject of diesel engines.

Brander, J. A., and Taylor, M. S. (1998). The simple economics of Easter Island: A Ricardo-Malthus model of renewable resource use. *American Economic Review* 88(1), 119–138.

An economist's perspective on the single most well-studied collapse of a human society, the decline in the population and culture of Easter Island.

Bruce, N., Perez-Padilla, R., and Albalak, R. (2000). Indoor air pollution in developing countries: A major environmental and public health challenge. *Bulletin of the World Health Organization* 78, 1078–1092.

A review of the major health threat from indoor air pollution, much of which is driven by the patterns of energy use in developing nations.

Bullard, C., and Herendeen, R. (1975). The energy cost of goods and services. *Energy Policy* 1, 268–277.

The first use of input–output analysis to quantify energy requirements for various goods and services.

Bullard, C., Fox-Penner, P., and Pilati, D. (1978). Net energy analysis: A handbook for combining process and input–output analysis. *Resources and Energy* 1, 267–313.

A thorough description of quantitative methods for calculating the energy costs of goods and services.

Cardwell, D. S. L. (1971). *From Watt to Clausius: The Rise of Thermodynamics in the Early Industrial Age*. London: Heinemann.

A history of the development of the science of thermodynamics and its practical applications.

Carnahan, W., Ford, K. W., Prosperetti, A., Rochlin, G. I., Rosenfeld, A., Ross, M., Rothberg, J., Seidel, G., and Socolow, R. H. (eds.) (1975). *Efficient Use of Energy, The APS Studies on the Technical Aspects of the More Efficient Use of Energy*. New York: American Institute of Physics.

A group of distinguished physical scientists and engineers look at the potential for energy conservation in the wake of the 1973–1974 energy crisis.

Carnot, S. (1890). *Reflections on the Motive Power of Heat and on Machines Fitted to Develop That Power*. Translated by R. H. Thurston, New York.

Carnot's work was originally published in 1824 and, although long ignored, forms the scientific basis of modern thermodynamics.

Castaneda, C. J. (1999). *Invisible Fuel: Manufactured and Natural Gas in America, 1800–2000*. New York: Twayne Publishers.

An especially strong treatment of the early years of the natural gas industry.

Cipolla, C. M. (1965). *Guns, Sails and Empire: Technological Innovation in the Early Phases of European Expansion, 1400–1700*. New York: Minerva Press.

An excellent historical account of how wind energy, as captured by the sail, has been a pivotal technology in human history.

Clausius, R. J. E. (1867). *The Mechanical Theory of Heat*, 1st ed. (J. Hirst, ed.) London: Van Voorst.

Translated (with additions) from the 1864 German edition, though translators are not specified. Contains Clausius' main thermodynamical papers. The second edition is quite different, however.

Cleveland, C. J. (1992). Energy quality and energy surplus in the extraction of fossil fuels in the U.S. *Ecological Economics* 6, 139–162.

The techniques of net energy analysis applied to U.S. energy resources.

Cleveland, C. J., Costanza, R., *et al.* (1984). Energy and the U.S. economy: A biophysical perspective. *Science* 255, 890–897.

An empirical investigation of the connection between energy, economic growth, and natural resource scarcity.

Costanza, R. (1980). Embodied energy and economic valuation. *Science* 210, 1219–1224.

An examination of how the energy cost of goods and services, including labor and government services, can influence the connection between energy use and economic production.

Cowan, C. W., and Watson, P. J. (eds.) (1992). *The Origins of Agriculture*. Washington, D.C.: Smithsonian Institution Press.

A good overview of the driving forces behind one of the fundamental energy transitions in human history.

Debeir, J. C., Deléage, and J.-P., Hémery, D. (1991) *In the Servitude of Power: Energy and Civilization Through the Ages*. London: Zed Books.

An excellent history of the role of energy conversion technologies and new energy sources in shaping human civilization.

DeCicco, J. M. (2001). *Fuel Cell Vehicles: Technology, Market, and Policy Issues*. Warrendale, Pennsylvania: Society of Automotive Engineers.

A well-executed integration of the issues surrounding the problems and prospects for fuel cell vehicles.

Fox, R. F. (1988). *Energy and the Evolution of Life*. New York: W. H. Freeman and Company.

A description of the role of energy in Earth's early history and in the origin of life.

Freese, B. (2003). *Coal: A Human History*. Cambridge, Massachusetts: Perseus Books.

A social history of the effects of coal use, with emphasis on Britain, the U.S., and China.

Georgescu-Roegen, N. (1971). *The Entropy Law and the Economic Process*. Cambridge, Massachusetts: Harvard University Press.

A comprehensive and technical discussion of economic theory and the economic process as constrained by the laws of thermodynamics.

Gibbons, J. (1997). *This Gifted Age: Science and Technology at the Millennium*. Woodbury, New York: AIP Press.

The potential for energy conservation as seen by one of its earliest proponents.

Gipe, P. (1995). *Wind Energy Comes of Age*. New York: John Wiley and Sons.

A description of the rise of the modern wind industry and its prospects for the future.

Gössling, S. (2000). Sustainable tourism development in developing countries: Some aspects of energy use. *Journal of Sustainable Tourism* 8(5), 410–425.

An overview of energy and environmental issues associated with ecotourism.

Goudsblom, J. (1992). *Fire and Civilization*. London: Allen Lane.

An excellent history of the first and perhaps the most fundamental energy transition in human history.

Gregory, C. E. (2001). *A Concise History of Mining*. Lisse, The Netherlands: A. A. Balkema.

A history of mining with an emphasis on coal.

Griffin, J.M., and Steele, H. B. (1986). *Energy Economics and Policy*, 2nd ed. Orlando, Florida: Academic Press.

One of the few college-level textbooks devoted entirely to energy economics.

Grübler, A., Nakicenovic, N., and Nordhaus, W. D. (eds.) (2002). *Technological Change and the Environment*. Washington, D.C.: RFF Press.

A discussion of the manner in which historic technological change has reduced environmental impact of economic activity, and of future possibilities. Includes extensive climate-related material.

Herendeen, R. (1998). *Ecological Numeracy: Quantitative Analysis of Environmental Issues*. New York: John Wiley and Sons.

Basic quantitative literacy described from an energy and ecological perspective.

Hill, P., and Peterson, C. (1992). *Mechanics and Thermodynamics of Propulsion*, 2nd ed. Reading, Massachusetts: Addison-Wesley.

An engineering treatment of a variety of propulsion technologies, written at the college level.

Hoffmann, P. (2001). *Tomorrow's Energy: Hydrogen, Fuel Cells, and the Prospects for a Cleaner Planet*. Cambridge, Massachusetts: MIT Press.

The technology, economics, and policy aspects of a hydrogen economy.

Home, W. W., with Gittins, M. J. (1984). *The History of Classical Physics: A Selected, Annotated Bibliography*. New York: Garland, New York.

A widely used reference source.

Houghton, J. T., Ding, Y., Griggs, D. J., Noguer, M. P., van der Linden, J., and Xiaosu, D. (eds.) (2001). *Climate Change 2001: The Scientific Basis. Contribution of Working Group I to the Third Assessment Report of the Intergovernmental Panel on Climate Change (IPCC)*. Cambridge, UK: Cambridge University Press.

The authoritative scientific source on the detection, attribution and impacts of climate change.

Hubbert, M. K. (1974). *Energy Resources: A Review as of 1972*. Washington D.C.: U.S. Senate Report 93-40.

The author is the world's most well-known forecaster of oil supplies. This report summarizes the various methods he developed and applied to U.S. oil and gas resources.

Interlaboratory Working Group. (2000). *Scenarios for a Clean Energy Future*. Oak Ridge, Tennessee: Oak Ridge National Laboratory and Berkeley, California: Lawrence Berkeley National Laboratory.

A report that seeks to develop a better understanding of the potential for research and development programs and public policies to foster clean energy technology solutions for the United States.

Jevons, W. S. (1965, originally published 1865). *The Coal Question*. New York: Augustus M. Kelley.

A founder of the neoclassical revolution in economics, Jevons famously but erroneously predicts the collapse of British society due to the depletion of the nation's coal resources.

Johansson, T. B., Kelly, H., Reddy, A. K. N., and Williams, R. H. (eds.) (1993). *Renewable Energy: Sources for Fuels and Electricity*. Washington, D.C.: Island Press.

A thorough overview of the economic, technological, and environmental aspects of renewable energy.

Karl, T. L. (1997). *The Paradox of Plenty: Oil Booms and Petro-States*. Berkeley, California: University of California Press.

A study of the social, economic and political effects of a nation's dependence on oil exports.

Klass, D. L. (1998). *Biomass for Renewable Energy, Fuels, and Chemicals*. San Diego, California: Academic Press.

A thorough and wide-ranging treatment of the sources and conversion pathways of biomass energy into fuels and chemicals.

Lawlor, D. W. (2001). Photosynthesis. New York: Springer-Verlag, USA.

A thorough and detailed treatment of the energetics of photosynthesis.

Leach, G. (1976). *Energy and Food Production*. Surrey, UK: IPC Science and Technology Press.
One of the first quantitative treatments of this subject that uses the techniques of net energy analysis.

Lovins, A. (1976). Energy strategy: The road not taken. *Foreign Affairs* 55, 65–96.
A classic paper by a noted expert on the potential for energy conservation.

McNeill, W. H. (1989). *The Age of Gunpowder Empires, 1450–1800*. Washington, D.C.: American Historical Association.
A history of the development of the technology of gunpowder, and the role it has played in shaping the global geopolitical landscape.

Michalski, L., Eckersdorf, K., and McGhee, J. (1991). *Temperature Measurement*. New York: John Wiley and Sons.
A comprehensive overview of the subject.

Munasinghe, M. (1993). *Environmental Economics and Sustainable Development*. Washington, D.C.: The World Bank.
An integrated look at the economic, environmental, and social dimensions of sustainable development.

Nadel, S., Elliot, N., Shepard, M., Greenberg, S., Katz, G., and de Almeida, A. (2002). *Energy-Efficient Motor Systems*, 2nd ed. Washington, D.C.: American Council for an Energy-Efficient Economy.
A study of how motors and motor systems can achieve greater efficiency through motor management, optimized controls, improved component sizing and repair, better transmission hardware, and comprehensive monitoring and maintenance.

Nagy, K. A., Girard, I. A., and Brown, T. K. (1999). Energetics of free-ranging mammals, reptiles, and birds. *Annual Review of Nutrition* 19, 247–277.
A review of the current state of knowledge on how living organisms use energy.

Nakicenovic, N., Grübler, A., and McDonald, A. (eds.) (1998). *Global Energy Perspectives*. Cambridge, UK: Cambridge University Press (as publisher for the International Institute for Applied Systems Analysis and World Energy Council).
Long-term energy projections from a well-respected energy research group.

Nye, D. E. (1998). *Consuming Power: A Social History of American Energies*. Cambridge, Massachusetts: MIT Press.
An excellent history of the development of electricity in the U.S. and the social and economic consequences thereof.

Priest, J. (2000). *Energy: Principles, Problems, Alternatives*, 5th ed. Dubuque, Iowa: Kendall-Hunt.
An excellent college-level introduction to the basics of energy physics, conversion, sources, use, and technology.

Prigogine, I., and Stengers, I. (1984). *Order Out of Chaos*. New York: Bantam Books.
A physicist's description of how living systems, including human society, dissipate energy to build structure.

Righter, R. W. (1996). *Wind Energy in America: A History*. Norman, Oklahoma: University of Oklahoma Press.
A thorough history of the development of wind power in the U.S.

Sachs, J., and Warner, A. (1999). The big push: Natural resource booms and growth. *Journal of Development Economics* 59, 43–76.
A description of the macroeconomic effects of dependence on oil exports.

Salstrom, P. (1994). *Appalachia's Path to Dependency: Rethinking a Region's Economic History, 1730–1940*. Lexington, Kentucky: University of Kentucky Press.
A history of one of the most famous coal mining regions in the world.

Schipper, L. (ed.) (2000). *The Road from Kyoto: Current CO_2 and Transport Policies in the IEA*. Paris: International Energy Agency.
A review of transport-related CO_2 abatement policies in Denmark, Germany, the Netherlands, Sweden, the United Kingdom, and the United States.

Schurr, S. H. (1984). Energy use, technological change, and productive efficiency: An economic-historical interpretation. *Annual Review of Energy* 9, 409–425.
A good historical overview of the macroeconomic trends in energy use, economic growth and energy efficiency by one of the pioneers of this field of inquiry.

Simmons, I. G. (1996). *Changing the Face of the Earth. Culture, Environment, History*, 2nd ed. Cambridge, Massachusetts: Blackwell Publishers.
An excellent overview of the driving forces of global, regional, and local environmental change, with an insightful energy focus.

Smil, V. (1994). *Energy in World History*. Boulder, Colorado: Westview Press.

Human history as shaped by changes in energy sources and converters.

Smith, C. (1998). *The Science of Energy: A Cultural History of Energy Physics in Victorian Britain*. Chicago: University of Chicago Press.

A history of the development of the branches of physics devoted to the study of basic principles of energy.

Tainter, J. A. (1988). *The Collapse of Complex Societies*. Cambridge, UK: Cambridge University Press.

An insightful description of the role that environmental degradation and diminishing returns to complexity play in the collapse of societies.

Teal, J. M. (1962). Energy flow in the salt marsh ecosystem of Georgia. *Ecology* 43, 614–624.

An early classic study of ecosystem energetics.

Thesing, W. B. (ed.) (2000). *Caverns of Night: Coal Mines in Art, Literature, and Film*. Columbia, South Carolina: University of South Carolina Press.

A study of the social and cultural impacts that coal mining has had on American culture.

Tucker, V. A. (1975). The energetic cost of moving about. *American Scientist* 63(4), 413–419.

A description of the energetics of locomotion.

Turns, S. R. (2000). *An Introduction to Combustion: Concepts and Applications*. New York: McGraw Hill.

A college-level engineering introduction to the subject of combustion.

United Nations Department of Economic and Social Affairs. (2000). *World Energy Assessment*. New York: United Nations Development Programme.

A thorough and sweeping overview of global energy options, with a focus on the role of energy in poverty reduction and the policy interventions needed to shift the global energy system to a sustainable path.

United States Geological Survey. (2000). *World Petroleum Assessment*. Washington, D.C.: USGS.

An exhaustive review of oil and gas availability across the world, with an abundance of useful data and maps.

Verhoogen, J. (1980). *Energetics of the Earth*. Washington, D.C.: National Academy of Sciences.

A detailed examination of energy flows on Earth from a physical science perspective.

Veziroglu, T. N. (2000). A quarter century of the hydrogen movement 1974–2000. *International Journal of Hydrogen Energy* 25, 1143–1150.

A thorough recounting of a quarter-century's progress in hydrogen energy.

Vincent, C. A., and Scrosati, G. (1997). *Modern Batteries*, 2nd ed. London: Edward Arnold.

A good introduction to this important technology.

White, L. (1959). *The Evolution of Culture*. New York: McGraw-Hill.

An anthroplogist's view of the role of energy in shaping human culture.

Wigley, T. M. L. (ed.) (2000). *The Carbon Cycle*. Cambridge, UK: Cambridge University Press.

Leading scientists examine how atmospheric carbon dioxide concentrations have changed in the past and how this may affect the concentrations in the future. They offer approaches to modeling the carbon cycle, providing mathematical tools for predicting future levels of carbon dioxide.

World Energy Council. (2001). *Survey of World Energy Resources*. London: World Energy Council.

This biennial publication provides valuable data on resources and reserves for all forms of energy, as well as individual country profiles.

Yergin, D. (1991). *The Prize: The Epic Quest for Oil, Money and Power*. New York: Simon and Schuster.

The monumental Pulitzer Prize-winning story about the history of oil.

INTERNATIONAL ENERGY DATA ORGANIZATIONS

WORLD ENERGY COUNCIL

http://www.worldenergy.org/

The World Energy Council (WEC) is a global multi-energy organization with member committees in over 90 countries, including most of the largest energy-producing and energy-consuming countries. The 80-year-old organization covers all types of energy, including coal, oil, natural gas, nuclear, hydro, and renewables, and is UN-accredited, nongovernmental, noncommercial, and nonaligned.

One notable publication is the *Survey of World Energy Resources*, which has data on resources, reserves, production, and consumption for conventional and alternative energy sources for most countries in the world. These data are available in HTML and XLS formats, and are free of charge.

INTERNATIONAL ENERGY AGENCY

http://www.iea.org/

The International Energy Agency, based in Paris, is an autonomous agency linked with the Organization for Economic Cooperation and Development (OECD) (http://www.oecd.org/home/).

Notable publications include the *World Energy Outlook*, which assesses current energy conditions and projects energy demand, energy supply, and CO_2 emissions from 20 to 30 years into the future. *Key World Energy Statistics* contains up-to-date data on the supply, transformation, and consumption of all major energy sources. *Energy Balances of OECD Countries* contains data on the supply and consumption of coal, oil, gas, electricity, heat, renewables, and waste presented as comprehensive energy balances expressed in million tonnes of oil equivalent. Historical tables summarize production, trade, and final consumption data as well as key energy and economic indicators. A companion volume, *Energy Statistics of OECD Countries*, presents corresponding data in comprehensive balances expressed in a common unit, million tonnes of oil equivalent. The IEA charges a fee for most of its data.

UNITED NATIONS STATISTICS DIVISION

http://unstats.un.org/unsd/energy/default.htm

The United Nations Statistics Division (UNSD) collects energy statistics and updates and maintains the Energy Statistics Database, which contains comprehensive energy statistics on more than 215 countries, regions, and areas for production, trade, and intermediate and final consumption (end use) for primary and secondary conventional, nonconventional, and new and renewable sources of energy.

The annual publication *Energy Statistics Yearbook* is a comprehensive collection of international energy statistics that provides a global framework of comparable data on long-term trends in the supply of mainly commercial primary and secondary forms of energy. The biennial publication *Energy Balances and Electricity Profiles* presents energy data for selected countries in a format showing an overall picture of energy production, conversion, and consumption for fuels utilized in the country.

Coal, crude petroleum, and electricity data are collected on a monthly basis and published in the *Monthly Bulletin of Statistics*, and the yearly production, trade, and consumption of commercial energy data are published in the *Statistical Yearbook*. The complete dataset of *Energy Statistics*, covering the period 1950–2000, is available on CD and in electronic format. The UN charges a fee for all of its energy data.

THE WORLD BANK

http://www.worldbank.org/data

The *World Development Indicators* (WDI) is the World Bank's annual compilation of data about development. WDI includes approximately 800 indicators in 87 tables, organized in six sections. Energy data include commercial use, annual growth, GDP per unit and per capita, depletion as share of GDP, net imports, investment in infrastructure, production, traditional fuel use as share of total energy use, and a number of electricity indicators. These data are available in print, CD-ROM, and online versions, and require a fee.

BP STATISTICAL REVIEW OF WORLD ENERGY

http://www.bpamoco.com/centres/energy/index.asp

This publication presents country-level data on energy production, use, prices, and reserves dating back to 1965 and is available in ZIP, XLS, and PDF formats. A new energy charting tool allows the user to view predetermined reports for each type of energy or chart-specific data according to energy type on a regional and annual basis. Charts and graphs can be created as images for exporting. These data are available free of charge.

FOOD AND AGRICULTURE ORGANIZATION

http://www.fao.org

The Food and Agriculture Organization of the United Nations was founded in 1945 with a mandate to raise levels of nutrition and standards of living, to improve agricultural productivity, and to better the condition of rural populations. Today, FAO is one of the largest specialized agencies in the United Nations system and the lead agency for natural resource and rural development. An intergovernmental organization, FAO has 183 member countries plus one member organization, the European Community.

The FAOSTAT database is an online and multilingual database containing over 1 million time-series records covering international statistics in a wide range of natural resource areas, especially forestry, fisheries, agriculture, and land use. Energy data include estimates of wood fuel use, both commercial and traditional. Data are available online (free of charge) and on CD-ROM (fee required).

ORGANIZATION OF PETROLEUM EXPORTING COUNTRIES (OPEC)

http://www.opec.org/

OPEC is an 11 nation organization that supplies a major share of global oil production; the members collectively agree on global oil production and/or price targets. The members are Algeria, Indonesia, Iran, Iraq, Kuwait, Libya, Nigeria, Qatar, Saudi Arabia, United Arab Emirates, and Venezuela.

One notable publication is the *Annual Statistical Bulletin*, which reports data on basic economic and demographic conditions in member countries, as well as detailed data on all aspects of oil production, use, imports, exports, earnings, and so on. Data are available in PDF and ZIP formats, and are free of charge.

ASIA PACIFIC ENERGY RESEARCH CENTRE

http://www.ieej.or.jp/aperc/

The Asia Pacific Energy Research Centre (APERC) was established as an affiliate to the Institute of Energy Economics, Japan. It covers all 21 nations of the Asia Pacific Economic Cooperation (APEC): Australia; Brunei Darussalam; Canada; Chile; People's Republic of China; Hong Kong, China; Indonesia; Japan; Republic of Korea; Malaysia; Mexico; New Zealand; Papua New Guinea; Peru; Philippines; Russia; Singapore; Chinese Taipei; Thailand; United States; and Vietnam.

One notable APERC publication is *Energy Balance Tables for the APEC Energy Demand and Supply Outlook*, which contains data on the trade, price, supply, and consumption of coal, oil, gas, electricity, heat, renewables, and waste presented as comprehensive energy balances for member countries. These data are available in PDF format. The annual *APEC Energy Demand and Supply Outlook* provides forecasts for 20 years out. These data are available free of charge.

ASEAN ENERGY CENTER

http://www.aseanenergy.org/index.htm

This is the energy database for the Association of Southeast Nations (Brunei Darussalam, Cambodia,

Indonesia. Lao PDR, Malaysia, Myanmar, Philippines, Singapore, and Vietnam). It contains data on the trade, price, supply, and consumption of coal, oil, gas, electricity, heat, renewables, and waste presented as comprehensive energy balances. The Energy Reporting Application is a Web-based application for accessing these data. The data also include detailed country profiles. These data are available free of charge.

MIDDLE EAST ECONOMIC SURVEY

http://www.mees.com/

The Middle East Economic Survey (MEES) is an authoritative source on oil and gas in the Middle East. It provides current and recent historical monthly data, OPEC member quotas and production, and spot market quotations for the OPEC reference basket of seven crude oils. Data are in HTML format and free of charge.

ENERGY INFORMATION ADMINISTRATION, U.S. DEPARTMENT OF ENERGY

http://www.eia.doe.gov/

The Energy Information Administration (EIA), created by Congress in 1977, is a statistical, modeling, and analysis agency of the U.S. Department of Energy. It provides policy-independent data, forecasts, and analyses to promote policymaking, efficient markets, and public understanding regarding energy and its interaction with the economy and the environment. Current and historical data for the U.S. are available in HTML, XLS, and PDF formats. Less detailed data are also available for the world in similar formats. Among its more notable publications are the *Annual Energy Outlook*, which forecasts energy market condition 20–25 years out, the *Annual Energy Review,* which includes historical data back to 1949, and the *International Energy Annual*. These data are available free of charge.

AMERICAN PETROLEUM INSTITUTE

http://www.api.org

API is the statistical arm of the U.S. oil and gas industry and represents more than 400 members involved in all aspects of the oil and natural gas industry. Notable data sources include *ACCESS API Online Data* and the *Basic Petroleum Data Book*. These sources include a wide array of data on all aspects of the industry: exploration, drilling, production, use, trade, transportation, refining, reserves, prices, finance and investment, offshore, and stocks for the U.S. Less detailed data sources are available for the world as a whole. The API charges a fee for most of its data.

OIL & GAS JOURNAL ENERGY DATABASE

http://orc.pennnet.com/energydatabase/energydatabase.cfm

This online data service has data for the U.S. on all aspects of the industry: exploration, drilling, production, use, trade, transportation, refining, reserves, prices, finance and investment, offshore, and stocks for the U.S. Data on industry operations appear in three databases: monthly and quarterly, annually, and weekly. Most data can be downloaded. There is a fee for most of these data.

BAKER-HUGHES RIG COUNT

http://www.bakerhughes.com/investor/rig/index.htm

This is the authority on oil and gas drilling and workover rigs around the world. (A rig rotates the drill pipe from surface to drill a new well to explore for, develop, and produce oil or natural gas.) Rig activity is an important business barometer for the drilling industry and its suppliers. The active rig count acts as a leading indicator of demand for products used in drilling, completing, producing, and processing hydrocarbons and represents an upstream indicator of the effort aimed at finding and producing oil and gas. Data are available in PDF and/or XLS formats, and are free of charge.

INTERNATIONAL ATOMIC ENERGY AGENCY

http://www.iaea.org

IAEA's Power Reactor Information System (PRIS) constitutes the most complete data bank on nuclear power reactors in the world. PRIS covers two kinds of data: general and design information on power reactors and information about operating experience with nuclear power plants. These data include

country-level data on electricity generation and the role of nuclear power in national energy budgets. These data are available free of charge.

NUCLEAR ENERGY AGENCY

http://www.nea.fr/

The Nuclear Energy Agency (NEA) is a specialized agency within the Organization for Economic Cooperation and Development (OECD). Notable publications include the annual *Nuclear Energy Data*, which is a compilation of essential statistics on nuclear energy in OECD countries. This provides the reader with a comprehensive overview on the status of and trends in the nuclear power and fuel cycle sector.

Another notable work is the annual *Uranium: Resources, Production and Demand*. This "Red Book," jointly prepared by the Nuclear Energy Agency and the International Atomic Energy Agency, is the foremost world reference on uranium. This world report provides compilations of statistics on resources, exploration, production, and demand for uranium for about 50 countries, and provides an international expert analysis of industry statistics and worldwide projections of nuclear energy growth, uranium requirements, and uranium supply. Both of these publications are available only in print form and require a fee.

WTRG ECONOMICS

http://www.wtrg.com

WTRG Economics gathers data on the oil and gas industry from industry, government, and proprietary sources. This site provides graphical overviews of spot and futures prices for crude oil, heating oil, natural gas, and motor gasoline; drilling and workover rig counts; and other industry barometers. The graphs are available free of charge; other data services require a fee.

NEW YORK MERCANTILE EXCHANGE

http://www.nymex.com

The New York Mercantile Exchange is the largest physical commodity exchange in the world. Here you can find up-to-the-minute and historical data on the spot and futures prices for the energy commodities traded on the exchange: home heating oil, crude oil, motor gasoline, natural gas, propane, coal, and electricity. These data are available free of charge.

WORLD RADIATION DATA CENTRE

http://wrdc-mgo.nrel.gov/

The World Radiation Data Centre (WRDC), located at the Main Geophysical Observatory in St. Petersburg, Russia, serves as a central depository for solar radiation data collected at over 1000 measurement sites throughout the world.

The WRDC centrally collects, archives, and publishes radiometric data from the world to ensure the availability of these data for research by the international scientific community. Data are available on line or via an email query system, and are free of charge. The WRDC archive contains the following measurements (not all observations are made at all sites):

Global solar radiation
Diffuse solar radiation
Downward atmospheric radiation
Sunshine duration
Direct solar radiation (hourly and instantaneous)
Net total radiation
Net terrestrial surface radiation (upward)
Terrestrial surface radiation
Reflected solar radiation
Spectral radiation components (instantaneous fluxes)

SOLAR RADIATION RESOURCE INFORMATION

http://rredc.nrel.gov/solar/

The National Renewable Energy Laboratory (NREL) maintains a substantial database of data pertaining to solar radiation in the United States. These data include the three most common measurements of solar radiation (global horizontal, direct normal, and diffuse horizontal), basic meteorological data, maps, and other data for hundreds of stations. These data are available on hourly, daily, monthly, and annual bases. Some data are available in time-series format. Most data are available online and are free of charge.

MAPS OF RENEWABLE ENERGY RESOURCES

http://www.nrel.gov/gi4s/index_of_maps.html

This site provides dynamically generated maps of renewable energy resources that determine which energy technologies are viable solutions in the United States. The National Renewable Energy Laboratory (NREL) analyzes the resources and inputs the data into the GIS (Geographic Information System). The software package that is being used is an ESRI product called ArcIMS (http://www.esri.com). The following sets of maps are available:

Renewable Energy Atlas of the West: Interactive maps with zoom-in capability that highlight the wind, biomass, geothermal, and solar resources in the 11 western states.

Federal Energy Management Program Maps: Maps showing the market potential for various technologies at federal facilities throughout the country.

Maps of Indian Lands: Created in support of the report Energy Consumption and Renewable Energy Development Potential on Indian Lands by the Energy Information Administration, U.S. Department of Energy.

Solar Maps: Maps of solar radiation resources available for several photovoltaic collector orientations in the United States.

Transportation Technologies: Interactive geographical map of the Clean Cities coalitions boundaries and the Alternative Fuel Station Locator mapping application.

Wind Maps: Maps of gridded wind resource potential are based on wind power density.

INTERNATIONAL GEOTHERMAL ASSOCIATION

http://iga.igg.cnr.it/

The International Geothermal Association (IGA), founded in 1988, is a scientific, educational, and cultural organization established to operate worldwide. It has more than 2000 members in 65 countries.

IGA's objective is to encourage research, development, and utilization of geothermal resources worldwide through the compilation, publication, and dissemination of scientific and technical data and information, both within the community of geothermal specialists and between geothermal specialists and the general public. The IGA Web site has country-level data on geothermal direct use and power generation as well as individual country reports. The data are in HTML format and free of charge.

OREGON INSTITUTE OF TECHNOLOGY GEO-HEAT CENTER

http://geoheat.oit.edu/

Resource and direct use maps for the United States and maps of potential user communities in 10 states in the western United States. Resource maps for the 10 western states are accompanied by county-by-county data on well and spring characteristics and geo-referenced location data. The CD-ROM has data in XLS and CVS format, and requires a modest fee.

SELECTED ENERGY-RELATED TABLES

1. GUIDE TO THE USE OF THE INTERNATIONAL SYSTEM OF UNITS

Source: U.S. National Institute of Standards and Technology

The International System of Units was established in 1960 by the 11th General Conference on Weights and Measures (CGPM). Universally abbreviated SI (from the French Le Système International d'Unités), it is the modern metric system of measurement used throughout the world.

SI units are currently divided into three classes:

- base units
- derived units
- supplementary units

which together form what is called "the coherent system of SI units." The SI also includes prefixes to form decimal multiples and submultiples of SI units.

1.1 SI Units

1.1.1 SI Base Units

Table 1 gives the seven base quantities, assumed to be mutually independent, on which the SI is founded; and the names and symbols of their respective units, called "SI base units." Definitions of the SI base units are given in Section 1.4 to follow.

TABLE 1

SI Base Units

	SI base unit	
Base quantity	Name	Symbol
Length	meter	m
Mass	kilogram	kg
Time	second	s
Electric current	ampere	A
Thermodynamic temperature	kelvin	K
Amount of substance	mole	mol
Luminous intensity	candela	cd

1.1.2 SI Derived Units

Derived units are expressed algebraically in terms of base units or other derived units. The symbols for derived units are obtained by means of the mathematical operations of multiplication and division. For example, the derived unit for the derived quantity molar mass (mass divided by amount of substance) is the kilogram per mole, symbol kg/mol. Additional examples of derived units expressed in terms of SI base units are given in Table 2.

TABLE 2

Examples of SI Derived Units Expressed in Terms of SI Base Units

Derived quantity	Name	Symbol
Area	square meter	m^2
Volume	cubic meter	m^3
Speed, velocity	meter per second	m/s
Acceleration	meter per second squared	m/s^2
Wave number	reciprocal meter	m^{-1}
Mass density (density)	kilogram per cubic meter	kg/m^3
Specific volume	cubic meter per kilogram	m^3/kg
Current density	ampere per square meter	A/m^2
Magnetic field strength	ampere per meter	A/m
Amount-of-substance concentration (concentration)	mole per cubic meter	mol/m^3
Luminance	candela per square meter	cd/m^2

1.1.2.1 SI Derived Units with Special Names and Symbols Certain SI derived units have special names and symbols; these are given in Table 3a and Table 3b.

TABLE 3a

SI Derived Units with Special Names and Symbols, Including the Radian and Steradian

Derived quantity	Special name	Special symbol	Expression in terms of other SI units	Expression in terms of SI base units
Plane angle	radian	rad		$m \cdot m^{-1} = 1$
Solid angle	steradian	sr		$m^2 \cdot m^{-2} = 1$
Frequency	hertz	Hz		s^{-1}
Force	newton	N		$m \cdot kg \cdot s^{-2}$
Pressure, stress	pascal	Pa	N/m^2	$m^{-1} \cdot kg \cdot s^{-2}$
Energy, work, quantity of heat	joule	J	$N \cdot m$	$m^2 \cdot kg \cdot s^{-2}$
Power, radiant flux	watt	W	J/s	$m^2 \cdot kg \cdot s^{-3}$
Electric charge, quantity of electricity	coulomb	C		$s \cdot A$
Electric potential, potential difference, electromotive force	volt	V	W/A	$m^2 \cdot kg \cdot s^{-3} \cdot A^{-1}$
Capacitance	farad	F	C/V	$m^{-2} \cdot kg^{-1} \cdot s^4 \cdot A^2$
Electric resistance	ohm	Ω	V/A	$m^2 \cdot kg \cdot s^{-3} \cdot A^{-2}$
Electric conductance	siemens	S	A/V	$m^{-2} \cdot kg^{-1} \cdot s^3 \cdot A^2$
Magnetic flux	weber	Wb	$V \cdot s$	$m^2 \cdot kg \cdot s^{-2} \cdot A^{-1}$
Magnetic flux density	tesla	T	Wb/m^2	$kg \cdot s^{-2} \cdot A^{-1}$
Inductance	henry	H	Wb/A	$m^2 \cdot kg \cdot s^{-2} \cdot A^{-2}$
Celsius temperature	degree Celsius	°C		K
Luminous flux	lumen	lm	$cd \cdot sr$	$cd \cdot sr^a$
Illuminance	lux	lx	lm/m^2	$m^{-2} \cdot cd \cdot sr^a$

[a] The steradian (sr) is not an SI base unit. However, in photometry the steradian (sr) is maintained in expressions for units.

TABLE 3b

SI Derived Units with Special Names and Symbols Admitted for Reasons of Safeguarding Human Health[a]

Derived quantity	Special name	Special symbol	Expression in terms of other SI units	Expression in terms of SI base units
Activity (of a radionuclide)	becquerel	Bq		s^{-1}
Absorbed dose, specific energy (imparted), kerma	gray	Gy	J/kg	$m^2 \cdot s^{-2}$
Dose equivalent, ambient dose equivalent, directional dose equivalent, personal dose equivalent, equivalent dose	sievert	Sv	J/kg	$m^2 \cdot s^{-2}$

[a] The derived quantities to be expressed in the gray and the sievert have been revised in accordance with the recommendations of the International Commission on Radiation Units and Measurements (ICRU).

Degree Celsius In addition to the quantity thermodynamic temperature (symbol T), expressed in the unit kelvin, use is also made of the quantity Celsius temperature (symbol t) defined by the equation

$$t = T - T_0,$$

where $T_0 = 273.15\,K$ by definition. To express Celsius temperature, the unit degree Celsius, symbol °C, which is equal in magnitude to the unit kelvin, is used; in this case, "degree Celsius" is a special name used in place of "kelvin." An interval or difference of Celsius temperature can, however, be expressed in the unit kelvin as well as in the unit degree Celsius. [Note that the thermodynamic temperature T_0 is exactly 0.01 K below the thermodynamic temperature of the triple point of water.]

1.1.2.2 Use of SI Derived Units with Special Names and Symbols Examples of SI derived units that can be expressed with the aid of SI derived units having special names and symbols (including the radian and steradian) are given in Table 4.

TABLE 4

Examples of SI Derived Units Expressed with the Aid of SI Derived Units Having Special Names and Symbols

Derived quantity	Name	Symbol	Expression in terms of SI base units
Angular velocity	radian per second	rad/s	$m \cdot m^{-1} \cdot s^{-1} = s^{-1}$
Angular acceleration	radian per second squared	rad/s^2	$m \cdot m^{-1} \cdot s^{-2} = s^{-2}$
Dynamic viscosity	pascal second	$Pa \cdot s$	$m^{-1} \cdot kg \cdot s^{-1}$
Moment of force	newton meter	$N \cdot m$	$m^2 \cdot kg \cdot s^{-2}$
Surface tension	newton per meter	N/m	$kg \cdot s^{-2}$
Heat flux density, irradiance	watt per square meter	W/m^2	$kg \cdot s^{-3}$
Radiant intensity	watt per steradian	W/sr	$m^2 \cdot kg \cdot s^{-3} \cdot sr^{-1}$[a]
Radiance	watt per square meter steradian	$W/(m^2 \cdot sr)$	$kg \cdot s^{-3} \cdot sr^{-1}$[a]
Heat capacity, entropy	joule per kelvin	J/K	$m^2 \cdot kg \cdot s^{-2} \cdot K^{-1}$
Specific heat capacity, specific entropy	joule per kilogram kelvin	$J/(kg \cdot K)$	$m^2 \cdot s^{-2} \cdot K^{-1}$
Specific energy	joule per kilogram	J/kg	$m^2 \cdot s^{-2}$
Thermal conductivity	watt per meter kelvin	$W/(m \cdot K)$	$m \cdot kg \cdot s^{-3} \cdot K^{-1}$
Energy density	joule per cubic meter	J/m^3	$m^{-1} \cdot kg \cdot s^{-2}$
Electric field strength	volt per meter	V/m	$m \cdot kg \cdot s^{-3} \cdot A^{-1}$
Electric charge density	coulomb per cubic meter	C/m^3	$m^{-3} \cdot s \cdot A$
Electric flux density	coulomb per square meter	C/m^2	$m^{-2} \cdot s \cdot A$
Permittivity	farad per meter	F/m	$m^{-3} \cdot kg^{-1} \cdot s^4 \cdot A^2$
Permeability	henry per meter	H/m	$m \cdot kg \cdot s^{-2} \cdot A^{-2}$
Molar energy	joule per mole	J/mol	$m^2 \cdot kg \cdot s^{-2} \cdot mol^{-1}$
Molar entropy, molar heat capacity	joule per mole kelvin	$J/(mol \cdot K)$	$m^2 \cdot kg \cdot s^{-2} \cdot K^{-1} \cdot mol^{-1}$
Exposure (x and rays)	coulomb per kilogram	C/kg	$kg^{-1} \cdot s \cdot A$
Absorbed dose rate	gray per second	Gy/s	$m^2 \cdot s^{-3}$

[a] The steradian (sr) is not an SI base unit. However, in radiometry the steradian (sr) is maintained in expressions for units.

1.1.3 Decimal Multiples and Submultiples of SI Units: SI Prefixes

Table 5 gives the SI prefixes that are used to form decimal multiples and submultiples of SI units. A prefix attaches directly to the name of a unit, and a prefix symbol attaches directly to the symbol for a unit. For example, one kilometer, symbol 1 km, is equal to one thousand meters, symbol 1000 m or 10^3 m.

TABLE 5

SI Prefixes

Factor	Prefix	Symbol
$10^{24} = (10^3)^8$	yotta	Y
$10^{21} = (10^3)^7$	zetta	Z
$10^{18} = (10^3)^6$	exa	E
$10^{15} = (10^3)^5$	peta	P
$10^{12} = (10^3)^4$	tera	T
$10^9 = (10^3)^3$	giga	G
$10^6 = (10^3)^2$	mega	M
$10^3 = (10^3)^1$	kilo	k
10^2	hecto	h
10^1	deka	da
10^{-1}	deci	d
10^{-2}	centi	c
$10^{-3} = (10^3)^{-1}$	milli	m
$10^{-6} = (10^3)^{-2}$	micro	μ
$10^{-9} = (10^3)^{-3}$	nano	n
$10^{-12} = (10^3)^{-4}$	pico	p
$10^{-15} = (10^3)^{-5}$	femto	f
$10^{-18} = (10^3)^{-6}$	atto	a
$10^{-21} = (10^3)^{-7}$	zepto	z
$10^{-24} = (10^3)^{-8}$	yocto	y

1.2 Units Outside the SI

Certain units that are not part of the SI are essential and used so widely that they are generally accepted for use with the SI. These units are given in Table 6. The combination of units of this table with SI units to

TABLE 6

Units Accepted for Use with the SI

Name	Symbol	Value in SI units
Minute (time)	min	1 min = 60 s
Hour (time)	h	1 h = 60 min = 3600 s
Day (time)	d	1 d = 24 h = 86,400 s
Degree (plane angle)	°	$1^\circ = (\pi/180)$ rad
Minute (plane angle)	′	$1' = (1/60)^\circ = (\pi/10{,}800)$ rad
Second (plane angle)	″	$1'' = (1/60) = (\pi/648{,}000)$ rad
Liter	l, L (b)	$1\,L = 1\,dm^3 = 10^{-3}\,m^3$
Metric ton[a]	t	$1\,t = 10^3\,kg$

[a] This is the name to be used for this unit in the United States; it is also used in some other English-speaking countries. However, this unit is called “tonne” in many countries.

form derived units should be restricted to special cases in order not to lose the advantages of the coherence of SI units.

1.3 Units Temporarily Accepted for Use with the SI

Because of existing practice in certain fields or countries, in 1978 the CIPM considered that it was permissible for the units given in Table 7 to continue to be used with the SI until the CIPM considers that their use is no longer necessary.

TABLE 7

Units Temporarily Accepted for Use with the SI

Name[a]	Symbol	Value in SI units
nautical mile	-	1 nautical mile = 1852 m
knot	-	1 nautical mile per hour = (1852/3600) m/s
ångström	Å	$1\ \text{Å} = 0.1\ \text{nm} = 10^{-10}\ \text{m}$
are	a	$1\ \text{a} = 1\ \text{dam}^2 = 10^2\ \text{m}^2$
hectare[a]	ha	$1\ \text{ha} = 1\ \text{hm}^2 = 10^4\ \text{m}^2$
barn	b	$1\ \text{b} = 100\ \text{fm}^2 = 10^{-28}\ \text{m}^2$
bar	bar	$1\ \text{bar} = 0.1\ \text{Mpa} = 100\ \text{kPa} = 1000\ \text{hPa} = 10^5\ \text{Pa}$
gal	Gal	$1\ \text{Gal} = 1\ \text{cm/s}^2 = 10^{-2}\ \text{m/s}^2$
curie	Ci	$1\ \text{Ci} = 3.7 \times 10^{10}\ \text{Bq}$
roentgen	R	$1\ \text{R} = 2.58 \times 10^{-4}\ \text{C/kg}$
rad	rad[b]	$1\ \text{rad} = 1\ \text{cGy} = 10^{-2}\ \text{Gy}$
rem	rem	$1\ \text{rem} = 1\ \text{cSv} = 10^{-2}\ \text{Sv}$

[a] This unit and its symbol are used to express agrarian areas.
[b] When there is risk of confusion with the symbol for the radian, rd may be used as the symbol for rad.

1.4 Definitions of the SI Base Units and the Radian and Steradian

Meter The meter is the length of the path travelled by light in vacuum during a time interval of 1/299,792,458 of a second.

Kilogram The kilogram is the unit of mass; it is equal to the mass of the international prototype of the kilogram.

Second The second is the duration of 9,192,631,770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium-133 atom.

Ampere The ampere is that constant current that, if maintained in two straight parallel conductors of infinite length, of negligible circular cross section, and placed 1 meter apart in vacuum, would produce between these conductors a force equal to 2×10^{-7} newton per meter of length.

Kelvin The kelvin, a unit of thermodynamic temperature, is the fraction 1/273.16 of the thermodynamic temperature of the triple point of water.

Mole The mole is the amount of substance of a system that contains as many elementary entities as there are atoms in 0.012 kilogram of carbon 12. When the mole is used, the elementary entities must be specified and may be atoms, molecules, ions, electrons, other particles, or specified groups of such particles. In the definition of the mole, it is understood that reference is being made to unbound atoms of carbon 12, at rest and in their ground state. Note that this definition specifies at the same time the nature of the quantity whose unit is the mole.

Candela The candela is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency 540×10^{12} hertz and that has a radiant intensity in that direction of (1/683) watt per steradian.

Radian The radian is the plane angle between two radii of a circle that cut off on the circumference an arc equal in length to the radius.

Steradian The steradian is the solid angle that, having its vertex in the center of a sphere, cuts off an area of the surface of the sphere equal to that of a square with sides of length equal to the radius of the sphere.

1.5 A Brief History of the International System of Units

The creation of the decimal metric system at the time of the French Revolution and the subsequent deposition of two platinum standards representing the meter and the kilogram, on June 22, 1799, in the Archives de la République in Paris can be seen as the first step in the development of the present International System of Units.

In 1832, Gauss strongly promoted the application of this metric system, together with the second defined in astronomy, as a coherent system of units for the physical sciences. Gauss was the first to make *absolute* measurements of the earth's magnetic force in terms of a decimal system based on the *three mechanical units* millimeter, gram, and second for the quantities length, mass, and time, respectively. In later years, Gauss and Weber extended these measurements to include electrical phenomena.

These applications in the field of electricity and magnetism were further developed in the 1860s under the active leadership of Maxwell and Thomson through the British Association for the Advancement of Science (BAAS). They formulated the requirement for a *coherent system of units* with *base* units and *derived* units. In 1874 the BAAS introduced the *CGS system,* a three-dimensional coherent unit system based on the three mechanical units centimeter, gram, and second, using prefixes ranging from micro to mega to express decimal submultiples and multiples. The following development of physics as an experimental science was largely based on this system.

The sizes of the coherent CGS units in the fields of electricity and magnetism proved to be inconvenient, so in the 1880s the BAAS and the International Electrical Congress, predecessor of the International Electrotechnical Commission (IEC), approved a mutually coherent set of *practical units*. Among them were the ohm for electrical resistance, the volt for electromotive force, and the ampere for electric current.

After the establishment of the Meter Convention on May 20, 1875, the CIPM concentrated on the construction of new prototypes taking the meter and kilogram as the base units of length and mass. In 1889 the first CGPM sanctioned the international prototypes for the meter and the kilogram. Together with the astronomical second as unit of time, these units constituted a three-dimensional mechanical unit system similar to the CGS system, but with the base units meter, kilogram, and second.

In 1901 Giorgi showed that it is possible to combine the mechanical units of this meter–kilogram–second system with the practical electric units to form a single, coherent, four-dimensional system by adding to the three base units a fourth base unit of an electrical nature, such as the ampere or the ohm, and rewriting the equations occurring in electromagnetism in the so-called rationalized form. Giorgi's proposal opened the path to a number of new developments.

After the revision of the Meter Convention by the sixth CGPM in 1921, which extended the scope and responsibilities of the BIPM to other fields in physics, and the subsequent creation of the CCE (now CCEM) by the seventh CGPM in 1927, the Giorgi proposal was thoroughly discussed by the IEC, the IUPAP, and other international organizations. This led the CCE to recommend, in 1939, the adoption of a four-dimensional system based on the meter, kilogram, second, and ampere, a proposal approved by the CIPM in 1946.

Following an international inquiry by the BIPM, which began in 1948, the 10th CGPM, in 1954, approved the introduction of the *ampere,* the *kelvin*, and the *candela* as base units for electric current, thermodynamic temperature, and luminous intensity, respectively. The name *International System of Units* (*SI*) was given to the system by the 11th CGPM in 1960. At the 14th CGPM in 1971, the current version of the SI was completed by adding the *mole* as base unit for amount of substance, bringing the total number of base units to seven.

2. COMMON SYMBOLS AND UNITS

Greek alphabet

A	**α**	alpha	I	**ι**	iota	P	**ρ**	rho
B	**β**	beta	K	**κ**	kappa	**Σ**	**σ ς**	sigma
Γ	**γ**	gamma	**Λ**	**λ**	lambda	T	**τ**	tau
Δ	**δ ∂**	delta	M	**μ**	mu	**Υ**	**υ**	upsilon
E	**ε**	epsilon	N	**ν**	nu	**Φ**	**ϕ φ**	phi
Z	**ζ**	zeta	**Ξ**	**ξ**	xi	X	**χ**	chi
H	**η**	eta	O	*o*	omicron	**Ψ**	**ψ**	psi
Θ	**θ ϑ**	theta	**Π**	**π**	pi	**Ω**	**ω**	omega

International system of unit prefixes

Prefix	Symbol	Multiple
exa	(E)	10^{18} (quintillions)
peta	(P)	10^{15} (quadrillions)
tera	(T)	10^{12} (trillions)
giga	(G)	10^{9} (billions)
mega	(M)	10^{6} (millions)
kilo	(k)	10^{3} (thousands)
hecto	(h)	10^{2} (hundreds)
deka	(da)	10^{1} (tens)
deci	(d)	10^{-1} (tenths)
centi	(c)	10^{-2} (hundredths)
milli	(m)	10^{-3} (thousandths)
micro	(μ)	10^{-6} (millionths)
nano	(n)	10^{-9} (billionths)
pico	(p)	10^{-12} (trillionths)
femto	(f)	10^{-15} (quadrillionths)
atto	(a)	10^{-18} (quintillionths)

International system derived units

Quantity	Name	Symbol	Dimension
Capacitance	farad	F	$A^2 s^4 kg^{-1} m^{-2}$
Charge	coulomb	C	A s
Conductance	siemens	S	$kg^{-1} m^{-2} s^3 A^2$ or Ω^{-1}
Energy	joule	J	$kg\,m^2\,s^{-2}$
Force	newton	N	$kg\,m\,s^{-2}$
Magnetic flux	tesla	T	$kg\,s^{-2}\,A^{-1}$
Polarizability		α	$A^2 s^4 kg^{-1}$
Potential	volt	V	$kg\,m^2\,s^{-3}\,A^{-1}$
Power	watt	W	$kg\,m^2\,s^{-3}$
Pressure	pascal	Pa	$kg\,m^{-1}\,s^{-2}$
Resistance	ohm	Ω	$kg\,m^2\,s^{-3}\,A^{-2}$

3. FUNDAMENTAL PHYSICAL CONSTANTS[a]

General Constants

Symbol	Quantity	Value	Units	Relative uncertainty (ppm)
Universal constants				
G	Newtonian constant of gravitation	6.672 59 (85)	$10^{-11}\,m^3\,kg^{-1}\,s^{-2}$	128
μ_0	permeability of vacuum	$4\pi \times 10^{-7}$	$N\,A^{-2}$	
		$\approx 12.566\,370\,614$	$10^{-7}\,N\,A^{-2}$	
ε_0	permittivity of vacuum	$1/\mu_0 c^2$		
		$\approx 8.854\,187\,817$	$10^{-12}\ F\,m^{-1}$	
h	Planck constant	6.626 0755 (40)	10^{-34} Js	0.60
	in electron volts, $h/\{e\}$	4.135 6692 (12)	10^{-15} eVs	0.30
$\hbar$	$h/2\pi$	1.054 572 66 (63)	10^{-34} Js	0.60
	in electron volts, $\hbar/\{e\}$	6.582 1220 (20)	10^{-16} eVs	0.30
l_P	Planck length, $\hbar/m_P c = (\hbar G/c^3)^{1/2}$	1.616 05 (10)	10^{-35} m	64
m_P	Planck mass, $(\hbar c/G)^{1/2}$	2.176 71 (14)	10^{-8} kg	64
t_P	Planck time, $l_P/c = (\hbar G/c^5)^{1/2}$	5.390 56 (34)	10^{-44} s	64
c	speed of light in vacuum	2.997 924 58	$10^8\ ms^{-1}$	
Electromagnetic constants				
μ_B	Bohr magneton, $e\hbar/2m_e$	9.274 0154 (31)	$10^{-24}\,J\,T^{-1}$	0.34
	in electron volts, $\mu_B/\{e\}$	5.788 382 63 (52)	$10^{-5}\,eV\,T^{-1}$	0.089
	in hertz, μ_B/h	1.399 624 18 (42)	$10^{10}\,Hz\,T^{-1}$	0.30
	in kelvins, μ_B/k	0.671 7099 (57)	$K\,T^{-1}$	8.5
	in wavenumbers, μ_B/hc	46.686 437 (14)	$m^{-1}\,T^{-1}$	0.30
e	elementary charge	1.602 177 33 (49)	10^{-19} C	0.30
$2e/h$	Josephson frequency–voltage ratio	4.835 9767 (14)	$10^{14}\,Hz\,V^{-1}$	0.30
Φ_0	magnetic flux quantum, $h/2e$	2.067 834 61 (61)	10^{-15} Wb	0.30
μ_N	nuclear magneton, $e\hbar/2m_P$	5.050 7866 (17)	$10^{-27}\,J\,T^{-1}$	0.34
	in election volts, $\mu_N/\{e\}$	3.152 451 66(28)	$10^{-8}\,eV\,T^{-1}$	0.089
	in hertz, μ_N/h	7.622 5914 (23)	$MHz\,T^{-1}$	0.30
	in kelvins, μ_N/k	3.658 246 (31)	$10^{-4}\,K\,T^{-1}$	8.5
	in wavenumbers, μ_N/hc	2.542 622 81 (77)	$10^{-2}\,m^{-1}\,T^{-1}$	0.30
e^2/h	quantized Hall conductance	3.874 046 14 (17)	10^{-5} S	0.045
R_H	quantized Hall resistance, $h/e^2 = \mu_0 c/2\alpha$	25,812.8056 (12)	Ω	0.045

Atomic Constants

Symbol	Quantity	Value	Units	Relative uncertainty (ppm)
a_0	Bohr radius, $\alpha/4\pi\,R_\infty$	0.529 177 249 (24)	10^{-10} m	0.045
α	fine-structure constant, $\mu_0 c e^2/2h$	7.297 353 08 (33)	10^{-3}	0.045
α^{-1}	inverse fine-structure constant	137.035 9895 (61)		0.045
E_h	Hartree energy, $e^2/4\pi\varepsilon_0 a_0 = 2R_\infty hc$	4.359 7482 (26)	10^{-18} J	0.60
	in eV, $E_h/\{e\}$	27.211 3961 (81)	eV	0.30

[a] Recommended values for fundamental physical constants; adapted from E. R. Cohen and B. N. Taylor from *CODATA Bulletin*, number 63, November 1986, and *Journal of Research of the National Bureau of Standards*, volume 92, number 2, pages 85–95, 1987. Values in bold are exact. In parentheses is the one-standard-deviation uncertainty of the final digit of a given value.

4. CONVERSION FACTORS FOR THE INTERNATIONAL SYSTEM OF UNITS

Source: U.S. National Institute of Standards and Technology

4.1 Introduction

Section 4.6 gives factors for converting values of quantities expressed in various units—predominantly units outside the SI that are unacceptable for use with it—to values expressed either in (a) SI units, (b) units that are accepted for use with the SI (especially units that better reflect the nature of the unconverted units), (c) units formed from such accepted units and SI units, or (d) decimal multiples or submultiples of the units of (a) to (c) that yield numerical values of convenient magnitudes.

4.2 Notation

The factors given in Section 4.6 are written as a number equal to or greater than 1 and less than 10, with 6 or fewer decimal places. The number is followed by the letter E, which stands for exponent, a plus (+) or minus (–) sign, and two digits which indicate the power of 10 by which the number is multiplied. For example,

$$3.523\,907\,\mathrm{E}-02 \text{ means } 3.523\,907 \times 10^{-2} = 0.035\,239\,07$$

$$3.386\,389\,\mathrm{E}+03 \text{ means } 3.386\,389 \times 10^{3} = 3386.389$$

A factor in boldface is exact. All other factors have been rounded to the significant digits given in accordance with accepted practice. Where less than six digits after the decimal place are given, the unit does not warrant a greater number of digits in its conversion. However, for the convenience of the user, this practice is not followed for all such units, including the cord, cup, quad, and teaspoon.

4.3 Use of Conversion Factors

Each entry in Section 4.6 is to be interpreted as in these two examples:

To convert from	To	Multiply by
atmosphere, standard (atm)	pascal (Pa)	1.013 25 E+05
cubic foot per second (ft^3/s)	cubic meter per second (m^3/s)	2.831 685 E–02

means

$$1\ \text{atm} = 101\,325\ \text{Pa}\ \ \text{(exactly)}$$
$$1\ \text{ft}^3/\text{s} = 0.028\,316\,85\ \text{m}^3/\text{s}$$

Thus to express, for example, the pressure $p = 11.8$ standard atmospheres (atm) in pascals (Pa), write

$$p = 11.8\ \text{atm} \times 101\,325\ \text{Pa/atm}$$

and obtain the converted numerical value $11.8 \times 101\,325 = 1\,195\,635$ and the converted value $p = 1.20$ MPa.

4.4 Factor for Converting Motor Vehicle Efficiency

The efficiency of motor vehicles in the United States is commonly expressed in miles per U.S. gallon, while in most other countries it is expressed in liters per one hundred kilometers. To convert fuel economy stated in miles per U.S. gallon to fuel consumption expressed in L/(100 km), divide 235.215 by the numerical value of the stated fuel economy. Thus 24 miles per gallon corresponds to 9.8 L/(100 km).

4.5 U.S. Survey Foot and Mile

The U.S. Metric Law of 1866 gave the relationship 1 m = 39.37 in ("in" is the unit symbol for the inch). From 1893 until 1959, the yard was defined as being exactly equal to (3600/3937) m, and thus the foot was defined as being exactly equal to (1200/3937) m.

In 1959 the definition of the yard was changed to bring the U.S. yard and the yard used in other countries into agreement. Since then the yard has been defined as exactly equal to 0.9144 m, and thus the foot has been defined as exactly equal to 0.3048 m. At the same time it was decided that any data expressed in feet derived from geodetic surveys within the United States would continue to bear the relationship as defined in 1893, namely, 1 ft = (1200/3937) m (ft is the unit symbol for the foot). The name of this foot is "U.S. survey foot," while the name of the new foot defined in 1959 is "international foot." The two are related to each other through the expression 1 international foot = 0.999 998 U.S. survey foot exactly.

In Section 4.6, the factors given are based on the international foot unless otherwise indicated. Readers may also find the following summary of exact relationships helpful, where for convenience the symbols *ft* and *mi,* that is, ft and mi in italic type, indicate that it is the *U.S. survey foot* or *U.S. survey mile* that is meant rather than the international foot (ft) or international mile (mi), and where rd is the unit symbol for the rod and fur is the unit symbol for the furlong.

1 *ft* = (1200/3937) m
1 ft = 0.3048 m
1 ft = 0.999 998 *ft*
1 rd, pole, or perch = 161/2 *ft*
40 rd = 1 fur = 660 *ft*
8 fur = 1 U.S. survey mile (also called "statute mile") = 1 *mi* = 5280 *ft*
1 fathom = 6 *ft*
1 international mile = 1 mi = 5280 ft
2721/4 ft^2 = 1 rd^2
160 rd^2 = 1 acre = 43 560 ft^2
640 acre = 1 mi^2

4.6 Factors for Units Listed Alphabetically

Factors in boldface are exact.

5. ENERGY CONVERSION EFFICIENCIES

Efficiencies of Common Anthropogenic and Natural Energy Conversions[a]

Conversion	Energies[b]	Efficiencies
Large electricity generators	$m \rightarrow e$	98–99
Large power plant boilers	$c \rightarrow t$	90–98
Large electric motors	$e \rightarrow m$	90–97
Best home natural gas furnaces	$c \rightarrow t$	90–96
Dry-cell batteries	$c \rightarrow e$	85–95
Home gas furnace	$c \rightarrow t$	85
Human lactation	$c \rightarrow c$	75–85
Overshot waterwheels	$m \rightarrow m$	60–85
Small electric motors	$e \rightarrow m$	60–75

Continues

Table continued

Conversion	Energies[b]	Efficiencies
Best bacterial growth	$c \rightarrow c$	50–65
Glycolysis maxima	$c \rightarrow c$	50–60
Home oil furnace	$c \rightarrow t$	60
Fluidized bed coal combustion	$c \rightarrow e$	40–50
Integrated gasification combined cycle	$c \rightarrow e$	40–50
Large steam turbines	$t \rightarrow m$	40–45
Improved wood stoves	$c \rightarrow t$	25–45
Large gas turbines	$c \rightarrow m$	35–40
Fossil fuel electric generating plant	$c \rightarrow e$	30–40
Charcoal production—earth kiln	$c \rightarrow c$	20–40
Modern wind turbine	$m \rightarrow e$	40
Diesel engines	$c \rightarrow m$	30–35
Mammalian postnatal growth	$c \rightarrow c$	30–35
Best photovoltaic cells	$r \rightarrow e$	20–30
Best large steam engines	$c \rightarrow m$	20–25
Internal combustion engines	$c \rightarrow m$	15–25
High-pressure sodium lamps	$e \rightarrow r$	15–20
Mammalian muscles	$c \rightarrow m$	15–20
Milk production	$c \rightarrow c$	15–20
Pregnancy	$c \rightarrow c$	10–20
Fluorescent lights	$e \rightarrow r$	10–20
Broiler production	$c \rightarrow c$	10–15
Traditional stoves	$c \rightarrow t$	10–15
Beef production	$c \rightarrow c$	5–10
Steam locomotives	$c \rightarrow m$	3–6
Peak field photosynthesis	$r \rightarrow c$	4–5
Incandescent light bulbs	$e \rightarrow r$	2–5
Paraffin candles	$c \rightarrow r$	1–2
Most productive ecosystems	$r \rightarrow c$	1–2
Global photosynthetic mean	$r \rightarrow c$	0.3

[a]All ranges are the first-law efficiencies in percent.
[b]Energy labels: c = chemical, e = electrical, m = mechanical (kinetic), r = radiant (electromagnetic, solar), t = thermal.

6. MASS-ENERGY EQUIVALENTS

Mass-Energy Equivalence

1 electron mass	1 atomic mass unit (amu)	1 gram (g)	1 kilogram (kg)
0.511 MeV	931.5 MeV	5.61×10^{26} MeV	5.61×10^{29} MeV
8.187×10^{-14} J	1.492×10^{-10} J	8.988×10^{13} J	8.988×10^{16} J
7.765×10^{-17} BTU	1.415×10^{-13} BTU	8.524×10^{10} BTU	8.524×10^{13} BTU
2.274×10^{-20} kWh	4.146×10^{-17} kWh	2.497×10^{7} kWh	2.497×10^{10} kWh
7.765×10^{-35} Q	1.415×10^{-31} Q	8.524×10^{-8} Q	8.524×10^{-5} Q

Continues

Table continued

1 ton	1 MeV	1 joule (J)	1 BTU
5.089×10^{32} MeV	1.957 electron masses	1.221×10^{13} electron masses	1.288×10^{16} electron masses
8.153×10^{19} J	1.074×10^{-3} amu	6.701×10^{9} amu	7.065×10^{12} amu
7.733×10^{16} BTU	1.783×10^{-27} g	1.113×10^{-14} g	1.173×10^{-11} g
2.265×10^{13} kWh	1.783×10^{-30} kg	1.113×10^{-17} kg	1.173×10^{-14} kg
7.733×10^{-2} Q	1.965×10^{-33} ton	1.226×10^{-20} ton	1.293×10^{-17} ton

	1 kilowatt-hour (kWh)	1 Q
	4.397×10^{19} electron masses	1.288×10^{34} electron masses
	2.412×10^{16} amu	7.065×10^{30} amu
	4.006×10^{-8} g	1.173×10^{7} g
	4.006×10^{-11} kg	1.173×10^{4} kg
	4.415×10^{-14} ton	12.93 tons

Note. This table can be used to calculate the energy released in a process in which the mass decreases by a known amount. This table cannot be used directly to calculate, for example, the energy available from a given quantity of U^{235}, because in the fission of 1 kg of U^{235}, the decrease in mass is much less than 1 kg.

7. CONVERSION SCHEME FOR COMMON ENERGY DEVICES

Device	Energy input	Useful output
Electric heater	Electricity	Thermal energy
Hair dryer	Electricity	Thermal energy
Electric generator	Mechanical energy	Electricity
Electric motor	Electricity	Mechanical energy
Battery	Chemical energy	Electricity
Steam boiler	Chemical energy	Thermal energy
Furnace	Chemical energy	Thermal energy
Steam turbine	Thermal energy	Mechanical energy
Gas turbine	Chemical energy	Mechanical energy
Automobile engine	Chemical energy	Mechanical energy
Fluorescent lamp	Electricity	Light
Silicon solar cell	Solar energy	Electricity
Steam locomotive	Chemical	Mechanical
Incandescent lamp	Electricity	Light

8. ENERGY FLOWS AND STORAGES

Energy flow or storage[a]	Actual multiple (J)	Order of magnitude
Solar radiation intercepted by the Earth[b]	5.5	24
Global coal resources	2	23

[a]LPG is a blend of multiple paraffinic hydrocarbons: ethane, propane, isobutane, and normal butane, each with their own heat content, density, and carbon content.

[b]Parameters presented are for naphthas with a boiling temperature less than 400 degrees Fahrenheit. Petrochemical feedstocks with higher boiling points are assumed to have the same characteristics as distillate fuel.

— no sample data available.

11. PROPERTIES OF GASEOUS FUELS

Energy source	Heat content (million Btu/barrel)
Petrochemical feedstocks	
Naphtha less than 401°F	5.248
Other oils equal to or greater than 401°F	5.825
Still gas	6.000
Petroleum coke	6.024
Plant condensate	5.418
Propane	3.836
Residual fuel oil	6.287
Road oil	6.636
Special naphthas	5.248
Still gas	6.000
Unfinished oils	5.825
Unfractionated stream	5.418
Waxes	5.537
Miscellaneous	5.796

Source. U.S. Department of Energy.

[a]Fuel ethanol, which is derived from agricultural feedstocks (primarily corn), is not a petroleum product but is blended into motor gasoline. Its gross heat content (3.539 million Btu per barrel) is used in *Annual Energy Review* calculations; its net heat content (3.192 million Btu per barrel) is used in the Energy Information Administration's *Renewable Energy Annual* calculations.

13. TYPICAL ENERGY CONTENT OF FOSSIL AND BIOMASS FUELS

Solid fuels	Net heating values (MJ/kg)
Biomass fuels	
Wood (wet, freshly cut)	10.9
Wood (air dry, humid zone)	15.5
Wood (air dry, dry zone)	16.6
Wood (oven dry)	20.0

Sources. World Energy Council, Survey of Energy Resources 2001, October 2001. United States: Energy Information Administration. Unpublished file data of the Coal Reserves Data Base (February 2002).

Notes. Formerly entitled "World Estimated Recoverable Reserves of Coal." The estimates in this table are dependent on the judgment of each reporting country to interpret local economic conditions and its own mineral assessment criteria in terms of specified standards of the World Energy Council. Consequently, the data may not all meet the same standards of reliability and some data, including the Energy Information Administration's (EIA)'s, may not represent reserves of coal that are known to be recoverable under current economic conditions and regulations. Some data, including the EIA's, represent estimated recovery rates for highly reliable estimates of coal quantities in the ground that have physical characteristics like those of coals currently being profitably mined. U.S. coal rank approximations are based partly on Btu and may not match precisely borderline geologic ranks. Further, data in this table may represent different base years. Data for the U.S. represent recoverable coal estimates as of December 31, 2000. Data for countries are as of December 31, 1999, the most recent period for which they are available. The Energy Information Administration does not certify the International reserves data but reproduces the information as a matter of convenience for the reader. Sum of components may not equal total due to independent rounding.

[a]World Energy Council definition of "Proved Recoverable Reserves" the tonnage within the Proved Amount in Place that can be recovered (extracted from the earth in raw form) under present and expected local economic conditions with existing available technology.

[b]Data represent both measured and indicated tonnage, as of January 1, 2001 (equated to December 31, 2000). The U.S. term "measured" approximates the term "proved" used by the World Energy Council. The U.S. "measured and indicated" data have been combined prior to depletion adjustments and cannot be recaptured as "measured alone."

Sources. Data from PennWell Publishing Co., Oil and Gas Journal Vol. 99, No. 52 (December 2001); Gulf Publishing Co., World Oil Vol. 223, No. 8 (August 2002); Energy Information Administration, U.S. Crude Oil, Natural Gas, and Natural Gas Liquids Reserves, 2001 Annual Report, DOE/EIA-0216 (2001) (November 2002). Table modified from Energy Information Administration/International Energy Annual 2001.

Notes. Sum of components may not equal total due to independent rounding. All reserve data except those for the Former U.S.S.R. and natural gas reserves in Canada are proved reserves. Former U.S.S.R. data are "explored reserves," which are understood to be proved, and some probable. World Oil only reported disaggregated data for the Former U.S.S.R. Republic of Russia. Aggregated data for the other Republics of the Former U.S.S.R. were reported as 11.5 billion barrels of crude oil and 235.2 trillion cubic feet of natural gas.

[a]Data for the United States are from the Energy Information Administration.

[b]Includes one-half of the reserves in the Neutral Zone.

NA, not available; (s), value less than 50 million barrels of crude oil or less than 50 billion cubic feet of natural gas.

Sources. WEC Member Committees, 2000/2001; *Hydropower and Dams World Atlas 2001*, supplement to The International Journal on Hydropower and Dams, Aqua-Media International; estimates by the editors.

Note. A quantification of hydropower capability is not available for Comoros, Equatorial Guinea, Mauritania, Réunion, São Tomé and Principe, Guadeloupe, Puerto Rico, St. Vincent and the Grenadines, French Guiana, Afghanistan, Korea (Democratic People's Republic), New Caledonia, and Palau. As the data available on economically exploitable capability do not cover all countries, regional and global totals are not shown for this category.

17. ESTIMATES OF TERRESTRIAL CARBON STOCKS

Estimates of Terrestrial Carbon Stocks and NPP (Global Aggregated Values by Biome)

		Global carbon stocks (PgC)[a]			Carbon density (MgC/ha)	
Biome	Area (10^9 ha)	Plants	Soil	Total	Plants	Soil
Tropical forests	1.76	212	216	428	120	123
Temperate forests	1.04	59	100	159	57	96

		Plants	Soil	Total	Plants	Soil
Croplands	1.60	3	128	131	2	80
Wetlands	0.35	15	225	240	43	643
Total	15.12	466	2011	2477		

Source. Data from WBGU (1988); forest data from Dixon *et al*. (1994). Table modified from Intergovernmental Panel on Climate Change.

[a]Soil carbon values are for the top 1 m, although stores are also high below this depth in peatlands and tropical forests.

[b]WBGU boreal forest vegetation estimate is likely to be to high, due to high Russian forest density estimates including standing dead biomass.

[c]In WBGU, ice is included in deserts and semi-deserts category.

18. COMPARATIVE LEVELS OF GREENHOUSE GASES

Pre-industrial (1750) and Present (1998) Abundances of Well-Mixed Greenhouse Gases and the Radiative Forcing due to the Change in Abundance

Gas	Abundance (1750)	Abundance (1998)	Radiative forcing (Wm^{-2})
Gases relevant to radiative forcing only

Source. Intergovernmental Panel on Climate Change.

Note. Volume mixing ratios for CO_2 are in ppm, for CH_4 and N_2O in ppb, and for the rest in ppt.

19. GLOBAL WARMING POTENTIALS

Numerical Estimates of Global Warming Potentials Compared with Carbon Dioxide (Kilogram of Gas per Kilogram of Carbon Dioxide)

Gas	Lifetime (years)	Direct effect for time horizons of		
		20 years	100 years	500 years
Carbon dioxide	5–200[a]	1	1	1
Methane	12	62	23	7
Nitrous oxide	114	275	296	156
Hydrofluorocarbons, perfluorocarbons, and sulfur hexafluoride				
HFC-23	260	9400	12,000	10,000
HFC-125	29	5900	3400	1100
HFC-134a	13.8	3300	1300	400
HFC-152a	1.4	410	120	37
HFC-227ea	33	5600	3500	1100
Perfluoromethane (CF_4)	50,000	3900	5700	8900
Perfluoroethane (C_2F_6)	10,000	8000	11,900	18,000
Sulfur Hexafluoride (SF_6)	3200	15,100	22,200	32,400

Source. Energy Information Administration/Emissions of Greenhouse Gases in the United States, 2001.

[a]No single lifetime can be defined for carbon dioxide due to different rates of uptake by different removal processes.

[a]Thousand Btu per barrel.

[b]Btu per cubic foot.

[c]Thousand Btu per short ton.

22. ENERGY USE OF TYPICAL HOME APPLIANCES

Appliance	Wattage
Aquarium	50–1210
Clock radio	10
Coffee maker	900–1200
Clothes washer	350–500
Clothes dryer	1800–5000
Dishwasher[a]	1200–2400
Dehumidifier	785
Electric blanket, single	60

Continues

Table continued

Appliance	Wattage
Electric blanket, double	100
Fans	
Ceiling	65–175
Window	55–250
Furnace	750
Whole house	240–750
Hair dryer	1200–1875
Heater (portable)	750–1500
Iron (clothes iron)	1000–1800
Microwave oven	750–1100
Personal computer	
CPU	120
CPU, sleep mode	30 or less
Monitor	150
Monitor, sleep mode	30 or less
Laptop	50
Radio (stereo)	70–400
Refrigerator (frost–free)	725
Television set (color)	
19-inch	65–110
27-inch	113
36-inch	133
Large screen projection	170
Flat screen	120
VCR	17–21
DVD	20–25
Toaster	800–1400
Toaster oven	1225
Vacuum cleaner	1000–1440
Water heater (40 gallon)	4500–5500
Water pump (deep well)	250–1100
Water bed (with heater)	120–380

Source. U.S. Department of Energy.

[a]Using the drying feature greatly increases consumption.

23. ENERGY COST OF HUMAN ACTIVITIES

Activity	METS[a]	Description
Bicycling	8	Bicycling, general
Bicycling	10	Bicycling, 14–15.9 mph, racing or leisure, fast, vigorous effort
Bicycling	16	Bicycling, >20 mph, racing, not drafting
Conditioning exercise	7	Bicycling, stationary, general
Conditioning exercise	7	Bicycling, stationary, 150 watts, moderate effort
Conditioning exercise	12.5	Bicycling, stationary, 250 watts, very vigorous effort

Continues

Table continued

Activity	METS[a]	Description
Conditioning exercise	8	Calisthenics, heavy, vigorous effort
Conditioning exercise	8	Circuit training
Conditioning exercise	6	Weight lifting
Conditioning exercise	5.5	Health club exercise, general
Conditioning exercise	9	Stair-treadmill ergometer, general
Conditioning exercise	3.5	Rowing, stationary, 50 watts, light effort
Conditioning exercise	12	Rowing, stationary, 200 watts, very vigorous effort
Conditioning exercise	6	Teaching aerobics exercise class
Conditioning exercise	4	Water aerobics, water calisthenics
Dancing	4.8	Ballet or modern, twist, jazz, tap, jitterbug
Dancing	5	Aerobic, low impact
Dancing	7	Aerobic, high impact
Dancing	5.5	Ballroom, dancing fast
Fishing and hunting	3	Fishing, general
Fishing and hunting	6	Fishing in stream, in waders
Fishing and hunting	2	Fishing, ice, siting
Fishing and hunting	5	Hunting, general
Home activities	3	Cleaning, heavy or major
Home activities	3	Cleaning, house or cabin, general
Home activities	3.5	Vacuuming
Home activities	2	Cooking or food preparation
Home activities	7.5	Carrying groceries upstairs
Home activities	2.3	Ironing
Home activities	1.5	Sitting—knitting, sewing, light wrapping (presents)
Home activities	4	Walk/run—playing with child(ren), moderate
Home repair	3	Automobile repair
Home repair	3	Carpentry, general workshop
Home repair	4.5	Painting
Home repair	4.5	Washing and waxing hull of sailboat, car, powerboat, airplane
Inactivity quiet	0.9	Sleeping
Inactivity light	1	Reclining—reading
Inactivity light	1	Meditating
Lawn and garden	5.5	Mowing lawn, general
Lawn and garden	2.5	Mowing lawn, riding mower
Lawn and garden	6	Mowing lawn, walk, hand mower
Lawn and garden	4.3	Raking lawn
Lawn and garden	4	Gardening, general
Miscellaneous	1.3	Sitting—reading, book, newspaper, etc.
Miscellaneous	1.5	Sitting—talking or talking on the phone
Music playing	4	Drums
Music playing	2.5	Piano or organ
Music playing	2.5	Violin
Music playing	3	Guitar, rock and roll band (standing)
Occupation	6	Coal mining, general
Occupation	5.5	Construction, outside, remodeling
Occupation	8	Farming, bailing hay, cleaning barn, poultry work
Occupation	2.5	Farming, driving tractor
Occupation	12	Fire fighter, general
Occupation	3.5	Locksmith

Continues

Table continued

Activity	METS[a]	Description
Occupation	2.5	Police, directing traffic (standing)
Occupation	1.3	Police, riding in squad car (sitting)
Occupation	4	Police, making an arrest (standing)
Occupation	1.5	Sitting—light office work, general
Occupation	1.5	Typing, electric, manual, or computer
Running	7	Jogging, general
Running	8	Running, 5 mph (12 min/mile)
Running	12.5	Running, 7.5 mph (8 min/mile)
Running	18	Running, 10.9 mph (5.5 min/mile)
Running	15	Running, stairs, up
Self care	1.5	Bathing (sitting)
Self care	1.5	Eating (sitting)
Sexual activity	1.5	Active, vigorous effort
Sexual activity	1.3	General, moderate effort
Sexual activity	1	Passive, light effort, kissing, hugging
Sports	8	Basketball, game
Sports	2.5	Billiards
Sports	3	Bowling
Sports	5	Children's games
Sports	9	Football, competitive
Sports	8	Frisbee, ultimate
Sports	4.5	Golf, general
Sports	4.5	Golf, walking and carrying clubs
Sports	3.5	Golf, using power cart
Sports	4	Hacky sack
Sports	8	Hockey, field
Sports	8	Hockey, ice
Sports	4	Juggling
Sports	8	Lacrosse
Sports	11	Rock climbing, ascending rock
Sports	5	Skateboarding
Sports	12	Roller blading (in-line skating)
Sports	10	Soccer, competitive
Sports	7	Soccer, casual, general
Sports	5	Softball or baseball, fast or slow pitch, general
Sports	5	Tennis, doubles
Sports	8	Tennis, singles
Transportation	1	Riding in a car or truck
Walking	7	Backpacking
Walking	6	Hiking, cross country
Walking	2.5	Bird watching
Walking	6.5	Race walking
Walking	2.5	Walking, 2.0 mph, level, slow pace, firm surface
Walking	3.3	Walking, 3.0 mph, level, moderate pace, firm surface
Walking	6.3	Walking, 4.5 mph, level, firm surface, very, very brisk
Water activities	16	Skindiving, fast
Water activities	10	Swimming laps, freestyle, fast, vigorous effort
Water activities	7	Swimming laps, slow, moderate or light effort
Winter activities	7	Skating, ice, general

Continues

Table continued

Activity	METS[a]	Description
Winter activities	7	Skiing, general
Winter activities	7	Skiing, cross country, 2.5 mph, slow or light effort, ski walking
Winter activities	9	Skiing, cross country, 5.0–7.9 mph, brisk speed, vigorous effort
Winter activities	8	Skiing, downhill, vigorous effort

[a]The term MET (metabolic equivalent) is the ratio of a work metabolic rate to the resting metabolic rate. One MET is defined as 1 kcal/kg/hour and is roughly equivalent to the energy cost of sitting quietly. A MET also is defined as oxygen uptake in ml/kg/min, with one MET roughly equivalent to 3.5 ml/kg/min. Multiples of 1 MET indicate a higher energy cost for a specific activity. For example, a 2 MET activity requires twice the energy cost of sitting quietly.

24. ENERGY CONTENT OF COMMON FOODS

Food	Kcal/100 g
Fruits	
Apples	52
Apricots	48
Bananas	89
Figs	74
Grapefruit	32
Guavas	51
Mangos	65
Melons, cantaloupe	34
Oranges	47
Strawberries, raw	32
Tomatoes, red	18
Vegetables	
Asparagus, raw	20
Broccoli, cooked	35
Carrots, raw	41
Chickpeas, cooked	164
Corn, sweet, yellow, raw	86
Cucumber, peeled, raw	12
Lentils, cooked	101
Lettuce, romaine, raw	17
Mushrooms, raw	22
Onions, raw	42
Peas, edible-podded, raw	42
Peppers, sweet, red, raw	26
Pickles, cucumber, dill	18
Potato, flesh and skin, raw	77
Potatoes, russet, raw	79

Continues

Table continued

Food	Kcal/100 g
Meats and proteins	
Beans, black, cooked	132
Beans, navy	67
Beef	230–400
Catfish, channel, wild, raw	95
Caviar	252
Chicken	200–500
Cod, atlantic, raw	82
Crab, blue, raw	87
Flatfish (flounder and sole), raw	91
Herring, atlantic, raw	158
Lamb	150–500
Mixed nuts, dry roasted	594
Peanut butter	635
Pork, cooked	418
Salmon, Atlantic, wild, raw	142
Shrimp, raw	106
Soybeans, cooked	141
Tofu, firm	77
Turkey	205
Dairy	
Cheese, brie	334
Cheese, cheddar	403
Cheese, swiss	380
Egg, whole, raw, fresh	147
Milk, whole, 3.25% milkfat	60
Yogurt, plain whole milk	61
Fats and Oils	
Butter	717
Margarine	719
Olive oil	884
Grains	
Bread, french	274
Bread, rye	259
Bread, whole-wheat	246
Cereal, breakfast	300–450
Cookies, chocolate chip	497
Crackers, matzo	351
Rice noodles, cooked	109
Rice, white, cooked	130
Spaghetti, cooked	141
Alcohol	
Beer	33
Whiskey, 86 proof	250
Wine	77
