The GG cycle (Fig. 1) is the most common type of rocket engine used for main propulsion. It is classified as an open-cycle engine and in its simplest form it is composed of a set of turbopumps for each propellant, a GG to provide power to drive the turbopumps, a set of control valves, and the main chamber and nozzle. The gas from the GG passes through the turbines that drive the turbopumps and is then expelled separate from the main chamber. Typically, 4 or 5% of the total propellant flow goes through the GG, which is usually operated at a fuel-rich mixture according to the limitations on turbine inlet temperature. This overboard turbine flow is a loss to the potential performance of the engine. Sometimes the GG flow is used to provide control capability to the vehicle, and sometimes it can be used as film cooling (also known as dump cooling) on the aft end of the nozzle.

The expander cycle is the simplest of the pump-fed engines and can be configured as either an open-cycle or a closed-cycle engine. In either case, the energy to pump the propellants is obtained not from burning propellants in a gas generator but rather from a transfer of heat from the main chamber. Fuel, typically hydrogen, is used as a regenerative coolant before it is used as the turbine drive gas. The thrust chamber and nozzle heat transfer limits the energy available for pumping the propellants and thus the achievable chamber pressure. Furthermore, the fuel must have a high heat capacity and good heat transfer properties and must vaporize easily without passing through a two-phase condition.

The expander cycle is inherently easy to start and control since the dynamics and stability concerns of preburner or GG combustion are avoided. An expander engine starts by using the latent heat capacity of the chamber and nozzle to initially accelerate the turbopumps, prior to main chamber ignition. The expander cycle is ideally suited for upper stages and space transfer applications, in which ease of starting and multiple restarts are required. Operational expander cycle engines used for upper stages include the RL-10-A5 and the LE-5. Thrust levels range from approximately 20 to 40 kN.

The staged combustion (SC) cycle engine (Fig. 3) is a closed-cycle engine that presents the highest performing and most complicated cycle in use. In SC cycles, part or all of the propellants go from the turbopump discharge to a high-pressure preburner, which produces turbine drive gas. The turbine effluent is mixed with the remaining propellants and combusted in the main combustion chamber. All the combustion gases are expanded from a high pressure, so the I_{sp} is high. However, the cycle demands high preburner pressures, which stress the turbomachinery.

The earliest identified SC cycle engine, the Topping Turbine Turborocket, was built by Reaction Motors and produced 5000 pounds of thrust. The turbopump was powered by a turbine located inside the combustion chamber. The drive shaft powering the pumps exited the chamber through the center of the injector. The first SC cycle engine to enter into production was the Soviet NTO/UDMH RD-253 engine, which was used on the first stage of the Proton booster, first launched in 1965. The Soviet Union also utilized the SC cycle on all of the LOX/kerosene NK series engines used for its N1 moon rocket program in the mid-1960s. A well-known SC cycle engine is the SSME, which is probably the most advanced engine in operation today.

The SC cycle can be categorized according to whether the turbine drive gas is either fuel rich or

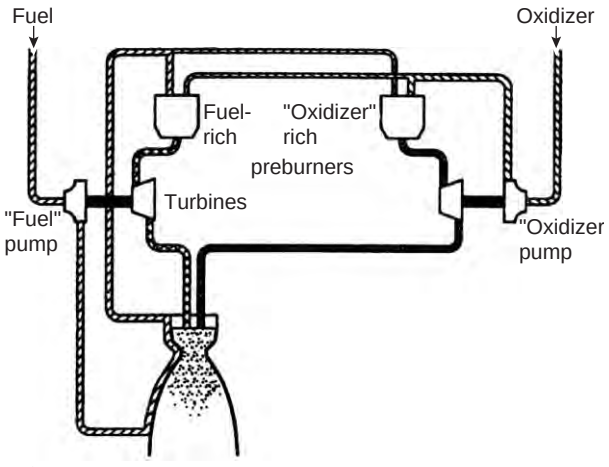

FIGURE 3 Full-flow staged combustion cycle rocket engine. Fuel and oxidizer are pumped to very high pressures before entering the fuel-rich and oxidizer-rich preburners. Prior to entering the preburner, the fuel is used to regeneratively cool the main combustion chamber and nozzle. Warm turbine exhaust gas enters the main combustion chamber, where it reacts further to produce a high-temperature and high-pressure gas that is expanded to very high velocities in a supersonic nozzle.

oxidizer rich. The fuel-rich SC (FRSC) cycle is typically applied to LOX/LH_2 engines (i.e., SSME, RD-0120, and LE-7). The oxidizer-rich SC (ORSC) cycle is used with hydrocarbon fuel-based engines and has been demonstrated in several Russian engines (i.e., RD-170, NK-33, and RD-253) using LOX/kerosene or NTO/UDMH. Another variant of the SC cycle is the full-flow SC (FFSC) cycle, which merges some of the virtues of the FRSC and ORSC cycles but has not been demonstrated in any engine system. The FFSC cycle engine requires two preburners, one producing fuel-rich hot gas to power the fuel turbopump and the other producing oxidizer-rich hot gas to power the oxidizer turbopump.

Although rocket propulsion is a fairly mature field, there is substantial room for improvement. Advancements in the following areas are required: system reliability and long-lived components; engine health diagnostics; high-energy density and storable propellants; lighter, higher temperature materials; nozzles that automatically adjust to ambient pressure conditions; and advanced thermodynamic cycles.

Glossary

chronic obstructive pulmonary disease (**COPD**) A disease characterized by a progressive airflow limitations caused by an abnormal inflammatory reaction to the chronic inhalation of particles.

global warming potential (**GWP**) The GWP of one molecule of CO_2 is set = 1, to which the GWP of other gases are placed in relation. For instance, in a period of 20 years, one molecule of CH_4 causes a direct warming effect, which corresponds to that of 35 molecules of CO_2.

ren min bi (**RMB**) The official currency of the People's Republic of China. One U.S. dollar is about 8.3 RMB.

small hydro In China, capacity less than 25,000 KW is categorized as small hydro.

Substantial changes have taken place in China. Energy development, as both a driving force and a consequence of such tremendous changes, has had profound impact on economic, social, and environmental development. Rural energy has always been a critical issue due to years of energy shortage for both households and industries. Biomass, for long time, has been the only available fuel in many rural areas. A series of policies and strategies have gradually been put in place to encourage alternative fuel exploration and utilization as well as area-based integrated energy systems. As a result, unelectrified rural population dropped from 60% in the 1950s to 5%, while the share of commercial fuel use increased to 43%. The importance of renewable energy has been recognized, not only because of its potential in rural and remote areas, but also as means of improving the environment and generating economic opportunities.

1. OVERVIEW OF RURAL ENERGY DEVELOPMENT

This article does not pretend to provide a complete in-depth assessment of rural energy in China. However, it is hoped that through a historic summary of the development in past 50 years and analysis of some relevant aspects, this discussion will contribute to a better understanding of the current situation and future challenges.

1.1 Rural Energy Path

Generally, the development of rural energy and rural energy policy in China can be divided into three stages.

1.1.1 Energy Shortage and the Development of Biogas, Small Hydro, and Local Coal Mines (1950–1979)

Despite the high level acknowledgement of the situation, rural energy shortage was severe throughout these three decades. By the end of 1979, the energy consumption per capita in rural areas was 19% of that in urban cities. Seventy percent of rural households lacked cooking fuel, among which 47% had no fuel for more than 3 months per year. Promotion of biogas for cooking and lighting and utilizing local coal resources were strategic decisions from the top since the 1950s; however, not until the late 1970s were specific institutional arrangements and policy measures clarified for a biogas program, with allocation of financial and human resources. Although large-scale biogas projects have been carried out, most digesters failed to perform soon after installation (1 to 3 years of average life time)

due to insufficient technical, managerial, and financial support. Because of this long period of lacking of alternative cooking fuels, regional deforestation, and excessive utilization of agricultural residues, among other factors, have contributed to serious degradation of rural ecological environment, which, in turn, has hampered the rural economic development. The impacts were felt well into the next stage.

1.1.2 Satisfaction of Energy Needs and Development of Policies and Regulations (1980–1990)

After the first national seminar on rural energy in 1980, series of energy policies and regulations have been announced focusing on reforestation, improvement of energy efficiency in both rural industries and households, and the development of renewable energy. The principle of integrated rural energy strategy was defined as developing all possible local alternative resources of energy while rationally utilizing the current sources. Nation wide programs have been carried out in this context, and most of them continuously constitute the current rural energy activities. Thus, it is worth while to have a detailed discussion on the following main results from this period:

Fuelwood Forest. As one of the five forest categories, the main products of the fuelwood forest are wood fuels. Reforestation plans were conceived according to local surveys on fuelwood supply and consumption. From 1981 to 1995, approximately 5 million hectares of forest have been established as fuelwood forest, which, in total, reached 6 million hectares and generated 20 to 25 million tons of wood as fuel per year. However, due to the decline of fuelwood demand, it is expected that the financial viability of these reforestation projects will be highly challenged. Technology optimization and standardization ensuring a diversified and reliable range of products are essential to improve the economic performance. Further more, flexible management and involvement of the private sector are crucial to gradually moving away from subsidies to a market-based operation.

Improved Cook Stoves and Energy Efficiencies in Rural Industries. From 1983, large-scale promotion of improved cooking and heating stoves has been carried out all over the country. By the end of 1999, it was reported that approximately 189 million rural households had been equipped with improved stoves. Generally the efficiency of these stoves, using coal and solid biomass as fuel, has improved by 20 to 40%, which enables energy saving of more than 30 million TCE (ton of coal equivalent) per year. However, to what extend these stoves have been used is not known. Rural industries have experienced a similar process. Improved boilers and kilns, mainly used in tea processing, tobacco drying, and brick and cement producing industries, could have brought about 2 million TCE per year energy saving, as well as significant quality improvement and control in production.

Rural Coal Mining. By the end of the 1970s, coal production from the mines developed at town and county level had already taken a significant role in the energy supply in China. The production of coal from these mines shared 18% of the national total in 1980. The continuous encouragement in collective and private coal mining has tripled their production to nearly 390 million tons and shared 36% of the coal production. Such increase climaxed in the year 1995–1996 when the production shared 45% of national total coal output. Despite low-efficient equipment and technologies and a poor safety record, the rural coal mines have contributed to the rural economy in three ways: easing the energy shortage, ensuring rural productivity, and improving rural employment. While majority of the coal produced from these mines has served market demand locally and from neighboring provinces, a small portion of the product, usually of better quality, has been transferred to the eastern coastal region. To a certain extent, replacing fuelwood with coal has also contributed to forest conservation. The low production and combustion efficiency of coal, however, has had adverse impact on rural environment and health. These effects have also been aggravated by the poor quality of coal in China and the fact that only a small amount has been processed. A case study on Xuan Wei County, Yunnan Province, showed that indoor air pollutants caused by coal combustion was the main health risk factor responsible for the high rate of lung cancer cases in the county.

Rural Electrification. Development of small hydropower has been the dominant strategy for rural electrification in China. In the late 1970s, several policy measures, including subsidy schemes, were adopted to promote small hydro, which resulted in a large increase in generation capacity from an average of 58,000 KW per year in the 1960s to more than 1 million KW in 1979. In the 1980s, local grids and local electricity companies have emerged, which has helped to overcome the disadvantages of standalone systems and also enhanced the rational utilization and distribution of electricity at county level. The

improvement of grid connection continues in the 1990s while the expansion moves toward cross-county connection. Establishment of hydroelectricity enterprises are further encouraged by introducing, among others, a private stockholder scheme. Per capita rural electricity consumption increased 7 times in 40 years and by the end of the year 2000, 28 million people (around 5 million households) in rural areas had no access to electricity, comparing to 450 million in 1978 (nearly half of the total population and 57% of rural population at that time).

1.1.3 Sustainable Energy Development and Market-Oriented Policy and Strategies (1990–2000)

Since the beginning of the 1990s, environmental policy has become one of the principle national development policies in China. As in many other developing and developed countries, renewable energy and energy efficiency have become more prominent in the energy agenda. Several rural energy policies have been published to address renewable energy and sustainable development, energy and environment, and rural energy technology in poverty alleviation. With the deepening rural economic reform since the mid-1980s, energy has been advocated as an integrated component of the rural development and rural market economy. The need for commercialization of conservation technologies, utilization of new and renewable energy resources, and the provision of energy services have been given great emphasis. Progresses in some of these aspects mentioned earlier are detailed in the following discussion:

Renewable Energy (RE). Direct combustion of biomass has gradually decreased both in share and absolute terms, while the utilization of solar, biogas, small and pico hydro, and biomass gasification have increased. Energy policies in addressing environmental problems in the country have set favorable conditions to RE. In particular, several financial measures, such as subsidies, low- or zero-interest loans, taxes, and so on have been essential in renewable energy development. Since 1987, the state council has financially supported more than 500 RE projects in the form of low-or zero-interest loans (more than 400 million RMB, e.g., approximately US$50 million). From 1990 to 1996, more than 1 million US$ subsidy was given to training and demonstration of RE technologies, while between 1996 and 2000, subsidies of about 7 million U.S. dollars were given to research and development of RE technologies and implementation. As a result, in 1998, renewable energy utilization, excluding traditional biomass, was 35 million TCE, accounting to more than 2% of the China's total energy consumption (including commercial and noncommercial sources).

Rural Energy Enterprises. Rural energy enterprise emerged with the promotion of biogas in the late 1970s to provide technical services and after build services. Under the strong support from the government on efficiency technologies, various types of devices and equipment have become commercialized. Into the 1990s, different renewable energy technologies have been demonstrated and promoted and, along with it, a more diverse rural energy industry has emerged. By the end of 1998, there were about 4300 rural energy enterprises, 1660 of which were in the industrial sector, manufacturing energy devices for rural users, such as solar water heater, PV, biomass gasifiers, and so on, and more than 2630 were in the service sector, providing technical, marketing, sales, and other services. Compared to 1997, the number of both types of enterprises increased by 8% and 18%, respectively, although the number of total employment has stayed roughly the same (approximately 42,000 to 43,000). Until 2000, such yearly increases have been consistent. However, data show that before 1996, enterprises and employment had been declining in the rural energy sector, and a relatively sharp decrease occurred to the collectively and state-owned enterprises. This short period of decline reflects the further market opening up in rural China, making many inefficient and less flexible state enterprises go bankrupt. Nonetheless, the rural energy industry has yet to mature and favorable policy environment is still essential, since its benefits to overall rural sustainable development have not been integrated and valued fairly (see also Section 3).

The development of rural energy, particularly in the past 20 years, has brought significant changes in the sector in terms of policy, structure, management, technology, and economy. Rural energy consumption increases at a steady rate of 4% per year from 330 million TCE in 1980 to 670 million TCE in 1998. Several comparisons of changes are listed in Table I, while the changes of rural energy structure are presented in Fig. 1.

The fall of rural energy consumption in 1996 is mainly due to the large decrease in the use of noncommercial energy sources (e.g., fuelwood and straw), while the use of coal and oil increased with the latter nearly doubled comparing to 1995.

TABLE I

1980–1998 Rural Energy Development in China

	1980	1998
Rural population (million)	796	869
Average rural income per person (RMB)	191	2162
Total energy consumption (million TCE)	330	670
Average energy consumption per capita (Kg CE)	420	770
Total electricity, consumption, including household and rural industry (billion KWh)	13	129
Average household electricity consumption per capita (KWh)	8	68
Population without electricity (million)	450	60
Clean fuel for cooking (electricity, LPG, coal gas, biogas, producer gas, solar, etc.) (million households)	3.7	56.3

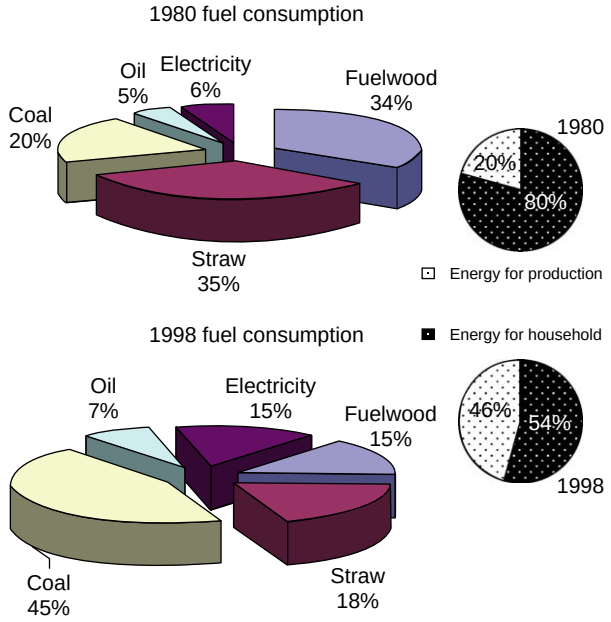

FIGURE 1 Fuel consumption structure changes in rural China 1980–1998.

Decrease in residential electricity consumed in 1996 was uncertain. Official figures from the Ministry of Agriculture show that the consumption was 29 million TCE, which was two-thirds of that in 1995 and, although increasing in the following years, it has not regained the level of 1995. However, according to the statistics from Department of Rural Electricity of the National Electricity Power Bureau, no such decrease has been observed. Nevertheless, energy

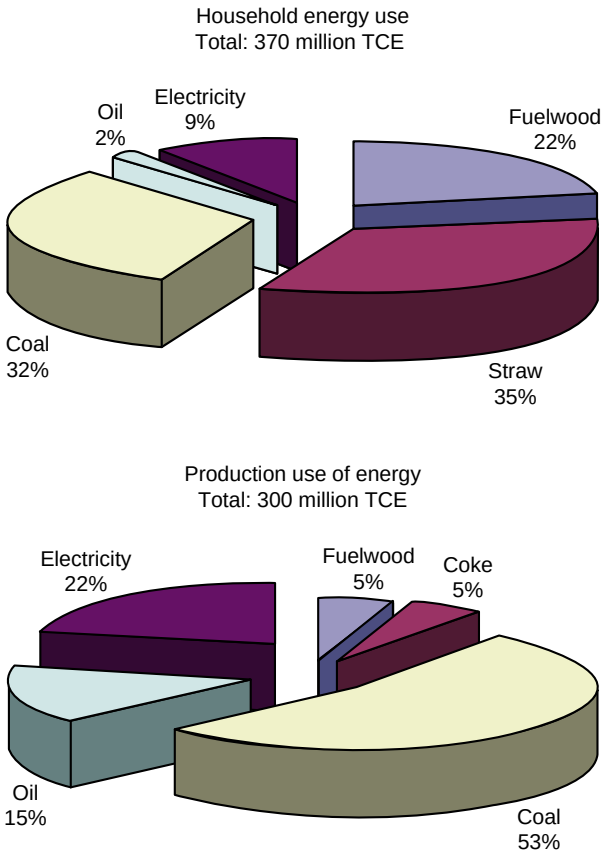

FIGURE 2 Rural energy consumption, 2000.

consumption in rural households has been grown in slow pace since 1995, if not decreased, mainly due to the closure of small coal mines and power producers. In the same period, rural productivity use of energy grew about 16% despite the successful efficiency program in rural industries nationwide. This has significantly contributed to higher income and improved livelihood in many rural areas in China.

1.2 Rural Energy Today

Since 2000, rural energy has accounted to approximately 45% of the total energy consumption and 35% of total commercial energy consumed (e.g., excluding fuelwood and straw). The total rural energy consumption was 670 million TCE in 2000 (see Fig. 2). The majority of rural households still use solid fuel for cooking and heating, while 84% of urban households are using gaseous fuels (LPG, natural gas, and coal gas). China has undergone series of reforms in the energy sector in the past 10 years, and the reform is being extended into rural power grid. The long-term goal of the power sector is

the establishment of a unified national grid. It would require a modern power market in which small and large plants are able to sell electricity to the grid at market-determined price. It would also require a well-defined regulatory role of the government. In the short to medium term, many rural areas will stay with local grid or isolated (village) grid, where renewable energy sources are most promising.

1.2.1 Energy Efficiency

As already mentioned, energy efficiency has been improved tremendously in the past years. However, comparing to national and international averages, rural industries still consume more energy per product unit as shown in Table II, and a significant difference exists between the western and the eastern regions, where efficiency is in general much higher. Because the out-of-date technologies and machinery still prevail in agricultural activities, energy consumption for mechanical power is very high, accounting for nearly half of the diesel used in the country. The current energy efficiency program, focusing on the modification of old equipment and technologies, results in diesel saving of 300,000 tons per year. However, the demand and consumption of diesel in agricultural sector will continuously increase since mechanical power is only responsible for approximately 50% of the productivity.

TABLE II

Energy Efficiency of Selected Rural Industries

Type of product (energy consumption/ unit)	Average of rural industries	National average	International average
Brick (kgce/10,000 pieces)	1093	780	780
Cement (kgce/t)	161	133	94
Coke (tce/t)	1.56	1.1	1.1
Pulp and paper (tce/t)	1.55 ~ 1.7	1.25	0.51
Electricity (from coal, gce/kWh)	450 ~ 550 (< 50 MW)	320 ~ 350 (300 MW)	329 (Japan)

1.2.2 Clean Energy

With the stabilized balance between demand and supply of energy, China has been moving forward to clean and modern energy and technologies. The demand for clean fuel (electricity, LPG, coal gas, and modern renewable fuels) from rural households has five-fold in the past 10 years, and this trend will continue. Currently, renewable energy and modern renewable energy (including small hydroelectricity) account for 19.8% and 2.3%, respectively, in the total national consumption, as shown in Fig. 3.

A detailed breakdown of the use of renewable energy resources in 1998 is presented in Table III, which shows that all new renewable energy (excluding traditional biomass and all hydroelectricity) constitutes 0.3% of total national energy consumption (i.e., 5.4 Mtce). According to national planning on renewable energy development, this figure is expected to reach 2% by the year 2015, which indicates that total consumption of new renewable energy would have to reach approximately 60 Mtce in 15 years, which may require hundreds of millions of U.S. dollars, as subsidies from central government. Thus, the commercialization of renewable energy and technologies, with a well-performing rural energy service sector, would be crucial. The existing rural energy industry covers almost all renewable energy technologies; however, their stage of development and commercialization varies greatly and are presented in detail in Section 3.

Although domestic coal meeting the demand will still be the strategy in rural energy development in the foreseeable future, coal combustion, particularly at the small scale, has been and will be unavoidably having a negative impact on rural environment and health. Modern renewable fuels, such as solar water

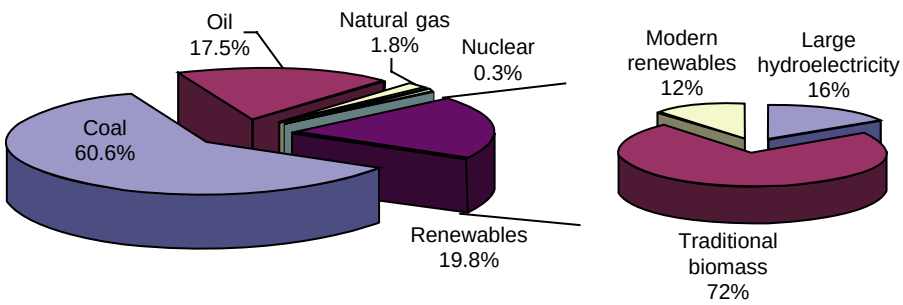

FIGURE 3 Renewable energy consumption in China.

TABLE III

Utilization of Renewable Energy Resources in China (1998)

Resources	Utilization	Mtce
Hydro electricity — small hydro[a]	208 billion kWh, 80 billion kWh	77.6, 29.84
Biomass	221.98 Mtce	221.98
Biogas	2.36 billion M^3	1.73
Bagasse for power	800 MW/2000 GWh	0.75
Geothermal for heat	0.4 Mtce	0.4
Geothermal for power	27.8 MW/110 GWh	0.05
Solar water heater	15 million M^2	1.8
Solar homes	15 million M^2	0.37
Solar cooker	244,000	0.04
Solar PV	13 MW/28.7 GWh	0.01
Wind	242 MW/641 GWh	0.24
Total		305

[a] Note: Micro hydro not included.

heaters, biogas, producer gas from agricultural residues, and electricity from wind and microhydro, could provide some viable alternatives for rural and remote areas. They have the potential in competing with the high cost of LPG and coal gas and meanwhile improving indoor air quality (see also Section 2).

A number of new and renewable energy projects, under the Tenth Five-Year Plan, are currently being carried out at nation wide. Since these projects are and will be of significance to the long-term development of the rural energy sector, it would deserve some discussions.

1.2.2.1 The "Brightness" Project By the end of the last century, about 7 million households, accounting for 3.55% of total rural households, have yet to be electrified. Most of these households are located in the western region and the majority of them are of minority origins. To address this situation, the "Light" project was initiated by the national Planning Committee and supported by several other countries [e.g., Japan, Germany, the Netherlands, the United States, and the United Nations Development Programme/Global Environment Facility (UNDP/GEF).] The 10-year target of the project is to provide electricity, in average 100W/person, to 23 million people in remote areas with renewable technologies such as wind and solar PV. The first period of the project (from 2000 to 2005) will install 1.78 million sets of household systems and 2000 sets of village systems, which will require, approximately, a total of US$1.2 billion. It is expected that the majority of the investment will come from the users themselves, while only 6.7% will be provided by the central and local government by means of subsidies, especially for the village systems and service networks. The project, in its first period, will focus on the development of domestic industries of wind generators and solar PV; the establishment of sales and a after sale service network; technical training on installation, optimization, repair and maintenance; standardization; and quality control mechanisms.

1.2.2.2 Biomass Gasification Demonstration Project With 65 million rural Chinese without electricity, 70 million are in shortage of cooking fuel. As shown in Fig. 2, agricultural residues, mainly straw, account for 35% of rural household energy use. The average efficiency of straw directly used for cooking is just 5 to 8%; however, after gasification, the overall efficiency reaches about 35 to 45%. Most of all, converting solid fuel to gaseous fuel could bring huge environmental, social, and economic benefits, such as improved indoor air quality and health, reduced of load of house work for women, the sense of modernization of rural communities, and reduced greenhouse gas emissions. However, these externalities are not internalized financially; thus, in average the daily expense on fuel in terms of producer gas is 7 to 8% higher than that in terms of coal gas. One of the first demonstration projects was initiated in Shangdong province with a gasification system and a village gas pipe line installed in 50 villages. It brought significant benefits to those villages in terms of reducing smoke and liberalizing women from the drudgeries of fuel handling. From 1999 to 2000, the national planning committee budgeted 12.5 million RMB ($\sim$US$1.5 million) for wider dissemination of the technology in seven other provinces. It is expected that 53,900 households would be using producer gas for cooking. Standardization and commercialization of gasifiers and gas stoves are key issues to be addressed, along with the demonstration projects (see Fig. 4; see also Section 2).

Modern energy is the main engineer of economic growth. Meanwhile, national policies and measures to promote such growth have a profound impact on sustainable energy development. One of the strategic developments focuses is the current Western Development Plan. Through rational and efficient exploration, distribution, and utilization of resources, the development plan aims at stimulating

FIGURE 4 Biomass gasifiers manufactured and used in Yunnan, China.

economic growth in the West and minimizes the social and economic disparities between the western and eastern regions. Western China is rich with both renewable and conventional energy resources. However, the demand of energy mainly comes form the Eastern coastal areas. Two major programs under the development plan are to transfer both natural gas and electricity (generated from coal) from the western to the eastern region. Mostly energy resources are located in rural areas and the pipe line and network will be most likely constructed along remote villages and rural towns, thus, it is hoped that these programs would enable those rural households to access clean energy services. These programs would also encourage the growth and development of energy service industries in the western region, which could provide employment and income generation opportunities.

The previously discussed rural energy development in China has had a profound impact on the sustainable development in all of its three dimensions (i.e., environment, economy, and society). The impacts are complex and interrelated. The following sections exam several characteristic issues in each of the three dimensions, and through that, the challenges and possibilities in advancing rural energy development are discussed.

2. ENERGY AND RURAL ENVIRONMENT

Small-scale coal mining has caused serious environmental problems in rural China. As mentioned in the previous section, these mines are mostly collectively or privately owned by the counties; little capital was invested in technology and equipment. The average efficiency of coal production (e.g., resource recovery)

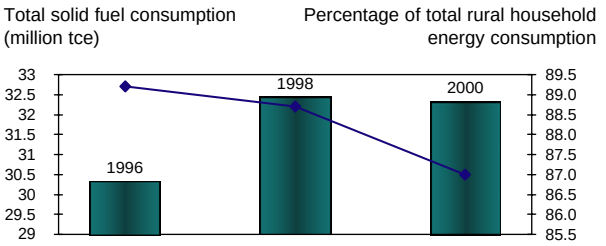

FIGURE 5 Reduced solid fuel consumption in rural household.

is much lower than 50%. Most of the mines are very labor intensive and some have the productivity as low as 1t/labor. Few environmental control measures have been adopted in these mines, and only a small portion of coal produced has been further processed with, for instance, de-sulfur technology. From the end user side, rural households and industries are the main consumers of the low-quality coal from the small mines. Rural industries are known to have outdated equipment with low efficiency (as presented in Table III). This situation has worsened as many high pollutant and energy intensive industries have moved to rural areas. In average, the brick, cement, paper, coking, and casting industries in rural areas shares 8% of the total production of the country, while they account for more than 50% of the total energy consumption in these industries. For rural households, since the late 1990s, the consumption of solid fuels (e.g., biomass and coal) has increased only marginally and their share in the total household energy use started decreasing, as shown in Fig. 5. This indicates that with the promotion of improved technologies, efficient stoves, coal, and biomass energy intensity decreased and resulted in energy saving and, consequently, emission reduction both indoors and outdoors. However, it is difficult to assess the actual changes and effects due to the lack of detailed data.

Overexploration of fuelwood still persist in some rural areas despite the relatively successful reforestation program since the 1970s. From the 1990s, fuelwood supply and consumption has been roughly kept in balance due to mainly improved energy efficiency and promotion of coal replacing fuelwood; however, statistics show that fuelwood consumption is higher than the sustainable supply at various degrees in more than ten provinces. For example, Yunnan Province, located in the Southwest of China, has relatively successful solar heating and biogas programs. However, data in 1999 show that fuelwood consumption was about 32 million M^3 while the total sustainable supply from all type of forest was only about 14 million M^3. Several counties in Yunnan

province are located upstream of, among others, the Yangtze and Mekong River. Years of over exploration of the forest for timber and fuel in these areas have resulted in soil erosion and degradation.

In 1998, agricultural plantation generated approximately 600 million tons of residues, of which 27% was utilized mainly as animal feed and for industries, 15% was returned to the field as natural nutrients, and 47% was used as fuel. On one hand, the declined consumption of agricultural residues as fuel has made the returning of residues back to the field possible. On the other hand, this has led to about 65 million tons of residues left for disposal. Since decomposing stem residues is a rather long process, most of it is burned openly to prepare the field for the next crop. In many areas of central China, this has become a serious seasonal environmental problem.

2.1 Rural Energy and Emission Reduction: The Potential of Biomass Gasification

Analysis has confirmed that China actually has reduced its greenhouse gas emissions, even as its economy has grown rapidly (as shown in Fig. 6). However, due to lack of data from monitoring and evaluation, it is difficult to analyze the share of the emissions from rural energy consumption. Estimates of all energy efficiency projects claim more than 32 million tce energy saving capacity (30 million tce from the improved fuel/stove projects in rural homes) per year, which would be responsible for about 70 million tons CO_2 avoided, that is, two-thirds of the CO_2 reduction from coal in 1998–1999 and twice of the total CO_2 reduced of the year. The steeper CO_2 reduction from coal indicates higher coal efficiency (comparing with coal consumption) and the increases of CO_2 emission from other sources.

As discussed previously, biomass gasification provides a promising alternative in replacing solid fuels for cooking and heating in rural areas. The amount of agro-residue available for energy use in 1998 was about 350 million tons (possible losses already taken into account), 58% of the total residues generated. Since 285 millions tons of the residues are already used as fuel, it could be assumed that all the available residues could be gathered and transported without imposing any major changes to practices and workload. Assuming 350 million tons of residues could be converted to gashouse fuel for rural cooking and heating, their contribution to emission reduction can be estimated. The average emission factors of coal and biomass fuel for household applications are shown in Table IV.

Based on technical specifications of producer gas in China, it is assumed that gas production rate is 2 M^3/kg residues and 1 M^3 of producer gas would replace 0.25 kgce; thus, 350 million tons of residues would generate 700 billion M3 of gas and equal to 175 million tce.

When producer gas replaces all the residues used for fuel (285 million tons) and partially replaces fuelwood (i.e., 32 million tce), it could avoid, in total, 109 million tons of CO_2; this is about the total emission reduction from coal in 1998–1999. When producer gas replaces all the residues (285 million tons) and partially replaces coal (32 million tce), it could avoid, in total, 167 million tons of CO_2.

2.2 Rural Energy and Health: A Possible Win-Win Strategy

The simple household solid-fuel stoves commonly used in rural areas do not obtain high combustion efficiency. They emit a substantial amount of fuel carbon as byproduct of incomplete combustion (PIC)—such as carbon monoxide (CO), methane (CH_4), and total non-methane-hydrocarbons (TNMHC)—as well as sulfur dioxide (SO_2) and

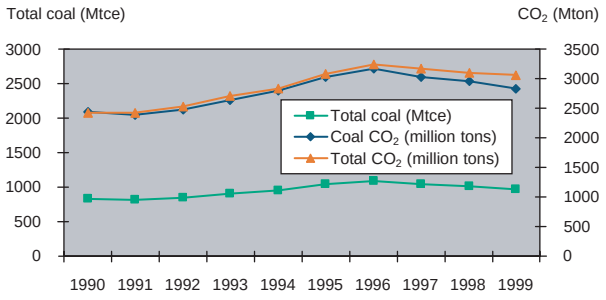

FIGURE 6 China CO_2 trends.

TABLE IV

Average Missions Factors of Household Fuels in China

Fuel	Overall efficiency (%)	g CO_2/kg fuel	g CH_4/kg fuel	Total g CO_2/kg fuel[a]
Crop residues	14	1130	5	311
Wood	23	1520	5	311
Coal	35	2280	3	2466

[a] Note that wood and residues are assumed to be CO_2 neutral. And in a 20-year time horizon, the Global Warming Potential (GWP) of one CH_4 molecule is 22.6 time higher than that as CO_2.

particulates. Some of these PICs are hazardous to health when inhaled under the concentrations commonly found in homes using unvented biomass or coal stoves. As discussed, China has carried out, in the past 20 years, efficient cooking stove dissemination programs, which claims that the various technologies have benefited 184 million households by the end of 1998, and this figure is increasing at 2.2% per year. However, again, no monitoring and evaluation data are available to exam the true effect of the stove program, particularly in terms of health improvement. With improved efficiency, carbon emissions could be reduced as discussed in the previous section. It could also result in fuel saving, if more energy is actually delivered in less PICs or if more carbon is converted to CO_2. Table V presents data from site analysis of Chinese stoves. The data show that improved efficiency does not necessarily accomplish emission reduction. However, processed and high-quality fuel is always preferable.

A study of the health benefits from emissions reduction in China has given some further interesting results. It was found that greenhouse gases (GHG) reductions resulting from changes in energy use are generally accompanied by substantial short-term health benefits. However, the degree of health benefits varies greatly with the choice of energy technologies and sectors. The variation appears to be larger when shifting between sectors rather than between technologies, and the largest benefit can be obtained in the household sector. Even conservative estimates show, for example, that the health benefits of one tonne reduction in particulates emission from household stoves are at least 40 times larger than those from coal-power plants. This study also shows that although GHG reduction itself is usually accompanied by increasing costs, when the economic benefits of improved health are counted, there is a net economic benefit for those household energy options, involving a shift from traditional use of coal and biomass. This strongly suggests that emission reduction in the household sector can be a real win-win strategy for China.

TABLE V

Health Hazardous Emissions — Improved Fuel/Stove

Fuel/stove	Efficiency	g PIC/MJ delivered	g NO_x/MJ delivered	g SO_2/MJ delivered
Unprocessed coal	37%	4	0.2	0.02
Coal briquette	14%	24	0.04	0.04
Wood/ improved	24%	20	0.1	—
Wood/brick	13%	12	0.2	—

PIC = CO + CH_4 + TNMHC-C (carbon in total none-methane hydrocarbons) + TSP (total suspended particulates).

3. ENERGY AND RURAL ECONOMY

As essential to industries, modern energy services are prerequisites for rural economic development. Most rural industries and agro-product processes have been limited to solid fuel (biomass and coal) with outdated equipment as main energy input. This, as already discussed, has resulted in unnecessary waste of energy and constraints to productivity improvement and products diversification. Figure 7 is a simplified diagram showing the inter linkages of lack of energy services and its impact on agriculture and local economy, which is complex and dynamic.

By no means, this section could provide a comprehensive overview of such complexities in rural China. Rural energy production, supply, and services as part of the rural economy have also undergone tremendous changes in terms of market potential and development, and the following will exam this aspect in detail.

3.1 Rural Energy Business

As discussed before, since 1996, the number of rural energy enterprises, as well as their market value and employment, has been increasing consistently. The current rural energy industry covers almost all renewable energy technologies; however, their stage of development and commercialization varies greatly. According to China Rural Energy Industry Association, the technologies and products are grouped in six categories and are under the mandate of six committees in the association. The market situation of these technologies/products is resented with some details.

Solar heating—including Solar Water Heater (SWH), Solar Cooker, Green House and Solar Homes—has been developed rapidly in the past 20 years in China and has become the main product of the sector. There are two main types of SWH on the market (flat-panel and vacuum tube), with an average heat production efficiency of 100 ~ 150 kgce/M^2. The total sale of the two types was 5 million M^2 in 1999, which was an increase of 25% from 1998. Total installed capacity of SWH has reached

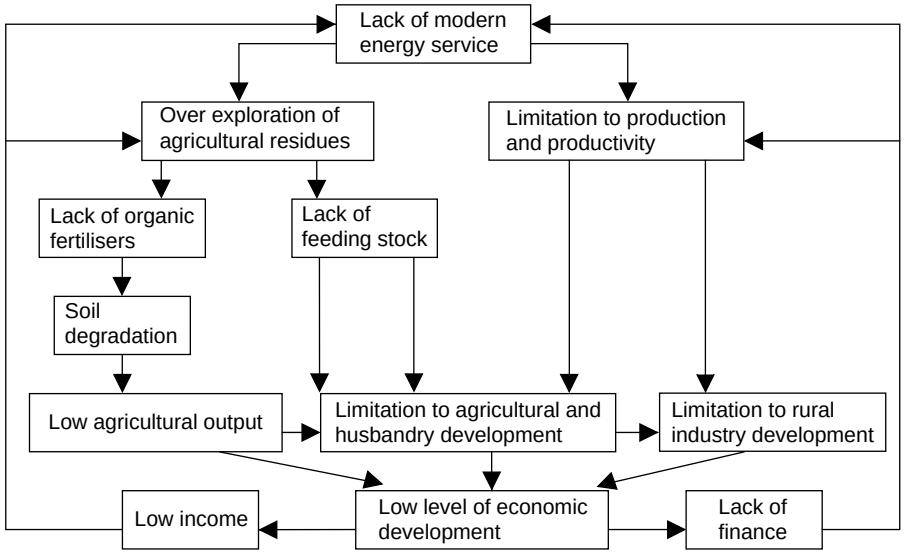

FIGURE 7 Example of energy shortage and its impact on rural economy.

20 million M^2, of which more than 50% is in rural areas. There are nearly 1000 factories with annual production capacity of 6 million M^2, which values more than US$600 million. In total, 20,000 people are employed by these enterprises. By the end of 1998, solar home system (SHS) construction reached 15 million M^2 in total, from which 6.5 million M^2 is located in rural areas. The rate of growth for SHS was 54% per year in the past 10 years. On average, SHS could accomplish 75 to 90% fuel savings on heating. Figure 8 shows a flat-panel solar water heater.

Although there is wide range of products in the energy-efficient cooking devices sector, only two have achieved a large market share. One is the drinking water heater, with a yearly production and sale of more than 300,000 and a value of more than US$12 million. There are more than 1000 factories, mainly small- and medium-sized enterprises (SMEs). The other one is coal-saving stoves. There are five factories reaching an annual production of more than 10,000 stoves.

There are more than 2600 biogas enterprises all over the country with nearly 18,000 employees. The service provided includes digesters (both large scale and household scale) and its design, necessaries, and end use devices, technologies, construction, consultation, repair maintenance, and so on. In total, about 7.6 million digesters have been installed in rural China. Still in technology demonstration stage, there are 740 large and 49,000 medium digesters installed in large farms, industries, and small cities. Although

FIGURE 8 Flat-panel solar water heater, Yunnan province.

small in size, the market for household biogas systems could be promising. Every year 300,000 new digester are being built, and another 100,000 need to be replaced, which implies approximately US$70 million per year. However, one of the key issues in commercializing small digesters is standardization. Semiconstructed digesters have been developed to secure consistent quality as well as reduce the time needed for construction.

Another technology is solid biomass conversion equipment, including briquetting, direct high efficiency combustion, gasification, liquadization, and carbonization equipment and facilities. Although these products are still in the stage of research and development and demonstration, some 50 factories have already been in production and their products are sold in several provinces. A study of the market potential of a village scale biomass gasification system shows that the average income level of a village

affects the current market of the technology. In the case study, it is shown that when yearly household income reaches 10,000 RMB (about US$1200), residues as fuel are abandoned and the financial implication of gasification is more acceptable.

A new type of liquid fuel/stove presents yet another technology. The liquid fuel in this category is mainly referring to methanol and ethanol from the waste of oil and chemical industries. There are about 600 research and production enterprises in this sector, among which several are more than $1 million enterprises. Although the technology is yet to be standardized and further improved, it has already reached more than 300,000 households.

Small-scale electricity production makes up another category. This sector includes small wind, solar, and hydropower industries. More than 50 enterprises are engaged in small wind power research and development and equipment production. Currently, the production of small wind turbines is about 20,000 units per year. Products range from 100W to 5 KW, of which the 100 to 300W types are most in demand. The technology has matured in the past 5 years and production quality has been stable. Solar PV industry has been commercially established. There are more than ten solar PV production lines in China, each with 4.5 MW per year capacity. The annual production has been around 2 MW. In total, 12 MW has been installed, of which 5 MW in rural areas. In average, the system cost is around US$10 to $12 per watt at peak and electricity could be generated at 30 U.S. cents/KWh. Other products associated with the systems include lighting appliances, batteries, and pumps. More than 100 enterprises are engaging in their production, mainly located in Gansu and Qinghai provinces. A small hydro industry has been developed to a relatively large scale with approximately 1 million employees. Meanwhile, the mini hydro industry is in expansion with annual sales of 15,000 systems, mainly in the Southwest provinces.

The development of these industries depends largely on the economic viability of these technologies in reality, which is influenced by several factors: the abundance of the energy resources, the demand and willingness to pay by end users, system configuration and performance, system costs, and financial and policy scenarios. Under these factors, the following specific and direct limitations have been identified based on past project experiences in rural China: There are no unified technical standards. Thus, it is difficult to guarantee the product quality with different standards in different regions. In some cases, markets and consumers are confused with bogus products of low quality; most of the companies are inexperienced in getting loans from banks. Therefore, the shortage of capital is a major barrier for companies to expand their sales and improve after-sales services. With China joining the WTO, increasing domestic and international competition is expected, especially for the PV and wind sectors due to their relatively low level of production technology. Markets need to be closely examined and regulated with proper financial means in order to sustain and develop rural energy enterprises, as well as to reflect their true economic benefits.

3.2 Rural Energy and Income Generation: The Biogas and Eco-Farm Model

As mentioned, biogas technology, for providing cooking and lighting fuel for rural households, was disseminated in the 1950s. However, due to the immaturity of the technology and lack of management and maintenance skills, most of the digesters failed to perform soon after being installed. Similar failures were experienced in the 1970s. More than 7 million units were built in just a few years. Despite the potential environment and health benefits of biogas technology, its economic performance was recognized as a key to success. Two variations of biogas system in combination with eco-farming model have been gradually developed in the past 20 years, the Southern model and the Northern model. The Southern model focuses on the utilization of the sludge from the digester as fertilizer, thus, animal stable, a biogas digester, and fruit/vegetable plantation have become components of one "eco farm." On average, production cost per hectare was reduced by US$360. Financial payback of the system is about 4 years. Due to low temperature, biogas use in the north had been limited. In the Northern model, animal stable, toilet, biogas digester, and green house are built on one spot to ensure sufficient and better temperature for animal growth and anaerobic reaction. The initial investment of the Northern model is about US$480 and the payback time is usually within 2 years. According to survey, households installing the Northern model were benefited with US$380 increased income per year. Currently, 210,000 and 81,300 households have adopted the Northern and Southern models, respectively. They produced more than 4 million tons of fruit and vegetable without using chemicals in 1998. By the end of 1999, 6.7 million households were provided with digesters, and their total gas production is around 2 billion M^3 annually.

4. ENERGY AND RURAL SOCIETY

Economic reform is changing the social structure and lifestyle of rural population. As part of the overall development in rural communities, the increasing availability of improved energy services has contributed to improved living and working conditions, better education facilities, saved time for other activities and leisure.

4.1 Rural Energy and Gender Equity

Based on the law of China, women and men are equal. While this has greatly increased the social significance of women in the cities, such development in rural areas has been lagging behind. Rural women have been, for centuries, taking care of household duties. They are not only responsible for the well-being of children and other members of the family, but also for the basic daily livelihood, such as food, cooking, feeding, and washing, in addition to helping in the field. With the broadening of economic reform in rural China, mobility and business opportunities largely increased, which led to more and more agricultural laborers, particularly men, transferring to nonagricultural sectors and working in peri-urban and urban factories. As a result, more responsibilities fell upon women. Thus, unless the household burden is alleviated, there will be little chance for true gender equality in rural society. For many rural women, fuel for cooking and heating has been drudgery in terms of time and labor spend on fuel collecting and smoke irritation from fuel burning. A typical rural family of five would require 3000 kg of firewood per year, which would need 80 days to collect, an average of 5 hours per day. Plus another few hours to cook food and feed, many have to work at least 15 hours a day. Women as users have deeply realized the benefits of improving their fuel situation and have been actively initiating and participating in rural energy projects.

The Forest Research Institute of Yunnan province in Southwest China has carried out a comprehensive research on women and rural energy based on case studies in nine different counties in the province. (In Yunnan province, the Forest Department of the provincial government is in charge of rural energy development.) The findings of the study show that although the form and type of technologies vary from project and region, several common achievements can be identified as follows:

- The energy project has brought great benefits to women in terms of health and living environment. The physical workload has been reduced, and in many cases less fuel consumption resulted in savings and more time available for increased opportunities for other activities.
- Decision making on fuel and household expenditures in rural China mostly relies on women. Thus, knowledge about energy technologies and related issues is as essential as active participation in energy projects. These energy projects have provided opportunities of training and self-improvement for many women, which in turn have ensured the success of project/technology promotion and implementation.
- Engaging women in energy projects has been seen as one of the means to increase their self-confidence in taking part in community development and getting involved thereafter in all other fields of rural development, some even becoming a leading force in rural economic reform.

4.2 Rural Energy and Community Development

The lifestyle of rural communities links closely to energy production and use. Issues discussed in previous sections all have a profound and complex impact on rural communities. The availability of modern energy services, such as electricity, heated water, and liquid cooking fuel, has affected rural life as it has in urban areas. It has contributed to the modernized agriculture and rural industries, improved the indoor air quality, enriched life with new information and opportunities, increased the speed of daily rhythm, and changed traditional habits and ideas. Closure of rural coal mines unavoidably seriously affected employment and income generation, directly and indirectly, since these coal mines employed more than 3 million rural laborers and were the main source of fuel for most rural industries where more than 20 million were employed. Moreover, coal has been the economic foundation of half of the coal-producing counties. The communities in these regions are in transition. Social security and training for reemployment are main issues of concern, among others.

Meanwhile, evolution of rural society, such as reduced family size and improved living standards, has in turn challenged the energy supply, technology, and policy. Stove programs in the past have helped millions of households to build stoves for large multigeneration families. Many of them are not used regularly, particularly when gaseous fuels became available and affordable. It is often observed that

various types of fuel are used in rural household due to mainly economic and security reasons. More and more agro-residues have been left unused when better quality fuel was available and higher living standard was achieved. The ban of open burning of residues would have to be combined with control and enforcement, which is rather costly. Also it does not provide alternatives to utilize the materials. As already discussed, gasification technology has been demonstrated to be a viable solution. One of the key issues on village scale application is the management of a gasification system. Village communities should be mobilized to either direct management or cooperation with service providers. Fuel supply policies, financial incentives, and energy market should be designed with these issues in mind.

5. LOOKING FORWARD

China's Tenth Five-Year Plan (2000–2005) has set several targets in relation to rural energy. By the year 2005, annual modern renewable energy utilization is expected to reach 13 Mtce (excluding hydroelectricity and traditional biomass). This would avoid 10 million tons of CO_2 and 600,000 tons of SO_2 and particulates emissions. It would also electrify 5 million to 6 million people and provide employment for 200,000 people. Annual production capacity and total installation of solar water heaters are expected to be 11 million M^2 and 64 million M^2, respectively, and for PV, 15 MW, and 53 MW, respectively. Wind power installation is expected to reach 1.2 million KW. Annual production of equipment would be equivalent to 150 ~ 200 MW capacity. Finally, large-scale biogas application in industries and husbandry and biomass gasification are expected to provide 2 billion M^3 fuel gas.

Compared to energy use in 1998, modern renewable energy utilization will more than double. Although consumption of modern renewables has been increasing fast, financial support remains crucial given the current immature development of the market and business environment. Experiences show that government plays an essential rule in this respect as an enabler rather than a controller. Financial support from all levels of government offices should be rightly focused, catalytic in nature with no distortion of the market, and costs and benefits truly reflected in economic values.

Traditional energy resources in many rural areas have been considered free. This concept does not only undermine the importance of energy efficiency, but also hinders the promotion of clean fuels, such as biogas and producer gas from gasification. Commercial utilization of biomass resources will be an important step toward better resource management, which is essential for sustainable rural development.

With the increasing gap in income and living standards among different rural regions, energy demand varies greater and greater from area to area. Income for farmers without any other source of income, accounting for 68% of total rural households, has been decreasing in 1999 and 2000, while the national average of rural income has increased 2%. Lower income households, most likely, will still rely on traditional biomass fuel, whereas, higher income farmers will demand modern and clean energy services. Rural energy policy and technology will need to be diverse and locally customized.

Glossary

administered price mechanism A government-run system of price subsidies aimed at making household energy more affordable.

commercial energy Typically this refers to fossil fuel-derived fuels, such as liquefied petroleum gas, kerosene, natural gas, and coal.

rural electric cooperatives (RECOs) Public–private institutions whose mission is to extend the network and provide services in villages.

traditional energy Typically this refers to biomass-based energy sources, such as fuelwood and animal manure.

India ranks sixth in the world in terms of energy demand, accounting for 3.5% of global commercial energy demand in 2001. India's energy sector is administered at the apex level by five ministries (including the Department of Atomic Energy), whereas the Planning Commission carries out the energy planning exercise for different sectors in the form of 5-Year Plans. Such plans have advocated a strategy focusing on rationalizing tariff, giving a greater role to market forces, enhancing private sector participation, and promoting renewable sources, among other strategies. The Ninth 5-Year Plan (1997–2002) stressed the need for research and development in the fields of energy conservation and demand-side management. It also focused on enhancing the pace of exploration and development in the hydrocarbons sector to reduce dependence on imports. A major thrust was placed on infrastructure development, particularly energy and power, with plans for enhancing related public expenditure. By the end of the Ninth Plan, the share of commercial energy was expected to increase from 66 to 75%, and the share of noncommercial energy was expected to decline from 34 to 25%. The main elements of power sector reforms in the Tenth Plan (2002–2007) include attempts at rationalization of power tariffs, unbundling of state electricity boards (SEBs), gradual privatization of distribution, and 100% metering of all consumers. In addition, it focuses on hydroelectricity and the possibility of expanding nuclear energy for electricity generation. The implementation of these plans is the responsibility of respective ministries that coordinate with the state governments; the National Development Council provides a forum for coordination at the highest levels of government. In terms of rural access, the more than 700 million rural poor in India have limited access to energy sources, such as electricity, and nontraditional cooking fuels, such as liquefied petroleum gas (LPG). Consequently, the rural energy scenario in India is dependent more on nonmonetized, biomass resources than on monetized or commercial forms of energy. This is amply borne out by the fact that over 72.3% of Indian households depend on traditional sources of energy, such as fuelwood, animal dung, and crop residues, for meeting their cooking and heating requirements. In this regard, over the years, the government, through its various committees and groups, such as the Fuel Policy Committee, the Working Group on Energy Policy, the Advisory Board on Energy, and the Energy Demand Screening Group, has formulated programs aimed at rural energy provision. The efforts have been primarily in the form of national programs for rural electrification, biogas development, improved cookstove dissemination, and promotion of renewable energy technologies (RETs), such as solar cookers and lighting devices. However, despite the existence of these programs for nearly two decades, their impact on the rural energy scenario has been limited.

1. ENERGY CONSUMPTION

In the context of energy consumption, considerations of equity have several dimensions. The most important of these is that adequate energy of good quality is available and accessible to all, such that the poor are able to meet their needs, particularly their needs for cooking fuel and basic lighting. In developing countries such as India, the aspect of quality is important because the use of biomass fuels with low calorific value has serious health implications on account of resultant high levels of indoor air pollution. Clean and good-quality fuels, therefore, need to replace the large-scale use of inferior fuels that are prevalent in India.

The per capita energy consumption in India stands at 479 kg of oil equivalent, which is only 20% of the global average in 1999. One of the main reasons for this is the fact that existing rural energy supply programs often bypass the rural poor because they are unable to interpret their needs and priorities. Even programs specifically meant for the rural poor—supply of kerosene through the public distribution system (PDS) or improved cookstove programs—do not reach them properly or are rejected by them because the initial design does not take into account their needs and priorities.

1.1 Electricity Consumption

With regard to electricity, the consumption pattern was 32% for agriculture, 31% for industry, and 20% for domestic use, and the remaining uses, including commercial and street lighting, make up the final 17%. At the national level, electricity and kerosene are the primary sources for lighting, in both rural and urban areas, and accounted for 99% of households. There has been an increase of 6.5% (from 37 to 43.5%) in the proportion of rural households using electricity as the major source of lighting since 1993–1994. On the other hand, there was a decrease in the percentage of households using kerosene as the primary source of energy for lighting, from 62 to 55.6% in rural India (Fig. 1).

1.2 Consumption of Biomass Fuels

Biomass fuels provide 85–90% of domestic energy and 75% of all rural energy (Table I). Of the total rural energy consumption, approximately 52.5% is met from fuelwood, and fuelwood consumption in 2001–2002 was estimated at 223 million tons (MT).

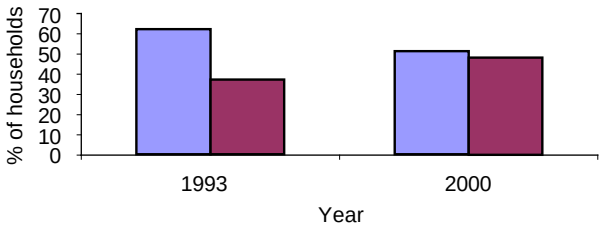

FIGURE 1 Percentage of rural households in India using electricity and kerosene for lighting.

TABLE I

Consumption of Traditional Fuels

- Biomass fuels provide ~90% of the energy in the rural domestic sector and 65% of all rural energy
- Fuelwood is the largest contributor to energy use in rural areas, followed by animal dung and crop residues
- Women and children collect most of the fuelwood, in the form of twigs and branches
- Inefficient use of biomass in traditional devices has serious global and local environmental effects
- Traditional fuels are responsible for adverse impacts on health, especially the health of women and children

Source. Reprinted from National Sample Survey Organization (2001).

Of this, 180 MT was for rural households and the balance was for cottage industries, large hotels, etc. However, against this demand the annual sustainable yield of fuelwood from different land sources is only approximately 86 MT. The consumption of animal dung and agro-waste is estimated at 130 MT; this does not include wet dung used for biogas plants.

The 55th Round of the National Sample Survey Organization survey indicated that firewood and chips were the most important source of energy used for cooking in rural India, with 76% of households dependent on it in 1999–2000. The survey also revealed that only 3% of households have switched from this source to other sources of energy since 1993–1994. The Rural Energy Database compiled by The Energy and Resources Institute has also indicated the highest per capita per day consumption for fuelwood (Fig. 2).

Among rural households, the use of fuelwood and chips declines and the use of kerosene and LPG increases with rising incomes. However, the transition across income classes is not significant, with the result that even in the highest income category, over 70% of rural households depend on fuelwood chips or dung cakes for cooking.

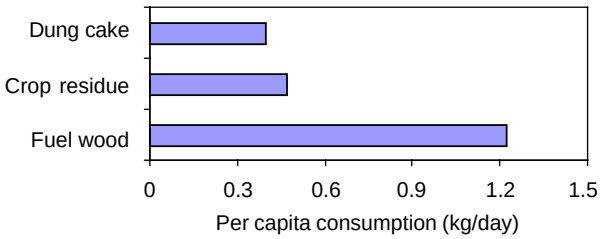

FIGURE 2 Daily per capita consumption of biofuels in rural households in India. Reprinted from TERI (2000), with permission.

There are regional variations in biomass consumption, borne out by the fact that the consumption of fuelwood ranges from 2.04 kg per household per day in Haryana to 14.14 kg per household per day in Orissa. The fuel mix also varies from region to region depending on the resource endowments. Fuelwood consumption is high in states that have considerable forest cover. For instance, in Arunachal Pradesh, it is 10.4 kg per household per day, and in Manipur, it is 10.34 kg per household per day. On the other hand, consumption of dung cakes is high in states such as Uttar Pradesh (4.95 kg per household per day) and Rajasthan (3.41 kg per household per day), which have little biomass cover. Crop residues, being inferior in quality, are used in most areas as backup fuels when there is a shortage of other fuels.

1.3 Commercial Fuel Consumption

Over the years, the dependence of rural households on dung cakes, coke, and coal has fallen and dependence on kerosene and gas has risen. However, in rural areas, the overall shift to commercial fuels has been marginal. Among commercial fuels, kerosene is used predominantly for lighting. Estimates put total kerosene consumption for rural lighting at close to 7 MT. Subsidies on petroleum products, such as kerosene, have contributed to an increase in the demand for kerosene. However, despite a significant increase in the supply of commercial energy, the consumption of commercial fuels, such as LPG, is still negligible in rural areas, with less than 5% of the households using the fuel for cooking.

1.3.1 Kerosene

Kerosene is the main source of lighting in rural India. The total kerosene consumption in India in 2000–2001 was estimated at 10.5 MT, over 50% of which was in the rural areas. In India, there are two systems for the supply of kerosene to households. One is through the PDS at subsidized rates, forming the main source of supply for rural consumers. The other is the parallel marketing system at market-determined prices. Traditional kerosene lighting devices are used by 74.62 million households throughout India. As is well known, the fuel consumption of these devices is much too high and the quality of light is very poor. Furthermore, their use has adverse impacts on the health of people. Hence, nonelectrified rural households and a majority of electrified households continue to use kerosene for lighting.

The per capita allocation (PCA) of kerosene for states ranges between 10 and 24 kg/year. In 1999–2000, the maximum PCA of kerosene had been frozen at 24 kg/year. Moreover, a private party can import kerosene after obtaining a rating certificate from an approved rating agency. The kerosene is to be sold at market-determined prices by the private parties through their own distribution networks. The quantity of kerosene marketed under the parallel marketing scheme in 1999–2000 accounted for approximately 10% of the total kerosene consumption in the country. The contribution of kerosene through parallel marketing in rural areas, therefore, remains very small.

1.3.2 Liquefied Petroleum Gas

Four public sector undertakings—Bharat Petroleum Corporation Limited, Hindustan Petroleum Corporation Limited, IBP Company Limited, and Indian Oil Corporation Limited—are engaged in the marketing of LPG in the country. With the increased availability of LPG, the number of customers enrolled by these companies has also been increasing. Consumption has grown from 100 MT in 1985 to over 6000 MT in 1999. The number of LPG customers served by the four oil companies as of January 1, 2000 was 43.6 million. However, the rural penetration during this period was just over 1% of the total households.

It is also estimated that in the next decade there will be a rapid increase in the consumption of LPG. Given the near-saturated scenario of the urban market, a large portion of this increase in estimated consumption will occur in rural areas. This is due to the fact that with the increasing nonavailability of traditional fuels, and LPG being a convenient and safe cooking fuel, the government has decided to commence marketing of LPG in rural areas. Furthermore, with a view to penetrate the rural areas, the Ministry of Petroleum and Natural Gas approved a special scheme in July 1999 for the release of new LPG connections in the rural sector against the

surrender of corresponding kerosene quota through the following strategies:

- Opening of extension counters in rural areas within a 15 km radius of the normal trading area of existing distributors operating in the urban areas.
- Award of interim LPG distributorships to the state civil supplies corporation or the concerned state government body until a regular distributor is approved.

In November 1997, the government decided to dismantle the administered price mechanism in a phased manner. As a result, the subsidy on domestic LPG was decreased to 15% in 2000–2001. Moreover, in order to increase LPG availability, the private sector has been allowed to participate in the schemes of parallel marketing of LPG since April 1993. Under the scheme, a private party can undertake the import of LPG and the procedure is the same as that for kerosene. As of January 1, 2000, 695.1 MT of LPG had been imported by the private sector under the scheme.

Despite the fact that LPG has been available for a number of years, it has not penetrated the rural areas of the country. The continued subsidy on LPG has basically hampered the growth of the parallel market and, thereby, adversely affected the penetration in rural areas. On the other hand, the low-income levels in rural areas are responsible for low buying capacities of the rural communities. Moreover, people in the rural areas are not shifting to LPG, as fuelwood is cheap and easily available. For LPG, delivery is not to their homes and means of transportation are not available. Also, there is a fear that LPG is a dangerous fuel. In most companies, the policy is that cylinders are refilled after 21 days. However, owing to logistic and economic reasons, rural customers usually take 3 months to get the cylinders refilled.

1.3.3 Consumption for Agriculture

The agriculture sector is the second largest energy consumer in rural India. Here, the animate energy (human and draught power) accounts for a substantial portion of the total energy consumed. However, the share of human labor and animal power in total energy consumption for agriculture has decreased over the years, indicating progress in farm mechanization. Agriculture accounts for approximately 32% of the total electricity and 95% of the total water consumption in India. Diesel oil and electricity are the major sources of energy used for irrigation. Very small numbers of solar pumps and wind-energy-based pumps are also used.

With the introduction of Green Revolution technologies, the demand for irrigation increased. To meet this increased water requirement, rapid farm mechanization programs along with policy measures such as underpricing of power and irrigation were initiated. As a result, the number of pump-sets has increased and was reported to be close to 20 million, of which just over 12 million had been energized. In 1999–2000, the average farm power availability was 1.15 kW/ha, whereas for desired levels of productivity and appropriate postharvest technologies, a minimum essential estimate is 2 kW/ha.

As mentioned earlier, irrigation is the most important end use, but owing to subsidies, the marginal cost of pumping water is zero. This leads to energy wastage, overpumping, and inefficient crop selection. Flat-rate pumping also masks the true cost of power to farmers. One study indicated that significant energy losses are associated with the distribution of electricity and in the poor selection, installation, maintenance, and operation of electrical motor pump systems.

Suboptimal allocation of resources toward the distribution system places a further burden on the already vulnerable system, causing deterioration in the quality and reliability of supply, leading to further burnout of motors and problems of overloading. The situation is further compounded by the fact that there are a number of illegal connections and cases of cheating in terms of practice of "motor nameplate switching," whereby higher capacity motors have their labels altered to indicate lower ratings. In a flat-rate tariff system, this further robs the utility of its legitimate revenue.

2. RURAL ELECTRIFICATION

Rural electrification received attention only after the formation of the SEBs in 1948. The Rural Electricity Corporation (REC) was formed in 1969 to administer the Central Plan outlay and provide loans to the SEBs and rural electric cooperatives (RECOs) for rural electrification. The RECOs were entrusted with the task of extending the network and providing services in villages. Thus far, 41 RECOs spread throughout 12 states have been sanctioned by the REC, of which 33 are still in operation and 8 have been taken over by SEBs. The important players in the power infrastructure scenario in India are the SEBs, Power Grid Corporation, Power Finance Corporation, public and private power-producing utilities such as the National Thermal Power

Corporation, Central Electricity Authority, and electricity regulatory commissions. All of the above entities play a very important role in the electrification of rural areas.

Of the 587,258 villages in the country (1991 census), 507,451 (86.4%) were declared electrified by December 31, 2000. Of the over 80,000 nonelectrified villages, most (99.14%) are in Uttar Pradesh, Bihar, Orissa, West Bengal, Meghalaya, Arunachal Pradesh, Tripura, and Rajasthan. The Tenth Plan envisages covering approximately 62,000 of the said villages and the remaining 18,000 remote villages are proposed to be covered by renewable and decentralized sources of energy.

On the other hand, although the per capita consumption of electricity in India was 360 kWh in 1998, the demand for electricity has been increasing at a faster rate, resulting in energy shortages. In order to further the efforts of extending the grid to rural areas, the Government of India launched special programs for rural electrification. One such program was the Minimum Needs Programme, introduced in 1974 with the objective of establishing a network of basic services and facilities in all areas within a given time frame. One of the basic services identified was rural electrification. Earlier, a 100% loan was released to the SEBs under this scheme, but since 2000–2001 it has been released to the state governments. Also, approximately 3.8 million households have been provided single-point light connections under the Kutir Jyoti scheme (1988–1989) for poor rural households.

A 7-year plan is being implemented for rural electrification and has been made part of the minimum needs program; funds are available under the Pradhanmantri Gramodaya Yojana. Under this scheme, 50% of the money is available in the form of grants. In the 2002–2003 budget, interest subsidy has also been provided to states borrowing under this scheme. Money can also be drawn through the Rural Infrastructure Development Fund. Moreover, the REC is also working on a scheme for electrification of 0.4 million hamlets. In addition, discussions are under way with the Ministry of Nonconventional Energy Sources regarding the electrification of 18,000 villages, which cannot be reached through the grid. These villages would be provided electricity through renewables.

However, a disturbing trend is that the rate of electrification of villages has been steadily declining after the Seventh Plan. State agencies are not keen on investing in areas of village electrification and pumpset energization. They do not consider them remunerative. Also, with increasing subsidies, the returns on the investment affected the loan-repaying capacity of the SEBs.

As mentioned earlier, 86% of the villages have been electrified. The remaining villages are in six states. However, there has been an 85% reduction in the outlay for rural electrification in the Ninth Plan as compared to the Seventh Plan. The situation is further compounded by the definition of village electrification as adopted by the Government of India: "A village will be deemed to be electrified if electricity is used in the inhabited locality within the revenue boundary of the village for any purpose whatsoever." Therefore, the electrification of a village does not imply that all the houses in a village have electricity. Moreover, long and cumbersome procedures for obtaining connections and paying bills and the distance to repair facilities were some of the factors that affected acceptability. It has also been observed that, starting from the electrification of a village to the procurement of a connection for a household, the time factor can vary from a couple of months to a few years.

Finally, rural India is characterized by small human settlements and given the fact that the energy requirements of these settlements are much lower than in urban and industrial centers, there is high cost of transmission along with severe transmission and distribution losses. Also, although close clusters characterize rural settlements in the plains, settlements in the hilly and forest regions are highly dispersed. Given such a sparse nature of the demand, it becomes economically infeasible to provide power transmission lines to a few houses with a load of a fraction of a kilowatt. Consequently, rural electrification programs have proved expensive and, with the existing constraints on incomes, customers have just not been able to pay for electricity supplies received by them.

3. SUBSIDY REGIME FOR FACILITATING ACCESS AND EQUITY

One of the fundamental causes of rural poverty is inaccessibility to the minimum amount of energy to meet people's basic needs. Hence, the decision makers and planners must assign a high priority to energy provision, irrespective of communities' ability to bear the costs of supply and delivery. Perhaps one of the most critical issues in rural energy development is the nonmonetized nature of many aspects of the rural economy—in particular, the bulk of energy supplies in the form of wood and other biomass fuels. Owing

to availability of "free" sources of energy, it has not been a priority in terms of expenditure on basic amenities. However, in order to move beyond satisfaction of basic needs toward higher levels of economic productivity does mean the introduction into rural societies of modern energy sources.

Recognizing the need to provide access to energy for the poor, the government has provided subsidized energy through either the PDS or the State Electricity Boards. Typically, these subsidies were provided to the residential and agricultural sectors in the form of LPG and kerosene for the former and electricity for the latter. However, the merits of government subsidies designed to accelerate substitution are debatable. Owing to the price distortions that they produce, it is inevitable that most of the subsidies benefit higher income strata and commercial establishments rather than disadvantaged households.

3.1 Subsidy for Irrigation

The total amount of the subsidy on electricity for agriculture and the rural domestic sector has been increased from 202,099 million rupees to 330,814 million rupees in 1999–2000. Of this, just over 70% is provided to the agricultural sector for meeting its irrigation requirements. In contrast, at the all-India level, only 10–12% of the cost of power supply for irrigation purposes is recovered. Moreover, Gulati *et al*. have estimated that the work of each unit of electricity going to agriculture in terms of its contribution to crop output turns out to be 9 rupees per kilowatt-hour for net output at 1995–1996 prices. The farmer, on the other hand, on an average, pays only 0.2 rupees per kilowatt-hour for power. Consequently, over the years, the impact of the subsidies has been twofold: (1) it has led to financial and technical starvation of SEBs and (2) highly subsidized power has led to the overexploitation and misuse of groundwater.

3.2 Deterioration in the Condition of State Electricity Boards

Owing to poor or negligible revenue, the operating as well as financial condition of most of the SEBs has deteriorated over time. The main cause is their inability to recover costs from different consumer segments. For SEBs to break even, state governments need to make budgetary provisions in excess of 5% of their total revenues. If the SEBs are to earn a commercial rate of return (15–16%) on their assets, the subsidies must be five times more than those needed to break even, so that the required subsidy, in 1999, would equal 25% of the state government revenues, or 12 billion dollars.

3.3 High Rate of Groundwater Withdrawal

The rate of groundwater withdrawal is closely linked to energy prices. In most states, power to agriculture is supplied at a flat rate based on the capacity (horsepower) of the pump rather than on the actual quantity of electricity consumed to pump the water. Thus, a high implicit subsidy is built into the system. As a result, many regions in India are witnessing shortages in water supply, with groundwater levels having fallen as much as 1 to 3 m per annum to levels more than 70 m or more below their levels 30 years ago. Approximately 12% of all aquifers are severely overdrawn. Overexploitation of groundwater by farmers has lowered water tables. Overexploitation is also a significant contributor to India's growing carbon emissions, as considerable additional pumping energy is required to extract deeper water supplies.

3.4 Subsidy on Liquefied Petroleum Gas and Kerosene

Even after the dismantling of the APM, it was decided that the government would continue to subsidize kerosene and cooking gas. Consequently, in the 2002–2003 union government budget, the government has set aside 64.95 billion rupees as a subsidy on kerosene and cooking gas for fiscal year 2002–2003.

4. ROLE OF RENEWABLES IN FACILITATING TRANSITION AND DECENTRALIZATION FOR REMOTE AREAS

India is endowed with abundant natural and renewable resources of energy. The country has been able to achieve significant capacity addition of 1367 MW through wind farms and ranks fifth in the world. Overall, the renewable energy sector contributes over 3400 MW, supplementing and complementing the conventional energy sector in meeting the country's growing energy needs. Moreover, it also helps in meeting the global demand for limiting the emissions of greenhouse gases into the atmosphere. The status of the installation of RETs is indicated in Table II.

TABLE II

Status of Installation of Renewable Energy Technologies

Technology	Potential	Achievement	India's position (in the world)
Biogas plants (units)	12 million	3.3 million	2nd
Improved cookstoves (units)	120 million	34 million	2nd
Wind (MW)	45,000	1702	5th
Small hydro (MW)	15,000	1463	10th
Biomass power/cogeneration (MW)	19,500	468	4th
Biomass gasification (MW)		53	1st
Solar photovoltaic (MW/km^3)	20	107	3rd
Waste to energy (MW)	2,500	25	—
Solar water heating	140 million km^2 collector area	0.68 million km^2 collector area	—

Source. Reprinted from Ministry of Nonconventional Energy Sources (2003).

By their very nature, rural areas lend themselves amenably to the use of renewable energy. RETs generally provide decentralized and modular ways of meeting energy demands. Rural areas in India have an abundance of solar energy that can be exploited for both thermal and electrical applications. Biomass energy is conventionally referred to as traditional energy but, when used in modern technology applications, also qualifies as renewable energy. The dissemination of RETs in the country has been mainly through government programs that have primarily helped in introducing rural people to the technologies, but have not been successful in wide-scale dissemination and penetration. Given the nonviability of extending the power grid to remote areas, RETs can provide a means by which a decentralized supply of energy for such areas becomes feasible and close to being economically viable. In this regard, the plans of the concerned ministry are indicated in Table III.

Clearly, most of these initiatives are geared to meet rural energy requirements. In essence, India is on the edge of a new revolution in the management of rural energy problems and must, therefore, devise policies that move away from the mindsets of the past and build on the technologies for the future.

5. CONCLUSION

Since a major part of the planning process pertaining to rural energy has been left to consumers themselves, the cost of the fuel, economic status of the community, and easy availability are the determinants for the type of fuel and technology used for meeting energy needs. One of the main reasons for the absence of a modern energy supply in rural India is the low purchasing power of the people. Given the fact that a vast majority of rural people have limited cash, they find it difficult to afford the initial costs of acquiring more efficient and cleaner fuels and technologies. Consequently, the rural poor are drawn into a cyclic pattern of energy consumption that adversely affects the resource base as well as the individuals.

With the emphasis on electricity reforms, accelerated rural electrification, and increasing the share of renewables in the overall energy consumption, the scenario is changing. The country is on the threshold of a major change in the energy supply-and-demand scenario and the right policies and initiatives will facilitate the realization of the objective of energy for all.

TABLE III

Renewable Energy Plan 2012 of the Ministry of Nonconventional Energy Sources, Government of India

- Coverage of 30 million households through improved cookstoves
- Setting up of an additional 3 million biogas plants
- Deployment of 5 million solar lanterns and 2 million solar home systems
- Deployment of solar water heaters in 1 million homes
- Addition of 10,000 MW of renewables-based power
- Electrification of 18,000 remote villages

commerce/services sector Contains commerce, handcraft, construction, public and private services, trade, agriculture, and others.
final energy Supplied to the consumer to be converted into useful energy (e.g., electricity at the wall outlet).
residential sector Comprises private households.

The world has to deal with an increase of the global energy consumption. This affects each of the classical consumer sectors: industry, transportation, residential, and commerce/services. To a large extent, the rising energy demand will be met by extending the use of conventional energy carriers such as oil, natural gas, and coal. This is a global trend, even though the characteristics of this development may vary from continent to continent and from country to country. To detect the reasons for energy use, inventories of energy consumption and analyses of energy application were always practical. Across-the-board comparisons of continents or countries are of little help. Taking into account parametrically effective factors on the energy consumption brings some transparency and understanding of what would otherwise be rated and commentated falsely. This applies in particular to the commerce/services sector, which had occupied a shadow existence in the national energy balances for a long period. Fortunately, the provision of data to this sector has improved substantially, and many gaps can be closed. Creating a first country-wise data framework for energy consumption, which can be consulted for comprehensive country-related analyses, is a large merit of international statistics. However, this may not lead to a blind belief in the reliability of energy consumption data. Critical notes are therefore always helpful and appropriate. This article deals with the energy consumption structure of the commerce/services sector, indicates parameters of influence and supplies results and perceptions that apply worldwide, for chosen countries, and in Germany.

1. COMMERCE/SERVICES: ELEMENT OF A FINAL ENERGY BALANCE

This article examines the significance and importance of the commerce/services sector by consulting the energy consumption data for 1995, as published in 1998 by the World Energy Council. Based on the six continents—North America, Central/South America, Europe, Africa, Asia, and Oceania—continental energy balances were set up as shown in Fig. 1. It appears that the proportion of the industry is situated between 18% and 40%, the transportation sector accounts for 22% to 45%, private households account for between 13% and 58%, and the proportion of the commerce/services sector varies from 3% to 12%.

By differentiating between continents, it is possible to mark out climatic influences as well as population density and economic prosperity, as shown in Figs. 2 and 3. As a consequence, a large bandwidth of the specific final energy consumption can be noted. In terms of final energy demand, North America consumes 155 GJ per capita and year, while Africa consumes 16 GJ per capita and year only.

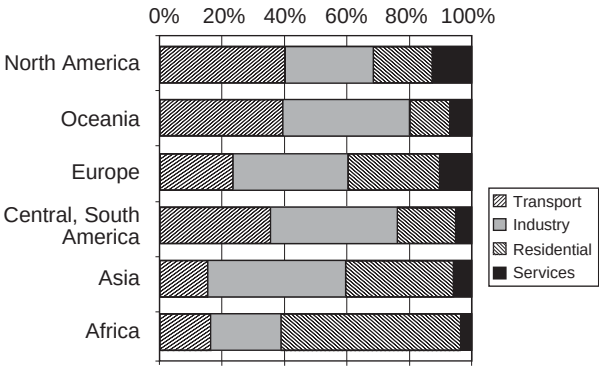

FIGURE 1 Contributions of the different sectors to the final energy demand in 1995; 100% represents the total demand of final energy.

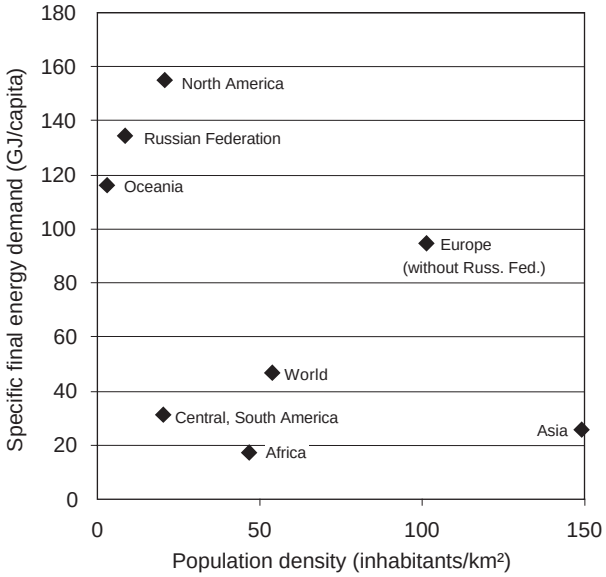

FIGURE 2 Specific final energy demand in relation to the continental population density in 1995.

It can be postulated that an increasing population density reduces the expenditure for transportation and thus its proportion of the final energy consumption. Shorter distances of transport and communication as well as shorter commuter distances result in lower consumption values in the traffic sector (Asia, Europe, Africa). On the other hand, a low population density causes substantial consumption impulses for the traffic sector. This does not remain without effect on the energy consumption in the sector commerce/services.

Each society requires products and services, whereby substantial levelings are to be assumed—not only depending on the prosperity and the gross domestic product, but also on the capability for exports. A

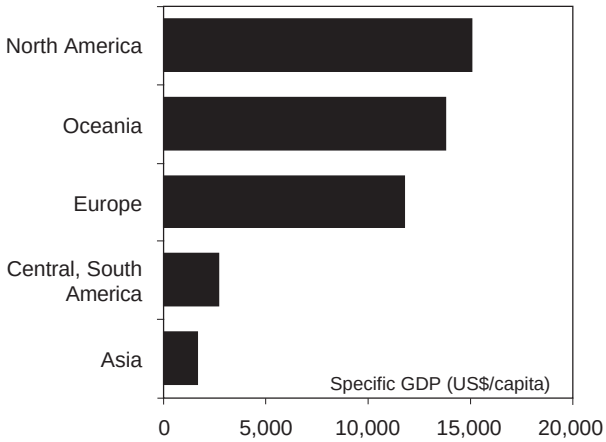

FIGURE 3 Specific GDP of the different continents in 1995.

sharp demarcation of industry and handcraft, respectively, of industrial structures and small trade activities regarding the associated energy consumption causes some problems. Thus, the proportions for industry and commerce/services in Fig 1 should be considered as a reference value instead of as a definite mirror image of accurate allocation.

The common life of each society, whether it is shaped industrially, agriculturally, or mixed, requires services and the supply of everyday products such as nourishments. In the course of social restructuring with increasing prosperity, the tendency toward division of labor is enforced. This means that while the national income is still low, handcraft, small trade, and agriculture are, to a large extent, connected to the residential sector. With increasing prosperity, a separate services sector emerges and organizes. These circumstances are also reflected in Fig 1: while in industrialized continents with above-average per capita income (North America, Oceania, Europe) the activities of commerce and public services are "appropriate," verifiable, and delimitable to other consumption sectors, this is not always possible in Asia and Africa, where these activities are partly contained in the residential sector.

We are still a long way from an accurate image and sharp delimitations, even though large progress in the collection of international consumption structure data has been made.

2. DEMARCATION OF RESIDENTIAL AND COMMERCE/SERVICES

The boundaries between the residential and commerce/services or handcraft and agriculture are often

diffuse as far as the associated energy consumption is concerned. This becomes relevant whenever the same building is used for residential and occupational purposes, when a household cannot be separated from an agricultural supplementary income, or if members of a family are temporarily bound in a business.

Statistically proven consumption delimitations have to be considered under these aspects too: what is separately accounted for as commerce/services in one country can be accounted for under the category of residential in another country. Therefore, careful handling of sector-specific consumption data is inevitable if these are to be analyzed or interpreted or if a landspreading transverse comparison is to be carried out, as is demonstrated next.

Figures 4 and 5 show the per capita consumption of electricity and fuels for households and commerce/services, again aggregated by continents. It is remarkable that the electricity consumption of commerce/services is generally higher than the electricity consumption of the residential sector; for residential it ranges from 0.3 GJ/cap in Africa to 10 GJ/cap in North America. The fuel consumption for residential is significantly higher than it is for commerce/services; the values of the latter spread between 0.6 GJ/cap in Africa and 12 GJ/cap in North America.

For a better understanding of these specific consumption values, one should know that from 20 to 50% of the population is involved in the sector "commerce/services/handcraft/agriculture" because of employment, occupation, or simply for covering vital needs.

This note seems necessary, if energy consumption is expressed as giga joule per capita and is not allocated to its origin (e.g., earner or employee of a consumption sector). If earner or employee is chosen as base factor, the specific consumption is between two and five times higher according to the relation of inhabitants per earner/employee.

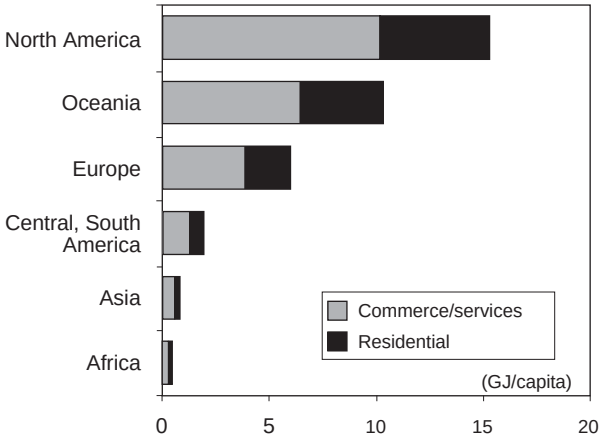

FIGURE 4 Specific electricity consumption of the commerce/services and residential sectors in 1995.

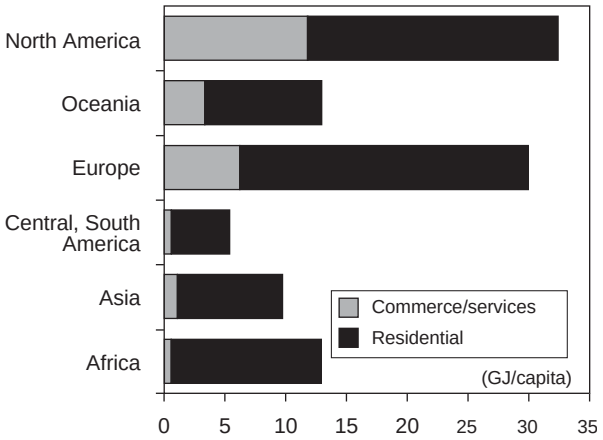

FIGURE 5 Specific fuel consumption of the commerce/services and residential sectors in 1995.

3. COMMERCE/SERVICES/ HANDCRAFT/AGRICULTURE

Figure 6 shows the final energy demand per capita for the sector commerce/services (handcraft and agriculture might also be avcontained). It is differentiated by continents and therefore also by climates and by consumption of fuel and electricity.

For the fuel consumption, mean values between 10 GJ/cap and 0.15 GJ/cap occur in the following order: North America, 10 GJ/cap; Europe, 5.6 GJ/cap; Oceania, 2.6 GJ/cap; Asia, 0.9 GJ/cap; Africa,

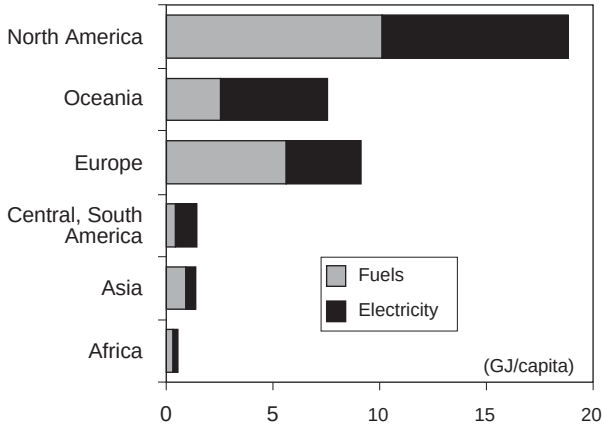

FIGURE 6 Specific final energy demand of the commerce/services sector in 1995.

0.25 GJ/cap; and Central, South America, 0.15 GJ/cap. The energy consumption values are mainly due to heating, conditioning of the work space, and the supply of warm water. The required area per employee at his or her workplace must be considered.

Based on temperature conditions as they occur in North America and Europe, an estimated area requirement of 40 m^2 per wage earner and a heating requirement of 200 kWh per m^2 and year and a specific consumption of 8000 kWh or 28.8 GJ per wage earner and year can be calculated. Rated by 0.3 wage earners per capita, an energy consumption for space heating in the sector commerce/services of 8.6 GJ per capita and year can be assumed.

This is a standard consumption level for heating purposes in many prospering industrial societies.

Another standard consumption level is represented by the need for heated water (for washing, bathing, showering), which accounts for 300 kWh per wage earner and year, respectively, 1.08 GJ per wage earner and year. This corresponds to 0.3 GJ per capita and year. Thus, with only a few characteristic values, the specific final energy demand of 10 GJ per capita and year can be explained and analyzed to a large extent.

Finally, area requirements of 40 m^2 per wage earner correspond to empirical average values, which may vary significantly in individual cases. Employment structures with areas per employee of 100 m^2 are also not unusual, if attractiveness within the service area and customer demands require this.

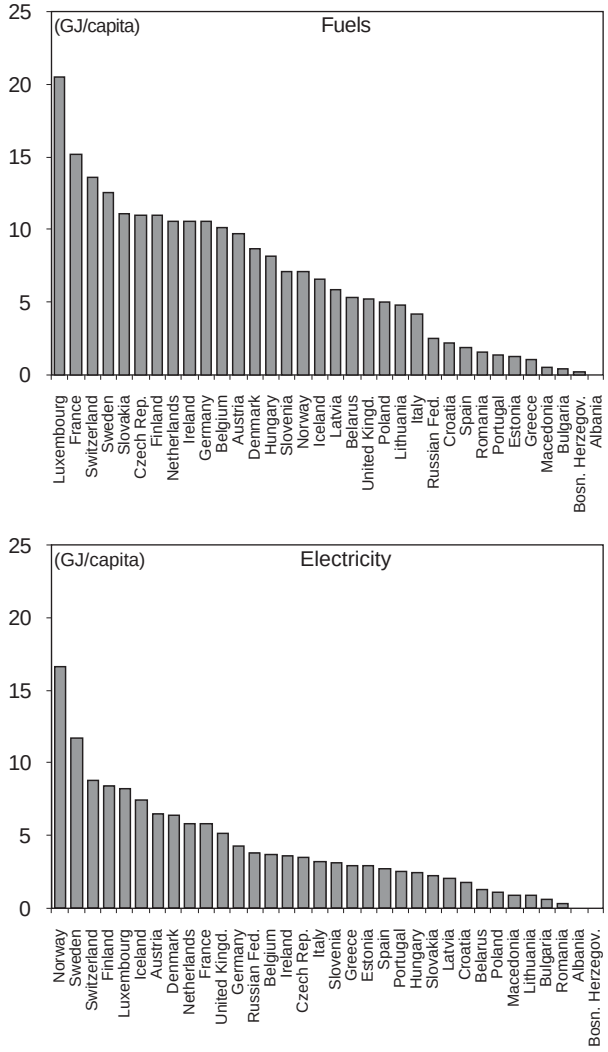

FIGURE 7 Final energy demand of the commerce/services sector in Europe in 1995.

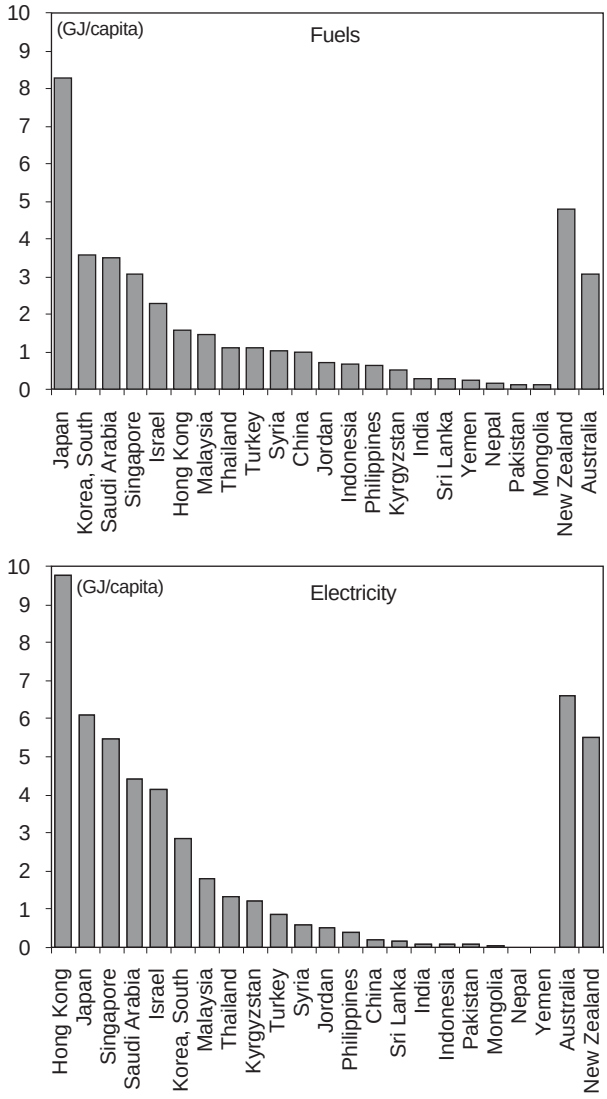

FIGURE 8 Final energy demand of the commerce/services sector in the United States in 1995.

Energy consumption values for room conditioning (heating, ventilation, air conditioning) of 200 kWh/$m^2 * a$ are also average values and result in a large bandwidth. On the one hand, thermal protection and heat recovery systems supply appropriate solutions for the reduction of consumption without a loss of comfort. On the other hand, objects with a specific consumption of more than 1000 kWh/$m^2 * a$—no rarity, by the way—are an unnecessary waste of energy.

More details can be derived from Figs. 7 to 10. The European countries indicate a large bandwidth in the specific electricity and fuel consumption, which is to due to climatic influences and different levels of prosperity (Fig. 7). This also applies to the countries in North and South America. Cool Canada and warm South America, rich North America and poor South America, compose basic conditions that influence the specific requirements of electricity and fuel (Fig. 8). The countries of Asia and Oceania are generally situated in warm and hot climates, which is reflected in low specific fuel consumption. While this temperature dependency applies to most of these countries, Japan and New Zealand show an unexpected behavior. In all remaining countries, this factor is temperature dependent as far as possible. The specific electricity consumption represents the prosperity of Hong Kong, Japan, Australia, and New Zealand (Fig. 9). Warm to hot climate zones in Africa lead inevitably to small specific fuel consumption. The economic position of Africa (with a small

specific national income) is again reflected in the low specific electricity consumption (Fig. 10).

Is it possible to deduce overall relations from the facts, like the influence of climate zones and prosperity on the electricity and fuel consumption? To explore this question, we gathered 93 countries in Table I and used these data as a basis for further analyses. Table I contains data for electricity and fuel consumption, GDP (each referred to the number of inhabitants), as well as climatical information.

Generally the application of electrical energy is favored if a high proportion of electricity is generated by hydropower. Therefore, the following countries are excluded from further analyses: Norway, Sweden, Finland, Iceland, Canada, Switzerland, and France.

In Fig. 11 depicts the relationships between the annual average temperature and the specific electricity and fuel consumption. The higher the annual average temperature, the smaller the influence of fuel consumption. The lower the annual average

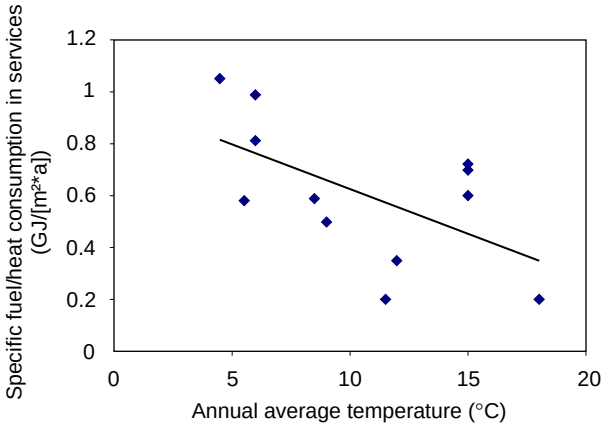

FIGURE 12 Specific fuel and heat consumption of commerce/services in relation to the annual average temperature in 1995.

temperature of a country, the higher the fuel consumption per capita, since space heating gains more and more importance. This behavior sets in from an annual average temperature of 12.5°C. With annual average temperatures between 10 and 0°C, the fuel consumption caused by space heating increases distinctly. Rising prosperity in general leads to a higher specific consumption of electricity and fuel due to more and better electric equipment and heating of larger and well-conditioned rooms.

In Table II presents interesting data for a cross-national comparison (as completed in 2000 by Geiger and Harrison). The average available floor area per capita in the commerce/services sector, GDP, the annual average temperature, and the resulting energy demand for space heating per area and year or per capita and year are included. In Fig. 12 the coherence between cold climate and rising energy consumption becomes obvious too.

4. STRUCTURE ANALYSIS OF THE SECTOR COMMERCE/SERVICES IN GERMANY

Much can be learned from observing the commerce/services sector in Germany. Figure 13 shows the energy consumption broken down into energy carriers and applications such as process heat, space heating, mechanical energy, lighting, and communication for a period of 10 years. By collecting energy requirement statistics, investigating energy consumption, and analyzing changes from year to year, we have come to the conclusion that short-term changes are, in most cases, caused by climatical or cyclical economical reasons fluctuations. Tendentious changes

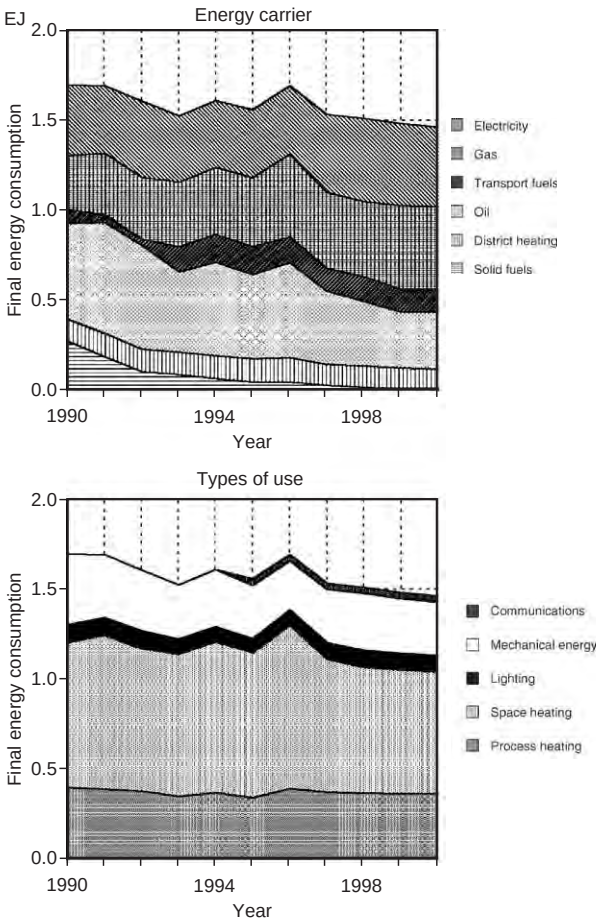

FIGURE 13 Final energy consumption of the commerce/services sector in Germany.

during larger periods result from changes in effective areas, technical equipment, and user requirements.

Beyond this, the question of who needs how much energy and for which purpose is gaining interest. "Who" refers to typical consumer groups from the commerce/services sector. By investigating how much, it is not only of interest to analyze the particular consumption proportions of different consumer groups, but also which consumption per person employed or per m^2 net area is typical. We select "persons employed" and "net area" as base factors, because these are relatively available and also are usually known. "For which purpose" specifies how the energy under investigation is being applied, such as for lighting, electrical drives, communication, space heating, or process heat.

On the basis of inspections, a metering campaign, and a survey of about 2800 companies and facilities during the 1990s, detailed information on the energy consumption and its key indicators could be sampled,

detected, and measured. Twenty-three consumer groups could be distinguished, and data for an additional nine consumer groups could be retrieved from secondary statistical material, with sufficient information quality. Within the scope of the survey, information on electricity and fuel consumption for heating and transportation could be collected. On the basis of equipment size, process load, and user profiles, the electricity and fuel consumption could be analyzed and differentiated according to the purpose of use.

Table III shows the calculated overall consumption by small consumers in 1994; additional

[a] Less than 20 employees.

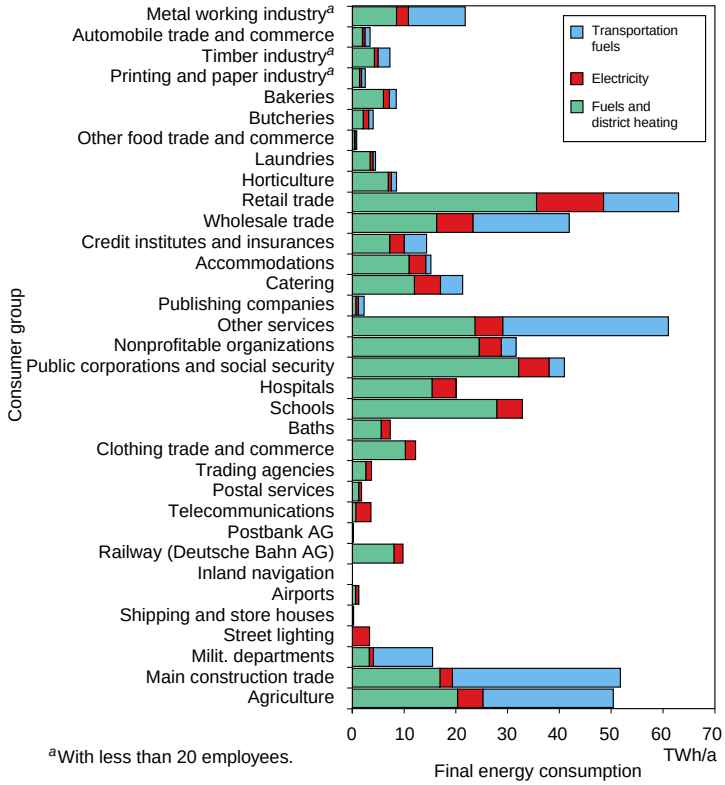

FIGURE 14 Final energy consumption: consumer groups of commerce/services and other sectors; Germany, 1994.

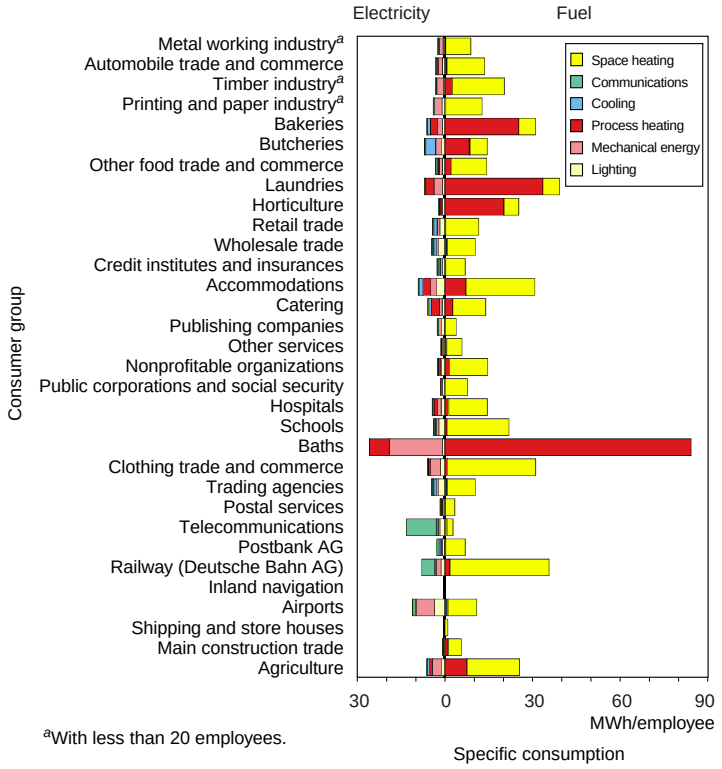

FIGURE 15 Electricity and fuel consumption related to employees; Germany, 1994.

information on the number of employees for each examined branch and the operating area is provided. This background knowledge suggests what sort of energy is consumed and where it is used.

The results for fuels (heating and transportation) and electricity are presented in Fig. 14. Table III and Fig. 14 contain all of the consumer groups, which were classified as small consumer in former times and which are now to a large extent accounted for in the commerce/services sector. These consumer groups also cover agriculture and main construction trade, which are often separated in the international consumer statistics or declared as industry.

The specifications concerning final energy consumption in Fig. 14 (electricity, fuels, space heating, and transportation fuels in the sector commerce/services) represent components of the German energy balance for the commerce/services sector. The given consumption of transportation fuels appears within the transportation sector in the German energy balance.

Figure 14 presents an overview of where the biggest proportions of energy onsumption (without transportation fuels) in Germany are situated. The most significant branches are agriculture, retail trade, public corporations and social security, schools, nonprofit organizations, and other services. These alone are responsible for about 50% of the final energy consumption in the commerce/services sector.

Figure 15 presents information on the specific electricity and fuel consumption, differentiated by purpose of use and based on the number of employees. It is obvious that the specific consumption within in the different consumer groups is very heterogeneous.

The main proportions constitute energy consumption due to baths, laundries, accommodations, bakeries, the clothing trade, and commerce. With regard

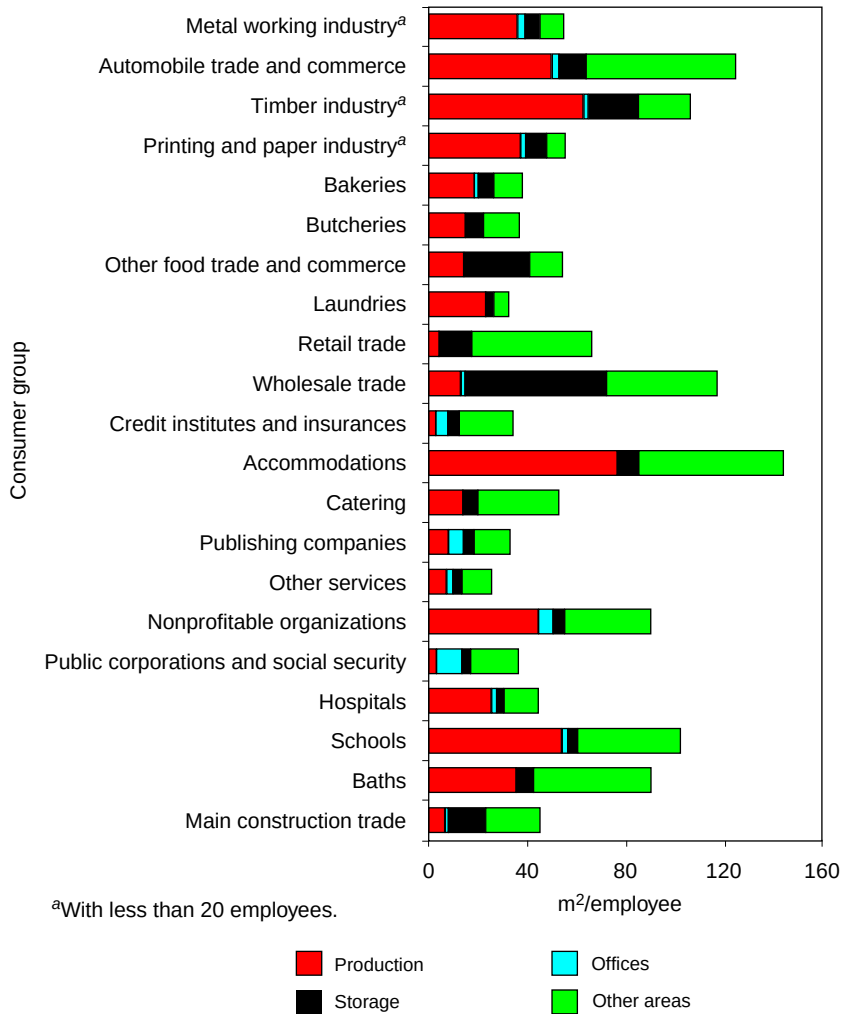

FIGURE 16 Operating area and types of use in commerce/services; Germany, 1994.

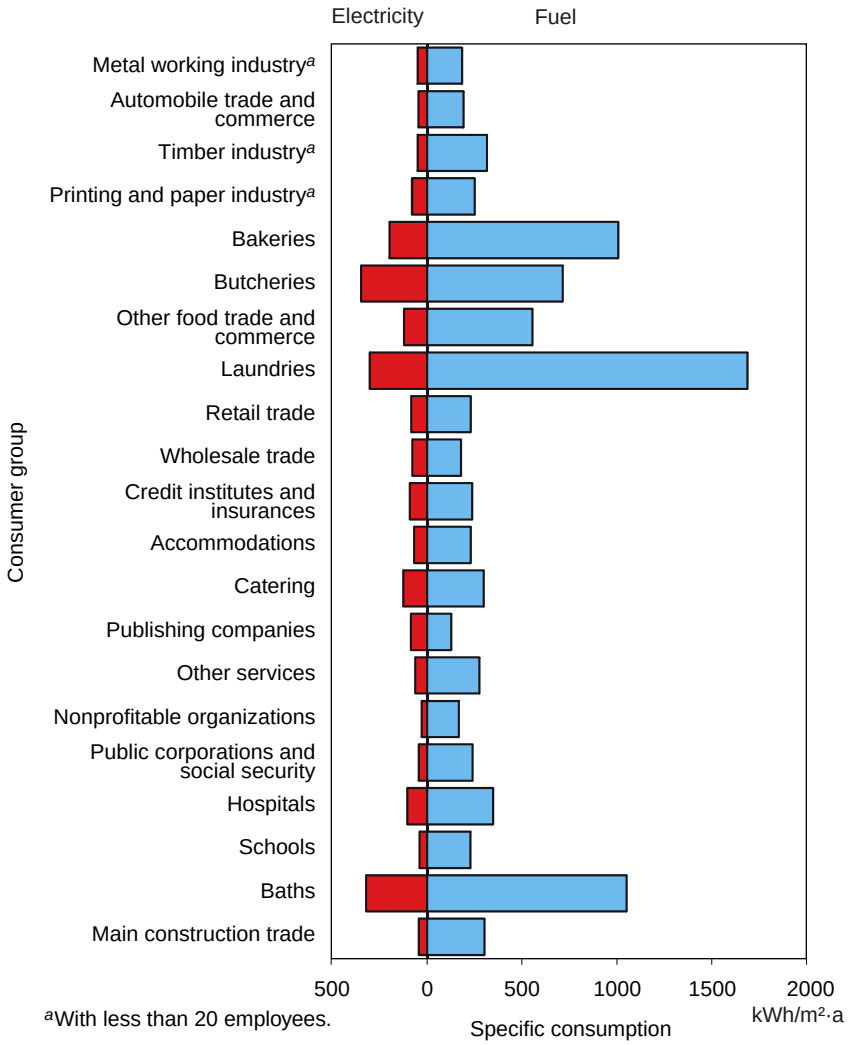

FIGURE 17 Electricity and fuel consumption related to operating area; Germany, 1994.

to the purpose of energy consumption, a differentiation is carried out by space heating, communication, cooling, process heat, mechanical energy, and lighting. Thus, the average proportions of energy consumption for certain applications are known for each consumer group. Note that the operationally effective area has a major influence on the space heating energy consumption. Production and office areas are always heated; warehouse and remaining areas are partly heated or kept at a moderate temperature.

The operating area per employee ranges from 30 m^2/employee (other services) to 150 m^2/employee (accommodation). By applying this information, the electricity and fuel consumption can be quoted by square meter operating area (see Fig. 16).

Figure 17 suggests that many branches with a very low or negligible process heat demand have a similar level of electricity and fuel consumption. Seventy-five percent of the consumer groups show a specific consumption in the range of 150 kWh/m^2 to 250 kWh/m^2, suggesting that these branches have a demand for space heating and hot water only.

Bakeries, butcheries, other food trade, and commerce, laundries, hospitals, and baths have a disproportionately high demand for fuels that process heat. Beyond this, these consumer groups are characterized by an extremely high specific electricity demand.

5. SUMMARY

This article explores the energy consumption of the commerce/services sector worldwide and particularly

in Germany. When comparing cross-national data, it has to be taken into account, that an accurate demarcation of energy consumption sectors is not always given. By analyzing surveys and data collected onsite, a significant analysis of the electricity and fuel consumption of the commerce/services sector is possible, as the example shows for Germany.

Energy consumption in the commerce/services sector mainly depends on economic prosperity, climate, and the technological status of development. One major influence on energy consumption is the conditioning of workspaces. Lower temperatures and larger workspaces per jobholder—as in the northern industrialized countries—cause higher fuel amounts of consumption for space heating, just as air conditioning in hot climates causes a higher demand for electricity. With economical development, technical standards and instrumentation improve and cause rising electricity consumption.

The analyses presented here are preconditions for better individual consumption consultation, strategic programs toward energy conservation, and an emphasis on technical development.

Glossary

collapse Rapid loss of an established level of social, political, or economic complexity.
complexity A measure of the differentiation in structure and organization of a system.
marginal return In an economic process, the amount of extra output per additional unit of input. Marginal returns may increase, remain constant, or diminish.
problem solving The process of responding to the challenges that confront a society or institution.
resources The inputs of matter, energy, or information that support continuity and problem solving.
sustainability Maintaining, or fostering the development of, the systemic contexts that produce the goods, services, and amenities that people need or value, at an acceptable cost, for as long as they are needed or valued.

Collapse is the rapid simplification of a society. It is the sudden, pronounced loss of an established level of social, political, or economic complexity. Widely known examples include the collapses of Mesopotamia's Third Dynasty of Ur (ca. 2100–2000 BC), Mycenaean society of Greece (ca. 1650–1050 BC), the Western Roman Empire (last emperor deposed 476 AD), and Maya civilization of the lowlands of Guatemala (ca. 250–800 AD). There are at least two dozen cases of collapse that are known from history, archaeology, or both. States and empires are not the only types of institutions that may rapidly simplify. The entire spectrum of societies, from simple foragers to extensive empires, yields examples of collapse. Since all but a few human societies existed before the development of writing, there may be dozens or even hundreds of cases that are not yet recognized archaeologically. Collapse is therefore a recurrent process, and perhaps no society is invulnerable to it.

1. NATURE OF COLLAPSE

Many scholars have argued that collapse develops from adverse changes in the energy flows on which a society depends. In this school, collapse is thought to follow from such misfortunes as pronounced droughts, depletion of resources, or natural cataclysms. Others have searched for causes internal to societies: poor leadership, mismanagement, peasant rebellion, or even intangible factors such as changes in morality. A few scholars argue that collapses occur because of chance concatenations of misfortunes and cannot be understood as a general process. Despite this diversity of views, collapses inevitably alter energy flows. Postcollapse societies are by definition simpler, so much so that colloquially they are sometimes referred to as "dark ages." The simpler societies that follow a collapse require less energy per capita. Collapses often involve massive loss of population so that human energy extraction is greatly reduced within the region affected.

Collapse affects societies proportionate to their level of complexity. Many scholars identify collapses by the loss of such cultural elements as great traditions of art, architecture, and literature (with the decline in the last leading to the term dark age).

 © 2004 Elsevier Inc. All rights reserved.

Recognizing that collapse can affect societies organized with any degree of complexity, including simple foragers, a conception of collapse based on great cultural traditions is clearly too restrictive. It would not apply, for example, to the collapse of Chacoan society of the U.S. Southwest (ca. 725–1150 AD). Although it is known for remarkable art and architecture, Chacoan society produced no literature.

A more encompassing approach focuses on complexity. Complexity refers to differentiation in structure and to degree of organization. Societies grow more complex as they develop more parts (institutions, levels of hierarchy, and social or occupational roles) and as they become increasingly organized (i.e., as they increasingly constrain the behavior of a society's parts). One of history's clearest trends is that human societies during the past 12,000 years have shown a seemingly inexorable tendency to increase in complexity. This process still continues, more rapidly than ever.

Collapse is the rapid, substantial loss of an established degree of social, political, or economic complexity. Collapses contravene the trend of social history toward greater complexity. In a society that has collapsed there are fewer institutions, occupations, social roles, and hierarchical levels. There is less flow of information and a lower capacity for organization. People know less about the world beyond their own community. The scale of society shrinks. The Roman Empire, for example, left in its aftermath a multitude of smaller polities, none of which could match Rome's capabilities in organization, engineering, energy extraction, or scale of information flow.

2. ENERGY BASIS OF ANCIENT SOCIETIES

Before the development of fossil fuels, societies were powered largely by solar energy. Through photosynthesis, solar energy produced fuels such as wood and the agricultural produce on which all else depended. Solar energy drove the weather patterns to which forests and farms were adapted. These weather patterns made sailing possible and thus overseas commerce. The products of photosynthesis enabled people to have animals for farm, transport, and military use and animal products on one's table. Photosynthesis supported peasant populations that provided food for the cities, sons for the army, and taxes for the state. The combination of peasant population, weather patterns, and favorable terrain made irrigation possible in some places. A society's natural endowment of raw materials could be put to use only with solar energy. Thus, photosynthesis, transformed into slaves and charcoal, made it possible to mine and smelt metal-bearing ores. Metals were in turn used to obtain more energy or products of energy. Works of art, architecture, and literature were possible in large part because of the solar energy embedded in artists, architects, and writers; in the production of the raw materials in which artists and architects worked; and in the precious metals with which they were remunerated. Ancient states and empires relied fundamentally on agricultural taxes. Although we marvel today at the monuments and artistic works of ancient societies, these were never more than a small part of ancient economies. A. H. M. Jones, the noted historian of the late Roman Empire, estimated that the Roman government's income was based 90% on agricultural taxes. Trade and industry were comparatively undeveloped.

The persistent weakness of ancient states and empires was that the peasant producers, whose taxes funded government and the military, lived on very small margins of production. Subsistence farmers generate little surplus per capita and often none at all. Taxes were a way to compel peasants to produce more, but excessive taxation could undermine peasants' well-being and ultimately the state. Photosynthesis produces little energy per unit of land (maximum of approximately 170 kcal/m^2/year), and it takes much labor and other inputs to appropriate increasingly more of that for human use.

In ancient societies in general, agriculture could support only approximately one person per arable hectare. Vaclav Smil estimates that in Roman or early medieval times, wheat farming could yield approximately a 40-fold net energy gain. This is before subtracting seed requirements and storage losses. (The figure for 1900 AD is approximately 500-fold.) In many areas, this harvest was gained by supplementing human labor with draft animals (which require farmland and labor) and with extensive manuring. Between 180 and 250 h of human labor were combined with approximately 200 h of animal labor to produce approximately one-half metric ton of grain per hectare. In the Middle Ages, European farmers had to set aside one-third to one-half of a crop for the next year's seed. Roman-era farmers in Europe would have faced the same constraint. As discussed later, a late Roman peasant owed between one-fourth and one-third of the gross yield in taxes.

After adding seed needed for sowing to that sold for taxes, it is clear that Roman farmers and their families subsisted on but a small fraction of what they produced. Tax rates were fixed, so when a harvest was low, as frequently it would be, the margin available to support the farmer's family could be inadequate. Tax rates could harm an ancient society by making it difficult for peasants to raise families large enough to sustain the population. The consequence would be a decline in future taxes and in military manpower.

This was the characteristic pattern in ancient states and empires, which were funded by aggregating the small surpluses of many thousands to millions of impoverished subsistence farmers. Thus, the dilemma faced by ancient states was that solar energy severely limited the revenues that they could raise. Often, the direction that ancient rulers chose was to raise revenues in the short term, not realizing that this would undermine the capacity of the productive system to generate future revenue. When confronted with fiscal limits, ancient governments were perpetually tempted to expand spatially, thereby capturing more of the earth's surface where solar energy falls.

3. THEORIES OF ENERGY FLOW AND COLLAPSE

There are many theories of why societies collapse. As emphasized in the following discussion, however, most of these fail in one way or another to explain collapse fully. After describing these theories and their limitations, a newer approach is introduced.

3.1 Approaches to Energy Flow and Collapse

Students of collapse frequently blame interruptions in the resources on which a society depends. Without sufficient energy flow to sustain people and their institutions, collapse must follow. This may occur either because a resource is used to depletion or because external events, such as a change in climate, cause a once-dependable resource to become insufficient.

Such theories have been developed for a number of collapses. J. Donald Hughes, for example, argued that the ultimate cause of Rome's collapse was environmental deterioration, especially deforestation. The American geographer Ellsworth Huntington believed that climate change caused the barbarian migrations that the Roman Empire could not survive. Karl Butzer, a noted scholar of paleoenvironments, argued that insufficient Nile floods caused the collapse of Egypt's Old Kingdom (ca. 3100–2181 BC) and exacerbated other political upheavals in Egyptian history. The spectacular collapse of the Southern Lowland Classic Maya has prompted scholars to search for environmental factors, such as erosion, soil nutrient depletion, or conversion of forests to savanna grasslands. Rhys Carpenter, an accomplished student of Mycenaean civilization, argued that the Mycenaean collapse came from drought, which caused famine, depopulation, and migration. Barbara Bell argued that two so-called dark ages encompassing the eastern Mediterranean and Near East, ca. 2200–2000 and 1200–900 BC, can both be explained by widespread droughts that lasted several centuries.

The arid lands of Mesopotamia (modern Iraq, eastern Syria, and southeastern Turkey) provide some of the most compelling examples of resource depletion and collapse. There were two catastrophic collapses here: those of the Third Dynasty of Ur (ca. 2100–2000 BC) and the Abbasid Caliphate (749–1258 AD). In each case, the collapse has been explained as resulting from overirrigation of desert soils, which caused soil salinization that destroyed agricultural productivity. Sociopolitical collapse was accompanied by depopulation and environmental damage that in each case lasted centuries. Working in upper Mesopotamia at the site of Tell Leilan, Syria, Harvey Weiss found evidence that led him to suggest that collapse ca. 2200 BC in this region was caused by an abrupt change in climate that affected hundreds of thousands of both agricultural and pastoral peoples.

Some scholars focus more on human than natural resources to understand collapse. Students of the Maya periodically reformulate the idea that the stresses of supporting the Maya ruling classes, which involved mandatory labor to build lavish limestone monuments, sparked a peasant revolt that toppled the elites and their cities. Similar ideas have been advanced for collapses in Mesopotamia, Highland Mesoamerica, Peru, China, and elsewhere. In regard to the Roman Empire, Boak and Sinnigen argued that "Rome failed to develop an economic system that could give to the working classes of the Empire living conditions sufficiently advantageous to encourage them to support it devotedly and to reproduce in adequate numbers." Even in the fourth-century AD, Ammianus Marcellinus attributed the problems of the later Roman Empire to the growth of bureaucracy and excessive taxation.

A few historians, archaeologists, and other writers indict unpredictable natural cataclysms in collapses. These alter energy flows so wrenchingly that continuity or recovery are impossible. Hurricanes, earthquakes, and epidemics have all been implicated in the Maya collapse. As early as 1939, Marinatos suggested that the collapse of Minoan society on Crete (ca. 2000–1200 BC) was caused by the great eruption of the Aegean island of Thera. Popular attempts to link Plato's parable of Atlantis to an actual place have kept this idea alive. Recent writers have elaborated on the theme, even extending the effects of the devastation to the entire eastern Mediterranean.

3.2 Assessment of Approaches to Energy Flow and Collapse

Vaclav Smil observed that many collapses occurred without any evidence of weakened energy bases. Thus, energy flow alone cannot explain collapse as a recurrent historical pattern. Every society has arrangements to ameliorate changes in energy flow. Indeed, societies have withstood even pronounced constrictions in energy flow, provided that they prove temporary. Nineteenth-century examples of pronounced disruption in energy flow include the Irish potato famine and the great eruption of Krakatoa in the South Pacific. These are sometimes compared to the disasters of antiquity (e.g., the eruption of Thera), but neither caused a collapse. Catastrophes fail to explain collapse because societies withstand disasters all the time without collapsing. Moreover, sometimes the date of the catastrophe fails to match the date of the collapse.

Changes in climate also seem inadequate to account for the matter. In studies of climate and collapse there are problems of logic. In the cases of Tell Leilan, Syria, and the Hohokam of the U.S. Southwest, archaeologists have postulated that deterioration in energy flows caused by changing climate caused, at different times, both collapse of complexity and its increase. These scholars do not explain how climate change can have such opposite effects, leaving an apparent contradiction in their arguments. In the case of drought and the Mycenaean collapse, the part of Greece with the least rainfall, Attica, was the last to collapse. If deforestation contributed to the Roman collapse, why did the same problem, later in European history, help spur economic development, as Wilkinson has shown? A change in resources can by itself rarely explain collapse.

There is no doubt that energy flow is almost always involved in collapse. Often, energy flow changes in the aftermath of simplification and depopulation. Rarely, if ever, has a change in energy flow been the sole cause of a collapse. To understand the role of energy in collapse, it must be considered in the context of social, political, and economic changes.

3.3 Embedding Energy Flow and Collapse within Economics and Problem Solving

A new approach embeds energy in the social, political, and economic changes that a society undertakes to solve problems. Problem solving among humans (and even among animals) shows a general tendency to move from simple, general, and inexpensive (known colloquially as plucking the lowest fruit first) to complex, specialized, and costly. Sustainability or collapse follow from the long-term success or failure of problem-solving institutions. Throughout human history, a primary problem-solving strategy has been to increase complexity. Often, we respond to problems by creating new and more sophisticated technologies, new institutions, new social roles, or new hierarchical levels or by processing more information. Each of these strategies increases the complexity of a society. Problem solving has been much of the force behind the increasing complexity of human societies, especially during the past 12,000 years.

Changes in complexity can often be enacted quickly, which is one reason why we resort to complexity to solve problems. This is illustrated by the response to the attacks on the United States on September 11, 2001. Much of the immediate response to the problem of preventing future attacks involved increasing the complexity of public institutions by establishing new agencies, absorbing existing ones into the federal government, and expanding the scale and degree of control over realms of behavior from which a threat might arise. Such changes can be implemented more rapidly than can changes in military technology, in the technology and other techniques of espionage, or in the technology to detect explosives in air travel baggage.

As a problem-solving strategy, complexity often succeeds. The difficulty is that complexity costs. In any living system each increase in complexity has a cost, which may be measured in energy or other resources or in transformations of these, such as money, labor, or time. Before the development of fossil fuels, increasing the complexity of a society typically meant that people worked harder. This is still often the case. In the response to the September 11, 2001, attacks, anyone who travels by air understands that doing so has become more complex, and

the personal cost has risen. The cost is reflected not just in the price of travel (which is controlled by competition) but also in such intangibles as time spent standing in lines, the indignity of personal searches, and greater care regarding what personal items one travels with. These are examples of the subtle costs of complexity in problem solving.

If an increase in complexity resolves a problem, it is likely to be adopted for its short-term value. The costs of complexity are cumulative and long term. As simple, inexpensive solutions are adopted for problems in such areas as organization, information flow, or technology, the strategies that remain to be deployed are increasingly complex and costly. Complexity is an economic function and can be evaluated by returns on effort. Early efforts at problem solving often produce simple, inexpensive solutions that may yield positive returns. Yet as the highest-return ways to produce resources, process information, and organize a society are progressively implemented, problems must be addressed by more costly and less effective responses. As the costs of solutions increase, the marginal return to complexity in problem solving begins to decline. Carried far enough, diminishing returns to problem solving cause economic stagnation and disaffection of the support population. As illustrated later, a prolonged period of diminishing returns to complexity in problem solving makes a society vulnerable to collapse.

4. EXAMPLES OF ENERGY FLOW IN SOCIOPOLITICAL COLLAPSE

Energy, leadership, political organization, taxation, and competition are all involved in collapse. To illustrate this, I describe five cases in detail, including two collapses in Mesopotamia in which energy and collapse are clearly linked, although not as simply as sometimes described. The case of the Lowland Classic Maya exemplifies how competition and pressures to produce great monuments create stress on peasantry that undermines the production system. The Roman and Byzantine empires illustrate how complexity in problem solving makes a society vulnerable to collapse. In the Roman case, the collapse lasted centuries. In the Byzantine example, the collapse actually provided a basis for recovery.

4.1 Mesopotamia

Ancient Mesopotamia produced two cases that illustrate the relationship of collapse to energy—the collapses of the Third Dynasty of Ur (ca. 2100–2000 BC) and the Abbasid Caliphate (749–1258 AD).

In southern Mesopotamia, intensive irrigation initially increases agricultural yields that support growing prosperity, security, and stability. The Third Dynasty of Ur pursued this course. It expanded the irrigation system and encouraged growth of population and settlement. To capture this enhanced energy flow, it established a vast bureaucracy to collect taxes. This strategy plants the seed of its own demise, however. After a few years of overirrigating, saline groundwaters rise and destroy the basis of agricultural productivity. The political system loses its resource base and is destabilized. Large irrigation systems that require central management are useless once the state lacks the resources to maintain them.

A few centuries earlier, in the Early Dynastic period (ca. 2900–2300 BC), crop yields averaged approximately 2030 liters per hectare. Under the Third Dynasty of Ur this declined to 1134 liters. At the same time, Third Dynasty of Ur farmers had to plant their fields at an average rate of 55.1 liters per hectare, more than double the previous rate. Badly salinized lands go out of production almost indefinitely, so the pressure intensifies to get the most from the remaining fields. As yields declined and costs rose, farmers had to support an elaborate state structure. It was a system that took a high toll in labor. The Third Dynasty of Ur was following a strategy of costly intensification that clearly yielded diminishing returns.

The Third Dynasty of Ur hung on through five kings and then collapsed, with catastrophic consequences for the larger population. By 1700 BC, yields were down to approximately 718 liters per hectare. Of the fields still in production, more than one-fourth yielded on average only approximately 370 liters per hectare. The labor demands of farming a hectare of land were inelastic, so for equal efforts cultivators took in harvests approximately one-third the size of those a millennium earlier. Soon the region was extensively abandoned. By a millennium or so after the Third Dynasty of Ur, the number of settlements had decreased 40% and the settled area contracted by 77%. Population densities did not rebound to those of the Third Dynasty of Ur until the first few centuries AD, a hiatus of 2500 years.

Rulers of Mesopotamia, from the last few centuries BC into the Islamic period, repeated the strategy tried 2000 years earlier by the Third Dynasty of Ur. Population increased fivefold in the last few centuries BC and the first few centuries AD. The number of urban sites grew 900%. These trends

continued through the Sassanian period (226–642 AD), when population densities came to exceed significantly those of the Third Dynasty of Ur. At its height, the area of settlement was 61% greater than during the Third Dynasty of Ur.

Under Khosrau I (AD 531–579) the Sassanian dynasty reached its height, but the needs of the state took precedence over peasants' ability to pay. Taxes were no longer remitted for crop failure. Because the tax was fixed whatever the yield, peasants were forced to cultivate intensively. State income rose sharply under Khosrau II (590–628). This level of income would have been needed for the perpetual wars in which he engaged with the Byzantine Empire. Under the Abbasid Caliphate, an Islamic dynasty, tax assessments increased in every category. Fifty percent of a harvest was owed under the Caliph Mahdi (775–785), with many supplemental payments. Sometimes, taxes were demanded before a harvest, even before the next year's harvest.

Under the Abbasids there was unprecedented urban growth. Baghdad grew to five times the size of 10th-century Constantinople and 13 times the size of the Sassanian capital, Ctesiphon. The capital was moved often and each time built anew on a gigantic scale. The Caliph al-Mutasim (833–842) built a new capital at Samarra, 120 km upstream from Baghdad. In 46 years, he and his successors built a city that stretched along the Tigris for 35 km. It would have dwarfed imperial Rome.

As the state undertook these constructions, however, it did not always fulfill its irrigation responsibilities. As the irrigation system grew in size and complexity, maintenance that had once been within the capacity of local communities was no longer so. Communities came to depend on the imperial superstructure, which in turn became increasingly unstable. Peasants had no margins of reserve, and revolts were inevitable. Civil war and rebellion meant that the hierarchy could not manage the irrigation system. Mesopotamia experienced an unprecedented collapse. In the period from 788 to 915 revenues fell 55%. The Sawad region, at the center of the empire, had supplied 50% of the government's revenues. This dropped within a few decades to 10%. Most of this loss occurred between the years 845 and 915. In many once-prosperous areas, revenue declined 90% within a lifetime. The perimeter of state control drew inward, which diminished any chance to resolve the agricultural problems. By the early 10th century irrigation weirs were listed only in the vicinity of Baghdad. In portions of Mesopotamia the occupied area shrank by 94% by the 11th century. The population declined to the lowest level in five millennia. Urban life in 10,000 square kilometers of the Mesopotamian heartland was eliminated for centuries.

Collapses in Mesopotamia present clear evidence of the role of energy flow disruptions. When the resource base was destroyed by excessive irrigation, population levels and political complexity could not be maintained. Yet the clarity of these cases is deceptive because it obscures a fundamental question: Why did Mesopotamian rulers push their support systems to the point at which large populations and their own political systems were endangered? Such a question cannot be answered here. Rather, it underscores the point made previously that energy flows, although vital in understanding collapse, do not fully explain it. This will be clear in the next two cases.

4.2 The Southern Lowland Classic Maya

The Southern Lowland Classic Maya (ca. 250–800 AD) present one of history's most enigmatic collapses. The Maya Lowlands (Fig. 1) were one of the most densely populated areas of the preindustrial world, with an average of 200 persons per square kilometer. Tikal, one of the major Maya cities, had a population estimated at nearly 50,000, which is roughly the same as ancient Sumerian cities. In the southern part of the area known today as Quintana Roo, there are stretches of terrain 40–50 km long in which there is no gap of more than 100 m between Maya structures. The Maya are best known for their art, their cities and temples, and, as Robert Netting phrased it, their "abrupt departure from the stage of world history."

To support so many people the southern Lowland Maya transformed their landscape. Over much of the area the natural rainforest was cleared. One technique they employed was to channel and store water. Although the area today is a high tropical forest, precipitation varies seasonally, and many areas have little surface water. The Maya accordingly built canals, dams, reservoirs, and small wells and in Yucatán modified the large limestone sinkholes known as *cenotes*. There are 180 km of canals along the Rio Candelaria. They represent at least 500,000 days of labor to move (entirely with human workers) 10 million cubic meters of earth.

Hillsides across the Lowlands were often terraced for planting. Terracing directs water flow, traps silt, and creates cultivable land. Terraces are spread across more than 11,000 square kilometers. Much of the southern Lowlands (the area known as the

FIGURE 1 The Maya Lowlands and major archaeological sites.

Petén) also contains walled fields, a type of feature that indicates intensive, sustained cultivation.

Perhaps the most interesting agricultural features of the Lowlands are systems of raised fields and associated canals. These were built to supply dry, cultivable land in areas otherwise inundated. Raised fields were built within lakes and lagoons and at river margins, but they were primarily built within swamps, thereby reclaiming land that could be highly productive. Modified and intensively cultivated swamps may have become the most valuable land. Not surprisingly, the larger cities tend to be located near swamps. By building raised fields in such areas, the Maya could have maintained a moist, root-level environment; fertilized fields with rich, organic muck from canal bottoms; and perhaps raised fish as well. Tended carefully, such fields could have supported continuous cropping.

By the use of such facilities the energy of the Lowlands was channeled to produce a simplified

biota consisting of maize, squash, avocado, cacao, cotton, root crops, and fruit-bearing trees. Simplified food webs became the foundation for a diverse and complex society. Ranks of bureaucrats, artisans, elites, and paramount rulers held sway in cities whose centers were built of gleaming limestone. Their sense of time was based on astronomical observations so precise that they were not equaled in Europe or China for centuries to come. The Maya developed a system of writing that has only recently been deciphered. Their art is greatly admired today. All of this complexity was based on the energy flow made available from their managed landscape.

One consequence of the development of complex societies in the Maya area is that the cities were often at war. Warfare is a prominent theme in Maya art, with many scenes of domination and execution of captives. There are great earthen fortifications at such sites as Becan, Calakmul, Oxpemul, and Tikal. The defensive works at Tikal include a moat and earthwork 9.5 km long. Warfare in turn reinforced centralized political authority.

Maya complexity imposed a high cost on the support population. Great efforts were required to transform the forest, keep the land from reverting to forest, and keep the soil fertile; to support non-producing classes of bureaucrats, priests, artisans, and rulers; and to build and maintain the great cities. Over time these costs actually grew. The construction of monuments increased over the years. Across the southern Lowlands, 60% of all dated monuments were built in a period of 69 years, between 687 and 756 AD.

All this effort took its toll on the support population. At Tikal, by approximately 1 AD, the elites began to grow taller than the peasants, and within a few centuries the difference averaged 7 cm. That elites should have enjoyed better nutrition during childhood is not surprising. By the late Classic (ca. 600–800 AD), however, the stature of adult males actually dropped among both elites and peasants. The nutritional value of the Tikal diet had apparently declined for both rulers and ruled. At the site of Altar de Sacrificios there was a high incidence of malnutrition and/or parasitic infections. Childhood growth was interrupted by famine or disease. Many people suffered from anemia, pathologic lesions, and scurvy. At Altar de Sacrificios, the stature of adult males declined in the first few centuries AD, and life expectancy declined in the late Classic. Not surprisingly, the population of the southern Lowlands, which had grown during the first several centuries AD, leveled off between 600 and 830 and thereafter grew no more. Such population trends often foreshadow collapse.

The magnificence of late Maya cities clearly came at the expense of the peasant population, and ultimately at the cost of the entire system's sustainability. It was a classic case of diminishing returns to complexity. As the complexity of the political system and the cities increased through time, the costs of the system, in human labor, also increased. It is clear that the marginal return to these investments was declining by the late Classic. Ever greater investments in military preparedness, monumental construction, and agricultural intensification brought no proportionate return in the well-being of most of the population. To the contrary, as the demands on the peasant population increased, the benefits to that population actually declined. This was particularly the case in the seventh and eighth centuries, when a great increase in laborious monumental construction fell on a stressed and weakened population that was no longer growing.

The consequences were predictable. One by one, the Maya polities began to collapse and their cities were progressively abandoned (Fig. 2). At the same time, the southern Lowlands experienced one of history's major demographic disasters. In the course of approximately a century, the population declined by 1–2.5 million people and ultimately declined to a fraction of its peak. There were not enough Maya left to control the landscape, nor did those remaining need to farm as they once had. Intensive agriculture was abandoned and the forests regrew. Cultural complexity in this region was based on an engineered landscape with low species diversity, short food chains, and diversion of energy from plant to human

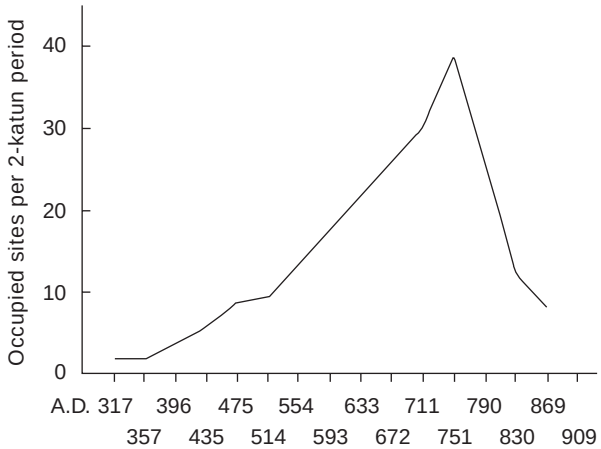

FIGURE 2 Occupation of Classic Maya centers. One katun is approximately 20 years.

biomass. In the long term, although the Lowlands landscape could seemingly support dense human populations, it could not sustain the complex political systems that large populations often require.

4.3 Collapse of the Western Roman Empire

The Western Roman Empire (Fig. 3) is one of history's most instructive collapses. The Romans' early success came from a means of expansion that was fiscally self-perpetuating. Defeated peoples gave the economic basis, and some of the manpower, for further expansion. It was a strategy with high economic returns. By 167 BC, for example, the Romans were able to eliminate taxation of themselves and still expand the empire. Yet the economics of an empire such as the Romans assembled are deceptive. The returns to any campaign of conquest are highest initially, when the accumulated surpluses of the conquered peoples are appropriated. Thereafter, the conqueror assumes the cost of administering and defending the province. These responsibilities may last centuries and are paid from yearly agricultural surpluses. The fiscal basis of such an empire shifts from accumulated surpluses (generally embodied in precious metals, works of art, and population) to current solar energy.

Once the phase of conquest was complete, and the accumulated surpluses spent, the Roman government was financed by agricultural taxes that barely sufficed for ordinary administration. When extraordinary expenses arose, typically during wars, the precious metals on hand frequently were insufficient to produce the required coinage. Facing the costs of war with Parthia and rebuilding Rome after the Great Fire, Nero began in 64 AD a policy that later emperors found irresistible. He debased the primary silver coin, the denarius, reducing the alloy from 98 to 93% silver. It was the first step down a slope that resulted two centuries later in a currency that was worthless (Fig. 4) and a government that was insolvent.

In the half century from 235 to 284, the empire nearly came to an end. There were foreign and civil

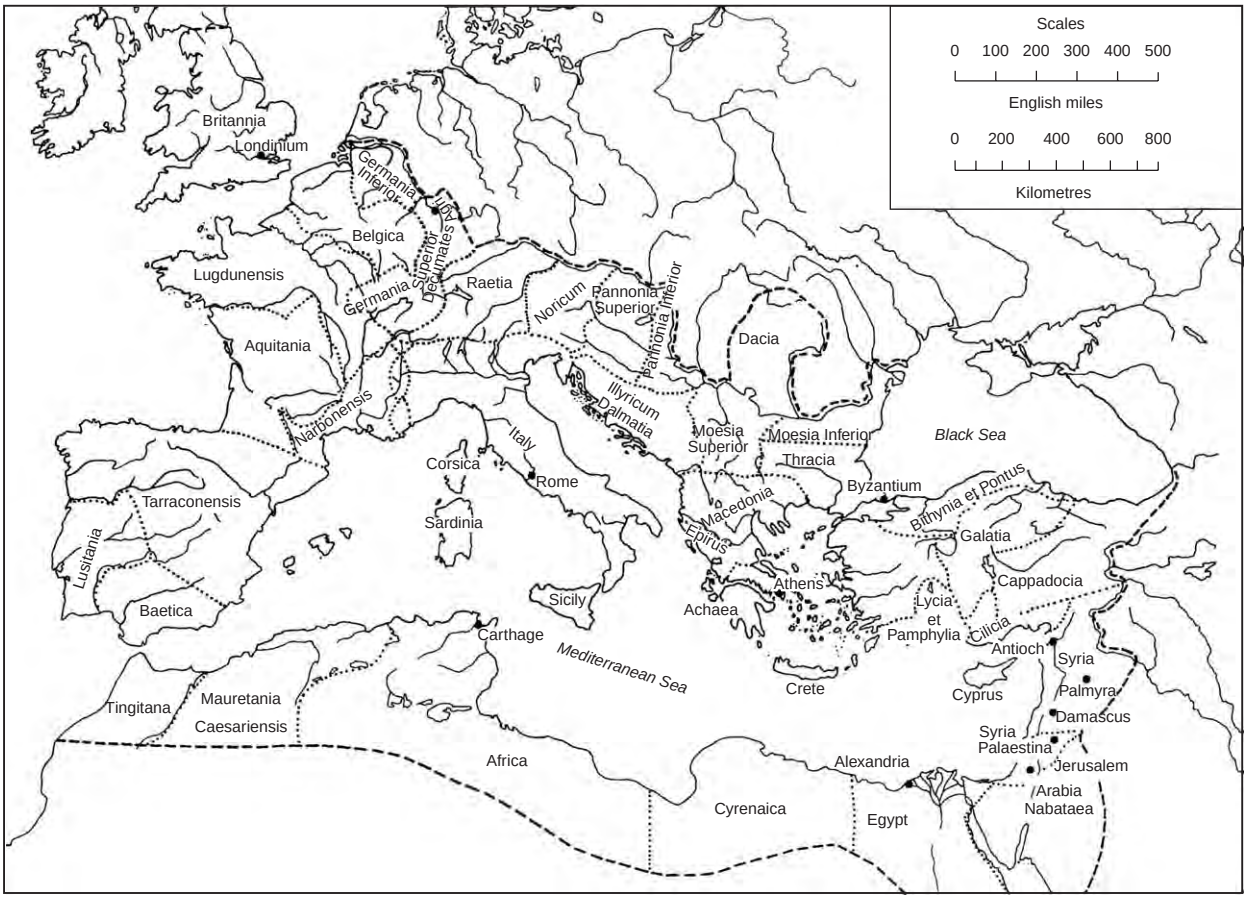

FIGURE 3 The Roman Empire in 117 AD.

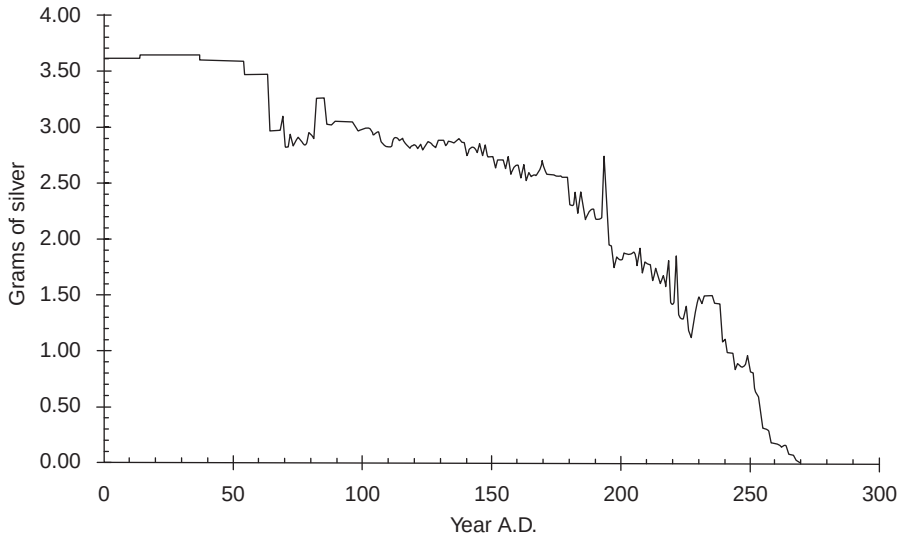

FIGURE 4 Debasement of the Roman silver currency to 269 AD.

wars almost without interruption. The period witnessed 26 legitimate emperors and perhaps 50 usurpers. Cities were sacked and frontier provinces devastated. The empire shrank in the 260s to Italy, the Balkans, and North Africa. By prodigious effort the empire survived the crisis, but it emerged at the turn of the fourth-century AD as a very different organization.

In the late third and early fourth centuries, Diocletian (284–305) and Constantine (306–337) designed a government that was larger, more complex, more highly organized, and much more costly. They doubled the size of the army, always the major part of imperial costs. To pay for this, the government taxed its citizens more heavily, conscripted their labor, and dictated their occupations. Increasingly more of the empire's energy was devoted to maintaining the state.

Diocletian established Rome's first budget, and each year a tax rate was calculated to provide the revenue. The tax was established from a master list of the empire's people and lands, tabulated down to individual households and fields. In an era when travel and communication were slow, expensive, and unreliable, it took substantial organization and personnel just to establish and administer a tax system so minutely detailed. Taxes increased, apparently doubling between 324 and 364. Villages were liable for the taxes on their members, and one village could even be held liable for another. Tax obligations were extended to widows, orphans, and dowries. Even still, to meet its needs, the government had to conscript men for the army and requisition services. Occupations were made hereditary and obligatory. Positions that had once been eagerly sought, such as in city senates, became burdensome because leading citizens were held responsible for tax deficiencies.

The tax system supporting the more complex government and larger army had unforeseen consequences. After plagues decimated the population in the second and third centuries, conditions were never favorable for recovery. There were shortages of labor in agriculture, industry, the military, and the civil service. The tax system of the late empire seems to have been to blame because the rates were so high that peasants could not accumulate reserves nor support large families. Whatever crops were brought in had to be sold for taxes, even if it meant starvation for the farmer and his family. Farmers who could not pay their taxes were jailed, sold their children into slavery, or abandoned their homes and fields. In such circumstances it became unprofitable to cultivate marginal land because too often it would not yield enough for taxes and a surplus. Despite government edicts, marginal lands went out of cultivation. In some provinces, up to one-third to one-half of arable lands came to be deserted by the late empire. Faced with taxes, peasants would abandon their lands and flee to the protection of a wealthy landowner, who was glad to have the extra labor.

On the death of the emperor Theodosius in 395 AD, the Roman Empire was divided into eastern and western parts, each of which had to raise its own revenues and most of its own troops. The east was by far the wealthier half, with fewer problems at its borders. From the late fourth century the barbarians

could no longer be kept out. They forced their way into Roman lands in western Europe and North Africa, initially causing great destruction. The government had no choice but to acknowledge them as legitimate rulers of the territories they occupied. Throughout the fifth century the western empire was in a positive feedback loop tending toward collapse. Lost or devastated provinces meant lower government income and less military strength. Lower military strength in turn meant that more areas would be lost or ravaged.

In the 20 years following the death of emperor Valentinian III (455), the western Roman army disappeared. The government came to rely almost exclusively on mercenaries from Germanic tribes. Finally, these could not be paid. They demanded one-third of the land in Italy in lieu of pay. This being refused, they revolted and deposed the last emperor in Italy, Romulus Augustulus, in 476.

The strategy of the later Roman Empire was to respond to a near-fatal challenge in the third century by increasing the size, complexity, power, and costliness of the primary problem-solving system—the government and its army. The higher costs were undertaken not to expand the empire or to acquire new wealth but to sustain the status quo. The benefit/cost ratio of imperial government declined as it lost both legitimacy and support. In the end, the Western Roman Empire could no longer afford the problem of its own existence.

5. ENERGY FLOW, COLLAPSE, AND RESILIENCY

It is common to think of collapse as a catastrophe, involving the loss of great traditions of art, architecture, and literature. In the case of the early Byzantine Empire (the Eastern Roman Empire, 395–1453 AD), though, the reduction of complexity that is the defining characteristic of collapse contributed to resiliency and recovery. The Byzantine case may be unique among collapses. It is especially instructive in regard to the economics of complexity in problem solving.

The Eastern Roman Empire survived the fifth-century debacle and met its end only when the Turks took Constantinople in 1453. The Byzantine Empire lost territory throughout much of its history and several times nearly fell. Yet it survived near catastrophes through one of history's most unusual strategies.

The eastern emperor Anastasius (491–518) established a sound coinage in the copper denominations on which daily life depended. He gave the army generous allowances for rations, arms, and food. Commerce was revitalized and the army again attracted native volunteers. Within a few decades these reforms had produced such results that Justinian (527–565) could attempt to recover the western provinces.

An army sent to North Africa in 532 conquered the Kingdom of the Vandals within 1 year. Almost immediately, the Byzantine general Belisarius was sent to reconquer Italy. He had captured the Ostrogothic King and nearly all of Italy when he was recalled in 540 to fight the Sassanian Persians.

In 541, when the job in Italy seemed about done, bubonic plague swept over the empire. It had not been seen before in the Mediterranean. Like any disease introduced to a population with no resistance, the effects were devastating. Just as in the 14th century, the plague of the sixth century killed one-fourth to one-third of the population. The enormous loss of taxpayers caused immediate financial problems. Army pay fell into arrears, and both Italy and North Africa were nearly lost. By debasing the currency and slashing expenditures, the emperor was able to send another army to Italy. Italy was reconquered by 554, but much of it was lost again when the Lombards invaded in 572. Throughout the rest of the sixth century, costly wars continued in Italy, North Africa, the Balkans, and with the Persians.

A rebellion of the Byzantine army in 602 rekindled the Persian war and began a crisis that lasted more than a century and nearly brought the empire to an end. The war against the Persians went badly. Sensing Byzantine weakness, Slavs and Avars overran the Balkans. North Africa and Egypt rebelled and placed Heraclius (610–641) on the Byzantine throne. The empire he took over was financially exhausted. The Persians captured Syria, Palestine, and Egypt, overran Anatolia, and besieged Constantinople from 618 to 626.

In 616, Heraclius cut the pay of troops and officials in half. He followed his predecessors by lowering the weight of the primary copper coin, the follis (Fig. 5). Heraclius' economic measures bought time for his military strategy to work. In 627, Heraclius destroyed the Persian army. The Byzantines got all their lost territory returned. The war had lasted 26 years and resulted in no more than restoration of the status quo of a generation earlier.

The empire was exhausted by the struggle. Arab forces, newly converted to Islam, defeated the Byzantine army decisively in 636. Syria and Palestine, which had taken 18 years to recover, were lost

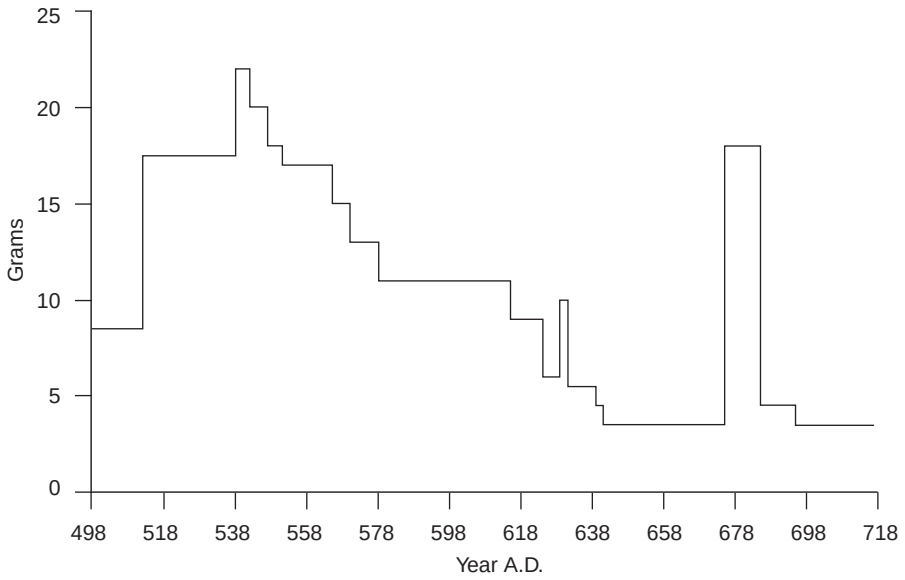

FIGURE 5 Weight of the Byzantine follis, 498–717 AD.

again. Egypt was taken in 641. The wealthiest provinces were permanently gone, and soon the empire was reduced to Anatolia, Armenia, North Africa, Sicily, and parts of Italy. The Arabs conquered the Persian Empire entirely. (In time, parts of the former Persian Empire became the center of the Abbasid Caliphate, described previously.)

Under Constans II (641–668) and throughout the seventh century, the situation continued to deteriorate. It appeared that it would be only a matter of time before the remaining Byzantine lands fell to the Arabs. The Arabs raided Asia Minor nearly every year for two centuries. Constantinople was besieged each year from 674 to 678, then continuously from 717 to 718. The Byzantines defeated both sieges, and this proved to be the turning point in a centuries-long struggle. The Arabs were never again able to mount such a threat.

During this century of crisis the social and economic life of the eastern Mediterranean was thoroughly transformed. Population declined. Monetary standards and economic institutions were destroyed. Around 659, Constans II cut military pay in half again. Army pay now stood at one-fourth its level in 615 so that the economy no longer received large influxes of new coin. By 700 most people of the eastern Mediterranean no longer used coins in everyday life. The economy developed into its medieval form, organized around self-sufficient manors.

Roman emperors of the late third and early fourth centuries had responded to a similar crisis by complexification. They increased the complexity of administration, the regimentation of the population, and the size of the army. This was paid for by levels of taxation so harmful that lands were abandoned and peasants could not replenish the population. Constans II and his successors could hardly impose more of the same exploitation on the depleted population of the shrunken empire. Instead, they adopted a strategy that is truly rare in the history of complex societies: systematic simplification, in effect a deliberate collapse.

The government had lost so much revenue that even at one-fourth the previous rate it could not pay its troops. Constans devised a way for the army to support itself. Available lands were divided among the troops. Soldiers (and later sailors) were given grants of land on condition of hereditary military service. Constans expected the troops to provide their own livelihood through farming, with a small monetary supplement. Correspondingly, the Byzantine fiscal administration was greatly simplified.

The transformation ramified throughout Byzantine society. Both central and provincial government were simplified. In the provinces, the civil administration was merged into the military. Cities throughout Anatolia contracted to fortified hilltops. Aristocratic life focused on the imperial court. There was little education beyond basic literacy and numeracy, and literature consisted of little more than lives of saints. The period is sometimes called the Byzantine dark age.

The simplification rejuvenated Byzantium. The new farmer–soldiers became producers rather than

consumers of the empire's wealth. From this new class of farmers came the force that sustained the empire. By lowering the cost of military defense the Byzantines secured a better return on their most important investment. The empire began to lose land at a much slower rate. The Arabs continued to raid Anatolia but were unable to hold any of it for long. Soldiers were always nearby. Fighting as they were for their own lands and families, they had much greater incentive and performed better.

Once the threat to the empire's existence was over, campaigns against the Bulgars and Slavs gradually extended the empire in the Balkans. Greece was recaptured. In the 10th century the Byzantines reconquered parts of coastal Syria. Overall after 840 the size of the empire was nearly doubled. The process culminated when Basil II (963–1025) conquered the Bulgars and extended the empire's boundaries again to the Danube. In two centuries the Byzantines went from near disintegration to being the premier power in Europe and the Near East, an accomplishment won by a deliberate collapse in which they systematically simplified, and thereby reduced the costs of, their army, government, and society.

6. ENERGY FLOW IN THE AFTERMATH OF COLLAPSE

Since collapse is the loss of complexity, and higher levels of complexity depend on greater flows of energy, a primary characteristic of postcollapse societies is that they require and produce less energy. This is a consequence of collapse that occurs because there are fewer elite ranks to extract resources from the populace, because expensive sectors of investment (such as the Roman army) disappear, or because a lower degree of social and economic specialization means that peasant households no longer have to support specialists. A late Roman peasant, for example, might have paid one-fourth to one-third of gross yields in taxes if he owned his own land. If he rented land, taxes and rent together took one-half to two-thirds of a crop. Thus, Roman peasants were perpetually impoverished, often undernourished, and sometimes forced to sell children into slavery when they could not be fed. This undermined the productive capacity of the empire and its sustainability. After the plagues of the second and third centuries AD, peasants were unable to replenish the population, and the empire lost much of its energy-producing capacity. In post-Roman Gaul, in contrast, taxes declined to as low as 10%. Early medieval peasants may have been better off and seen more of their children survive.

The Byzantines responded to lower energy flow by simplifying their social, political, and economic systems and by shortening energy flow networks. In the sixth-century AD, energy would typically have flowed from the sun to farms; from farms to peasants; from peasants to purchasers of grain, thereby converting the grain to coinage; from peasants to tax officials; from tax officials to the government; and from the government to the army. At each step some energy was lost to transaction costs. Just as in a trophic pyramid, energy was lost each time it was transformed or passed to another level. After the mid-seventh century, the energy on which the empire depended flowed through fewer transactions and levels. Energy passed from the sun to farms. From there part of it was harvested and used directly by soldiers, eliminating many intermediate steps. Other peasants still paid taxes, but since the government spent less of this revenue on the army there was more to allocate to other needs. Overall much less energy went to transaction costs, so net energy increased as a proportion of gross production. The empire revived and went on to expand.

In general, postcollapse societies are smaller, with simpler hierarchies and less socioeconomic specialization. They produce less monumental architecture or none at all. Population often declines, sometimes dramatically as in the Maya collapse. Many settlements are abandoned, and those that remain may contract. Long-distance trade declines. The known world shrinks, and over the horizon lies the unknown. There are often declines in literacy and numeracy because the simpler society requires less of these. Since there are fewer elites for whom to produce art, and fewer artisans, postcollapse societies produce less art. All these changes involve reductions in energy extraction and flow, either as cause or as consequence. In some cases, energy flow is so greatly reduced that postcollapse societies are nearly impossible for archaeologists to detect.

7. SYNTHESIS AND IMPLICATIONS

Collapse is a recurrent historical process. It affects the entire range of societies, from those that are least complex to the most complex. Perhaps no society is immune to the possibility of collapse, including the very complex societies of today. The misfortune of

some previous societies is potentially our good fortune. By understanding the processes that cause collapse we can develop tools to assess our own vulnerability.

Earlier research often pinpointed diminished energy flow as the cause of collapse. In many cases, though, diminished energy flow was the product of human management. This is evident in the examples of the Third Dynasty of Ur and the Abbasid Caliphate. In both cases, excessive irrigation caused salinization that destroyed productive soils. In these cases energy does not suffice to explain collapse. Other factors were involved, particularly the tendency of rulers to demand more than the land could sustainably produce. When we ask why the rulers did this, we realize that energy is but a small part of explaining these collapses. The Maya drastically altered their environment, shortening food chains and diverting large parts of the region's productivity to support dense human populations and their complex societies. Yet demands to support complexity so stressed the population that the system collapsed, the population plummeted, and the region reverted to rainforest. Again we see the interplay of energy with politics and human strategies of survival and competition.

Problem solving links these examples to a more general understanding of collapse. Moreover, problem solving is the key to using past collapses to understand our situation today. As noted previously, sustainability is a function of problem solving, as is its opposite, collapse. As the problems that a society or institution faces grow in size and complexity, problem solving grows in complexity and costliness. Problem solving is an economic process, and its success depends on the ratio of the benefits of problem solving to its costs. Problem solving tends to develop from solutions that are simple and inexpensive to those that are increasingly complex and costly. Each increase in complexity has costs, which may be measured in labor, time, money, or energy. Growth in complexity, like any investment, ultimately reaches diminishing returns, at which point increments to complexity no longer yield proportionate returns. When this point is reached, a society or other institution begins to experience economic weakness and disaffection of the populace. A fundamental element of a sustainable society is that it must have sustainable institutions of problem solving. These will be institutions that give stable or increasing returns (e.g., by minimizing costs) or diminishing returns that can be subsidized by energy supplies of assured quality, quantity, and cost. Ancient societies, constrained by photosynthesis, lacked the energy resources to pay for ever-increasing complexity. The problem persists among today's complex societies, which can pay for complex problem solving only as long as energy is abundant and inexpensive.

The role of problem solving is especially clear in the collapse of the Roman Empire. Confronted in the third century AD with severe challenges to its existence, the empire responded by greatly expanding the complexity and size of its primary problem-solving institutions: the army and government. This was costly and had to be paid for by greatly increasing taxation. The costs were so high that the empire survived by consuming its capital resources: producing lands and peasant population. This was an unsustainable strategy and collapse was inevitable. All that the empire could accomplish was to postpone it. Collapse resulted from the economic consequences of diminishing returns to complexity in problem solving. Ironically, though, had the empire not taken the steps it did, it would have collapsed even sooner.

Problem solving is the element missing in earlier collapse studies that focused unsatisfactorily on energy alone. A prolonged period of diminishing returns to complexity in problem solving renders a society fiscally weak (Figs. 4 and 5) and causes disaffection of the support population. Both factors render a society more vulnerable to stresses than would otherwise be the case. Thus, a fluctuation in energy flow that a fiscally prosperous society would survive can cause the collapse of a society weakened by the cost of great complexity in problem solving. This helps to clarify why changes in climate can have different effects in different circumstances. A society weakened by the costs of problem solving may be vulnerable to a change in climate that in other circumstances may be survivable.

Problem solving links the experiences of the past to understanding our own circumstances. The economics of problem solving, from less to more complex and from increasing to diminishing returns, constrain all institutions, including those of today. An institution that experiences a prolonged period of diminishing returns to complexity in problem solving will find itself in fiscal distress and ineffective at solving problems. If such an institution is part of a larger system that provides its funding (such as a government agency funded by appropriations), it may be terminated or require ever-larger subsidies. If an entire society finds itself in this position, as ancient societies sometimes did, the well-being of its

populace will decline and it may be unable to surmount a major challenge. Either weakness can make a society vulnerable to collapse.

How might this dilemma make itself felt today? As an example, consider the relationship of global climate change to complexity in problem solving. Nothing before in history equals contemporary global change in magnitude, speed, and numbers of people affected. Our response will involve changes in the complexity of technology, research, and government. We need much research to comprehend climate, the economic dislocations that it will entail, and the new technologies that we will need. We will experience increasing government centralization and regulation. In research, technology, and regulation, and in resettlement of people living in low-lying areas, global change will require societal expenditures that are currently beyond calculation. As discussed previously, past societies were made vulnerable to climate change when such a perturbation came after a period of diminishing returns to investment in complexity. If this is so, it would be wise for us to understand the historical position of our own problem-solving efforts. This is not to suggest that climate change will cause today's complex societies to collapse. What it may do is combine with other challenges to increase the complexity and cost of our problem-solving efforts. Barring dramatic developments that increase the availability and decrease the cost of energy, such developments would reduce fiscal resiliency and living standards and make it more difficult to resolve our problems.

The factors that lead to collapse or sustainability develop over decades, generations, or centuries. We need historical research to understand our position in a problem-solving trajectory. In medicine, for example, we have long been in a phase of diminishing returns in which ever-greater expenditures yield smaller and smaller increments to life expectancy. Once we understand this, it is clear that the costs of health care cannot be contained as long as we demand health and long lives, which we will certainly continue to do. Conversely, our investments in microelectronics appear to be in a phase of increasing returns. This happy state, of course, cannot last forever. A primary element to understanding the sustainability of a society, an institution, or a sector of investment is to understand long-term changes in the complexity and costliness of problem solving.

Our citizens and policy makers have such confidence in science that a problem such as global climate change can generate complacency. We assume that a technological solution will emerge. Few of us are aware that problem solving can reach the point of diminishing returns and become ineffective. One of our great advantages over societies of the past is that it is possible for us to learn where we are in the long-term historical patterns that lead to sustainability or collapse. The historical sciences are an essential aspect of being a sustainable society.

Glossary

diffuse insolation Solar radiation received from the sky, excluding the solar disk.

direct (beam) insolation Solar radiation received directly from the visible solar disk.

efficiency Fraction of incident light power converted to electrical power by a solar cell or module.

global insolation The sum of direct and diffuse insolation components.

insolation Flux of radiant energy from the sun, measured as power per unit area, whose intensity and spectral content varies at the earth's surface due to time of day, season, cloud cover, moisture content of the air, and other factors, but is constant outside the atmosphere at 1353 W m^{-2}.

peak watt (Wp) Rating for a cell, module, or system that produces 1 W electrical output under standard peak insolation conditions and at a standard cell or module temperature, usually 1000 W m^{-2} with global AM1.5 spectrum at 25°C for terrestrial applications, intended to simulate midday conditions at middle latitudes.

photovoltaic effect Generation of an electromotive force (voltage) due to incident photon radiation.

solar module Protectively packaged set of solar cells, electrically interconnected (usually several cells connected in series) to provide useful voltage and current output.

solar spectra Sunlight power content as a function of light color (of radiation frequency) and for which there exist several "standard" representations to aid calculations and comparisons, particularly the air-mass 1.5 (AM1.5) spectrum, which models transmittance through 1.5 atmospheric thicknesses for terrestrial modeling, air-mass zero (AM0), which models extraterrestrial sunlight, and ideal black-body spectra that model the sun as a thermodynamic black body at temperatures of 6000 K or less.

Solar cells are semiconductor devices that exploit the photovoltaic effect to directly create electric current and voltage from the collection of photons (quanta of light). They convert sunlight to electricity silently and without moving parts, require little maintenance, and are reliable. They are sold with warranties of up to 30 years, generate no greenhouse gases in operation, and are modular, rapidly deployable, and particularly suited to urban rooftops and façades. Solar cells power anything from lanterns in remote villages; to watches, calculators, solar home systems, and grid-connected rooftop arrays; to satellites and exploration vehicles on Mars.

1. INTRODUCTION

According to the review of the field edited by Archer and Hill, solar cells of 15% efficiency covering an area equivalent to just 0.25% of the global area under crops and permanent pasture could meet all the world's primary energy requirements, when most or all of that area would be otherwise alienated land. However, solar cells remain an expensive option for most power-generation requirements relative to fossil and nuclear sources, especially when the natural environment is attributed little or no value, and to some other sustainable options such as wind energy or energy efficiency enhancement.

There is a wide range of solar cells materials and approaches in production, under development, or having been proposed. One way to understand the range is to see the field as comprising three generations of technology. The first includes "bulk" or "wafer" cells, made from layers of semiconductor material thick enough to be self-supporting, usually up to 0.5 mm. This generation, which dominates

 © 2004 Elsevier Inc. All rights reserved.

markets, is exemplified by single and multicrystalline silicon cells and commercial production cells, which currently have efficiencies of 10 to 15%. Cost reductions for such cells will eventually be limited by the costs of the wafers. The second generation aims for lower cost at the expense of efficiency by using thin layers of active material. A rigid substrate or superstrate provides mechanical support for the semiconductor, which is deposited rapidly over large areas. It is hoped that eventually the relatively low material cost of the substrate or superstrate will dominate the cost of the complete device. Unlike the wafer-based cells described earlier, which are mechanically and electrically connected together to form weatherproof solar modules that produce convenient voltages and currents, the thin film materials are deposited on large areas of sub/superstrate and subsequently patterned to form multiple cells. Hence, the basic production unit is the module, rather than the individual cell. The four important thin-film technologies are amorphous silicon, polycrystalline silicon, cadmium telluride, and copper indium diselenide. Current production efficiencies are 4 to 9%. Thin-film cells have been expected to overtake the first-generation cells' dominance for decades, but this has not yet occurred. In fact, the evolution may be faltering since one major cell manufacturer ceased production of its thin-film products late in 2002 and others struggle for financial viability. Third-generation approaches intend to eventually combine high efficiency and low cost. One type of third-generation cells, tandem cells, are already commercially available as both low-cost, low-efficiency amorphous silicon-germanium and, at the other performance extreme, ultra-high efficiency cells made from elements of Groups III and V of the Periodic Table (known simply as III-V cells).

Market surveys estimated world production to be around 560 MW_p in 2002, an estimated 39% increase over the previous year. Ten companies accounted for 84% of global production in 2002. The three largest were Sharp, BP Solar, and Kyocera, in order of production volume. Sharp's rapid expansion during 2002 gave it nearly twice the capacity of its next largest rival. Figures 1 and 2 indicate the history of regional and global production levels and the end uses.

One figure of merit on which solar cells and modules are compared is their efficiency. Record efficiencies for research cells and modules using different technologies are published regularly by the journal *Progress in Photovoltaics*. Another more commercially important but less precisely defined

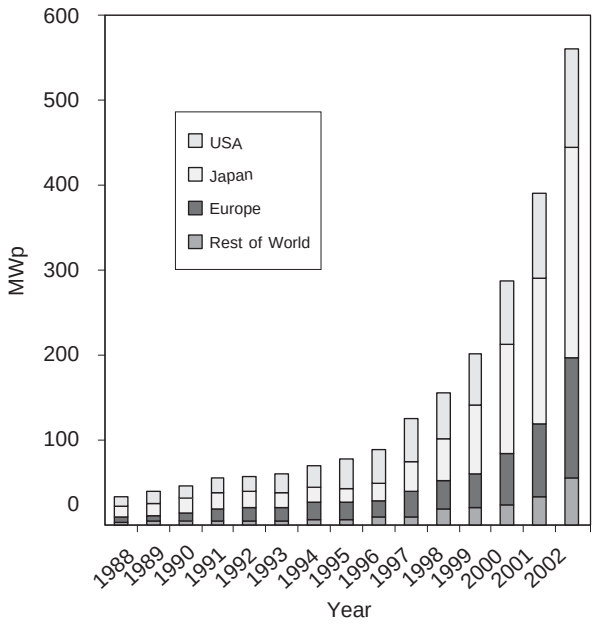

FIGURE 1 World solar cell production, 1988–2002, for the three main production zones and for the rest of the world (ROW). Data from *Photon International* and *Renewable Energy World*.

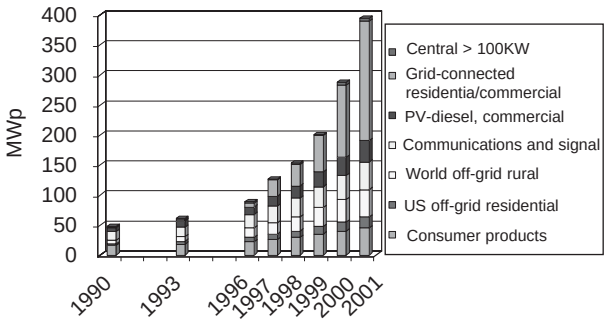

FIGURE 2 World PV market by application, 1990–2001. Data from Renewable Energy World.

figure of merit is the cost per W_p. This recognizes that efficiency is only of prime importance in some applications, and for many potential users, the capital cost and the cost of the resultant electricity are more useful measures on which to base decisions. Hence, technologies that are less efficient but cheaper per unit area are able to compete in the market.

2. HOW SOLAR CELLS WORK

Solar cells use semiconducting materials to achieve two basic tasks: (1) the absorption of light energy to generate free charge carriers within the material and (2) the separation of the negative and positive charge

carriers to produce unidirectional electrical current through terminals that have a voltage difference between them. The separation function is usually achieved by a p-n junction, the interface of regions of material that have been "doped" with different impurities to give an excess of free electrons (n-type) on one side of the junction and a dearth of them (p-type) on the other. The interface region therefore has a built-in electrostatic field that sweeps electrons one way and holes the other. In other words, a solar cell is an illuminated, large-area diode.

Figure 3 indicates the main processes. Photons enter the cell volume through the front surface. High-energy (blue or violet) photons are absorbed strongly close to the cell surface, but those from the other end of the visible spectrum are weakly absorbed and penetrate more deeply. Each absorption of a photon annihilates the photon and transfers its energy to an electron in the semiconductor, freeing the electron from its parent atom and leaving behind a positively charged vacancy, or "hole." In some materials, known as direct bandgap semiconductors, the absorption involves just the photon and the created carrier pair, but in others, indirect bandgap semiconductors, the process also needs one or more phonons (quanta of crystal atomic vibration) to take part. Absorption is weaker in the latter semiconductors. Gallium arsenide and silicon are examples of direct and indirect bandgap semiconductors. The electrons and holes are mobile within the cell and will move in response to an electric field ("drift") or by diffusion to regions of lower concentration. They are also prone to recombination with each other. Cell theory usually concentrates on minority carriers (electrons in p-type material and holes in n-type) since their flows (currents) principally determine the performance. Electron-hole pairs generated near the junction are split apart by the strong electric field there. Minority carriers are swept across the junction to become majority carriers and each crossing of the junction is a contribution to the cell's output current. Minority carriers that are generated too far from the junction to be immediately affected by the junction field can be transported to the junction by diffusion due to the minority carrier population being reduced near the junction by the field action there. Metal contacts at the front and rear of the cell allow connection of the generated current to a load. The front contact is normally in the form of a fine metallic grid to reduce blockage of the light's access to the semiconductor.

However, survival of a minority carrier is tenuous since it is always prone to recombination with one of the surrounding majority carriers. Recombination can be radiative, the inverse of the optical generation process that produced the carrier pair, in which the carrier energy is lost in the production of a new photon, or nonradiative, in which the energy is dissipated as heat in the cell. Crystal defects, accidental impurities, and surfaces are all strong nonradiative recombination sites. Most nonradiative recombination processes are, in principle, avoidable, but radiative recombination is fundamental.

The result of these processes is a light-generated flow of current in what is normally thought of as the

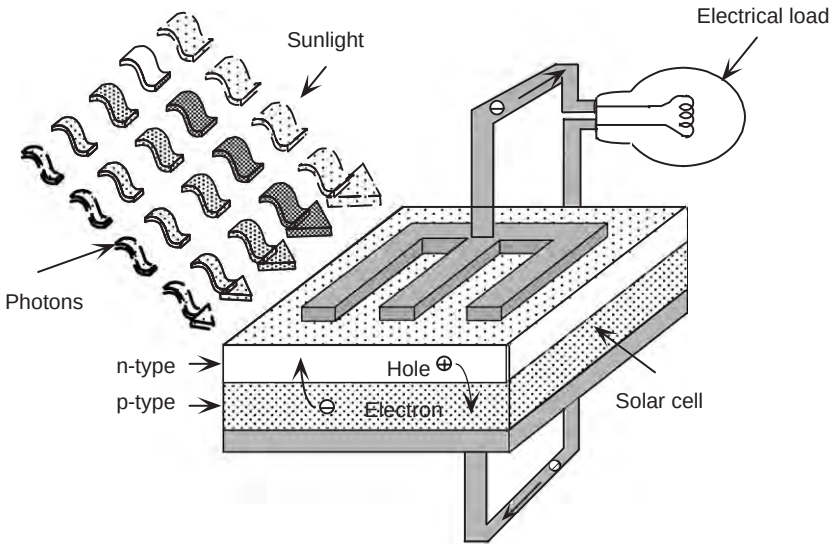

FIGURE 3 Solar cell operation. Adapted from M. A. Green and J. Hansen (2003). *Catalog of Solar Cell Drawings*. University of New South Wales.

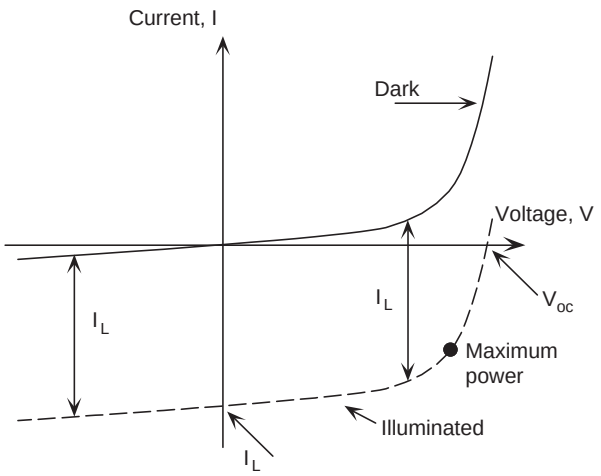

FIGURE 4 Typical current-voltage characteristic. Adapted from M. A. Green and J. Hansen (2003). *Catalog of Solar Cell Drawings*. University of New South Wales.

reverse direction in diode theory (i.e., electrons flow out of the cell into the circuit from the n-type contact and back into the cell through the p-type contact) even though the voltage across it is in the forward bias direction (i.e., positive at the p-type contact). The light-generated current is approximately independent of the voltage across the cell. Unfortunately, the normal diode current, which would remain even in the dark at the same contact voltage, may be thought of as simultaneously flowing in the opposite direction to the light-generated current. That dark current (solid line in Fig. 4) increases strongly with the voltage and at some voltage, known as the open circuit voltage (V_{oc}), completely cancels the light-generated current. As a result, we see the typical current-voltage characteristic shown as a dashed line in Fig. 4. The (forward) dark current is added to the (reverse) light-generated current to make the resultant current negative for a range of positive voltage. In that range, the cell generates power. Power is zero at zero volts and at V_{oc} with maximum power being produced near the so-called knee of the curve. The electrical load connected to the cell should be chosen to keep the operating point close to the optimum knee point during normal operation.

3. EFFICIENCY

In that brief description of cell operation we considered the main processes occurring after photons enter into the semiconductor volume. However, reflection from the surface must first be reduced to allow efficient absorption. A polished semiconductor surface will reflect a significant fraction of incident photons from the sun, around 30% for silicon. Additional antireflection layers of other materials can be applied to the front surface. In addition, texturing of the front surface can assist with reflection reduction by deflecting rays of light so that they strike the semiconductor surface again. Texturing also redirects photons into oblique paths within the cell, giving longer paths for weakly absorbed (red) photons and more opportunity for absorption (light trapping).

The bandgap energy of the semiconductor from which a cell is made sets the fundamental upper limit of the cell's conversion efficiency. The choice of a low bandgap material allows the threshold energy to be exceeded by a large fraction of the photons in sunlight, allowing a potentially high current. However, a solar cell can extract from each photon only an amount of energy slightly smaller than the bandgap energy, with the rest lost as heat. On the other hand, a semiconductor is transparent to photons with energy less than its bandgap and cannot capture their energy. These, thermalization and transparency, are two of the largest loss mechanisms in conventional cells. The best solar cell materials have bandgaps giving a compromise between these two effects. Solar cell performance is limited by the laws of thermodynamics. Thermodynamic methods and the related principle of detailed balance can be used to calculate the limits. Shockley and Queisser showed in 1961, by use of the balance between incident and escaping photons and extracted electrons, that the efficiency limit for a single-material cell is around 31% for an optimal bandgap of around 1.1 eV. That work assumed that the only unavoidable losses from the cell are the emission of photons produced by radiative recombination.

For such limit calculations, the sun is commonly assumed to behave as a thermodynamic "black body," or perfect radiator at 6000 K, although this is only a rough approximation to the solar spectrum at the earth. The cell is usually assumed to be another perfect radiator at 300 K (27°C). Other losses are assumed to be, in principle, avoidable or controllable and are neglected. Within that framework, a range of different solar cell concepts produces a range of efficiency limits (Table I) from 31% to 86.8% for maximum concentration, which refers to focusing only the solar disk onto the cell, with a concentration of around 46,000 times.

The Carnot limit for solar conversion under the preceding temperatures is 95%, but this could be achieved only if the cell were to produce infinitesimal

TABLE I

Efficiency Limits for Single and Multiple Bandgap Solar Cells for Unconcentrated Sunlight and for Sunlight Concentrated Maximally[a]

Number of bandgaps	Unconcentrated light	Maximal concentration
1	31.0%	40.8%
2	42.9%	55.7
3	49.3%	63.9%
∞	68.2%	86.8%

[a] Only the solar disk is seen by the cell and all emissions from the cell are directed back toward the solar disk. The sun is assumed to be a thermodynamic black body radiator with absolute temperature 20 times that of the cell (e.g., cell and sun temperatures of 300 K and 6000 K). From De Vos (1992).

electrical output since the cell would need to emit light at the same spectrum and intensity as the sun in order to avoid entropy production in the energy transfer. The Landsberg efficiency for direct sunlight conversion (93.3%) is the ultimate solar conversion efficiency and results from the assumption that the cell generates no entropy during absorption and emission of light but is lower than the Carnot limit because the light emitted by a cell is considered lost, not returned to the sun for later use. Inclusion of those additional entropy production mechanisms yields, for a multibandgap converter with an infinite number of bandgaps, the 86.8% value in Table I.

4. TYPES OF SOLAR CELLS

4.1 Silicon Cells

Silicon enjoys the advantages of being nontoxic and of great abundance, and its native oxide, silicon dioxide, is easily able to passivate the surfaces to improve the electronic properties there. Silicon solar cell research takes advantage of the vast body of research carried out for the silicon-based electronics industry and, until recently, off-specification silicon rejected by the electronics industry supplied most of the feedstock for the solar cell industry. In addition, useful chemical techniques, such as directionally selective etches, are available for monocrystalline silicon processing. As a result, silicon has dominated the solar cell industry since 1954 and continues to do so. Silicon is used in monocrystalline, multicrystalline, polycrystalline thin-film, and amorphous forms for different types of cells, with the first two supplying most of the market at present.

4.1.1 Silicon Wafer Cells

4.1.1.1 Monocrystalline Silicon Large (up to 300 mm diameter), cylindrical ingots of extremely pure, single-crystal silicon are grown from molten silicon. The entire ingot is doped, usually p-type with boron, during the melt phase and is sawn into circular wafers less than 0.5 mm thick, from which solar cells are made. According to *Photon International*, such monocrystalline silicon cells supplied 36% of the terrestrial PV market in 2002.

Different manufacturers use variations of the same basic process for making screen-printed cells (Fig. 5). Wafer surfaces are etched to form textured surfaces for antireflection and light trapping. Light trapping is implemented to increase the path length within the cell volume for weakly absorbed light at the red end of the spectrum. An n-type dopant, usually phosphorus, is then diffused into the surface to form the p-n junction, producing the in-built electric field to separate the charge carriers (Fig. 3). Heavily doped layers are formed at each surface to aid electrical contact and the metal contacts are formed by the screen printing of a metallic paste before firing. Optical coatings may be added to the front surface to further reduce reflection.

Production cells, using the normal boron doped, solar-grade silicon wafers grown by the Czochralski technique, have efficiencies of typically 12 to 15% although elevated temperatures during operation lead to reduced output power, characterized by a temperature coefficient in the range -0.4 to $-0.5\%/^{\circ}C$. Much higher efficiency, up to 24.7%, has been achieved in laboratory cells that use expensive photolithographic processes and purer float-zone wafers in their production, but such cells are only commercially viable for high-value applications.

4.1.1.2 Buried and Point Contact Cells An alternative production sequence, used commercially by BP Solar at their Spanish factory, is the buried contact solar cell (Fig. 6). Front contacts are plated into grooves in the cell formed by laser or mechanical grooving, allowing lower metallic shading of the surface while still permitting sufficient metal cross section to have low electrical resistance. BP Solar have reported that processing costs per unit area are only slightly higher than those of the screen-printed cell, but efficiency is significantly higher. These cells may be made from either monocrystalline or multicrystalline silicon.

Sunpower (USA) produce point contact silicon cells with front surfaces completely free from metal

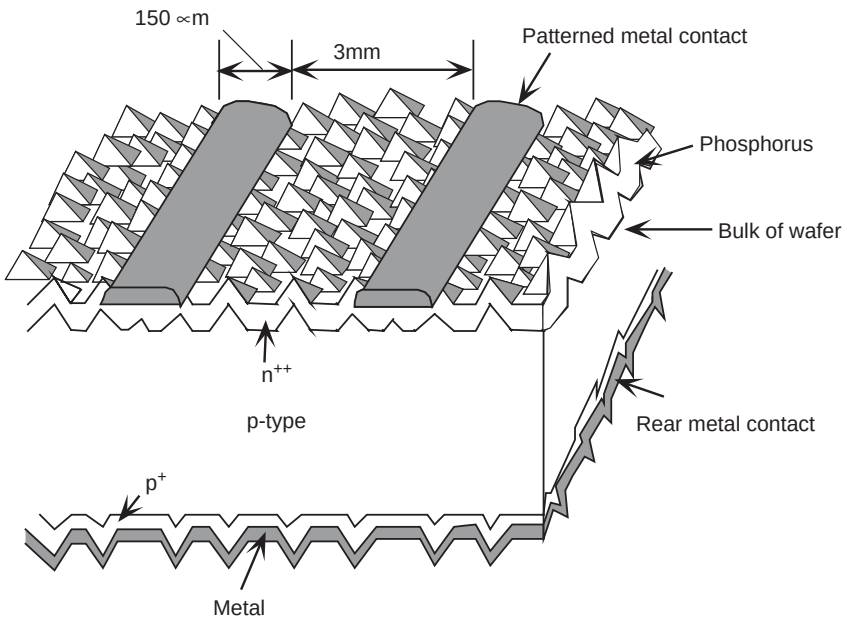

FIGURE 5 Structure of a typical commercial cell with textured surface and screen-printed contacts. From M. A. Green and J. Hansen (2003). *Catalog of Solar Cell Drawings.* University of New South Wales.

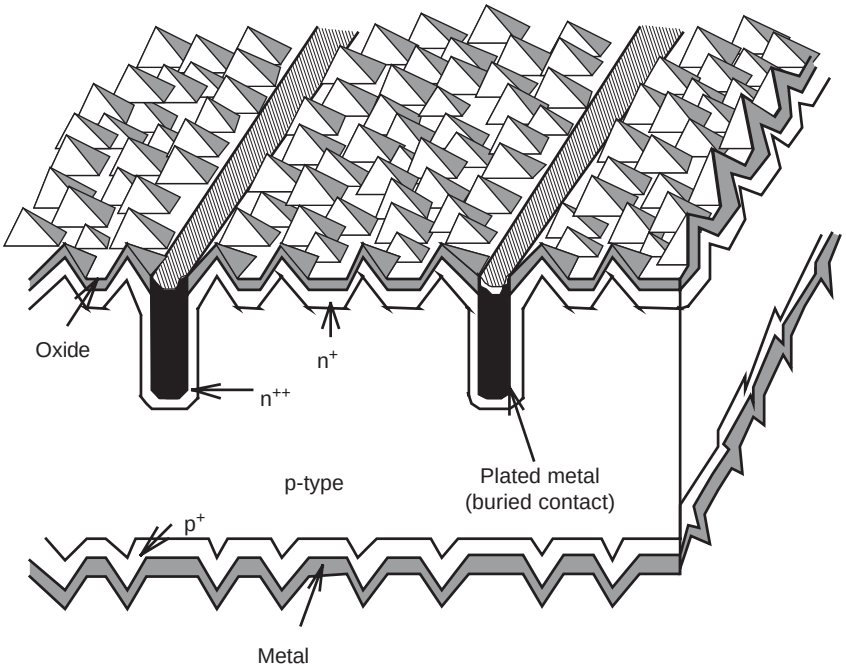

FIGURE 6 Structure of buried-contact silicon cell. From M. A. Green and J. Hansen (2003). *Catalog of Solar Cell Drawings*. University of New South Wales.

contacts. Both the n- and p-type contacts are at the rear. These cells were originally developed for concentrator applications but are predicted to be available in flat plate modules of nominally 20% efficiency from 2004.

4.1.1.3 Semitransparent Monocrystalline Silicon Different approaches have been taken toward making photovoltaic products that are aesthetically attractive for architectural applications. Semitransparency has been achieved with monocrystalline

silicon by, for example, Sunways in Germany. The cells are laser scribed through half the thickness in multiple parallel lines from the front and scribed again orthogonally from the rear. A mesh of holes through the cell is thereby created at the intersections of the lines. The holes and the additional surface area reduce their efficiency, but 9.0% cell and 7.4% module efficiencies are still achieved. Australian National University announced late in 2002 the development and imminent commercialization of a new monocrystalline silicon cell process that uses tiny interconnected cells about 1 mm wide, cut from 1-mm-thick wafers, with light trapping between lower and upper glass sheets.

4.1.1.4 HIT Sanyo's HIT (heterojunction with intrinsic thin-layer) cell, shown schematically in Fig. 7, combines crystalline and amorphous silicon (amorphous silicon is discussed below). n-type crystalline silicon wafers have layers of intrinsic and doped amorphous silicon applied to the front and rear. The junction has intrinsic amorphous layers between the n-type crystalline and p-type amorphous silicon regions to reduce recombination. Contacts are made by metal electrodes and layers of transparent conducting oxide (TCO). Unwelcome absorption in the TCO and electrically inactive doped amorphous layers is compensated by the excellent passivation of the crystalline silicon by the amorphous. Their negative temperature coefficient ($-0.33\%/^{\circ}C$) is smaller than that of conventional silicon cells. Large-area laboratory cell efficiency of 21.3% has been reported, and Sanyo's nominal cell production efficiency is up to 19.5%. Sanyo's HIT200 module has nominal cell and module efficiencies of 19.5% and 17%, respectively. Sanyo produced about 16 MW_p during 2001 and reportedly intends to increase production from to 120 MW_p per annum by 2005.

4.1.1.5 Cast Multicrystalline Silicon Cheaper and less energy-intensive wafers are produced by casting (cooling molten silicon in a mould) and sawing. These materials are produced specifically for PV production and have the advantage that the usually square wafers make cells that pack together more closely in modules, leaving less unproductive space between. The resulting material is of lower quality due to the poor electronic qualities of the boundaries between the randomly oriented silicon grains (crystals). Cast and deposited silicon is denoted as multicrystalline, polycrystalline, microcrystalline or nanocrystalline, depending on the average sizes of the crystals. An additional cause of reduced cell performance is the difficulty in texturing such material, and commercial multicrystalline cells are commonly untextured. The use of a passivating/antireflection coating such as silicon nitride is therefore common. Otherwise, processing is similar to that described earlier for monocrystalline silicon cells, and multicrytalline material is used for both screen-printed and buried-contact cells. In 2002, 52% of global production was of cast multicrystalline cells.

4.1.1.6 Ribbon and Sheet Silicon Various methods are used to directly produce silicon sheets of thickness suitable for production of self-supporting

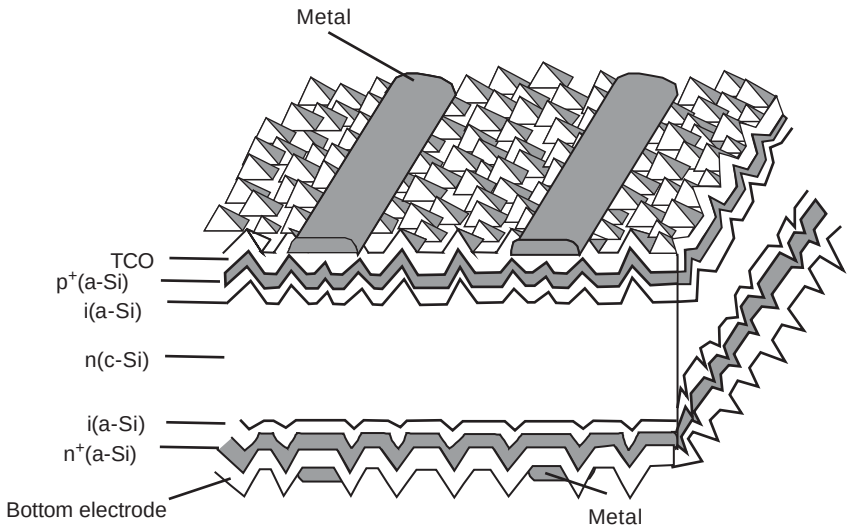

FIGURE 7 Structure of HIT cell. From M. A. Green and J. Hansen (2003). *Catalog of Solar Cell Drawings*. University of New South Wales.

cells without the wasteful sawing process. Edge-defined film growth (EFG) cells and modules are produced by RWE Schott Solar in the United States. A large, hollow nonagon of silicon is drawn through a graphite dye, and wafers are cut from each side. The material is multicrystalline with large, elongated grains and the resulting cells have efficiency exceeding 14% in production and 15 to 16% for best cases. Evergreen Solar grow cell material by a so-called string ribbon process, achieving 15 to 16% best-cell efficiency at standard temperature. Molten silicon forms a film between two carbon strings as they are withdrawn from the crucible. The company was reported in 2003 to be seeking investment to double capacity to 14 MW_p per year. Alternative processes, dendritic web and RGS silicon foil are also proceeding toward pilot production. Ribbon or sheet crystalline silicon cells accounted for 4.7% of world production in 2002, reduced from 5.6% in 2001.

4.1.2 Detached Silicon

Several approaches have been developed to grow thin crystalline silicon films on substrates from which they are detached and the substrates reused. These are aimed at greatly reducing the silicon used, saving a fraction of the necessary investment of energy and money. One, developed by Mitsubishi, involves deposition and laser-crystallization of silicon on an oxidized silicon wafer after holes have been etched through the oxide. More silicon is then grown epitaxially to increase the layer thickness prior to detachment. Another approach is to form a porous silicon layer on a wafer and use that as a crystalline template for growth of a silicon layer before detaching at the porous layer.

4.1.3 Spheral Silicon Cells

Spheral cells are currently being commercialized by Spheral Solar Power (Canada) in partnership with Photowatt (France) and by Kyosemi Corp. (Japan). Small silicon spheres, each a tiny cell of 0.5 to 2 mm diameter, are interconnected in sheets. This results in a flexible and lightweight cell structure, which uses significantly less silicon than conventional wafer cells.

4.1.4 Amorphous Thin-Film Silicon and Silicon-Germanium Cells

In amorphous silicon (a-Si), the silicon atoms are arranged more randomly than in the strict geometric order found in crystals. Many atoms have bonds that are unsatisfied by neighboring silicon atoms so hydrogen is usually incorporated into the material to reduce recombination, forming a-Si:H. Its absorption coefficient is higher than that of crystalline silicon, allowing it to absorb more strongly and to require lower film thickness ($\sim 0.4\,\mu m$). Relative to wafer-based silicon, thin-film (second-generation) amorphous cells have the potential for lower cost per unit area but also lower efficiency.

However, a light-induced degradation effect has severely restricted the early promise of this technology. Degradation has been minimized by making the cells as thin as possible, and textured TCO surfaces have been used to recover the absorptivity lost by thinning. Germanium is sometimes alloyed with the silicon to modify the bandgap energy since amorphous silicon's bandgap of around 1.7 eV is higher than optimal.

a-Si:H is usually applied by plasma-enhanced chemical vapor deposition. Amorphous cells use a p-i-n structure, with a layer of intrinsic (undoped) material between the n- and p-doped layers to take advantage of the better properties of intrinsic material. In the p-i-n design the junction electric field extends across the intrinsic region, permitting more thickness for generation and collection within the field region. Up to three junctions can be stacked in series for higher output, and triple-junction tandem modules (discussed later) are available commercially. There are two main motivations for this structure: first, the very thin layers required by stability considerations are too thin to absorb all the sunlight; second, it allows the opportunity to have a different bandgap in each junction by alloying a different fraction of germanium in each, giving a better match to the solar spectrum.

Amorphous modules have only a small negative temperature coefficient of power ($-0.1\%/^\circ C$), making them less subject to output reduction due to heat, and they are more tolerant of reduced intensity and diffuse light. The relatively low-temperature deposition technology allows plastics to be used as substrates in flexible modules. They also lend themselves to use in semitransparent building products and car sunroofs. Amorphous silicon's share of production has been steadily declining, falling to 6.4% in 2002. Best reported stabilized efficiency for an amorphous module is 10.4% for a triple-junction alloy device, and commercial triple-junction modules are around 6.3% efficient.

4.1.5 Micro- and Polycrystalline Thin-Film Silicon Cells

Various methods are being investigated to develop thin-film silicon cells deposited on foreign substrates.

If the ratio of hydrogen to silane in the gas from which amorphous silicon is deposited is increased, the resulting material becomes microcrystalline, with columns of crystallites separated by amorphous regions. The optical and electronic properties are similar to those of bulk silicon. Such material has been used as an alternative to silicon/germanium alloys in hybrid structures with amorphous silicon by Kaneka (Japan), who report stable 10% efficiency in a 39W module and who also manufacture amorphous silicon modules. The hybrid modules are suggested to be more stable than amorphous, but that has not yet been independently verified. Particular measures are necessary to allow the amorphous layers to be kept thin enough to avoid light-induced degradation while producing similar current to the microcrystalline cell(s) in series. The University of Neuchâtel, Switzerland, has developed a microcrystalline/amorphous tandem design with around 11% efficiency on a laboratory scale.

Astropower was first to commercially produce thin-films cells with millimetre-sized grains on foreign substrates. Small area cell efficiency of 16.6% has been demonstrated on an unspecified substrate and 9% on a proprietary ceramic. However, the product has evolved to films deposited on a silicon buffer layer, now resembling silicon ribbon cells. Pacific Solar is approaching commercial production with a process in which a thin-film silicon cell is formed on a textured glass superstrate. A laser is used to form craters through the active material to contact the n-type layer closest to the glass. Low-quality material is deposited then improved by subsequent thermal steps. The best efficiency achieved at the time of writing is 8.2% for 30 cm by 40 cm modules, and work is in progress to achieve the same performance from larger modules.

4.2 Thin-Film Cadmium-Telluride Cells

Cadmium telluride (CdTe) thin-film cell efficiency of 16.5% has been achieved, and the record module efficiency currently stands at 10.6%. CdTe comprised 0.7% of global cell production in 2002, and most of that was for indoor use in consumer products. Commercial modules are generally less than 7% efficient. The basic structure has a glass superstrate and a layer of transparent conducting oxide (TCO) as front contact, near-transparent *n*-type cadmium sulphide (CdS) window layer, *p*-type CdTe, and metallic rear contact. The contact films are scribed to divide the module into cells, which are series-connected to produce the required voltage.

Potential restrictions on market growth are the toxicity of cadmium and limited global supply of tellurium. Unencapsulated cells are sensitive to moisture. The toxicity issue is controversial and affects public acceptance of the technology. Relatively small-scale production has begun in Japan, the United States, and Germany but production by major players in Germany and the United States ceased in late 2002.

4.3 Thin-Film Chalcopyrite Cells

Copper indium gallium diselenide ($Cu(In,Ga)Se_2$, abbreviated to CIGS, or to CIS if the gallium is absent, is another promising thin-film PV material, although it is still only in small-scale production. Laboratory efficiencies have been difficult to transfer to reliable mass production of high-efficiency large modules. Large grains can be produced on foreign substrates, grain boundaries can be passivated, and the material is tolerant of deviations from exact ratios of the constituent elements. Problems include the need to develop specific deposition equipment, the great complexity of co-depositing so many elements, process control, inhomogeneity across large areas, and moisture sensitivity of unencapsulated cells. Global supplies of indium may be a restriction on widespread use in the long term. Toxicity of the cadmium in the window layer may possibly be avoided by use of alternative compounds such as In(OH, S), although CdS appears to be most commonly used.

A molybdenum rear contact is deposited on a soda-lime glass substrate and patterned by laser to divide into cells. The elements of the CIGS absorber layer are evaporated simultaneously before a heterojunction is formed with a cadmium sulphide layer. A TCO front electrode, mechanical scribing, contact formation, and encapsulation complete the module. One manufacturer expects to achieve better than 8% efficiency in mass production of modules.

Confirmed best cell and module efficiencies are currently 18.4% and 13.4%, respectively. Commercial production in 2002 amounted to just 0.2% of world solar cells. Flexible modules for portable, personal power provision is one high-value market being targeted by CIGS manufacturers.

4.4 Group III-V Cells

Compounds of elements from Groups III and V of the Periodic Table, exemplified by gallium arsenide (GaAs), are used extensively in the optoelectronics

and electronics industries and may be used to make excellent but expensive solar cells

4.4.1 Single Junction III-V Cells

High-efficiency solar cells are produced almost entirely for space applications where low weight, high efficiency, and hardness to cosmic radiation are more important than price. Active semiconductor layers are deposited by a variety of techniques on inactive substrates. High-efficiency single-junction cells have been made from GaAs, GaInAsP, and InP. High-bandgap AlGaAs windows are commonly used to reduce surface recombination.

Gallium and indium are not abundant elements, implying high cost and a limited ability to supply a large fraction of the global energy needs in terrestrial applications, except possibly with high concentration. Best terrestrial cell efficiency is currently 27.6% for a GaAs cell under 255 times concentration.

4.4.2 Tandem and Multijunction III-V Cells

Tandem cells are one approach to exceeding the efficiency limits of single-material cells. They reduce the two main losses mentioned earlier, the thermalization of the excess energy of high-energy photons and transparency to low energy photons. Tandem cells are stacks of *p-n* junctions, each of which is formed from a semiconductor of different bandgap energy. Each responds to a different section of the solar spectrum, yielding higher overall efficiency. By stacking the component cells in order of decreasing bandgap, as shown in Fig. 8, the light is automatically filtered as each cell extracts photons which exceed its bandgap.

The technique is applied commercially in triple-junction amorphous cells (noted earlier) and in crystalline III-V cells, but using the method with crystalline materials in high-efficiency devices presents several challenges. The materials used in the various junctions must be compatible with each other in several ways over a wide temperature range (defined by the fabrication temperatures), and this severely restricts the options. In particular, the thermal expansion coefficients should be similar and the bandgaps should be a good match to the spectrum. For monolithic devices, the crystal lattice constants must be similar to permit low-defect epitaxial growth.

Tandem cells with up to three bandgaps are commercially available, but they are used almost exclusively for space applications, especially the powering of satellites. There have long been plans for extensive terrestrial use in solar concentrators

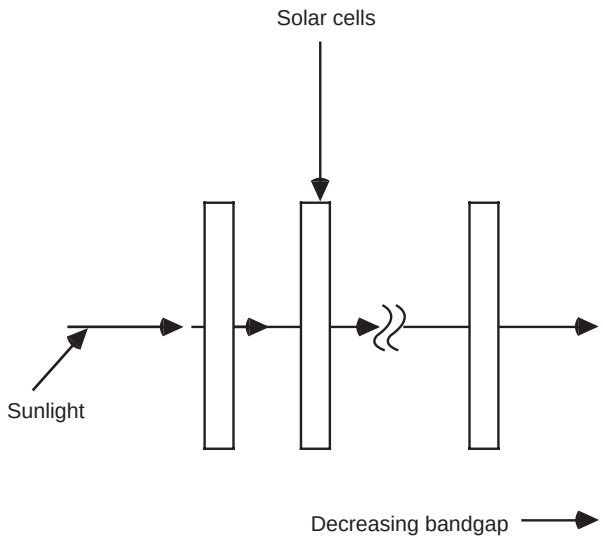

FIGURE 8 Arrangement of bandgaps in a tandem cell. From M. A. Green and J. Hansen (2003). *Catalog of Solar Cell Drawings.* University of New South Wales.

(discussed later), where the concentration of the light from a large collection area onto a cell may be able to justify such expense, but this has not yet occurred to a significant extent. The overall record cell efficiency of 35.2% is for a triple stacked GaInP/GaAs/Ge tandem cell operating under 66-times concentration. Work in Germany during 2003 achieved the first five-junction tandem cell.

4.5 Dye-Sensitized Cells

Dye-sensitized nanocrystalline cells are fundamentally different from the others discussed here in that they do not rely on semiconductor *p-n* junctions. Instead, they are electrochemical devices in which the optical absorption and carrier-collection processes are separate. A porous film of a wide-bandgap semiconductor, usually titanium dioxide (TiO_2), is coated with a redox charge-transfer dye (Fig. 9). The dye is excited by the absorption of a photon and an electron is injected into excited energy level of the oxide, and the dye is regenerated by a liquid electrolyte. The excited electron in the oxide reaches an electrode and is then able to migrate through an external circuit, do work in the load, and pass to the other electrode, where it regenerates the electrolyte. The front contact is formed from a transparent conducting oxide.

The best-demonstrated efficiency for a laboratory device is 8.2%, and reasonable stability under illumination has been demonstrated. Dye-sensitized cells coming into small-scale commercial production

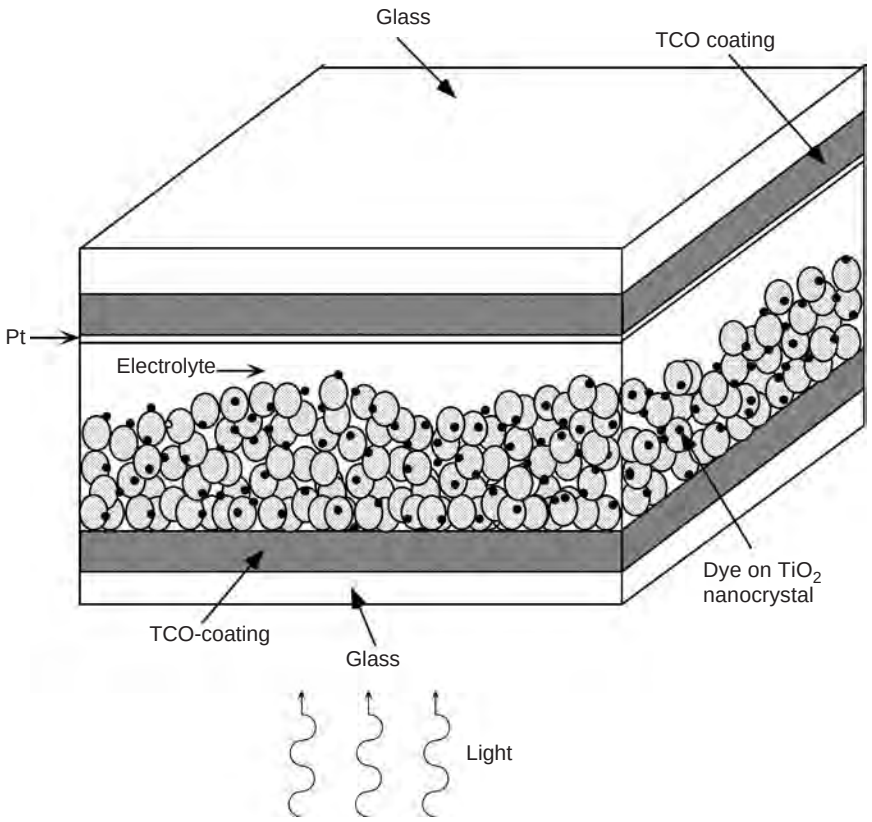

FIGURE 9 Dye-sensitized nanocrystalline cell structure. From M. A. Green and J. Hansen (2003). *Catalog of Solar Cell Drawings*. University of New South Wales.

in Australia, and the installation of the first wall panel has been announced. Dye-sensitized cells exhibit promise as potentially low-cost cells, in terms of finance and energy. Their temperature coefficient can be positive, giving increased power at elevated operating temperatures. Main concerns are to improve high temperature stability and to scale up production. A solid electrolyte would be preferable.

Tandem dye-sensitized cells are aimed particularly at the direct splitting of water for hydrogen production rather than at electricity production. In one experimental system, yielding 4.5% conversion efficiency from sunlight to chemical energy, two semiconductors, TiO_2 and WO_3 or Fe_2O_3, are used with the water being the electrolyte.

4.6 Concentrator Cells

Sunlight may be optically concentrated to reduce the cell area and reduce costs. Efficiency increases with concentration but at the expense of acceptance of only the direct fraction of the sunlight. Hence, the solar resource is reduced, especially in cloudy or coastal regions. In addition, the concentrating optics are always less than 100% efficient. Concentrators, other than static concentrators, must track the sun across the sky. They often take the form of Fresnel lenses (point or line focus) or paraboloidal dish or trough reflectors.

Cells can be of either silicon or III-V materials and several commercial products exist, although their undoubted promise has not yet been fulfilled for a variety of reasons. Only a tiny fraction of global production of cells is specifically for concentrators, and one prominent producer of silicon concentrator cells began in 2003 to manufacture flat-plate modules instead. Special care must be taken in the design of concentrator cells, particularly with respect to optics, heating, and high currents. The additional complexity is justified by the reduced cost fraction of the cells in a concentrating system. The heat production in concentrator cells becomes a benefit if it can be economically extracted and there exists a nearby market for low-grade thermal energy. A few combined photovoltaic/thermal systems have been developed.

Few modifications are needed for standard screen-printed silicon cells to operate at low concentration

up to about 10 times. Buried contact silicon cells, for example, operate satisfactorily up to around 30 times concentration, but special cells are required for higher concentration.

4.7 Innovative Solar Cells

In addition to the commercial or near commercial solar cell technologies described earlier, there is a wide array of further ideas for innovative types of cells, aimed at increasing efficiencies or reducing costs or both. Only some of the most prominent, none of which are fully developed and some of which are as yet only ideas, will be mentioned here.

Quantum well cells remain controversial since their proposal in the early 1990s. Multilayer sandwiches of extremely thin alternating layers of high- and low-bandgap semiconductors are held in the static electric field between p and n regions on either side. The layers are thin enough that quantum effects become important, modifying the material properties. The basic intention is that carrier pairs created in the low-bandgap regions will gain sufficient energy optically or thermally to permit their extraction at the higher voltage that is characteristic of the high-bandgap material. Quantum dot cells, in which the quantum effects are evident in three spatial directions instead of one, are a development that promises reduced opportunities for carriers to dissipate their additional energy as heat.

Attempts are being made to apply the impurity photovoltaic and impurity band effects in devices that would be able to utilize two or more photons in multistep absorptions via impurities that introduce energy states within the normally forbidden bandgap. These states also introduce additional recombination pathways, but calculations have shown that in the optimal situation, very high efficiencies would be possible. Making an electrically separate optical upconverter or downconverter by putting the impurities in a separate pieces of material instead of in the cell itself would avoid those recombination paths for some carriers. An all-silicon tandem cell is being pursued through the modification of the silicon bandgap in the upper subcell by forming superlattices of alternating thin silicon layers with layers of silicon dioxide or nitride.

If carriers due to high-energy photons could be collected while still energetic or "hot," the thermalization loss could be avoided and that is the aim of researchers investigating hot carrier cells. Carriers either have to reach the contacts rapidly or thermalization must be slowed. In addition, development of contacts that select the energy of the collected carriers is required.

All the approaches mentioned so far in this section are intended to produce very high efficiencies. Organic semiconductor solar cells, on the other hand, are not expected to be as efficient as present commercial cells but are expected to be produced extremely cheaply, at relatively low temperatures over large areas of cheap substrates. These cells take several forms, including interpenetrating networks of two polymers that are chosen to form a heterojunction that separates electrons and holes from each other.

5. CONCLUSIONS

Solar cells technology is evolving through three generations, with the first, comprising cells made from relatively thick (100s of μm thick) wafers of monocrystalline or multicrystalline silicon, continuing to dominate the industry. Silicon has several advantages over competing materials, but ultra-pure semiconductor wafers are inherently expensive in terms of both finance and energy. The second-generation cells—based on thin-films of amorphous, nanocrystalline, or polycrystalline semiconductors, deposited on cheap substrates or superstrates for mechanical support—are entering the market, or, as in the case of a-Si, are already established with a small market share. Second-generation cells may eventually be available at significantly lower cost per unit of delivered energy than first-generation cells, but a range of scientific, materials, production, and environmental issues have hampered the market penetration of the thin-film cells. When their market matures, it is expected that material input costs will eventually dominate their price. However, the production share of thin-film cells is currently declining, while the established first-generation approaches continue to be produced more cheaply due to enhanced manufacturing scale and technical improvements. Silicon may come to dominate the second generation of solar cell production too. Research is already under way into a wide range of attempts to combine the attributes of very high efficiency and low-cost production.

The global market, and particularly in Japan and Europe, is growing rapidly, fuelled by energy security and environmental concerns. Solar cells are complementing wind and waste-derived biomass energy in satisfying the growing demand for energy with low environmental impact. After several false starts, solar cells are finally coming of age.

Glossary

chemical energy Energy stored in a substance and released when the substance changes form or combines with another substance.
compound parabolic concentrator (CPC) A device that consists of two curved reflecting segments, which are part of parabolas.
concave Surface curved like the interior of a circle or a sphere.
energy Capacity, or ability, to do work.
flux concentration Density of radiation falling on and/or received by a surface or body.
parabola Plane curve formed by the intersection of a cone with a plane that runs parallel to its side.
paraboloid A solid, some of whose plane sections are parabolas.
pyranometer An instrument that measures solar radiation.
radiant energy Energy received in the form of photons or electromagnetic radiation.
rim angle An angle measured at the focus from the axis to the rim or a point where a paraboloid has been truncated.
solar concentrator A device that focuses the solar radiation received on the receiver.
solarimeter An instrument that measures solar radiation.
solar insolation Intensity of solar radiation.
solar radiation A form of electromagnetic radiation.
specific heat capacity The amount of heat energy absorbed or lost by a substance.
thermal energy Also known as heat; the kinetic energy associated with rapid random motion.

1. INTRODUCTION

Cooking is a very important and essential chore in every household. Unfortunately, this activity is also a major cause of deterioration of forest cover and soil fertility. It is also responsible for drudgery and ill health among women in developing countries. The main reason is the use of traditional biomass fuels, such as wood, cow dung, and agricultural residues, in inefficient cookstoves, in poorly ventilated kitchens. It has been estimated that there are 180 polar, 75 aliphatic, and 225 aromatic hydrocarbon compounds in smoke produced from biomass. The exposure of women and children to these carcinogenic, ciliotoxic, and mucus-coagulating agents results in numerous diseases related to the respiratory system, such as colds in adults and acute respiratory infections in infants and young children.

It has been estimated that the use of solar cookers by 2000 families for 10 years would mean a savings of $0.1 million in terms of reduced firewood consumption, $2 million worth of coal, or $0.25 million worth of kerosene oil.

1.1 History

Cooking with energy from the sun is an old concept. There are many landmarks in the history of the design of solar cookers.

 © 2004 Elsevier Inc. All rights reserved.

The first attempt to cook fruits was made by Swiss scientist Horace de Saussure in 1767. He achieved 88°C in a hot box-type cooker. In 1837, astronomer Sir John Frederick Herschel achieved 116°C in his solar cooker and cooked meat and vegetables. Muguste Mouchot designed a community cooker for baking bread and potatoes for French troops in 1870. The first manual on solar cookers, entitled "Solar Heat: A Substitute for Fuel in Tropical Countries," was written by William Adam in 1878 in India.

Maria Telkes and George O. G. Lof performed extensive studies on solar cooking at the Massachusetts Institute of Technology.

A significant attempt to introduce nearly 200 of the concentrator-type solar cookers developed at the University of Wisconsin was made in the states of Sonora, Coahuila, and Oaxaca, Mexico, with the help of the Rockefeller Foundation. After initial problems, the cooker was redesigned and the modified version of the cookers was used for many years.

One of the largest attempts to introduce solar cookers was made in India in 1953, when 200,000 paraboloid concentrator-type solar cookers developed by M. L. Gai of NPL New Delhi were brought in. The cooker consisted of a paraboloid reflector of equation $Y^2 = 180X$, with a focal length of 45 cm; the reflector was spun from an aluminum sheet into the desired shape and then anodized to protect it from the weather and to maintain reflectivity. The first commercial version of the hot box-type cooker was designed by M. K. Ghosh in India in 1945.

1.2 Cooking Methods and Solar Cookers

The principal methods of cooking food can be divided into four categories based on cooking temperature and cooking media. These are boiling, frying, baking, and roasting.

1.2.1 Boiling

Water is used as a medium in this type of cooking. This sets the upper temperature limit. In this mode of cooking, food is cooked at only 100°C. In cooking by boiling, the mixture of food and water is brought to a boil and allowed to simmer until completion of the chemical reaction of the food. Due to the presence of a large amount of water in this type of cooking, the specific heat of the water and food mixture is assumed to be equal to that of water, i.e., 4 kJ/kg °C. Thus, once the boiling point is reached, not much heat is required except that the heating rate should be equal to the rate of heat loss. The thermal losses from the cooking vessel area include the following: loss due to vaporization of water (35%), heating of the food–water mixture to the boiling point (20%), and convection losses from the vessel (45%). Box-type solar cookers are suitable for this type of cooking.

1.2.2 Frying

Oil is used as a medium in this type of cooking. The upper temperature limit of this mode is dependent on the characteristics of the oil used. Cooking is dependent on the boiling temperature of oil, which is generally between 200 and 300°C. Frying is a high-power cooking process and cooking is normally completed in a short time. Otherwise, food may become burned. Concentrator cookers are suitable for this type of cooking.

1.2.3 Roasting/Grilling

In this mode of cooking, heat is transferred to the food primarily through radiation and to some extent through convection. It is also a very high power process. Concentrating cookers are suitable for this type of cooking.

1.2.4 Baking

Baking is also a high-power cooking process in which heat is transferred from the oven wall by convection and radiation. Solar ovens are suitable for this type of cooking.

2. CLASSIFICATION OF SOLAR COOKERS

Solar cookers can be classified into four main categories: (1) concentrator cookers; (2) solar ovens; (3) box cookers; and (4) indirect (combined) solar cookers. These main categories can be further subdivided into different categories, as shown in Fig. 1.

3. PARABOLIC CONCENTRATOR COOKERS

A parabolic solar cooker is a concave bowl-shaped dish, whose inner surface is made of reflective material. Sunlight falling on the inner surface is focused onto a dark cooking pot that is suspended or set on a stand in front of the cooker.

The power output of the cooker depends on the size of the dish, the intensity of the solar radiation, the reflectivity of the inner lining, and the perfection

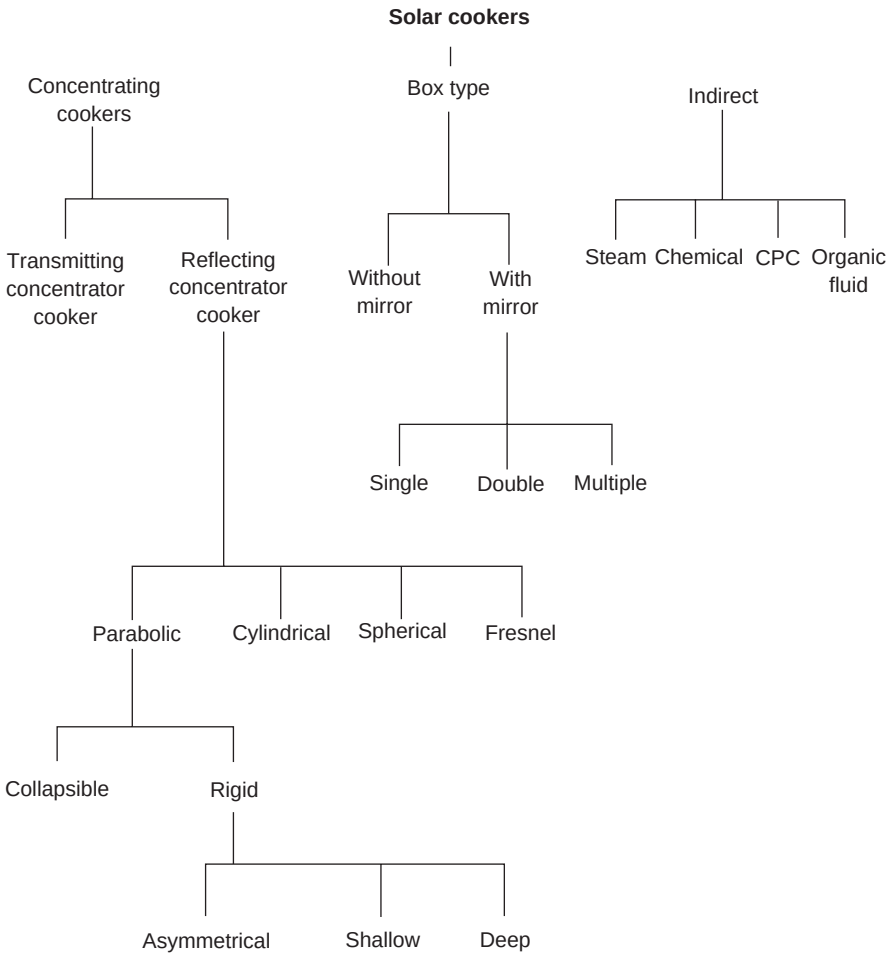

FIGURE 1 Types of solar cookers.

of the geometry. A concentrator cooker having 400 to 600 W output requires an area of 1 m^2. Concentrator cookers work only in direct sunlight; they work poorly under cloudy conditions. They require constant tracking. They also become unstable under windy conditions.

Maximum numbers of models of this category of concentrating cooker have been developed, as focusing of solar radiation is achieved much better using this geometry. However, constant tracking is required for this type of cooker as these cookers are sensitive to small changes in the relative position of the sun. Fabrication of parabolic geometry is also difficult compared to spherical geometry. In view of this, large sizes are fabricated with small strips and careful calculations are required to arrive at a suitable geometry. Some simpler methods, such as wire-reinforced concrete shells, soil cement depressions in the ground, and papier-maché shells, have been suggested. Parabolic concentrators can be classified into two categories: rigid parabolas and folding parabolas.

The majority of models that have been developed are based on the rigid parabola design. This category can be further subdivided into the following three subcategories: shallow parabolic cookers, asymmetrical parabolic cookers, and deep parabolic cookers.

3.1 Shallow Parabolic Cookers

In this type of cooker, the focus is outside the rim of the reflector.

A separate cradle-type stand is used to hold the cooking vessel as well as the reflector. In some designs, only the reflector is moved to track the sun.

3.2 Asymmetrical Parabolic Cookers

Asymmetrical parabolas are partial parabolas. This configuration enables the cooking to be done as close

as possible to the vessel. In the former design, there is a hole in the center of the reflector, where a stand is inserted to support the cooking vessel.

In the deep asymmetrical parabolic configuration, several small parabolic reflectors are arranged in an asymmetrical parabolic configuration. See Figs. 2, 3, and 4.

3.3 Deep Parabolic Cookers

In these cookers, the focus is within the rim of the reflector. The cooking vessel is hung from a stand inside the deep parabolic reflectors. Focusing is essential once every 20–30 min. These cookers were not very successful, due to bright sunlight hitting the eyes during cooking, the need to handle hot cooking vessels, and the need for periodic tracking. See Figs. 5 and 6.

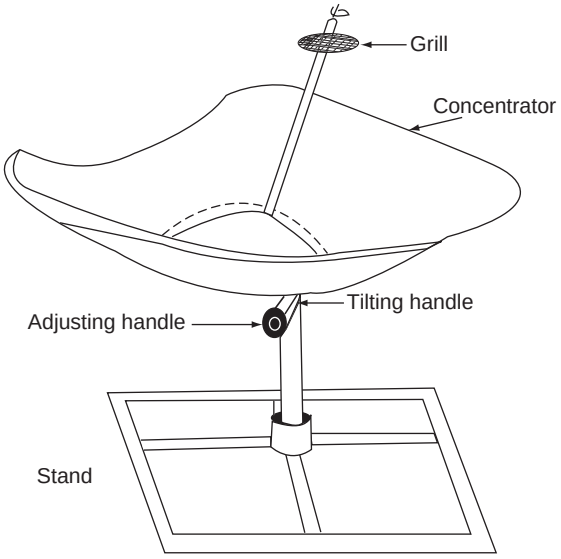

FIGURE 2 Asymmetrical parabolic cooker.

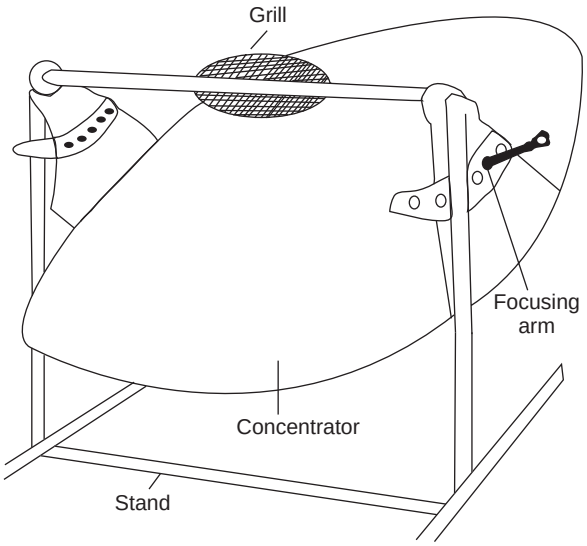

FIGURE 3 Asymmetrical parabolic cooker.

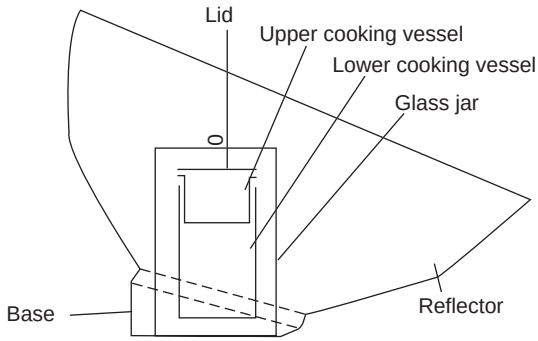

FIGURE 4 Asymmetrical parabolic cooker.

FIGURE 5 Deep parabolic cooker.

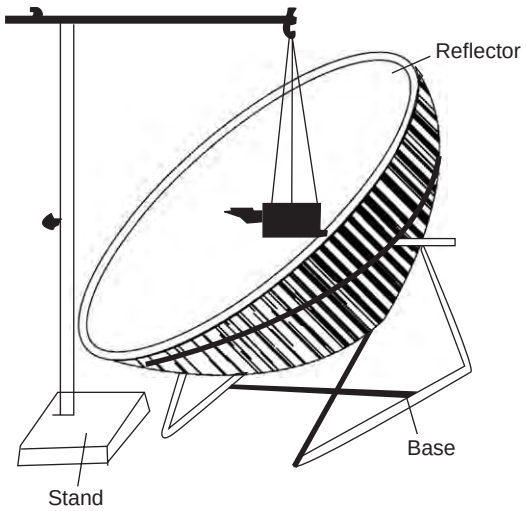

FIGURE 6 Deep parabolic cooker.

3.4 Collapsible Parabolic Cookers

Parabolic cookers are difficult to transport due to their bulky size. To facilitate easy transportation, collapsible parabolic cookers were designed. Some of the designs open like an umbrella. In others, inflatable plastic configurations have been used. Fluttering focus and unstable reflectors were significant impediments in the large-scale propagation of these cookers. See Figs. 7, 8, and 9.

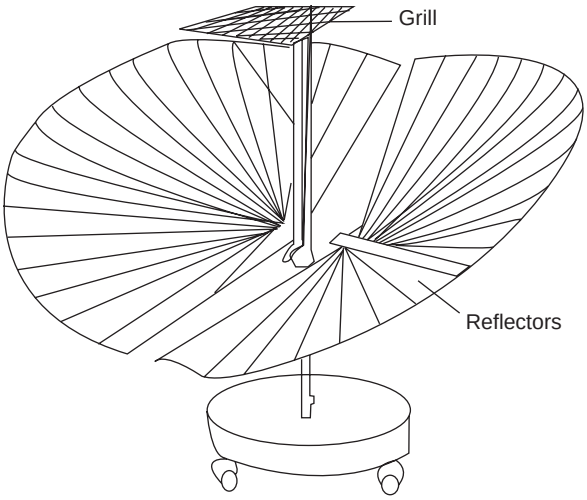

FIGURE 8 Collapsible parabolic cooker.

3.5 Cylindro-Parabolic Cookers

In cylindro-parabolic cookers, rays are focused in an insulated box in which the cooking pots are placed. One or more cylindro-parabolic mirrors can be used. The tracking arrangement of these mirrors is such that they focus solar radiation into the cavity of the insulated box. See Figs. 10 and 11.

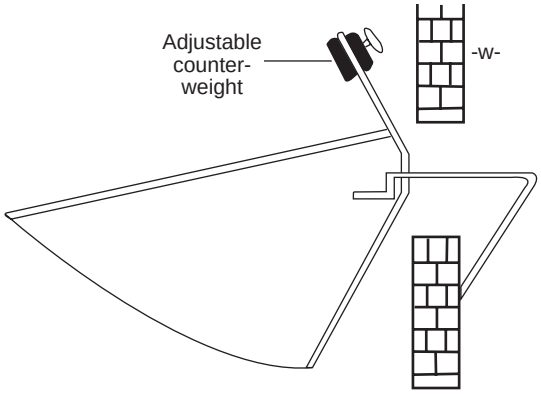

FIGURE 7 Collapsible parabolic cooker.

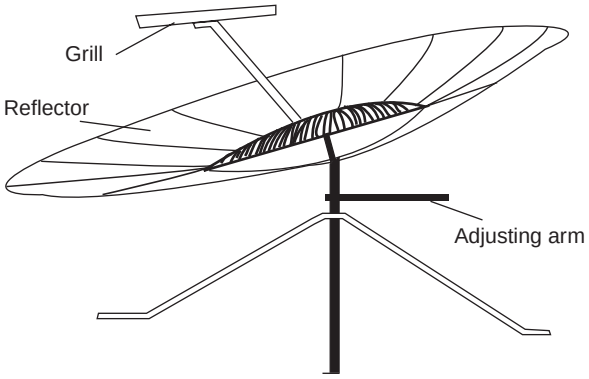

FIGURE 9 Collapsible parabolic cooker.

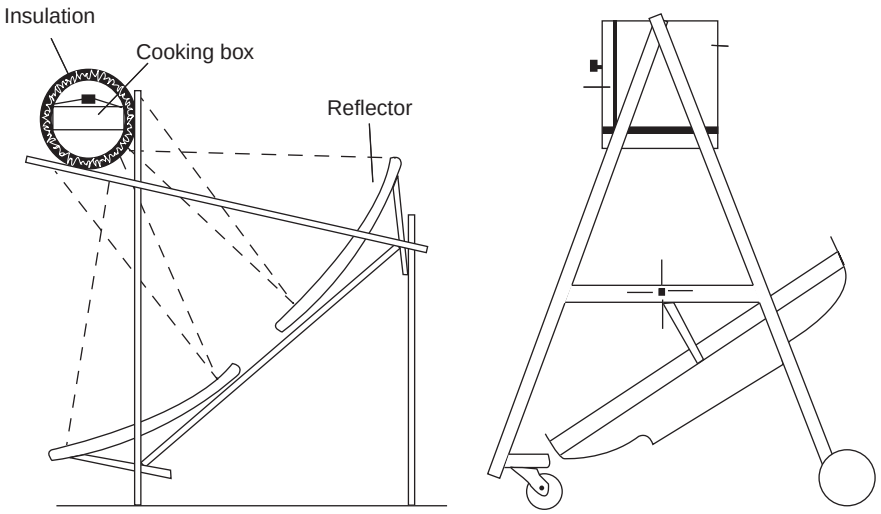

FIGURE 10 Cylindro-parabolic cooker.

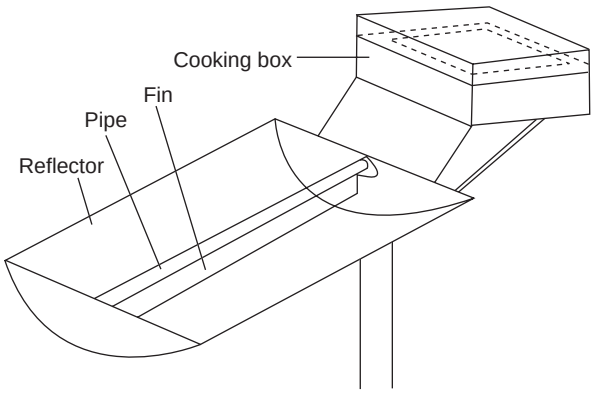

FIGURE 11 Cylindro-parabolic cooker.

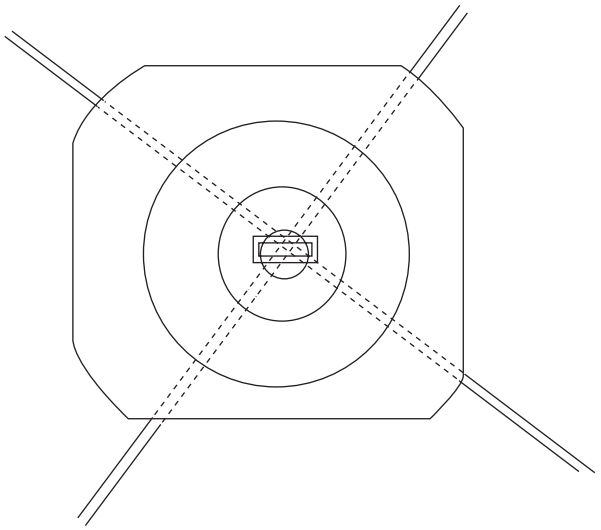

FIGURE 12 Fresnel reflector cooker.

4. FRESNEL REFLECTOR COOKERS

The reflectors for these types of cookers are made by using reflecting rings in a concentric Fresnel geometry. Any size of solar cooker can be made using this technique. However, designing such cookers requires considerable skill. See Fig. 12.

5. PLANE MIRROR CONCENTRATING COOKERS

Plane mirrors have been used in different configurations, such as cones or folding plane stands, such that these mirrors focus rays onto the cooking pot. Provisions are made to tilt the mirror assembly to focus the sun's rays onto the cooking pot during cooking. However, these designs did not become popular due to the large size of the stands. See Fig. 13.

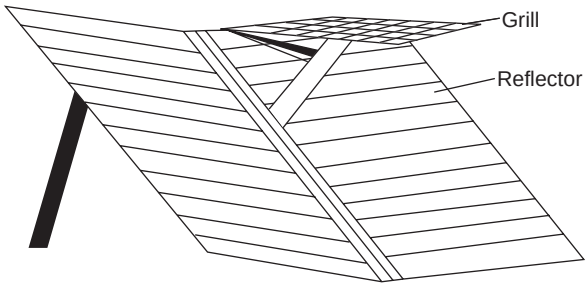

FIGURE 13 Plane mirror concentrating cooker.

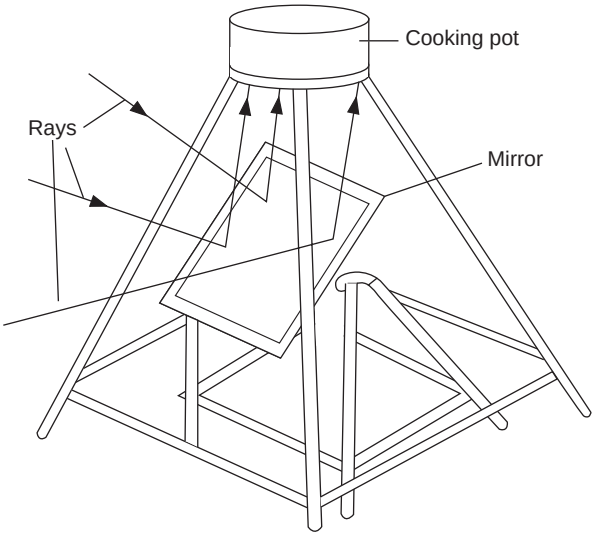

FIGURE 14 Water lens cooker.

6. TRANSMITTING CONCENTRATOR COOKERS

These cookers can be divided into three categories: water lens, dome lens, and Fresnel lens cookers.

6.1 Water Lens Cookers

These types of cookers concentrate light from above. The concentrator in such cookers consists of either plastic or glass concave sheets that are filled with water or alcohol. In some designs, an additional lens of small diameter is used to form a sharp focus. In a modified version, a deflector is used to focus the light onto the bottom of the pot. See Figs. 14 and 15.

6.2 Dome Lens Cookers

In such cookers, a dome comprising multiple cookers is used. However, fabrication of an assembly of lenses having a long focus is difficult.

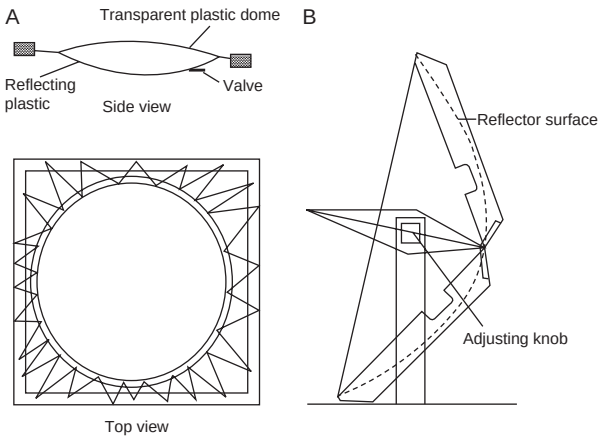

FIGURE 15 Water lens cooker.

7. FRESNEL LENS COOKERS

The use of transparent Fresnel lenses has been suggested for cooking applications. Two configurations of this design have been suggested. In one, the vessel is tracked, and in the other, the lens assembly is tracked. These designs did not become popular due to the high cost of Fresnel lenses. Also, plastic lenses deteriorate very fast. With the availability of ultraviolet-resistant polymers, such cookers may become a feasibility.

8. PRINCIPLES OF PARABOLOID COOKERS

Only the beam component of solar radiation is normally collected by paraboloid concentrating solar cookers, which are reflected to the focal point. Thus, for satisfactory performance, predominantly sunny skies are required. Thermal energy input to the cooking vessel is immediately cut whenever there is an obstruction between the sun and the cooker. The length of time spent in the shade and other factors, such as wind and the size of the cooking vessel, determine the recovery time.

8.1 Theoretical Consideration in the Design of Concentrator Cookers

The basic function of a concentrator is to collect radiation over a large area and concentrate it onto a smaller area so as to attain higher temperatures. Concentration can be defined by the following two methods: geometric concentration and flux concentration.

Geometric concentration is defined as the ratio of aperture area to receiver area

$$C_{\text{Area}} = A_{\text{A}}/A_{\text{R}}. \tag{1}$$

and flux concentration is defined as the ratio of intensity at the aperture to intensity at the receiver

$$C_{\text{Flux}} = I_{\text{A}}/I_{\text{R}}. \tag{2}$$

This involves an absorption effect in addition to geometry.

In concentrator solar cookers, geometric flux is the most widely used method.

According to the second law of thermodynamics, the maximum possible concentration for a given acceptance half-angle, θ_{c}, for a line-focusing concentrator collector is given by

$$C_{\text{Ideal 2D}} = 1/\sin\theta_{\text{c}}. \tag{3}$$

For point-focusing concentrators (cones, dishes, pyramids), the ideal concentration is given by

$$C_{\text{Ideal 3D}} = 1/\sin^2\theta_{\text{c}}, \tag{4}$$

where θ_{c} is the acceptance angle, which is defined as the angular range over which all or almost all rays are accepted without the collector being moved.

8.2 Concentration Limit

The angular radius of the sun $\Delta s = 0.25^\circ$.

Thus, the thermodynamic limit of a tracking two-dimensional solar cooker is 200 and that for a three-dimensional solar cooker is 40,000. However, the actual values achieved are much lower due to the nonoptimized design of the concentrator, tracking errors, nonspecular behavior of the optical system, and atmospheric scattering.

Focal length is an important parameter in the design of concentrator cookers. For spherical concentrator cookers, focal length changes with the length of the curve in a spherical mirror, as described by

$$B = (1/2)r^2/(r^2 - y^2)^{1/2}, \tag{5}$$

where r is radius and y is height.

In parabolic cookers, focal length depends only on the nature of the curve; it does not change with the length of the curve or the point on the curve, as is the case with spherical cookers.

8.3 Performance of Parabolic Concentrators

Parabolic concentrator performance depends mainly on two parameters, namely, the optical efficiency factor, $F\eta_o$, and the heat loss factor, FU_L. The optical efficiency factor depicts the perfection of the reflector surface area, its reflectance, and the absorption of the outer surface of the cooking pot. Thus, it defines the theoretical upper limit of the overall efficiency of a concentrator solar cooker.

The heat loss factor FU_L depends on the temperature of the water in the pot, the wind speed, the surface area of the cooking pot, and the orientation of the reflector. The heat loss factor can be evaluated by studying the cooling curve and optical efficiency can be evaluated by studying the heating curve.

8.4 Heat Loss Factor

8.4.1 Theory

The infinitesimal time interval dt for a fall of infinitesimal temperature of dT_w can be depicted by the following equations:

$$dt = \frac{(MC)\S_w dT_w}{Q_L}. \tag{6}$$

$$= \frac{(MC)\S_w dT_w}{A_{t'} F\S U_L (T_w - T_a)}. \tag{7}$$

Assuming that the heat loss factor U_L and the ambient temperature T_a are constant during the cooling test, the above equations can be integrated over the time interval t during which water temperature falls from $T_{wo}-T_w$.

$$t = \frac{(MC)\S_w}{A_t F\S U_L} \ln\left[\frac{(T_w - T_a)}{(T_{wo} - T_a)}\right]. \tag{8}$$

$$(T_w - T_a) = (T_{wo} - T_a) e^{t/t_0}, \tag{9}$$

It can be inferred from the above equations that t_o is time constant, as after time $t = t_o$, the temperature difference $T_w - T_a$ falls to $1/e$ of the initial value.

8.4.2 Optical Efficiency

Optical efficiency can be evaluated by the heating curve method. In this method, the time taken, dt, for a rise in temperature, dT, of water during heating is measured.

$$dt = \frac{(MC)\S_w dT_w}{Q_u}. \tag{10}$$

$$dt = -\frac{(MC)\S_w dT_w}{F\S[Ap\eta_o I_b - A_t U_L (T_w - T_a)]}. \tag{11}$$

If the insulation and ambient temperature are constant over a certain interval of time t, the above equations can be integrated over this time interval when temperature rises from T_{w1} to T_{w2} as

$$t = -t_o \ln\left\{\frac{f\S\eta_0 - \frac{F\S U_L}{C}\left[\frac{T_{w_2} - T_a}{I_b}\right]}{F\S\eta_o - \frac{F' U_L}{C}\left[\frac{(T_{w_1} - T_a)}{I_b}\right]}\right\}, \tag{12}$$

where t_o is the time constant obtained from the cooling curve and C is the ratio of aperture area of the cooker to the area of the pot surface (A_p/A_t).

The above equation can be rewritten as

$$F\S\eta_o = \frac{F\S U_L}{C}\left\{\frac{[(T_{w_2} - T_a)/I_b][(T_{w_1} - T_a)/I_b]}{1 - e^{-t/t_o}}\right\}^{e^{-t/t_o}}, \tag{13}$$

where $F\eta_o$ is the optical efficiency.

Time to boil can be calculated by writing the equation

$$t_{boil} = t_o \ln\left\{\frac{1}{1 - [(F\S U_L)/(F\S\eta_o)](1/C)[(100 - T_a)/I_b]}\right\}. \tag{14}$$

8.4.3 Procedure

The dimensions of the parabolic reflector cooker, such as aperture diameter and rim angle, are measured. The height, diameter, and weight of the cooking vessels are also measured. The cooking vessels are loaded with water and the parabolic concentrator solar cooker is pointed toward the sun in such a manner that the bright spot is positioned on the cooking vessel. A heating curve is obtained until the water temperature reaches 90–95°C. The concentrator is then shaded and a cooling curve is obtained until the temperature is close to ambient.

A semilogarithmic graph between $\ln(T_w - T_a)$°C and length of time of cooling is plotted. The slope of the line is equal to $(-1/t_o)$.

The heat loss factor is calculated using the following equation:

$$F' U_L = \frac{(MC)\S_w}{t_o A_t}. \tag{15}$$

Using this heat loss factor, the optical efficiency is calculated using Eq. (13).

9. SOLAR BOX COOKERS

Box-type solar cookers/ovens use the greenhouse effect to cook food. A transparent glass or plastic cover over the insulated box allows short-wave radiation to pass through. The black-coated inner box absorbs this radiation. With the increase in the temperature of the inner tray, energy is reradiated at longer wavelengths. The glass cover does not allow long-wave radiation to pass through it. The temperature of the box increases and an equilibrium temperature is reached, where the input of solar energy is balanced by the heat losses. In order to enhance the performance of this cooker, a plane reflector is attached to the box. This type of cooker can hold a number of pots of food. Food does not burn, as it is cooked at low temperatures. Due to its light weight, it is easy to carry. The cost of this type of cooker is less than that of concentrating cookers.

The most popular box solar cooker was designed by M. K. Ghosh, in 1945. It consists of a rectangular aluminum tray. This tray is placed in a box made of fiberglass-reinforced epoxy resin, wood, aluminum, and a galvanized iron sheet. The space between the aluminum tray and the outer box is filled with insulation. The tray is covered with a movable double-glass cover, attached by a hinge to one side of the outer box. A flat glass mirror encased in a fiberglass-reinforced epoxy resin shell is fixed to serve as a reflector and also as a cover when the cooker is closed. A hinge arrangement is provided to tilt the reflector at different angles to focus solar radiation into the tray. Cylindrical tight-fitting vessels with flat bottoms and top lids are used for cooking food.

The aluminum tray, the outside of the cooking vessels, and the lids of the vessels are painted dull black. A temperature of 120°C can be attained in this type of cooker, which is sufficient for boiling-type cooking. Keeping the general configuration intact, a number of alternate materials have been used by different designers to reduce costs and to use local materials. Aluminized Mylar film/anodized aluminum sheets have been used for the reflector. Agricultural residues, crushed newspapers, and other materials have been used for insulation. Cardboard has been used for the outer box and top lid. Plastic sheets have been used in place of glass. Although these cookers are cheap, food can be cooked properly in these configurations at only climatically favorable places. The lifetime of these cookers is shorter than that of custom-made cookers. See Fig. 16.

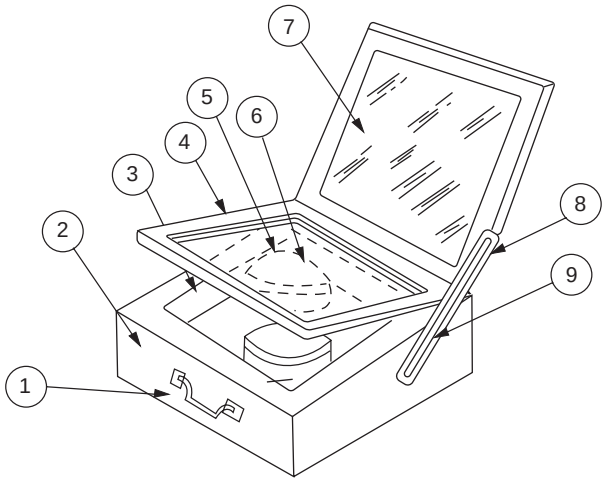

FIGURE 16 Box-type solar cooker. (1) Handle; (2) outer box; (3) insulation material (glass wall); (4) cover; (5) glass sheet; (6) cooking container; (7) plane mirror; (8) mirror support; and (9) hinged adjustor and guide.

9.1 Specifications of the Components (Bureau of Indian Standards)

9.1.1 Cover Plate

The inner cover plate is constructed of toughened glass 3 mm in thickness; the outer cover plate is constructed of plane glass 4 mm in thickness. Spacing is 10×2 mm. Solar transmittance should be 80% at a minimum. The aperture area is 500×500 mm. Tolerance is ± 5 mm.

9.1.2 Cooking Tray

The size should be $500 \pm 5\,\text{mm} \times 500 \pm 5\,\text{mm} \times 82 \pm 2$ mm. The construction material is aluminum. The sheet should be 0.56 ± 0.05 mm. The tray should be painted in a matte black finish to withstand temperatures up to 175°C. A scratch test should be carried out on a sample 10×10 mm in area.

9.1.3 Cooker Box

The material thickness for the galvanized iron sheet should be 48 ± 0.05 mm and that for the aluminum sheet should be 56 ± 0.05 mm. The FRP should be 2 mm, at a minimum. The size of the cooker box is $600 \pm 5 \times 600 \pm 5 \times 500 \pm 3$ mm.

9.1.4 Gasket

The gasket should be constructed of neoprene or silicon rubber and have a thickness of 3 mm.

9.1.5 Insulation

Insulation should consist of glass wool or mineral wool in 50 mm thick uniform pads. The insulation should be free of volatile material at 200°C.

9.1.6 Reflecting Mirror

The reflecting mirror should be 540 ± 5 mm $\times$ 540 ± 5 mm in size. The thickness should be 3 mm. Solar reflection should be equal to 65%.

9.1.7 Cooking pots

The construction material for the cooking pots should be aluminum or stainless steel. The depth of the pots should be 63 ± 2 mm. For aluminum pots of 200 ± 5 mm or 150 ± 5 mm in diameter, the thickness should be 1 mm. There should be three pots. For stainless steel pots of 200 ± 5 mm or 150 ± 5 mm in diameter, the thickness of the pots should be 50 mm. Two pots are needed.

9.1.8 Wheels

The wheels should be 25 mm in diameter, with ball bearings.

9.2 Performance Evaluation of Box-Type Cookers

Energy requirements are at a maximum during the heating period in boiling-type cooking and only a small amount of heat is required for the physical and chemical changes involved in the cooking process. Once the cooking temperature is attained, energy is required only to compensate for thermal losses and that required for physical and chemical changes and so the cooking is practically independent of the heat input rate. Thus, the time required to cook the same food in different cookers will depend on the heating period.

Two parameters have been recommended to evaluate the performance of box-type solar cookers. These are the first figure of merit, F_1, and the second figure of merit, F_2. The first figure of merit depicts optical efficiency and is the ratio of optical efficiency to heat loss factor; it is evaluated by a stagnation test without load. The second figure of merit, F_2, gives an indication of the heat-exchange efficiency factor (F') and involves heating of a full load of water.

In a box-type solar cooker, there is no control over its temperature and the operation is transient, in contrast to a solar water heating system, where a steady state is obtained by circulating water at different temperatures through the tubes. A quasi-steady state is achieved when a stagnation temperature is obtained. The heat loss factor at stagnation, UL_s, can be calculated.

Only cookers with good optical transmission of glass covers and a low overall heat loss factor will have a high value for the first figure of merit (F_1). However, good heat transfer to the vessel and its contents will be ensured by the second figure of merit, F_2. Since there is no arrangement for the flow of liquid to obtain a steady-state withdrawal of energy from the cooker, as is the case with solar water heaters, it is difficult to measure the heat-exchange efficiency factor F' between the cooker plate and the contents of the pot. A factor, F_2, is proposed for this purpose; it includes F' as well as U_{LS} and CR for the cooker utensil combination.

During both tests, the mirror booster is not used and the measurements are started approximately 2 h before solar noon.

To estimate the first figure of merit, F_1, a solar cooker with utensils is kept in the sunshine and the rise in plate temperature, the solar radiation intensity, and the plate temperature are recorded. When the stagnation temperature is reached, the ambient temperature and solar insulation are measured. The figure of merit, F_1, is calculated by

$$F_1 = \frac{\eta_o}{U_{LS}} = \frac{T_{ps} - T_a}{I_{Gs}}, \tag{16}$$

where η_o is the optical efficiency; I_{Gs} is the insulation on the horizontal surface at the time the stagnation temperature is reached (in watts per square meter); U_{LS} is the heat loss factor at stagnation; T_{ps} is the stagnation plate temperature (in degrees centigrade); and T_a is the plate temperature (in degrees centigrade).

To evaluate the second figure of merit, F_2, the solar cooker without the reflector but with a full load of water and utensils is kept in the sun. Initial water is kept at an average temperature between ambient and the boiling point. Temperature and solar radiation are measured until the temperature reaches 95°C.

The second figure of merit, F_2, is calculated using the equation

$$F_2 = \frac{F_1(MC)_w}{A(t_2 - t_1)} \times \ln\left\{\frac{1 - (1/F_1)[(T_{w2} - T_a)/I_G]}{1 - (1/F_1)[(T_{w1} - T_a)/I_G]}\right\}, \tag{17}$$

where F_1 is the first figure of merit from the stagnation test; $(MC)_w$ is the product of the mass of water and specific heat (in joules per degrees centigrade); A is the aperture area of the cooker of the cover plate (in square meters); $t_2 - t_1$ is the time taken for heating from T_{w1} and T_{w2} (in seconds); T_a is the average air temperature during the time period $t_2 - t_1$ (in watts per square meter); and I_G is the radiation during the time period $t_2 - t_1$ (in watts per square meter).

It has been assumed that the global radiation, I_G, remains constant during the test. This assumption introduces some error into the data.

9.3 Testing Methods for Box-Type Solar Cookers (Bureau of Indian Standards)

The following tests have been recommended by the Bureau of Indian Standards (BIS) for evaluating the durability and thermal performance of box-type solar cookers. These tests include leakage tests, breakage tests, reflectivity tests, exposure tests, and thermal performance tests.

9.3.1 Leakage Tests

9.3.1.1 Cooking Tray Leakage Test

1. The cooking tray should be dismantled from the main body.
2. The cooking tray is filled with water; after 1 h, the joints of the tray should be examined for any signs of leakage.

9.3.1.2 Rubber Gasket Leakage Test

1. A piece of paper is inserted between the gasket and the cover plate in at least four positions along each side of the cooker.
2. The paper used should be 50 mm wide and 0.01 mm thick.
3. The cover plate should be properly tightened.
4. The paper should exhibit a firm resistance to withdrawal by hand at all points tested.

9.3.1.3 Cover Plate Leakage Test Leakage from the cover plate may occur from the upper and lower sides. Therefore, the cooker should be tested using the following two tests:

i. Leakage test for the upper side of the cover plate:

1. The cover plate should be properly tightened.
2. A thin film of water should be poured onto the cover plate.
3. After 1 h, the cover plate should be examined for any signs of water having entered between the two glass sheets.

ii. Leakage test for the lower side of the cover plate:

1. The cooking pots are filled with water and kept in the cooking tray.
2. The cover plate is tightened.
3. The cooker is placed out in the open for exposure to the sun's rays for 4–5 h.
4. Then, the cooker should be placed in the shade for 15 min to allow any vapor to condense.
5. The cover plate is examined for any signs of water vapor entry between the inside and outside of the cover plate.

9.3.2 Rain Penetration Test

9.3.2.1 Apparatus The basic apparatus is a 5 mm spray nozzle and a balance.

9.3.2.2 Procedure

1. The closed cooker is sprayed with 10 liters of water on all sides using a spray nozzle at a pressure of 0.1 MPa.
2. Spray nozzles are directed downward from the cooker top and also toward the four corners of the cooker.
3. The cooker should be weighed before the test.
4. After the test, the external surfaces of the cooker are wiped dry and the cooker should be reweighed.
5. During wiping, transport, and placement on the weighing machine, the cooker should remain in a horizontal position.
6. The balance used to weigh the cooker should have an accuracy of at least 20 g.
7. The permissible gain in weight should not be more than 30 g.

9.3.3 Slam Tests

This test is performed to ensure that the mirror or cover plate will not be damaged when allowed to fall from the fully opened position as given below:

9.3.3.1 Cover Plate Slam Test With the lid open, the cover plate is lifted as high as possible and then it is allowed to fall to a closed position. There should be no damage to the glass sheets.

9.3.3.2 Slam Test Mirror The lid should be held at near vertical and is allowed to fall to a closed position. There should be no damage to the mirror, the cover plate, or any other part of the cooker.

9.3.4 Mirror Reflectivity Test

9.3.4.1 Apparatus The basic apparatus consists of a photovoltaic-based solarimeter and a stand for mounting a sample piece of the reflecting mirror. The

stand should have a vertical pointer of 15 cm in height and an arrangement for mounting the solarimeter in a plane parallel to the plane of stand and at a height of 30 cm.

9.3.4.2 Procedure

1. The stand is adjusted for normal incidence such that there is no shadow of the vertical pointer.
2. This sample of reflecting mirror (540 mm × 540 mm) is placed on the stand in an open space. The open space should be free of any shadows and it should not receive any reflecting radiation from the surroundings.
3. The solarimeter should be placed in the stand provided for it in such a way that the sensor is near normal ($\pm 10^{\circ}$) to the sun's rays. The solarimeter (R_1) is then read.
4. The position of the solarimeter is changed in such a way that the sensor now faces the mirror at a near normal angle. The solarimeter (R_2) is then read.
5. The reflectivity of the mirror is calculated as follows: $R = R_2/R_1$.
6. The test should be repeated six times at 10 min intervals.
7. The average of the six values is calculated. This value will represent the reflectivity of the mirror.
8. The permitted conditions of solar radiation during the test are that it should be greater than 600 W/m^2.

9.3.5 Exposure Test Apparatus

The basic apparatus consists of a solar pyranometer, along with recording devices.

9.3.5.1 Procedure

1. The solar cooker is left to stagnate, which may lead to the following types of possible degradation:
   - Breakdown of rubber or plastic material;
   - Outgassing from the insulating material;
   - Discoloration or peeling of black paint on the cooking pots and cooking tray; or
   - Deposition of water vapor, dust, or any other material inside the double-glass lid.
2. The solar cooker is left in an unshaded area for at least 30 days having irradiation levels of at least 14 MJ/m^2 on the horizontal surface.
3. These days need not be consecutive.
4. The cooking pots inside the cooker should be empty.
5. The mirror is placed vertically and the cooker should be oriented to face south.

9.3.6 Cooking Tray Paint Peeling Test

A 10 mm × 10 mm area of painted surface is selected from squares of I mm × I mm by scratching horizontal and vertical lines with a pointed tool. The surface portion is covered with adhesive cellophane tape and then the tape is removed with a jerk. The test surface should be inspected and there should be no peeling of paint.

9.3.7 Transmittance Test for Cover Plate

The solar radiation is measured with a pyranometer/photovoltaic-based solarimeter directly (without the glass) and then measured with the cover plate above the pyranometer and solarimeter. The ratio of the two readings should be at least 0.8.

9.3.8 Thermal Shock Test for Gasket/Sealant

The gasket/sealant of 10 cm in length should be kept in an electric oven at a temperature of 150°C for 4 h. It should be cooled in air for 2 h, again placed in the oven at 150°C for 4 h, and then again cooled in air. After the test, the gasket and sealant should exhibit no cracking or brittleness.

9.4 Thermal Performance Test

The thermal performance test should be conducted under the conditions given below; values of $F_1$and F_2 are then calculated.

9.4.1 Testing of Box-Type Cookers

9.4.1.1 Stagnation Temperature Condition Apparatus The apparatus consists of a pyranometer and a platinum resistance thermometer along with a recording device.

9.4.1.2 Procedure The test for evaluating F_1 should be carried out as follows in the morning hours before 10:00 A.M. so that the stagnation temperature is achieved near solar noon.

1. The solar cooker is placed in full sun.
2. The reflector of the solar cooker is covered with a black cloth.
3. The temperature inside the solar cooker is measured using RTD for a continuous 5 min interval.
4. When the cooker temperature has reached a steady state, the final temperature inside the cooker (T_{ps}), the corresponding ambient air temperature (T_a), and solar insolation are noted.

The steady-state conditions are defined as a 10 min period when:

1. The cooker temperature is constant within 1°C;

2. Solar radiation is constant within 20 W/m^2;
3. Ambient temperature is constant within 0.2°C; and
4. Solar radiation is greater than 600 W/m^2.

The performance factor F_1 is calculated using Eq. (16).

9.4.2 Heat-Up Condition

The figure of merit F_2 should be estimated as follows.

9.4.2.1 Apparatus The apparatus consists of a pyranometer and a platinum resistance thermometer, along with a recording device.

9.4.2.2 Procedure The empty cooking pots are weighed and then filled with water at 50°F (15°C). They are reweighed and the mass of water is calculated. The pots are placed in the cooker from which the mirror has been removed or covered. A temperature probe of RTD is placed in the largest of the cooking pots with the measuring tip submerged in the water. The temperature probe lead should be sealed where it leaves the cooking pots and the cooker.

The ambient temperature and wind speed are measured throughout the test. The test should start in the morning between 11:00 and 11:30 A.M. of local solar time. If radiation and temperature are measured by spot checks, these should be no more than 5 min apart.

Constant monitoring at 30 s intervals or less is desirable, with averages of radiation recorded over 2 min intervals. The following measurements should be taken:

1. Water temperature is measured along with the exact time that that measurement was recorded.
2. The data recording is continued until the water temperature exceeds 95°C.
3. Initial and final temperature/time data pairs are chosen. The initial temperature should be between 60 and 65°C and the final temperature should be between 90 and 95°C. These are denoted T_{w1}, and T_{w2}, respectively, and the corresponding times are t_1 and t_2, respectively.
4. The average air temperature (T_a) between times t_1 and t_2 is calculated.
5. The radiation recorded between the two points should not have varied by more than ± 10 W/m^2 and should always have exceeded 600 W/m^2.
6. The average radiation (I_g) over the time t_1 and t_2 is calculated.
7. The second figure of merit, F_2, is calculated as per Eq. (17).
8. As per the BIS standard, the value of F_1 should be >0.12 for grade A cookers and >0.11 for grade B cookers.

Theoretical analysis as well as experimental evaluation shows that it not possible to achieve these values with the BIS-proposed specifications. However, these values can be achieved by increasing optical efficiency and decreasing the overall heat loss coefficient.

10. MULTIPLE GLASS BOX COOKERS

It is difficult to cook food in a single reflector box-type solar cooker at higher latitudes during the winter season due to higher losses resulting from low ambient temperatures. To overcome this problem, folding two-step asymmetrical reflector box solar cookers have been designed. These consist of a hot box and two plane mirrors fixed at an angle of 13.5°. The hot box has double glazing at the top and insulation on the bottom and sides. At the end of cooking, mirrors can be folded onto the top of the hot box. See Figs 17 and 18.

Solar radiation through the aperture, AL_1, AL_2, and AL_3, can be calculated by the following equations:

$$AL_1 = B\sin(\phi). \tag{18}$$

$$AL_2 = B\sin(\theta_1 - \phi). \tag{19}$$

$$AL_3 = \sin(\theta_2 - \phi). \tag{20}$$

$$\theta_1 = \pi/3 + 2/3\phi. \tag{21}$$

$$\theta_2 = \theta_1 - 13.5. \tag{22}$$

See Fig. 19.

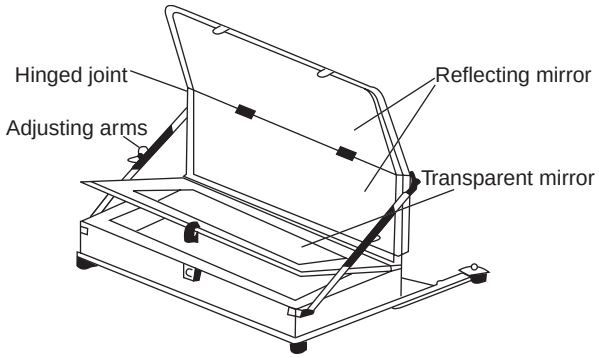

FIGURE 17 Multiple glass box cooker.

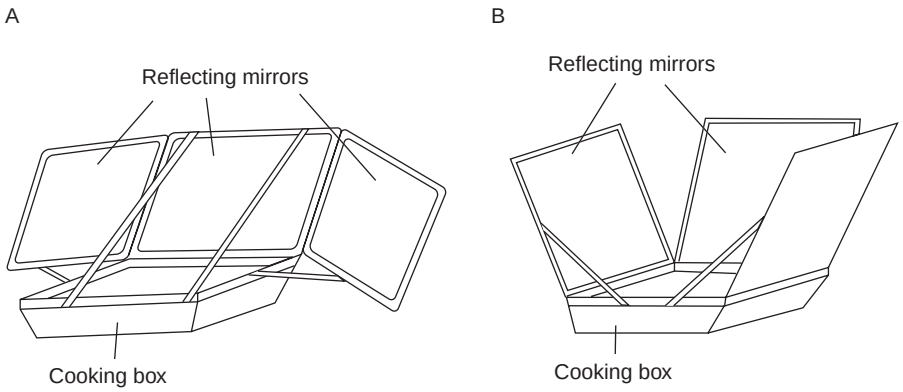

FIGURE 18 Multiple glass box cooker.

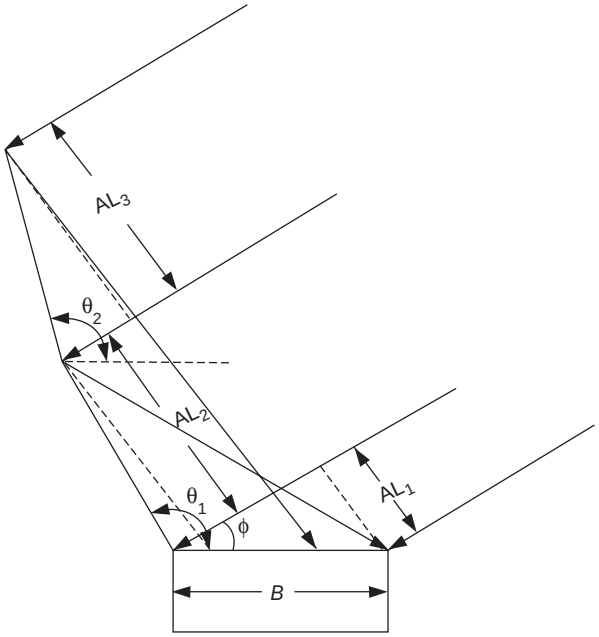

FIGURE 19 Depiction of the geometry used to determine the solar radiation through the aperture in multiple glass box cookers.

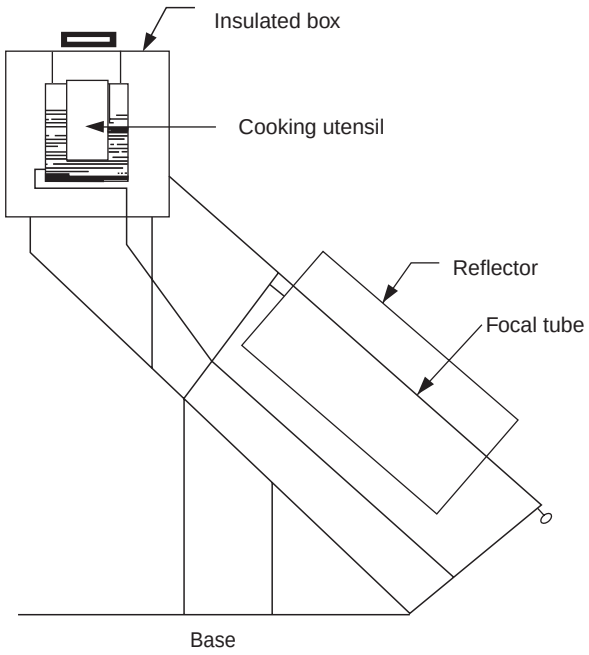

FIGURE 20 A typical configuration of an organic fluid cooker.

11. INDIRECT SOLAR COOKERS

There are no provisions in the conventional box-type or concentrator-type cookers for cooking inside the kitchen or during the period when solar radiation is not available. A number of strategies have been used for special types of indirect solar cookers.

11.1 Organic Fluid Cookers

In this type of cooker, organic fluid is heated using a cylindrical parabolic reflector/CPC/flat-plate collector outside the kitchen. The hot fluid is stored inside the kitchen using the thermosphon principle for cooking applications.

A typical configuration of this type of cooker is shown in Fig. 20.

11.2 Steam Cookers

This type of cooker is similar to the organic fluid cooker, except that low-pressure steam is used as the working fluid. Using flat-plate or concentrating reflectors, low-pressure steam is produced. Food is cooked in a double-jacketed vessel.

11.3 Chemical Cookers

These cookers are based on a reversible chemical reaction between a working fluid (gas or vapors) and

FIGURE 21 A typical configuration of a Scheffler community cooker.

a chemical compound. The reaction is endothermic in one direction and exothermic in the reverse direction. Working fluid becomes desorbed by solar energy and is stored for later use. When heat is required, the desorbed fluid is again allowed to adsorb in the chemical. The liberated heat is used for cooking.

12. SCHEFFLER COMMUNITY COOKER

This cooker has a 6.5 m^2 parabolic reflector dish, which is placed nearly 3 m away from the north-facing wall. The reflector reflects and concentrates solar radiation onto a secondary reflector through an opening in the wall. The secondary reflector deflects the radiation to the bottom of the cooking vessel. Temperatures of up to 400°C can be attained. Cooking can be carried out in a conventional manner in the kitchen. The reflector is tracked with a clockwork mechanism to ensure continuous cooking. There is an arrangement for seasonal adjustment of the reflector. Figure 21 shows the configuration of the cooker.

13. RATING OF SOLAR COOKERS

At the Third International Conference on Solar Cooker Use and Technology, the question of rating solar cookers based on field tests for comparing different models and types of solar cookers was discussed. It was proposed that apart from thermal performance, there are other important parameters that need to be considered from the user's point of view. The selection process in the field should take into consideration the particulars of the sites, conditions, and consumers. The rating criteria should include, in addition to thermal performance, critical factors such as the following: (1) cost, (2) safety, (3) heating and cooking capacity, (4) convenience, (5) durability, (6) ease of maintenance, (7) stability in the wind, and (8) operating instructions on the use of the cooker.

For wider acceptability of the solar cooker, the cost should be reasonable so that ordinary users in developing countries can afford it. It should meet the cooking needs of an average family. It should be convenient to cook food in the cooker, as women do not prefer a gadget that is cumbersome to use. The equipment should be safe to work with and should not cause burn injuries while one is cooking or removing cooked food from the apparatus. As solar cooking is done outdoors, the construction material should be durable so that the cooker may last for a minimum of 8–10 years. Cookers should be easy to maintain as there is a lack of availability of technically trained personnel for maintenance in developing countries and there is a high cost of maintenance in developed countries. A maintenance manual should be provided. Under windy conditions, the cooker can be blown off or fall, resulting in breakage of the glass components and spoiling of the food. There should be provisions for holding the cooker steady under windy conditions. A complete operating manual should be provided in written text as well as in pictorial form to overcome language barriers.

Glossary

absorption A thermodynamic cycle powered by heat and employing a working fluid pair (absorbent/refrigerant) to produce cooling.

closed-cycle system Cooling/dehumidification device in which the working fluid is enclosed in the machine and interacts with the cooled medium by heat transfer through solid walls.

coefficient of performance (COP) Ratio of the cooling produced to the heat/work supplied.

desiccant Hygroscopic material serving to attract and retain humidity from surrounding air.

heat engine Cyclic device receiving heat from a high-temperature heat reservoir, rejecting part of it to a low-temperature heat reservoir, and converting the difference to work.

heat pump Cyclic device extracting heat from a low-temperature heat reservoir and rejecting it to a high-temperature heat reservoir, powered by work.

heat reservoir A source/sink of heat at constant temperature.

open-cycle system Cooling/dehumidification device in which the working fluid (water and/or air) forms part of the cooled medium.

The possibility of providing cooling and air-conditioning by means of energy from the sun has attracted the attention of humans since the early development of solar technology. The necessity of air-conditioning for thermal comfort in hot areas of the world and the abundance of sunshine in these areas have intrigued researchers with regard to how to combine the two for people's benefit. Furthermore, in contrast to other solar applications such as heating, the greatest demand for cooling occurs when the solar radiation is most intense, thus making its use for this application all the more attractive.

1. INTRODUCTION TO SOLAR COOLING

Among the various thermal applications of solar energy, cooling is one of the more complex, both in concept and in construction. This is no doubt one of the reasons why its utilization is not as widespread as space or water heating. It is not sufficient to collect, store, and distribute the solar heat. The energy must be converted to cold by means of a heat-actuated device capable of extracting heat at a low temperature from the conditioned space and rejecting it into the higher temperature of the outside air. In thermodynamic terms, a heat-pumping operation is required.

A schematic diagram of a complete solar air-conditioning system is presented in Fig. 1 showing the different components common to most such systems. A heat transfer fluid is heated in the solar collectors to a temperature well above ambient and used to power a cooling device—a type of heat-actuated heat pump. The heat transfer fluid may be air, water, or another fluid; it can be stored in a hot state for use during times of no sunshine. Heat extracted by the cooling device from the conditioned space and from the solar energy source is rejected to the environment using ambient air or water from a cooling tower. The cooling device may produce the cooling effect in a number of different ways. It can

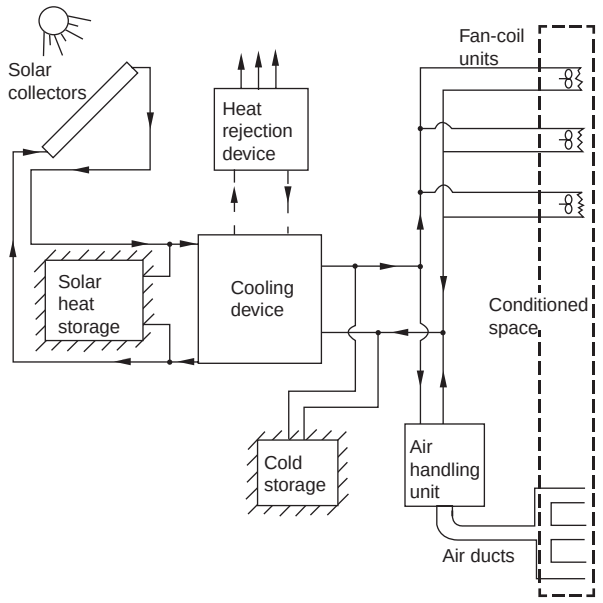

FIGURE 1 Schematic diagram of a solar cooling system.

generate chilled water that may be distributed through fan coil units or used to cool air, which is then distributed through air ducts; the chilled water may be stored for use when the cooling device is not in operation. Alternatively, the machine can cool the conditioned air directly.

Solar collectors are a major part of every solar cooling system. They convert solar radiation into heat at a temperature suitable for powering the cooling device. The collectors vary in type from low-temperature flat plates to more sophisticated high-temperature evacuated tubes or concentrators.

Growing demand for air-conditioning in recent years, particularly in hot and humid climates, has imposed a significant increase in demand for primary energy resources. Electric utilities experience peak loads on hot summer days and are often faced with brown-out situations, barely capable of meeting the demand. With suitable technology, solar cooling can help alleviate, if not eliminate, the problem. This article describes trends in solar cooling, dehumidification, and air-conditioning. It is divided into two main parts and considers closed-cycle and open-cycle alternatives, each with its own advantages and limitations.

2. THERMODYNAMIC PRINCIPLES

In considering the various options for heat pumping systems that may be employed for solar cooling, one must take into account the thermodynamic principles of a heat-powered cooling device. Typically, the system operates between heat reservoirs at three temperature levels: T_L, the low temperature of the cooled medium or the conditioned space; T_H, the high temperature supplied by the solar heat source; and T_A, the intermediate temperature of the environment serving as a sink for the reject heat. The cooling device may be described in basic thermodynamic terms as a combination of a heat engine and a heat pump, as illustrated in Fig. 2. The former receives heat Q_H from the high (solar) heat reservoir at T_H, rejects part of it to the heat sink at T_A, and converts the rest to mechanical work W. The latter employs this work to pump heat Q_L from the low-temperature reservoir at T_L to the heat sink at T_A. According to the second law of thermodynamics, best results are obtained from this machine when both cyclic devices are reversible and operating at the Carnot limit. Under these optimum conditions, the overall coefficient of performance (COP) of the cooling device is found to be

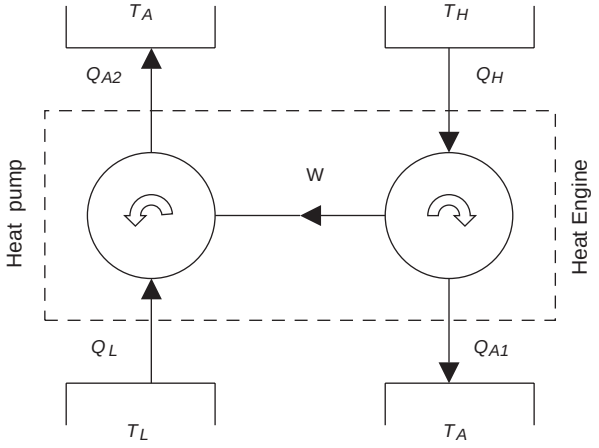

FIGURE 2 Thermodynamic description of a heat-powered cooling device.

$$\mathrm{COP} = \frac{Q_L}{Q_H} = \frac{T_L}{T_H}\frac{(T_H - T_A)}{(T_A - T_L)}. \qquad (1)$$

As evident from Eq. (1), the performance of the heat-powered cooling device is highly dependent on the temperature of the heat source, with better results obtained with higher T_H. The type of solar collector employed to supply the heat thus imposes a limitation on the COP. With common flat-plate collectors, the heat is obtained at relatively low temperatures. Concentrating collectors reach higher temperatures but are more expensive and complex to operate due to their need to track the sun. Another conclusion

from Eq. (1) is that performance improves by lowering the heat rejection temperature T_A. From this standpoint, heat rejection by water cooling is preferred to that by air cooling.

3. CLOSED-CYCLE SYSTEMS

In practice, there need not be a clear distinction between the heat engine and the heat pump parts of the machine. Cycles such as absorption or ejector (jet) have been proposed in which the work produced by part of the machine is "invisible" and goes directly to power the other. Nevertheless, the fundamental thermodynamic principles of the cooling device described previously still hold and set the Carnot upper limit for the COP as given by Eq. (1).

During the great surge in solar energy research and development following the energy crisis of the 1970s, there have been several attempts to build solar-driven cooling systems by means of a solar heat engine driving a heat pump, according to Fig. 2. The former varied from Stirling engines to Rankine engines employing organic fluids; the latter were conventional vapor-compression cooling devices with common refrigerants. These efforts have generally not gone beyond the laboratory. Experience has shown that closed-cycle systems most suitable for solar cooling are based on absorption cycles, which totally eliminate the mechanical interaction between the two parts of the machine. Absorption systems have many advantages: operation at wide ranges of heat source and heat sink temperatures; multistaging for improving COP with high-temperature heat sources; quiet operation with no moving parts; and environmentally safe working fluids. Moreover, absorption systems are amenable to combining available solar heat with backup heat for meeting the cooling demand.

Figure 3 is a schematic diagram of a typical absorption chiller in the simplest, single-effect configuration. The system employs the working fluid pair lithium bromide (LiBr)–water, in which the water serves as the refrigerant and the LiBr as the absorbent. The diagram is plotted in a system of coordinates showing the temperature on the horizontal axis and the pressure prevailing in the system's exchange units on the vertical axis.

The operation of single-effect absorption chillers is well documented in the literature and is described only briefly here. Liquid refrigerant (water) leaving the condenser at state 12 in Fig. 3 expands through the throttle valve (6) into the evaporator (1), where it evaporates from state 13 to 9, taking its heat of evaporation from the stream of chilled water and cooling it from state 1 to 2. The vapor leaving at

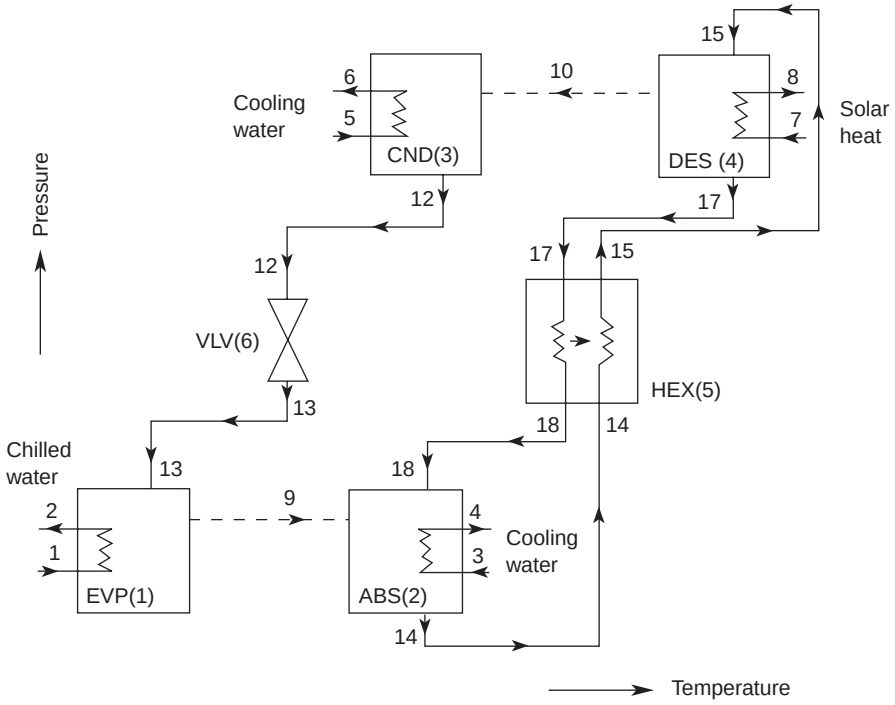

FIGURE 3 Schematic description of a single-effect LiBr–water absorption chiller.

state 9 is absorbed in the absorber (2) by a hygroscopic solution of LiBr entering concentrated (strong) at state 18 and leaving diluted (weak) at state 14. The exiting solution is pumped via heat exchanger (5) to desorber (4) by means of a small pump (not shown), requiring a small and negligible amount of work. The desorber serves to regenerate the solution from a weak to a strong state by applying to it heat from the solar-heated water stream 7–8, causing the desorption of water at state 10. The solution entering the desorber (4) at the weak state 15 is thus concentrated to state 17 and returns to the absorber (2) through the recuperative heat exchanger (5). The desorbed vapor at state 10 condenses in the condenser (3) to liquid state 12, then expands into the evaporator. The absorber and condenser are cooled by streams of cooling water 3–4 and 5–6 to reject the heats of absorption and condensation, respectively. As evident, the system operates between two pressure levels and interacts with heat sources/sinks at three temperature levels: low-temperature cooling in the evaporator, intermediate-temperature heat rejection in the absorber and condenser, and high-temperature (solar) heat supply in the desorber. These correspond to T_L, T_A, and T_H, respectively, in Fig. 2 and in the Carnot equivalent of Eq. (1).

From the previous description, it is clear that an absorption system employs a working fluid pair (absorbent/refrigerant), unlike the vapor compression heat pump, which employs a single fluid. The previously mentioned LiBr–water is the most common fluid pair in solar as well as other heat-powered absorption air-conditioning systems. Another fluid pair is water–ammonia, which generally requires higher firing temperatures and yields lower performance but can produce below-freezing temperatures and hence is suitable for refrigeration applications. Other working fluid pairs have been proposed but are rarely found in solar applications.

A great deal of experience is available on solar-powered absorption systems from demonstration projects carried out in the past three decades, most of which have employed single-effect LiBr–water chillers with low-temperature solar collectors. The first projects employed conventional machines originally designed for gas- or oil-fired operation. The heat to the desorber of these units was supplied by hot water from a solar heat source (e.g., flat plate, evacuated tube, or concentrating collectors). However, lowering the desorber temperature with respect to the original fuel-fired design—without making proper alterations in the machine—resulted in considerable downgrading of the entire device. Attempts were made to redesign the units and modify the desorber in particular, such that they could operate efficiently with solar-heated water. The first commercial absorption air conditioner built specifically for solar operation was the 3-TR Solaire unit by Arkla Industries based on an earlier gas-fired model. This unit is well-known among solar cooling engineers because it was used in a large number of demonstration projects. Its cost, however, was quite high for its small size. Soon thereafter, other manufacturers brought to the market new and improved absorption chillers based on LiBr–water and designed specifically for solar operation.

Two basic requirements must be considered by the designer of a solar absorption system that distinguish it from conventional fuel-fired systems. The first is the need to operate at a low temperature of the heat source: The temperatures available from flat-plate collectors are usually limited to below 90°C. The other is the need for a backup system that can supply the cooling load when insufficient or no energy is available from the sun. For the former requirement, a desorber design based on falling film instead of the conventional pool type has proven effective. Also, a solution preheater placed between the heat exchanger outlet and the desorber inlet was found to be effective in reducing the size and cost of the desorber and improving performance.

The problem of backup is more complicated. A good design must not only supply the full cooling demand at times of low or no sunshine but also make use of whatever solar radiation is available and take only the rest from primary sources. One possible approach is to heat the desorber of the same chiller both from the solar collectors and from an additional source of hot water (e.g., a fuel-fired boiler). However, the hot water coming from the boiler will normally interfere with the relatively colder water available from the collectors and hence drastically reduce the use of available solar radiation. Simulation results show that under conditions of low sunshine, the collectors connected in series with the backup boiler can turn into a heat sink instead of a heat source. Another possibility is to operate a second cooling machine powered by primary energy alongside the solar machine powered only from the sun, with the former supplying whatever load the latter cannot deliver. This requires installation of a complete additional unit, which would be idle a significant portion of the time. To solve the problem effectively, it has been proposed to incorporate an auxiliary desorber in the single-effect absorption

cycle. The auxiliary desorber is powered by the backup, whereas the original desorber is solar powered. The weak solution from the absorber goes first to the solar-powered desorber, where it is concentrated as much as possible with the available solar heat; it then proceeds to the auxiliary desorber and is concentrated further by means of heat from the backup source. The vapor from both desorbers is sent to the condenser. Other variations of this cycle have been proposed.

Experience from the numerous solar-powered air-conditioning demonstration projects with single-effect LiBr–water absorption systems has shown their main limitation to be cost, dominated by the solar part of the system. Single-effect absorption systems are limited in COP to approximately 0.7 and hence require a large collector area to supply the solar heat needed for their operation. This area could be reduced by employing systems with improved COP, which may be achieved with a higher temperature of the heat source, as indicated by Eq. (1). A single-stage absorption system is not suited to utilize a heat source at a temperature higher than approximately 100°C; unlike other heat-activated heat pumps that follow the Carnot trend, the absorption COP levels off with the increase in desorber temperature due to increased mixing and circulation losses. To take advantage of a high-temperature heat source, absorption systems must be configured in stages. The principle is to utilize the heat rejected from the condenser to power additional desorbers, thereby approximately doubling or tripling the amount of refrigerant extracted out of solution with no extra solar heat spent.

The principle of multistaging may be explained by referring to Fig. 4, which depicts a double-stage LiBr–water absorption chiller comprising two desorbers and two condensers serving one absorber/evaporator combination. The system may be regarded as an extension of the single-stage chiller of Fig. 3, with an additional condenser (7), desorber (8), heat exchanger (9), and expansion valve (10). As

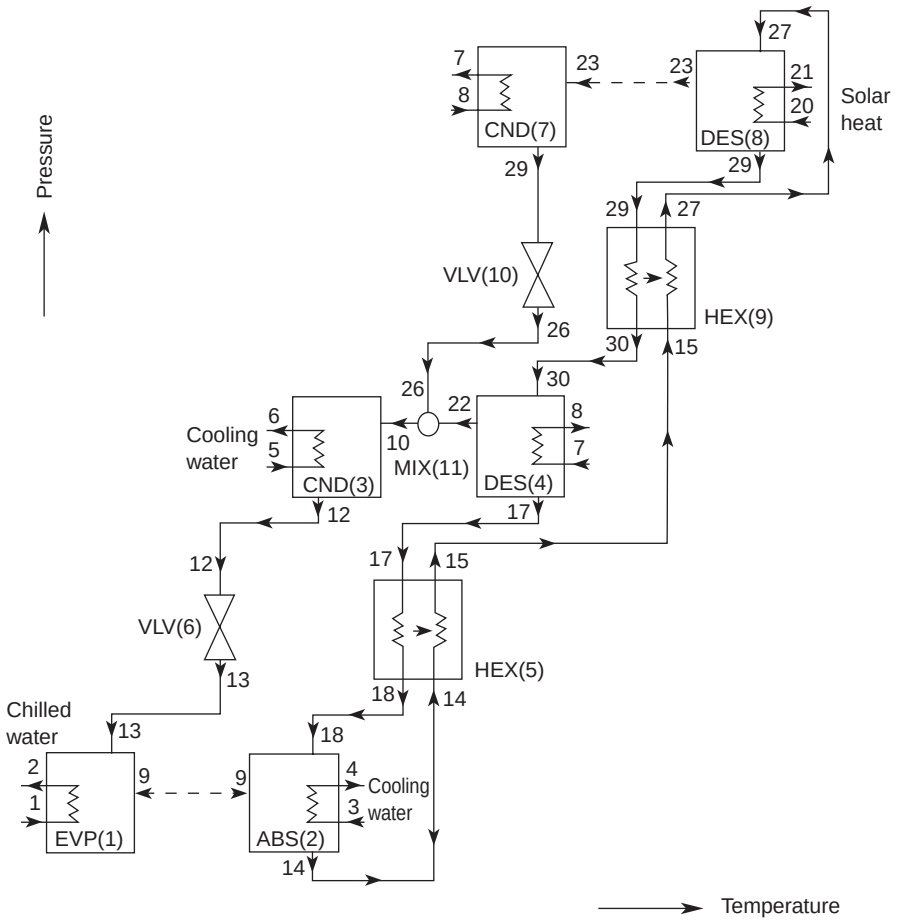

FIGURE 4 Schematic description of a double-effect LiBr–water absorption chiller.

evident, the system operates at three pressure levels and four temperature levels. The weak solution leaving the absorber (2) at state 14 is circulated to the two desorbers, connected in series, and regenerated in two stages, with each desorber doing part of the regeneration task. High-temperature solar heat is applied to the high-temperature desorber (8), whereas the low-temperature desorber (4) receives the reject heat from the high-temperature condenser (7) through the hidden loop 7–8. The condensate from both condensers expands into the evaporator and yields approximately double the cooling effect for the single-stage system of Fig. 3. The system is thus termed double-effect. The same principle may be extended with three desorbers and three condensers to give a triple-effect system when sufficiently high temperature of the heat source is available.

As mentioned previously, most solar-powered absorption cooling projects have utilized single-effect systems with low-temperature solar collectors. Due to developments in gas-fired absorption systems in recent years, mainly in the United States and Japan, higher COP LiBr–water chillers have become available: double-effect systems, available on the market, with COP in the range 1.0–1.2, and triple-effect systems, still under development but close to market, with estimated COP of approximately 1.7. These systems may be adapted to and employed in a solar-powered installation with high-temperature solar collectors. Figure 5 compares the performance of several multieffect chillers, showing the COP as a function of the solar heat supply temperature for typical single-, double-, and triple-effect chillers with the same size components under the same operating conditions: cooling water inlet at 30°C and chilled water outlet at 7°C. The corresponding Carnot performance curve, according to Eq. (1), is plotted for comparison. It is evident that for each absorption system, there is a minimum value of the heat supply temperature below which it does not perform at all. As this temperature increases, the COP increases sharply, then levels off to some asymptotic value. The reasons for this behavior are well understood and documented but are beyond the scope of this article. The single-effect system gives best results in the temperature range 80–100°C; above these temperatures, it is worthwhile to switch to the double-effect system, up to approximately 160°C, and then to the triple-effect system. Note, however, that with a double-effect system, if the solar-supplied temperature should drop below 100°C, the performance will drop sharply—below that of a single-effect system. It is therefore of utmost importance to incorporate a backup in a way that will ensure the supply of heat above the required minimum temperature.

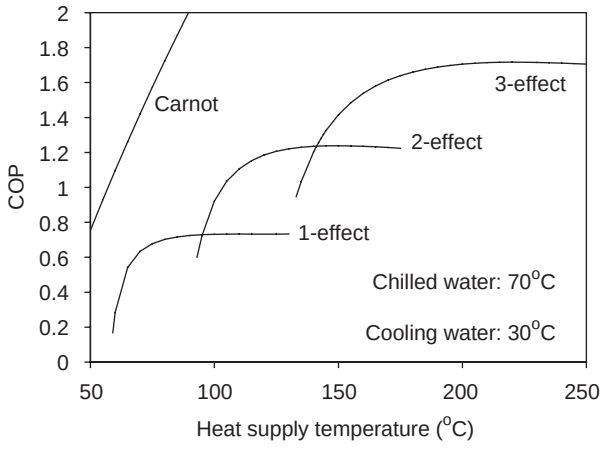

FIGURE 5 Coefficient of performance (COP) as a function of solar heat supply temperature for single-, double-, and triple-effect LiBr–water absorption chillers.

With the availability of high-temperature gas-fired systems, the following question arises: Due to their high COP, are multieffect systems more suitable for solar-powered cooling than their single-effect counterparts? It is attempted to answer this question by conducting a comparison between single-, double-, and triple-effect systems. The results of the comparison clearly indicate that the economics of solar-powered air-conditioning is dominated by the cost of the solar part of the system. This seems to show preference for the multieffect absorption systems, whose higher COP results in less collector area per kilowatt of cooling. Despite this fact, the higher cost of the high-temperature collectors often makes the total system cost higher than that of the low-temperature systems. The challenge before the solar industry is to reduce the price of high-temperature collectors, which will pave the way to employ the high-COP absorption cooling machines.

4. OPEN-CYCLE SYSTEMS

Open-cycle desiccant-type cooling systems represent a potentially promising alternative to other methods of solar-powered air-conditioning. Although the main thrust in research on novel closed-cycle absorption systems has been toward increasing the operating temperature in order to improve efficiency through multistaging, open-cycle absorption and desiccant systems have been developed for use with low-temperature heat sources such as flat-plate solar collectors. Relatively little work has been done in this

area in comparison with studies on the high-temperature alternative, despite the high cost of the latter and its various limitations: the need for sun tracking with concentrating solar collectors, their ability to use only the direct component of the solar radiation, and difficulty in storing high-temperature heat.

Desiccant systems are essentially open absorption cycles, utilizing water as the refrigerant in direct contact with air. The desiccant (sorbent) can be either solid or liquid and is used to facilitate the exchange of sensible and latent heat of the conditioned airstream. The term open is used to indicate that the refrigerant is discarded from the system after providing the cooling effect and new refrigerant is supplied in its place in an open-ended loop. In both liquid and solid desiccant types of systems, the process air is treated in a dehumidifier and goes through several additional stages before being supplied to the conditioned space. The sorbent is regenerated with ambient or exhaust air heated to the required temperature by the solar heat source.

The operation of the desiccant cycle is made possible by the property of desiccants of attracting and holding water vapor from the surrounding air at low temperatures and releasing water to air at high temperatures. The exchange of water vapor between air and desiccant depends on the relative magnitudes of water vapor pressure in the air and on the surface of the desiccant, respectively. The vapor pressure in the air is a function of the water mole fraction, per Dalton's law, and independent of temperature. The vapor pressure in the desiccant is a function of its temperature and water content: Vapor pressure increases with both temperature and water content. Thus, at low desiccant temperatures dehumidification of air will take place in a sorption process, whereas at high desiccant temperatures the same air could be used to regenerate the desiccant—that is, reduce its water content in a desorption process. A sorption process is always exothermic; that is, it generates heat due mainly to the condensation of vapor on the surface of the desiccant as well as to the heat of mixing (in the case of liquids) or heat of wetting (in the case of solids). Conversely, desorption is endothermic; that is, it requires heat input to separate and evaporate water from the desiccant.

A desiccant air-conditioning system in its simplest form consists of conditioning and regenerating cycles, as illustrated in Fig. 6. The conditioning cycle consists of a dehumidifying stage with simultaneous or subsequent removal of the heat of sorption. Warm

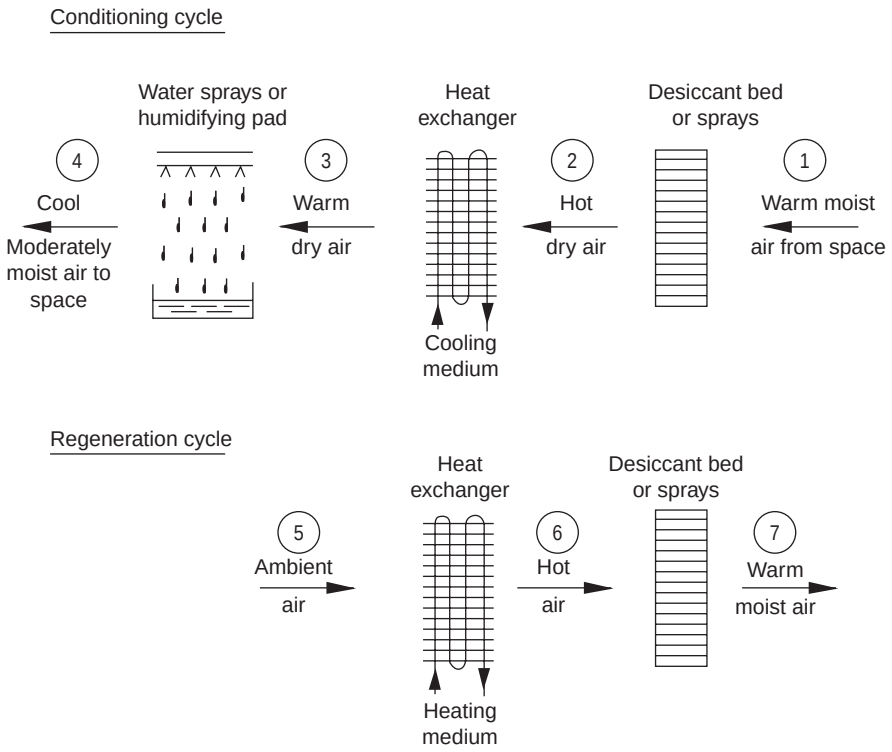

FIGURE 6 Principle of open-cycle desiccant air-conditioning.

and moist process air from the conditioned space or from the outside (state 1) is first brought into contact with an active desiccant. Water vapor is removed from the air and absorbed (in a liquid desiccant) or adsorbed (on a solid desiccant). This exothermic process causes an increase in the temperature of the air, whereas its humidity is reduced (state 2). The hot and dry air is then cooled to near ambient temperature, without change in water content (state 3), in a heat exchanger using a moderately cool medium (cooling tower water, exhaust air, or evaporatively cooled ambient air). If necessary, a humidifying stage 3–4 is added in which evaporative cooling is carried out. Sensible heat is changed into latent heat; that is, the air temperature is reduced while its water content is increased to slightly below the original value at state 1. This air thus has both sensible and latent cooling capabilities when released into the conditioned space.

The capacity of the desiccant to attract water vapor decreases with the increase in its water content, and at a certain point it has to be regenerated. In the regeneration cycle illustrated in Fig. 6, ambient air at state 5 is heated in a heat exchanger with solar-heated water (or equivalent) to state 6 and is brought into contact with the desiccant. Water vapor is transferred from the desiccant to the air in the desorption process 6–7. Warm and humid air at state 7 is exhausted and the dry desiccant is ready to be used again in the conditioning cycle.

Desiccant systems possess several advantages relative to their closed-cycle counterparts: They operate at ambient pressure and not in a vacuum or at an elevated pressure; heat and mass transfer between the air and the desiccant take place in direct contact; and both cooling and dehumidification of the conditioned air may be provided, in variable quantities, to fit the load in the conditioned space. The latent load is handled without the necessity to cool the air below its dew point; consequently, reheat is never required. The following are disadvantages: They have a low COP due to inherently inefficient regeneration; relatively large air volumes must be pumped, leading to potentially high parasitic losses; and contamination of the desiccant by dirt and dust contained in the air may require its replacement after some period of operation.

Solid desiccant systems employ adsorbents (rather than absorbents) such as silica gel or various types of molecular sieves. The humidity is adsorbed on the surface of the desiccant, which is highly porous. Since the solid desiccant cannot be circulated by pumping, these systems usually employ a rotary bed carrying the sorbent material, referred to as a desiccant wheel. The wheel features continuous operation of the system by rotating between the process and regenerating airstream. A typical desiccant wheel is shown in Fig. 7. It consists of a rotary bed or drum made of an inert material, corrugated or extruded, forming axial flow channels for the air. The wheel is packed or impregnated with the desiccant material, covering the walls of the channels. The wheel in Fig. 7 forms part of a natural gas-boosted solar air-conditioning system, employing molecular sieves as desiccant. The wheel is divided into four sections: the sorption section, through which the process airstream flows; the low-stage regeneration section, in which desorption of the desiccant by means of solar-heated air takes place; the high-stage regeneration section, in which desorption is boosted by flue gas from a burner; and a purge section in which cooling of the matrix, as it leaves the regeneration section, is carried out. The purge section ensures that the desiccant entering the process airstream is cooled sufficiently for dehumidification to take place, thus reducing the average process airstream humidity and temperature.

Solid desiccants usually allow a higher degree of dehumidification than the liquids but require a higher temperature for their regeneration. They usually operate according to the cycle depicted in Fig. 6. The past decade witnessed a significant increase in solid desiccant systems on the market, usually for gas-fired operation in applications requiring dehumidification in addition to conventional cooling, such as in supermarkets. Solar-powered operation with solid desiccants normally requires higher temperatures than required for liquids,

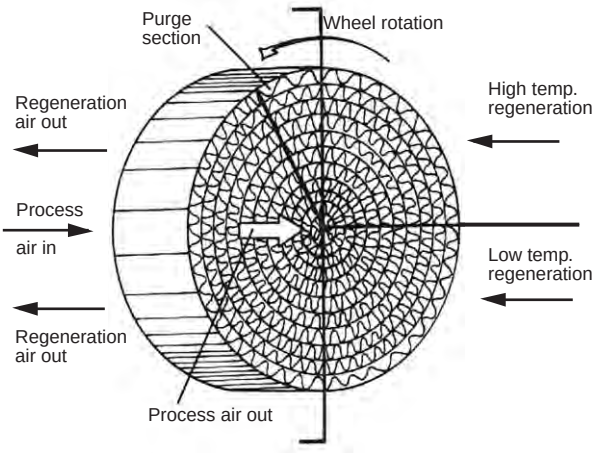

FIGURE 7 Diagram of a typical desiccant wheel.

possibly beyond the range of flat-plate collectors. The regeneration air may be heated directly in air-heating collectors or indirectly using water as a heat-carrying medium.

Liquid absorbents of water comprising aqueous solutions of lithium bromide, lithium chloride, or calcium chloride are employed in the open systems using a cycle similar to that of a closed absorption system. In comparison to the system shown in Fig. 3, the evaporator (1) and condenser (3) are eliminated. The absorber is replaced by a dehumidifier, which is designed differently to bring into contact the conditioned air with the sorbent solution in order to absorb the humidity directly from the airstream. Similarly, the desorber is replaced by a regenerator, which again brings the sorbent solution to be regenerated into direct contact with ambient or exhaust air. The net result of the operation of this device is the dehumidification of the conditioned airstream, which handles the latent load. To handle the sensible load, the temperature of the conditioned air must be lowered either by an external cooling device or by evaporating water into the now dry airstream using an evaporative cooler in place of the evaporator (1) of Fig. 3.

The basic solar desiccant system as depicted in Fig. 6 can be improved when using liquid desiccants by the addition of a number of heat exchangers for better energy economy. Such a system is shown schematically in Fig. 8. The two main components, the dehumidifier and the regenerator, have a similar design, suitable for contacting the sorbent solution with air. Both are vertical, packed towers, with the solution sprayed over the packing and flowing down and air brought in at the bottom and flowing up, in counterflow to the solution. A cooling coil inserted in the dehumidifier and employing cooling tower water serves to remove the heat of sorption during dehumidification. Similarly, a heating coil in the regenerator supplies the heat of desorption during regeneration. This is a deviation from the schematic shown in Fig. 6, in which the dehumidifier and regenerator are adiabatic; one of the advantages of a liquid desiccant system is that it allows nonadiabatic dehumidification and regeneration processes, as in closed absorption systems, which makes these processes more efficient. In the system of Fig. 8, outside (fresh) air is dehumidified in the dehumidifier and then sent to the conditioned space. Building exhaust air is preheated in the air–air heat exchanger by regenerator exhaust air and used for solution regeneration. Building exhaust air is preferred to outside air for this purpose since it is dryer. Figure 8 also shows a liquid–liquid heat exchanger between the weak and cool solution leaving the dehumidifier and the strong and hot solution leaving the regenerator for recovering heat from the latter to the former; this is again similar to the recuperative heat exchanger of a closed absorption system. Figure 8 further shows the solar part of the system, consisting of collectors and storage, for supplying heat to the regenerator.

Liquid desiccant systems have many of the same advantages of closed-cycle absorption: They allow

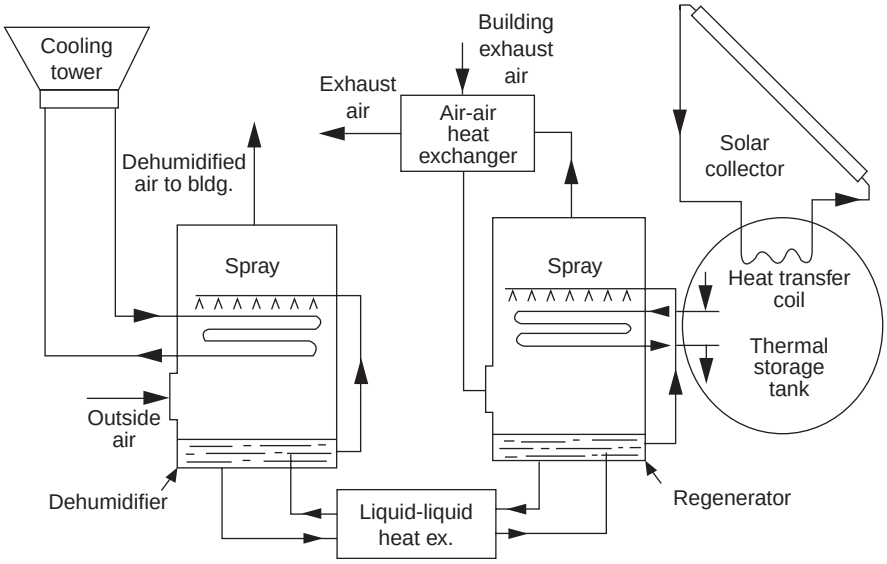

FIGURE 8 Diagram of a liquid desiccant system for dehumidification.

internal heat recovery from the strong and hot solution to the weak and cool solution by means of a recuperative heat exchanger; circulating the sorbent from one unit in the system to the next is easily done by pumping the liquid; and pressure drop in the liquid–air contactors, dehumidifier and regenerator, is relatively low, reducing parasitic losses. The liquid desiccant may be filtered to remove dust and dirt picked up from the air. For solar-powered operation, desorption is possible in a special regenerating collector exposing the desiccant directly to the sun, which can make the regeneration process simpler and more efficient. It also makes it possible to store cooling capacity by storing concentrated liquid desiccant. One disadvantage is the potential carryover of sorbent in the air, which may lead to sorbent loss and contamination of the conditioned space. There are relatively few liquid desiccant systems available on the market. A limited number of solar-powered air-conditioning systems employing liquid desiccants, mostly experimental, have been constructed during the past three decades.

A promising open-absorption heat pump cycle makes it possible to utilize the solar heat at relatively low temperatures to produce both chilled water and cold and dehumidified air in variable proportions, as required by the load. The cycle, referred to as dehumidifier–evaporator–regenerator (DER), employs environmentally benign liquid desiccants in direct contact with the air. The system typically treats the make-up supply air to handle the latent load and supplies chilled water to handle the sensible load independently. A schematic of the cycle is shown in Fig. 9. It consists of six major components, indicated by roman numerals: an indirect contact evaporative cooler (I), an air dehumidifier or absorber (II), a solution regenerator or desorber (III), two air–air heat exchangers (IV, V), and a solution–solution heat exchanger (VI). Ambient air entering the absorber at state 7 is brought into contact with a strong (concentrated) absorbent solution entering the unit at state 16 and leaving it at state 17. Water vapor is removed from the airstream by being absorbed into the solution stream. The heat of condensation and dilution Q_A released during this absorption process is rejected to a stream of cooling water or ambient air (states 3 and 4). Dehumidified air leaving the absorber at state 8 is drawn through an air–air heat exchanger (IV) into the evaporative cooler. By evaporating externally supplied water into the airstream, the heat Q_E is removed from the chilled medium (states 1 and 2) at a low temperature. The air leaves the evaporative cooler at state 10 humid,

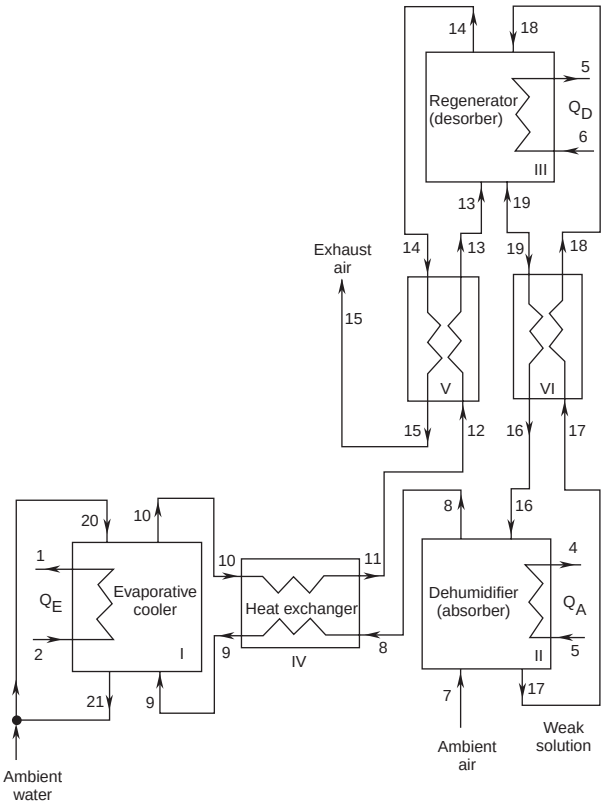

FIGURE 9 Schematic description of the DER open-absorption chiller.

but at a lower temperature than at its inlet, and passes again through the heat exchanger (IV), where it provides precooling for the airstream 8–9 in order to allow for a low cooling temperature. After being preheated in the second air–air heat exchanger (V) by exhaust air, the airstream enters the regenerator at state 13, where it serves to reconcentrate the weak absorbent solution (state 18). The heat of desorption Q_D required to remove water vapor from the solution is provided by an external (solar) heat source (states 5 and 6). The exhaust air leaves the regenerator (state 14), preheats the airstream 12–13 in the air–air heat exchanger (V), and is rejected into the environment. The solution–solution heat exchanger (VI) facilitates preheating of the weak solution (states 17 and 18) and precooling of the strong solution (states 16 and 19).

The advantages of open-cycle DER absorption chillers compared to closed-cycle systems are evident from the previous description. First, the number of main components is reduced by one by transferring condensation of the refrigerant from a condenser to the environment. Second, capital-intensive pressure-sealed units are avoided because the whole system

can be operated at atmospheric pressure. Third, efficient utilization of very low heat source temperatures is possible. The open-cycle DER chiller can be operated with any heat source temperature that is only slightly above the heat rejection temperature. This is particularly favorable for the efficient utilization of heat sources with varying temperatures, such as solar heat from flat-plate collectors. Chilled water at state 21 and/or dehumidified and cooled air at state 9 are the products of the system and may be extracted at varying quantities as required by the air-conditioning application.

5. CONCLUSION

Current trends in solar air-conditioning show a clear preference for absorption cycles over other heat-powered cycles, in two alternative directions: closed-cycle and open-cycle systems. Whereas the main thrust in research on closed-cycle absorption systems has been toward increasing the operating temperature in order to improve efficiency through multi-staging, open-cycle absorption (desiccant) systems have been developed for use with low-temperature heat sources such as flat-plate solar collectors. With both alternatives, the economics of solar cooling are dominated by the solar part of the system—collectors and storage.

Open-cycle systems hold promise for reducing the cost of the solar part of the system and for providing quality air-conditioning with independent temperature and humidity control. Both liquid and solid desiccants are already penetrating the market. Systems such as the DER open-absorption heat pump cycle form the basis for promising cooling systems capable of efficiently exploiting low-temperature solar heat as well as other, similar sources of low-grade heat.

Glossary

biodegradable compounds Compounds that can be metabolized by microorganisms.

compound parabolic concentrator (CPC) Static collectors with a reflective surface following an involute around a cylindrical reactor tube.

conduction band A vacant or only partially occupied set of many closely spaced electronic levels resulting from an array of a large number of atoms forming a system in which the electrons can move freely or nearly so. This term is usually used to describe the properties of semiconductors.

electron/hole Negative and positive charge generated in an illuminated semiconductor.

mineralization Conversion of organic compounds to inorganic ones. Inorganic compounds are usually carbon dioxide, water, and acids (nontoxic substances).

photocatalysis Acceleration of a photoreaction by the presence of a catalyst.

photoreactor Reactor where a photochemical reaction takes place.

semiconductor Material with an appropriate energetic separation between its valence and conduction bands that can be surpassed applying external energy. Metal oxides and sulfides represent a large class of semiconductor materials suitable for photocatalytic purposes.

solar detoxification Photochemical processes driven by solar photons able to destroy toxic substances. The process is based on the generation of hydroxyl radicals in water.

total organic carbon Quantity of organic compounds dissolved in water measured as pure carbon.

The solar heterogeneous photocatalytic detoxification process consists of utilizing the near-ultraviolet (UV) part of the solar spectrum to photoexcite a semiconductor catalyst in the presence of oxygen. In these circumstances, oxidizing species, either bound hydroxyl radical ($^{\bullet}OH$) or free holes, which attack oxidizable contaminants, are generated, thus producing a progressive breaking of molecules yielding CO_2, H_2O, and dilute inorganic acids. The most commonly used catalyst is the semiconductor TiO_2 (a cheap, nontoxic, and abundant product). The solar homogeneous photocatalytic detoxification process (photo-Fenton) is based on the production of $^{\bullet}OH$ radicals by Fenton reagent. This is an extension of the Fenton process, which takes advantage of UV-visible light irradiation at wavelength values higher than 300 nm. During the past decade, thousands of studies and patents related to the heterogeneous photocatalytic removal of toxic and hazardous compounds from water and air have been published, and applications and target compounds are numerous. Where medium to high solar radiation is available, solar detoxification is useful for treating water contaminants with several hundreds of milligrams per liter of nonbiodegradable contaminants and for disinfecting water. This process has proven promising for the treatment of contaminated water, air, and soil. Nevertheless, the specific solar technology employed is not commercially available. This article reviews the use of sunlight to produce $^{\bullet}OH$ radicals. The experimental systems necessary for performing pilot plant-scale solar photocatalytic experiments are described. The basic components of these pilot plants and the fundamental parameters related to solar photocatalysis reactions are outlined. A description is given of how solar photocatalysis may become a significant segment of the wastewater treatment technologies related to disinfection and the degradation of very persistent toxic compounds.

1. SOLAR PHOTOCHEMISTRY

A specific characteristic of solar photochemical processes is that the photons from the solar spectrum must be absorbed by some component(s) of the reacting system, transferring their energy to the chemical system. Solar photons can be directly absorbed by reactants (direct photochemistry) and/or by a catalyst or sensitizer (photocatalytic processes). Solar detoxification and disinfection are included within photocatalysis.

Photochemical processes use the intrinsic energy of photons (i.e., wavelength) from the solar irradiation to provoke specific reactions. The energy of a photon is a function of its wavelength, according to Eq. (1):

$$E = \frac{hc}{\lambda}, \tag{1}$$

where h is Planck's constant (6.626×10^{-34} Js), c is the speed of light, and λ is the wavelength. Approximately 4 or 5% of the sunlight at the earth's surface is in the near-ultraviolet (UV) region (wavelengths from 300 to 400 nm), approximately 45% is in the visible range (400–760 nm), and the rest is in the near-infrared (IR) and IR regions. Solar photons from the visible and near-UV spectrum are energetic enough to be used in photochemical processes. Infrared photons are normally useless in photochemistry and can be considered as waste heat in chemical processes.

2. PHOTODEGRADATION PRINCIPLES: PHOTOCATALYSIS

A wide range of contaminants to a varying degree resist photolytic, biological, and chemical degradation. In such cases, it is necessary to adopt much more effective systems: air stripping, adsorption on granulated activated carbon, incineration, ozone, and oxidation. Obviously, methods based on chemical destruction, when properly developed, provide complete pollutant abatement, whereas those that only perform phase separation leave a consequent problem of final disposal. Air stripping and adsorption on granulated activated carbon, merely transferring toxic materials from one medium to another, is not a long-term solution to the problem of loading hazardous waste on the environment. Incineration is capable of converting toxic compounds to carbon dioxide, water, and inorganic acids, but negative public perception has slowed and very often prevented its implementation. Concerns over emissions of undestroyed components and organic products of incomplete combustion have caused incineration to be a source of continuing controversy. Ozone is not very often able to completely destroy pesticides to harmless compounds.

Chemical oxidation aims at the mineralization of the contaminants into carbon dioxide, water, and inorganics. Much research has addressed this goal in the past decade, indicating the prominent role of a special class of oxidation techniques defined as advanced oxidation processes (AOPs), which usually operate at or near ambient temperature and pressure. AOPs, although making use of different reaction systems, are all characterized by the same chemical feature: production of OH radicals ($^{\bullet}OH$). This radical is strongly oxidative, much more so than other traditional oxidants (e.g., ozone, hydrogen peroxide, chloride dioxide, and chlorine). These can then be used to chemically decompose a pollutant into harmless end products. For example, in aromatic compounds, the aromatic part is hydroxylated and successive steps in oxidation/addition lead to ring opening. The resulting aldehydes and carboxylic acids are decarboxylated and finally produce CO_2. Methods based on UV, H_2O_2/UV, O_3/UV, and H_2O_2/O_3/UV combinations utilize photolysis of H_2O_2 and ozone to produce the hydroxyl radicals. In addition, other methods, such as heterogeneous photocatalysis or homogeneous photo-Fenton, are based on the use of a wide band gap semiconductor or the addition of H_2O_2 to Fe^{2+} salts and by irradiation with UV-visible light. Both processes are of special interest since sunlight can be used. The main problem with the AOPs is their high cost due to the use of expensive reactants (i.e., H_2O_2) and energy consumption (generation of UV radiation). Therefore, the future applications of these processes may be improved diminishing reactants and energy consumption through the use of catalysis and solar energy.

2.1 Definitions

The term photocatalysis implies the combination of photochemistry with catalysis. Both light and catalyst are necessary to achieve or to accelerate a chemical reaction. Photocatalysis may be defined as the acceleration of a photoreaction by the action of a catalyst. It also refers to a general label to indicate that light and a substance (the catalyst or initiator) are necessary entities for influencing a reaction. Heterogeneous processes employ semiconductor slurries for catalysis, whereas homogeneous photochemistry is used in a single-phase system.

In the case of homogeneous photocatalytic processes, the interaction of a photon-absorbing species (transition metal complexes, organic dyes, or metalloporphyrines), a substrate (e.g., the contaminant), and light can lead to a chemical modification of the substrate. The photon-absorbing species is activated and accelerates the process by interacting through a state of excitation. In the case of heterogeneous photocatalysis, the interaction of a photon produces the appearance of electron/hole pairs, the catalyst being a semiconductor (e.g., TiO_2 and ZnO). In this case, the excited electrons are transferred to the reducible specimen at the same time that the catalyst accepts electrons from the oxidizable specimen that occupies the holes. In both directions, the net flow of electrons is null and the catalyst remains unaltered.

2.2 Heterogeneous Photocatalysis

When a semiconductor is in contact with a liquid electrolyte solution containing a redox couple, charge transfer occurs across the interface to balance the potentials of the two phases. An electric field is formed at the surface of the semiconductor. This means that the two charge carriers should react at the semiconductor/electrolyte interface with the species in solution. The semiconductor-mediated redox processes involve electron transfer across the interface. When electron/hole pairs are generated in a semiconductor particle, the electron moves away from the surface to the bulk of the semiconductor as the hole migrates toward the surface. If these charge carriers are separated fast enough, they can be used for chemical reactions at the surface of the photocatalyst (i.e., for the oxidation or reduction of pollutants).

Metal oxides and sulfides represent a large class of semiconductor materials suitable for photocatalytic purposes. Table I lists selected semiconductor materials, which have been used for photocatalytic reactions, together with band gap energy required to activate the catalyst. The table also indicates the wavelength of radiation required to activate the catalysts.

Whenever different semiconductor materials have been tested under comparable conditions for the degradation of the same compounds, TiO_2 has generally been demonstrated to be the most active. TiO_2's strong resistance to chemical and photocorrosion, its safety, and its low cost limit the choice of convenient alternatives. Furthermore, TiO_2 is of special interest since it can use natural (solar) UV (Table I). Other semiconductors are degraded during the repeated catalytic cycles involved in heterogeneous photocatalysis:

TABLE I

Selected Properties of Several Semiconductors

Material	Band gap (eV)	Wavelength corresponding to band gap (nm)
SnO_2	3.9	318
ZnS	3.7	336
$SrTiO_3$	3.4	365
$BaTiO_3$	3.3	375
ZnO	3.2	380
TiO_2	3.0	390
WO_3	2.8	443
CdS	2.5	497
GaP	2.3	540
Fe_2O_3	2.2	565
CdO	2.1	590
CdSe	1.7	730
GaAs	1.4	887

$$TiO_2 \xrightarrow{h\nu} e^- + h^+ + TiO_2 \quad (2)$$

$$e^- + h^+ + TiO_2 \rightarrow TiO_2 + \text{heat and/or } h\nu' \quad (3)$$

$$(TiO^{IV} - O^{2-} - Ti^{IV}) - OH_2 + h^+_{BV} \rightarrow (TiO^{IV} - O^{2-} - Ti^{IV}) - OH^{\bullet} + H^+ \quad (4)$$

$$O_{2(ads)} + e^-_{BC} \rightarrow O^{-\bullet}_{2(ads)}. \quad (5)$$

The first effect, after absorption of near-UV radiation ($\lambda < 390$ nm), is the generation of electron/hole pairs, which are separated between the conduction and valence bands (Eq. 2). In order to avoid recombination of the pairs generated (Eq. 3), if the solvent is oxidoreductively active (water) it also acts as a donor and acceptor of electrons. Thus, on a hydrated and hydroxylated TiO_2 surface, the holes trap $^{\bullet}OH$ radicals linked to the surface (Eq. 4). In any case, it should be emphasized that even trapped electrons and holes can rapidly recombine on the surface of a particle (Eq. 3). This can be partially avoided through the capture of the electron by preadsorbed molecular oxygen, forming a superoxide radical (Eq. 5). The oxidative species formed (particularly the hydroxyl radicals) react with the majority of organic substances.

2.3 Homogeneous Photocatalysis

Although the oxidizing power of the combination of Fe^{2+} and H_2O_2 (i.e., the Fenton reaction; Eq. 6) has

been known for more than 100 years, the fact that the reaction can be enhanced by UV-visible irradiation ($\lambda < 580$ nm) was determined only recently. The so-called photo-Fenton reaction (Eq. 7) produces additional hydroxyl radicals and leads to a reduction of the photocatalyst by the irradiated light. Under these conditions, the photolysis of Fe^{3+} complexes allows Fe^{2+} regeneration, and the occurrence of Fenton reactions due to the presence of H_2O_2 and iron may be considered a true catalyst. The main advantage of the photo-Fenton process is the light sensitivity up to a wavelength of 580 nm. The depth of light penetration is high and the contact between pollutant and oxidizing agent is close since a homogeneous solution is used.

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + {}^{\bullet}OH \qquad (6)$$

$$Fe^{3+} + H_2O + h\nu \rightarrow Fe^{2+} + H^+ + {}^{\bullet}OH \qquad (7)$$

$$[Fe^{3+}L_n] + h\nu \rightarrow [Fe^{2+}L_{n-1}] + L^{\bullet}. \qquad (8)$$

Only a very simplified description is given in Eqs. (6–8). Note that reaction 8, which involves organic ligands L (e.g., RCOO−, RO−, and RNH+), is more efficient than the oxidation of organic substrates via $^{\bullet}OH$. Therefore, usually contaminants degradation is getting faster during the reaction since the more inert hydrocarbons are first oxidized by $^{\bullet}OH$ to yield substances containing several hydroxyl or carboxyl groups that are able to participate in reactions thereafter.

3. FUNDAMENTAL PARAMETERS IN PHOTOCATALYSIS

3.1 Influence of Oxygen and pH

Whatever the formation pathway, it is well-known that O_2 and water are essential for detoxification. There is no degradation in the absence of either. The pollutants are usually organic; therefore, Eq. (9) summarizes the overall process. Given the reaction stoichiometry of this equation, there is no photomineralization unless O_2 is present. Oxygen is necessary for complete mineralization and does not seem to be competitive with other reactives during the adsorption on TiO_2 since the places where oxidation takes place are different from those of reduction. The concentration of oxygen also affects the reaction rate, but the difference between using air ($pO_2 = 0.21$ atm) or pure oxygen ($pO_2 = 1$ atm) is not drastic. Oxygen also intervenes, governing the efficiency of a photocatalytic oxidative degradation, thus minimizing electron/hole recombination by capturing the photogenerated electron (see Eq. 5).

$$\text{Organic pollutant} + O_2 \xrightarrow{\text{photocatalysis}} CO_2 + H_2O + \text{mineral acids.} \qquad (9)$$

The oxide/electrolyte interface has an electrical surface charge that strongly depends on the pH of the medium. The pH of the aqueous solution significantly affects TiO_2, including the charge of the particle and the size of the aggregates it forms. The zero surface charge (PZC) yields zero electrostatic surface potentials that cannot produce the interactive rejection necessary to separate the particles within the liquid. This induces a phenomenon of aggregation and TiO_2 clusters become larger. This effect is clearly related to the capability of the suspension to transmit and/or absorb light. Furthermore, larger clusters sediment more quickly than small particles; thus, the agitation necessary to maintain perfect homogeneity must be more vigorous. The PZC for TiO_2 is approximately 7. Above and below this value, the catalyst is negatively or positively charged according to $TiOH \geq 80\%$ when $3 < pH < 10$, $TiO^- \geq 20\%$ when $pH > 10$, and $TiOH_2^+ \geq 20\%$ when $pH < 3$. Under these conditions, the photocatalytic degradation of ionizable organic compounds is affected by the pH. At first sight, a very acidic solution appears to be detrimental and a very basic solution to be favorable since the variations are modest or nonexistent around neutrality. In many cases, a very important feature of photocatalysis is not taken into account when it is to be used for decontamination of water: That is, during the reaction, a multitude of intermediate products are produced that may behave differently depending on the pH of the solution. To use only the rate of decomposition of the original substrate could yield an erroneous pH as the best for contaminant degradation. Therefore, a detailed analysis of the best pH conditions should include not only the initial substrate but also the rest of the compounds produced during the process.

3.2 Catalyst Concentration Influence

Incident radiation on the reactor and length of path of light inside the reactor are fundamental in determining optimum catalyst concentration. If the radiation comes from a source outside the photoreactor (as in a reactor illuminated by solar radiation) and the path length is short (1–2 cm maximum), maximum reaction rate is obtained with 1 or 2 g/liter

of TiO_2. If the path length is several centimeters long, the appropriate catalyst concentration is several hundred milligrams per liter. The major difference between considering the TiO_2 from dry powder and TiO_2 particles suspended in an aqueous medium involves the mean size of the particles. If two samples with the same catalyst concentration but that are dispersed with different protocols (ultrasounds, stirring, etc.) are compared; sonicated samples are found to be more efficient. Although in stirred samples there are fewer TiO_2 clusters, larger clusters screen light better than small ones. It has been demonstrated that efficiencies are better with small particles than with larger particles only when reactor diameter and catalyst concentration are optimized to allow UV photons to penetrate along the entire photoreactor path length. In this case, it is not possible to talk about particle radius because TiO_2 powder is irregularly shaped, and when it is dispersed in an aqueous medium the "particles" (300–600 nm) are clusters of primary particles (20–40 nm), not spherical or monodisperse. This leads to the conclusion that light extinction in colloidal suspensions is a determining parameter for solar photoreactor design. It should also be recalled that small particle sizes cause additional problems for catalyst separation after photocatalytic treatment. The best inner reactor diameter for solar photocatalytic applications is in the range of a few centimeters with a few hundred milligrams of TiO_2 per liter. The area:volume ratio is also a crucial parameter, and if this ratio is optimized the reactor efficiency would also be increased.

Because iron acts as a catalyst in the photo-Fenton reaction, the degradation rate should increase with the increasing amount of iron added, but it reaches a maximum at the optimum iron concentration. Further addition of iron does not increase the degradation rate. This threshold is dependent on the light source, the thickness of the irradiated layer, and the type of wastewater because internal light filtering may occur. For solar reactors, it is therefore necessary to determine the optimum iron concentration experimentally—that is, the minimum concentration at which the maximum reaction rate is obtained. When catalyst concentration is very high, after traveling a certain distance on an optical path length, turbidity impedes further penetration of light in the reactor. The percentage of photons absorbed by the suspension and the percentage of photons scattered is a very complex problem that cannot be solved experimentally but must be experimentally estimated.

3.3 Influence of Initial Contaminant Concentration

The degradation rate observed for an organic substrate follows saturation behavior. After a certain concentration is achieved, the rate increases very little and in some cases a decrease is observed. If possible, the optimum contaminant concentration in water before the photocatalytic treatment should permit the maximum reaction rate. Due to the kinetics of the photocatalytic reaction, the rate decreases considerably when contaminant concentration is low. The photocatalytic disappearance of contaminants with TiO_2 follows apparent first-order kinetics when the initial concentration is low enough and no catalyst saturation occurs. It should be emphasized that contaminants decompose, giving rise to intermediates, which could also be competitive on the surface of the TiO_2. Their concentration varies throughout the reaction until their mineralization, and thus Eq. (10) (based on the Langmuir–Hiselwwod model) may describe the kinetics:

$$r = \frac{dC}{dt} = \frac{krKC}{1 + KC + \sum_{i=1}^{n} K_i C_i (i = 1,\ n)}, \qquad (10)$$

where k_r is the reaction rate constant, K is the reactant adsorption constant, C is the concentration at any time, K_i is the adsorption constant of the intermediates, and C_i is their concentration at any time. When C_0 is low enough, Eq. (10) can be simplified ($1 + KC + \Sigma \ldots = 1$) to an order one-reaction rate equation ($r = k_{ap}C$). Likewise, at higher concentrations Eq. (10) can be simplified by adjusting it to a zero-order one: $(C_0 - C) = k_r t$.

During the treatment of real wastewaters, since the reaction is not expected to follow simple models such as first- or zero-order kinetics, very often overall reaction rate constants cannot be calculated. Total organic carbon (TOC) analysis is highly recommended for this because of its versatility and, at the same time, its suitability for "on-line" treatment plant installations. Mineralization (TOC disappearance) only occurs when the last step of the oxidation process yields CO_2. The maximum gradient of the mineralization curve, $TOC = f(t)$, which is the gradient of the tangent at the inflection point ($r_{TOC,\ 0}$), is employed to obtain a practical point of comparison for different experiments since it has a zero-order rate constant (mg/liter/min) and therefore appears easy to handle. This parameter ($r_{TOC,\ 0}$) is referred to as the maximum rate.

Once the optimum initial concentration for degradation is known, a model for predicting plant

behavior is necessary. This model should enable one to calculate the solar collector area required for treating water contaminated with different amounts of pesticides. A developed model, which has the analytic form of a Langmuir–Hinshelwood equation, has been preferred for fitting experimental data in large solar photocatalytic plants by approximate solution of the general photocatalytic kinetic system. With these considerations, the rate of TOC disappearance is given by

$$r_{TOC} = \frac{\beta_1[\mathrm{TOC}]}{\beta_2 + \beta_3[\mathrm{TOC}]}. \tag{11}$$

Experimental results can be used to calculate the constants (β_i). Equation (12) enables one to predict TOC degradation as a function of the initial TOC and of the available time (or radiation energy) and, reciprocally, to predict the incident energy on the reactor necessary to reach a specific degree of mineralization. Nevertheless, UV radiation data for the final plant location must be available.

$$\frac{1}{\beta_1}\left\{\beta_2 \ln\left(\frac{[\mathrm{TOC}]_0}{[\mathrm{TOC}]}\right) + \beta_3([\mathrm{TOC}]_0 - [\mathrm{TOC}])\right\} = t. \tag{12}$$

3.4 Influence of Radiant Flux

Since 1990, there has been clarification of the kind of solar technology that should be involved in detoxification and disinfection. The question was whether concentrating the radiation is really necessary for the photocatalysis technology and whether a nonconcentrating collector can be as efficient as concentrating ones. Initially, it was thought that concentrating collectors were the ideal alternative and, in fact, the first large pilot plants use them. However, their high cost and the fact that they can only operate with direct solar radiation (implying their location in highly insolated areas) led to consideration of static nonconcentrating collectors. Early engineering-scale tests with solar systems were based on parabolic troughs with concentrations in the range of $10\times$, but a second generation of nonconcentrating collectors soon began to be tested, including thin films, flat plates, and compound parabolic collectors (CPCs). Use of one-sun systems for water treatment is based on two factors: the high percentage of UV photons in the diffuse component of solar radiation and the dependence of rates on light intensity.

It was shown experimentally that above a certain flux of UV photons, the reaction rate changes from one to a half order depending on the intensity. This modification does not seem to happen at a specific radiation intensity because different researchers have obtain different results. Presumably, the experimental conditions have a significant effect. Most authors attribute the transition of $r = f(I^{1.0})$ to $r = f(I^{0.5})$ to excess photogenerated species (e^-, h^+, and $^\bullet$OH). Because the reaction rate depends on the amount of hydroxyl radicals present, and these are generated in the holes (see Eq. 4), $r \propto I^{0.5}$ when I is high. At higher radiation intensities, another transition from $r = f(I^{0.5})$ to $r = f(I^0)$ occurs. At this moment, the photocatalytic reaction ceases to depend on the received radiation and instead depends only on the mass transfer within the reaction. Thus, the rate is constant even though the radiation increases. This effect can be attributed to different causes, such as the lack of electron scavengers (i.e., O_2) and organic molecules in the proximity of the TiO_2 surface and/or excess products occupying active centers of the catalyst. These phenomena occur more frequently when working with supported catalyst and/or at a low agitation level. This implies a low catalyst surface in contact with the liquid and smaller turbulence. This does not favor the contact of reactants with the catalyst and the diffusion of products from the proximity of the catalyst to the liquid.

These effects may be appreciably attenuated if a product that reduces the importance of the electron/hole recombination is added. When the electrons are trapped, recombination of e^-/h^+ is impeded. Either way, the addition of oxidants can improve the efficiency of the process at high illumination intensities. Moreover, oxidants can increase the quantum yield even at low irradiation levels due to their strong oxidizing character. The use of inorganic peroxides has been demonstrated to enhance the rate of degradation of different organic contaminants because they trap the photogenerated electrons more efficiently than O_2. The increased photocatalytic reaction rate with these additives would decrease photoreactor dimensions proportionally and dramatically decrease overall costs. The oxidizing substance should not generate any toxic by-product, so hydrogen peroxide is the obvious candidate. The effect depends on H_2O_2 concentration, generally showing an optimum range of concentration. Peroxydisulfate can also be a beneficial oxidizing agent in detoxification because it reacts with the semiconductor photogenerated electrons (e^-_{CB}). The peroxydisulfate ion accepts an electron and dissociates (Eq. 13). The sulfate radical proceeds through the reaction shown in Eq. (14). In addition, the strongly oxidizing $SO_4^{-\bullet}$ ($E^o = 2.6$ V) can

directly participate in the degradation processes.

$$S_2O_8^{2-} + e_{CB}^- \rightarrow SO_4^{-\bullet} + SO_4^{2-}. \quad (13)$$

$$SO_4^{-\bullet} + e_{CB}^- \rightarrow SO_4^{2-}. \quad (14)$$

4. SOLAR DETOXIFICATION AND DISINFECTION TECHNOLOGY

4.1 Collectors for Solar Water Detoxification

CPCs are a good option for solar photochemical applications. CPCs are static collectors with an involute reflective surface around a cylindrical reactor tube. They have been found to provide the best optics for systems with a low solar radiation concentration and can be designed with a concentrating ratio close to 1 for capturing both direct and diffuse UV sunlight. The reflector design enables almost all the UV radiation arriving at the CPC aperture to be collected and available for processing in the reactor. The light reflected by the CPC is distributed around the back of the tubular photoreactor so that most of the reactor tube circumference is illuminated. It is easy to pipe water in and to distribute it. Most of the components of solar photochemical systems are made of standard materials with no special requirements except for the reactor, the reflective surface, and the catalyst.

4.2 Reflective Surfaces

The optical quality requirements of reflective surfaces for solar applications are usually related to the concentration required by the particular application under consideration. The higher the concentration desired, the stricter the requirements for quality of parameters. In the case of solar photochemical applications, the strictest requirements are for parabolic trough collectors (PTC); for example, UV-mirror materials must have a specular reflectance between 300 and 400 nm to achieve concentration ratios from 1 to 20. The larger the errors, particularly the reflective surface errors, the lower the effective concentration ratio. The reverse is also true: The lower the effective concentration ratio, the higher the optical errors may be, and therefore the lower the quality of reflective surface required. This is an important characteristic favoring low or nonconcentrating systems since these lower quality requirements (lower specular reflectance) directly translate into lower manufacturing cost; the reflector element can represent a considerable fraction of collector cost. With regard to the reflector/concentrator, another important factor is the reflective base material. The majority of solar photochemical processes require a highly reflective material for UV radiation. Reflectivity (reflected radiation/incident radiation) between 300 and 400 nm for traditional silver-coated mirrors is very low, so aluminum-coated mirrors are the best option. The ideal reflective surface for solar photochemical applications must have high reflectivity in the UV range, acceptable durability under outdoors conditions for extended service lifetimes, and a reasonable cost. The surfaces that best fit these requirements are electropolished-anodized aluminum (electrolytically formed aluminum oxide outer layer) and organic plastic films with an aluminum coating.

4.3 Photocatalytic Reactor

The photochemical reactor must contain the working fluid, including the catalyst or sensitizer, and must transmit solar UV light efficiently with minimal pressure drop across the system. When a large array of solar collectors are going to be used, such as in the case of treatment of water contaminants by solar photocatalysis, the reactor must be hard enough to work under usable water pressure. Tube configurations are clearly most appropriate for fluid containment and pumping when large volumes are to be processed. The choice of materials that are both transmissive to UV light and resistant to its destructive effects is limited. Photochemical reactors must be able to withstand summer temperatures of approximately 70–80°C. In addition, reactor material must be inert with regard to the chemicals that must be contained. Common materials that meet these requirements are fluoropolymers, acrylic polymers, and several types of glass. Quartz has excellent UV transmission, but the advantage in transmission in the terrestrial solar spectrum compared to other materials does not justify its high cost. Fluoropolymers are a good choice for photoreactors due to their good UV transmittance, but one of their major disadvantages is that in order to achieve a desired minimum pressure rating, the wall thickness of a fluoropolymer tube may have to be increased, which in turn will lower its UV transmittance. Glass is a natural alternative for photoreactors. Standard glass, used as a protective surface, is not satisfactory because it absorbs part of the UV radiation that reaches it due to its iron content. Borosilicate glass has good transmissive properties in the solar range with a cutoff

of approximately 285 nm. Therefore, such a low-iron content glass would seem to be the most adequate. Because both fluoropolymers and glass are valid photoreactor materials, cost is an important issue.

5. SOLAR DETOXIFICATION AND DISINFECTION APPLICATIONS

5.1 Wastewater Treatment

The hydroxyl radical ($^{\bullet}OH$) is the major intermediate reactive responsible for organic substrate oxidation. The free radical $HO_2^{\bullet}$ and its conjugate $O_2^{\bullet-}$ are also involved in degradation processes but are much less reactive than free hydroxyl radicals. These radicals react strongly with most organic substances by hydrogen abstraction or electrophilic addition to double bonds. Free radicals further react with molecular oxygen to give a peroxy radical, initiating a sequence of oxidative degradation reactions that may lead to complete mineralization of the contaminant. In addition, hydroxyl radicals may attack aromatic rings at positions occupied by a halogen, generating a phenol homologue. The electrons of the conduction band can also degrade organic compounds by reductive pathways.

In general, the types of compounds that can been degraded include alkanes, haloalkanes, aliphatic alcohols, carboxylic acids, alkenes, aromatics, haloaromatics, polymers, surfactants, pesticides, and dyes. Equation (15) generally holds true for a halogenated organic compound of the general formula $C_nH_mO_pX_q$:

$$C_nH_mO_pX_q + \left(\frac{(m-2p)}{4} + n\right)O_2 \rightarrow nCO_2 + \frac{m-q}{2}H_2O + qHX. \quad (15)$$

In photodegradation, transformation of the parent organic compound is desirable in order to eliminate its toxicity and persistence, but the principal objective is to mineralize all pollutants. Furthermore, the stoichiometry proposed for the general reaction (Eq. 15) has to be demonstrated in each case by a correct mass balance. Reactives and products might be lost, producing unreliable results. Mineralization rate is determined by monitoring inorganic compounds, such as CO_2, Cl^-, SO_4^{2-}, NO_3^-, and PO_4^{3-}. When organics decompose, a stoichiometric increase in the concentration of inorganic anions is produced in the treated water, and very often there is an increase in the concentration of hydrogen ions (decrease in pH). In order to demonstrate that there are no product losses, the molar ratio must be in accordance with the organic substrate structure. The absence of total mineralization has been observed only in the case of *s*-triazine herbicides, for which the final product obtained is essentially 1,2,5-triazine-2,4,6-trihydroxy (cyanuric acid), which is not toxic. This is due to the strong stability of the triazine nucleus, which resists most methods of oxidation. Nitrogen-containing molecules are mineralized into NH_4^+ and NO_3^-. Ammonium ions are relatively stable and the proportion depends mainly on the initial oxidation degree of nitrogen and on the irradiation time. Analyses of aliphatic fragments resulting from the degradation of the aromatic ring have mainly revealed formate and acetate ions. Other aliphatics (presumably acids, diacids, and hydroxylated compounds) have also been found. Formate and acetate ions are rather stable, which in part explains why total mineralization takes much longer than dearomatization.

Solar photocatalytic mineralization of organic pollutants in water, using the interaction of UV radiation and semiconductor catalysts, has major potential in the industrial destruction of toxic organics in water, and the number of applications and target compounds are numerous. In areas with medium to high solar radiation, solar detoxification is useful for treating water with a maximum organic concentration of several hundred milligrams per liter, nonbiodegradable contaminants, and hazardous contaminants present within complex mixtures of organics. As a result of intense research carried out by groups all over the world during the past 20 years, solar detoxification is a good solution with many interesting applications. During the past decade, there have been thousands of publications and patents on heterogeneous photocatalytic removal of toxic and hazardous compounds from water and air. Some examples are phenols and chlorophenols, chlorinated hydrocarbons, pharmaceutical compounds (antibiotics, antineoplastics, and other hazardous pharmaceutical waste), agrochemical waste (pesticides), and cyanides. They are produced in industrial quantities in processes such as the manufacture of phenol-formaldehyde resins, volatile organic compound (VOC) scrubbers, PVC production, wood-preserving waste, cleaning of marine tank terminals and pipelines, and manufacture of pesticides and rinse water from the equipment used for their application.

Here, pesticides are used as an example for demonstrating the practical application of solar photocatalysis. Although pesticides, and agrochemical compounds in general, have been detected in water since the 1950s and 1960s, in the past 15 years their use has increased dramatically throughout the

world and has nearly doubled every 5 years since 1975. The United Nations estimates that of all pesticides used in agriculture, less than 1% actually reach the crops. The remainder ends up contaminating land, air, and especially water. Therefore, pesticide pollution of water is one of today's greatest environmental problems, with widespread ecological consequences. In areas where agriculture is intensive, the following are major sources of water pollution:

Pesticide treatment as a routine agricultural practice: Approximately 0.2 tons/ha are usually applied in intensive agriculture by classical spraying or in the irrigation pipeline.

Rinse water polluted with pesticides from containers and spray equipment: Small amounts of pesticide remaining in empty containers (approximately 70 units/ha) are typically spilled out into the environment.

Wastewater from the agricultural industry: Water from cleaning or postharvest treatment of fruits and vegetables before packing produces approximately 1 m^3/day/ha of wastewater.

Plant waste contaminated with pesticides: It is estimated that 30 tons/ha/year of untreated plant waste is normally disposed of in landfills.

One of the major problems is the uncontrolled dumping of empty pesticide containers. Although the amount of pesticide remaining in each container is very small, millions of them are dumped every year, making it one of the most important sources of pollution in areas with this type of agriculture. A proposed solution is their selective collection and transportation to a recycling plant, where they are rinsed for later reuse. The resulting rinse water, contaminated by the different mixtures of pesticides, must be treated. Simple, inexpensive, and accessible technologies for the *in situ* treatment of such water are therefore necessary. Herbicides are traditionally removed from water using granular or powdered-activated carbon, nanofiltration, ozonation, etc., but these processes have inherent limitations in applicability, effectiveness, and costs. On the other hand, the problems associated with their disposal are quite well suited to solar photocatalytic treatment for the following reasons: (i) The initial pesticide concentration can be controlled as a function of the number of containers washed with the same water, so the most appropriate concentration for optimum photocatalytic efficiency can be chosen; (ii) toxicity is extreme, low volume, and in a well-defined location; (iii) such point sources of pollution may be ideally treated in small-scale treatment units; and (iv) intensive agriculture in greenhouses is usually concentrated in sunny countries.

Solar detoxification has also demonstrated efficiency in the degradation of the halogenated solvents found in much of pharmaceutical industry waste and VOC emissions. Environmental regulations and directives are pushing industrial managers to control VOC emissions. One of the VOC emission control methods is wet scrubbing, but the contaminated water from the scrubbers has to be treated. This could easily be done by solar detoxification. Another source of halogenated wastes is halocompound fabrication. The waste can be estimated as a low percentage of total production, dissolved at 100–200 mg/liter. PVC, for example, produces 2.5 m^3 of wastewater effluent contaminated with short-chain polymers or PVC monomer for each ton of PVC. A feasibility study determined that a 6-m^2 photoreactor can completely mineralize 100 mg/liter of chloroform in 250 liters of wastewater in 8 h of sunlight.

Decontamination of water effluents is one of the most successful photochemical applications of solar photons. The technology has been validated with the construction of large pilot plants. Solar photocatalysis promises to be an important breakthrough in the implementation of solar processes as a specific solar technology for water treatment becomes commercially available. Market analyses show that this environmentally friendly technology, which can destroy many of the most problematic persistent organic pollutants, has numerous potential applications. There can be no doubt that photocatalytic water detoxification is full of promise, as demonstrated by the progress made during the past 10 years.

However, an analysis of the historical evolution of solar photocatalysis clearly identifies three different stages of development. Initial efforts of solar-conscious researchers focused on transferring laboratory research to solar-engineered testing with existing technology. These first results produced excitement in the photochemical research community. Their extrapolation to practical situations assumed an ability to degrade almost any organic contaminant as well as some metals. Later, more appropriate collectors and designs were developed, but the need to know the fundamentals of certain aspects of the reaction led to an increasing number of studies on kinetics, mechanisms, performance of mixtures, and operating parameters with mixed results. It was a period of both promising and discouraging results. In the third stage, which seems to be under way, the boundary conditions of applications are being determined, and the technology is focusing on a specific initial applications, with the particularity that early development and unsolved questions

coexist with near-commercial and industrial applications of the technology. As a result, the environmental market, although very receptive to clean energy resources, is reluctant to accept such a "risk-assuming" initiative.

5.2 Water Disinfection

In many areas of developing countries, cross-contamination of the water supply with both chemical and microbiological contaminants is a major problem; water decontamination and disinfection is recognized by the World Health Organization as one of the most important barriers for human health protection. Solving the problem of trace levels of hazardous nonbiodegradable contaminants is very difficult in developing countries. However, microbial contamination of drinking water due to the lack of treatment sewage or to inadequate working conditions remains the principal water-quality problem in these countries. Access to clean water is restricted by the contamination of water resources, the lack of adequate storage facilities, and the absence of effective delivery systems. Chlorine is widely used as a main disinfectant, but reports show that overall water service coverage in rural areas is low because of many factors (technological, cost, maintenance, social, cultural, logistic, education, etc.). In addition, there is risk caused by the chlorinated by-products, such as trihalomethane and other total organohalides. Chlorine, the most common treatment, is best suited for broad municipal water supply projects for which it is relatively easy to control and monitor the dosage level of disinfectant. However, in the smaller rural and marginalized communities, chlorine use can be impractical or even dangerous. Without proper dosage regulation, chlorine overdoses can cause carcinogenic by-products and strong odors and tastes. Other existing technologies, such as ozone and UV disinfection, are clearly very difficult to implement in rural areas. UV light and ozonation are particularly unsuitable for isolated areas because of the amount of complicated equipment necessary and, in the case of ozone, the danger of toxic waste leakage.

The use of solar energy as a primary alternative to chlorination could prove to be economically viable in countries with a high degree of sunlight. Solar treatment could also be an efficient way to degrade organic matter, making chlorinated drinking water harmless for human consumption. Photocatalytic oxidation is a promising technology for the disinfection of water and wastewater because the $^{\bullet}OH$ radical is highly toxic toward microorganisms.

6. CONCLUSION

Although its development presents difficulties, treatment of industrial wastewater seems to be one of the most promising fields of application of solar detoxification. The only general rule is that there is no general rule; each case is completely different from any other. Consequently, preliminary research is almost always required on a case-by-case basis to assess and optimize potential pollutant treatment for any problem.

Glossary

absorptivity A property of a surface, defined as the fraction of incident energy absorbed on the surface.
convection A mode of heat transfer in which heat is transferred due to the motion of the fluid.
dessicant A material that absorbs moisture from air.
dew point The temperature at which water vapor in air starts to condense when cooled.
drying capacity The quantity of products that can be dried in a single batch of loading.
drying potential The ability of air to evaporate water from the material to be dried, which depends on the temperature and relative humidity of the air.
drying ratio The ratio of the weight of wet products entering the dryer to the weight of the products leaving the dryer.
humidity ratio The ratio of the mass of water vapor in the air to the mass of the dry air.
liner Any natural black or painted material that can withstand the operating temperature and saline water.
natural convection The motion of the fluid due to buoyancy forces, which arise from density differences, caused by temperature variations in the fluid.
regeneration The process of removal of water from the desiccant.
relative humidity The ratio of the mass of water vapor in a given volume of air to the maximum amount of vapor that the same volume of air can hold at the same temperature and pressure.
saturation The condition at which a fluid holding another substance cannot hold any additional amount at the given conditions.
scale The deposition of minerals on any solid surface.
solubility limit The maximum amount of solid that can be dissolved in a liquid at a specified temperature.
sublimation The phase change of a material directly from solid to gas without passing through a liquid phase.
vapor pressure The actual pressure exerted by vapor.

Solar distillation is the process in which solar heat is used to purify water from an impure water source by evaporation and condensation. When solar distillation is used to purify water from saline water, the process is also called solar desalination. Desalination converts saline water with high salt content, about 3.5% by weight in seawater and about 0.6% in brackish water, into fresh water suitable for drinking and other purposes. Solar energy can be used for desalination, either as thermal energy through the use of solar thermal collectors or solar ponds, or as electricity. mainly through the use of photovoltaic cells.

1. SOLAR DISTILLATION BACKGROUND

Solar distillation has been practiced for a long time. The first large-scale solar distillation plant was constructed in 1872 at Las Salinas, Chile, and

 © 2004 Elsevier Inc. All rights reserved.

consisted of solar stills of about 4700 m^2 total area, producing about 23,000 l/day. Solar distillation gained more attention after World War I, when many devices were developed. Solar distillation is suitable for remote, arid, and semiarid areas, where drinking water shortage is a major problem and solar radiation is high. The drawbacks to using solar energy for distillation are the high initial cost and the intermittent nature of the sun. Due to these limitations, the present capacity of solar desalination systems worldwide is about 0.01% of the existing large-scale conventional distillation plants. Those plants are small- to medium-capacity installations serving a small number of people and poor communities.

2. SOLAR DISTILLATION PROCESSES

Solar energy can be used to supply the required energy for a desalination process either in the form of thermal energy needed for distillation or as electricity that can be used to drive processes requiring electricity. Solar desalination processes can be classified into two categories:

1. *Indirect systems*. These are usually of small or medium capacity and involve two separate subsystems, a solar energy system and a conventional plant for using the collected solar energy to produce fresh water.
2. *Direct systems*. Here the heat collection and distillation processes take place in the same equipment. In such systems, solar energy is used to produce the distillate directly in the solar still. The still acts as a trap for solar radiation (the greenhouse effect). As solar radiation passes through the transparent cover, it gets absorbed by the water and the absorber surface. As a result the water temperature, thus the vapor pressure, increases and becomes greater than that of the cover and the water evaporates. The vapor rises to the cover by natural convection where it is condensed on the inner side of the cover. A gravity feed funnels the condensate into the collection tank.

3. SOLAR STILL

The most common solar still is a greenhouse type. Greenhouse solar stills are simple to construct and operate with a transparent cover, which may be symmetrical (Fig. 1) or asymmetrical. The main parts of a greenhouse solar still are described next:

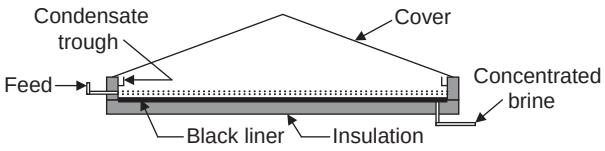

FIGURE 1 Schematic of a symmetrical greenhouse solar still.

Basin. Saline water is kept for distillation in the basin. The basin may be insulated from the bottom to minimize heat loss to the ambient. It is painted black or lined with a black sheet to maximize its absorptivity. The basin may range from 10 to 20 mm deep (shallow basin) to 100 mm or more (deep basin). The basin floor must be inclined slightly, around 1°, to allow for easy drainage of the concentrated brine. The materials needed to construct a still must be resistant to saline water corrosion, and preferably be inexpensive, durable, and available locally. Aluminum, concrete, wood impregnated with a resin, iron painted to resist corrosion, or plastic may be used.

Transparent cover. The cover acts as the condenser, so that the vapor condenses on its inside surface and collects at the bottom. It also reduces heat losses from the hot water by keeping the wind away from it. The slope of the cover must be steep enough to allow the water to flow all the way down to the collection troughs, without falling back into the basin. The cover is usually made of glass or plastic, though glass is preferred because of its high transparency, rigidity, and comparatively low cost. One disadvantage of glass is that it breaks on impact. Plastics, on the other hand, are lightweight, inexpensive, less likely to break, and easy to handle. Their main disadvantages are discoloration and deterioration due to ultraviolet (UV) radiation in the sunlight.

Collection trough. The collection troughs are placed at the lower edges of the cover to collect the distillate. Troughs are pitched along its length so that the distillate flows to the lower end of the still, from where it is collected.

The design of a solar still requires optimization of many factors: brine depth, thermal insulation, cover slope, shape, and material for the still. A well-designed still must also have adequate provision to collect the rainwater that falls on it, so that the surrounding ground is not eroded or flooded.

A variety of basin type solar still designs are used in practice. They differ from each other in the type of

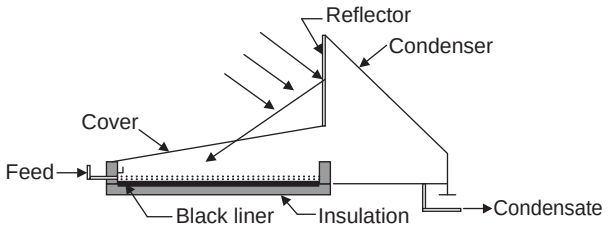

FIGURE 2 Schematic of a greenhouse solar still with a reflector.

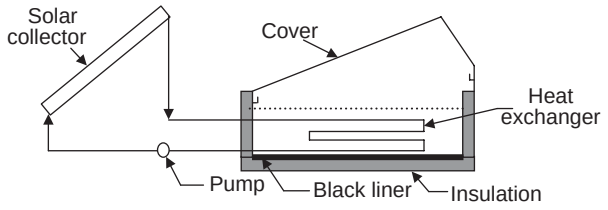

FIGURE 3 Schematic of a greenhouse solar still with a solar collector.

materials used, geometry, the method of supporting the transparent cover, and the arrangements for supply and discharge water. The incident solar radiation on the still can be increased by using a reflector (Fig. 2), which focuses it, so that the still receives both the reflected as well as incident radiation. The temperature of the saline water inside the still may be increased by connecting the still to a solar collector (Fig. 3), or the saline water may be preheated in the collector before entering the still. The latent heat of condensation may be partially utilized by means of a multieffect solar still (Fig. 4). As the vapor from one stage condenses at the lower surface of the next stage, it gives up its latent heat at that stage thus evaporating a part of the water there. The condensate flows toward the trough and is collected as the output. Thin film evaporation creates a higher output than pool evaporation. This idea may be used in a tilted solar still, as shown in Fig. 5. The still is tilted to face the sun and the feed water flows from the top inlet toward the bottom. The flow rate needs to be properly controlled to generate the optimum output. Other designs include a tilted wick, which looks like a tilted solar still, an inflated solar still where a plastic sheet is used as the transparent cover, and a still with an internal condenser to enhance the condensation process and to preheat the feed water. Stills based on the humidification-dehumidification principle have also been developed. In a humidification-dehumidification still, saline water is heated in a collection system and pumped to the top of a humidification column. Air is

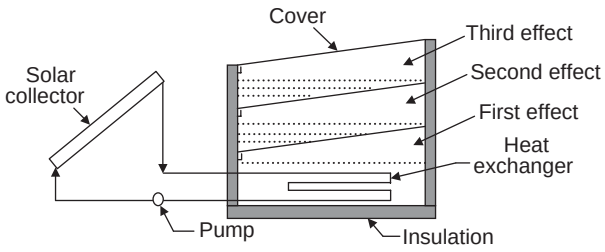

FIGURE 4 Schematic of a multieffect solar still.

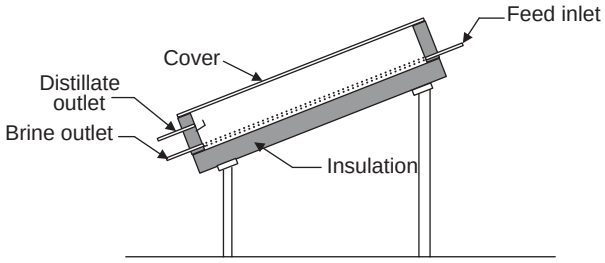

FIGURE 5 Schematic of a tilted solar still.

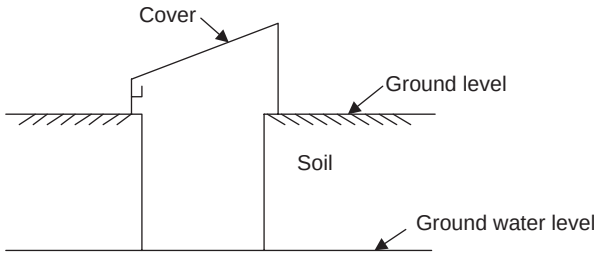

FIGURE 6 Humidity solar still.

circulated in the opposite direction and becomes humid. The humid air goes to the condenser, where the condensing vapor creates fresh water. In humid areas where there is no fresh or saline water available, fresh water can be obtained from the atmosphere. This can be done by using desiccant materials, which absorb water vapor from the atmosphere. The cooling coil of an air conditioner may be used to produce fresh water, but its temperature must be lower than the dew point of the humid air. As the humid air comes in contact with the coil, the water vapor temperature reduces below the dew point, which condenses as fresh water. For locations with very low humidity and no water resources, fresh water may be obtained from the soil moisture. At a certain depth below the earth surface, the soil remains moist. If that layer of moist soil is heated, vapor will be formed that can be condensed and collected as fresh water. Figure 6 shows a schematic of a possible arrangement.

4. STILL PERFORMANCE

Although the construction and operation of a solar still is simple, the theoretical analysis is complicated and mostly depends on experimental observations. Basic concepts of a solar still were set forth by R. V. Dunkle in 1961.

The mass transfer rate $\dot{m}$, in ($Kg/m^2.s$), can be written as

$$\dot{m} = 9.15 * 10^{-7} h_c (p_{wb} - p_{wg}).$$

The heat transfer by evaporation-condensation is

$$q_e = 9.15 * 10^{-7} h_c (p_{wb} - p_{wg}) * h_{fg},$$

where, h_c is the convection coefficient in the still, given by

$$h_c = 0.884 \left[T_b - T_g + \left(\frac{p_{wb} - p_{wg}}{2016 - p_{wb}} \right) T_b \right]^{1/3},$$

where, p_{wb} and p_{wg} are the vapor pressures, in mm Hg, of the solution in the basin at the temperature of the basin (T_b) and of water at the cover temperature (T_g). Temperatures are in degrees Kelvin and h_{fg} is the latent heat of water (J/kg).

Still efficiency, η, is defined as the ratio of the heat transfer, q_e, in the still by evaporation-condensation to the incident solar radiation, I, on the still, as given by

$$\eta = \frac{q_e}{I}.$$

Still efficiency is usually low and rarely exceeds 50%, with an average of 30 to 40%. The daily production from a solar still is about 3 to 4 l/m^2.

5. OPERATION AND MAINTENANCE

As the water inside the still is almost stagnant, suspended solids in the feed water may settle inside the still. To prevent this, suspended material should be removed from the feed before it enters the still. Growth of algae and other organisms may occur in the still. This can be minimized through the addition of algicides such as copper sulfate to the supply. The presence of scale leads to operating difficulties or loss of efficiency by reducing the heat transfer through the affected surfaces. Therefore, scale prevention is an integral part of the design, operation, and cost of the process. The scale is formed by the dissolved solids in raw water and from corrosion products. Scale usually contains chemical compounds of magnesium oxide, calcium carbonate, and calcium sulfate. The formation of scale can occur where the solubility limits of these compounds are exceeded. When pure water is separated from saline water, the concentration of dissolved solids increases and eventually reaches the saturation limit of one or more salts. Although supersaturated solutions are unstable, solid salts do not necessarily deposit immediately from these solutions. When these solutions come into contact with a solid crystal, the excess dissolved solid in the supersaturated solution precipitates. Crystals of the salt in supersaturated solution and other solids particles can act as centers of crystallization. Therefore, the best way to eliminate the scale formation problem is to flush the still before it reaches saturation.

Stills are designed to operate with water in them, if they are left dry for a period of time they may suffer serious damage. It is also necessary to clean the transparent cover periodically to maintain high transmittance of solar radiation.

6. SOLAR DRYING: DEFINITION AND BACKGROUND

Drying is one of the most important post harvest steps. It enhances the storage life of the crop products, minimizes losses during storage, and saves shipping costs. The drying process is the removal of water from the wet surface of the food. In this process, heat is transferred by convection and radiation to the surface of the produce. This heat raises the temperature and evaporates the moisture from the exterior of the agricultural products, diffusing the interior moisture to the surface and replenishing the evaporated surface moisture. Vapor in the surrounding air is removed by diffusion and movement of air. This process continues until the required drying ratio is reached. So the drying process requires a mechanism for heating the ambient air, a drying unit where moisture removal takes place, and an air handling unit (in some dryers).

The ability of the air to evaporate water from the produce is known as the drying potential. The drying potential depends on both air temperature and relative humidity. Besides the air drying potential, the airflow rate is another major factor determining the drying time. To reduce the drying time, the airflow rate and temperature need to be increased while and air's relative humidity needs to be decreased.

The food type of product to be dried determines the rate of moisture transfer from the interior to the

surface. Nonhygroscopic materials can be dried to zero moisture content; however, hygroscopic materials will always have residually bound moisture. The moisture content present in the agricultural product at equilibrium conditions (when it loses moisture to the environment at the same rate at which it absorbs moisture from the ambient) is known as the equilibrium moisture content or hygroscopic equilibrium. In such a case, increasing the temperature of the drying air will be more effective than increasing the flow rate. It is clear that the process of drying is controlled by the air properties, mainly temperature and relative humidity, and by the agricultural product properties, mainly moisture content.

The main objective of drying is to supply the required heat in the most effective way to yield the best result with a minimum overall expenditure of energy. For industrial drying hot combustion gases may be allowed to pass directly through the agricultural products, but this method is not preferred because of possible contamination by the unburned fuel. Electrical air heating is preferred, but expensive. In many cases, solar energy may be the most promising source for drying, as some agricultural products, like rice, may be better suited to drying by solar than by fossil fuel systems because case hardening and other damage are less likely at low temperatures.

7. DRYING PROCESSES

Drying processes range from simple natural sun drying to large-scale industrial drying. Based on the temperature required for drying, the processes may be classified as follows:

1. *Low-temperature drying*. In this slow-drying process (usually performed at temperatures between 15 to 50°C), the air is heated to about 1 to 6°C above the ambient. The main advantages of low-temperature drying include decreased chances of overheating and low capital and running costs, but the process is slow and does not work well for some climates. For low-temperature drying, low-cost solar collectors may be used to heat the air before it enters the dryer.
2. *High-temperature drying*. In this method, air at temperatures above 50°C is used to dry the agricultural products at a fast rate. In such systems, exhaust air from the dryer may be too hot and unsaturated to be wasted, so circulation becomes necessary to improve effectiveness and reduce costs. For this kind of drying, simple solar collectors may not be able to provide the required temperature. Concentrating collectors could be used to achieve the required temperature; however, it may be more economical to use simple solar collectors to preheat the air, and then increase the temperature of the air further using conventional fuel.
3. *Freeze drying*. In such a process, the agricultural product to be dried is first frozen, then placed inside a vacuum chamber connected to a condenser at a low temperature or a desiccant. Heat is applied to the products allowing the water to sublimate, which condenses in the condenser or is absorbed by the desiccant.
4. *Osmovac drying*. This process is normally used for drying fruit juices to make a concentrated powder. It involves two processes, an osmotic process followed by vaporization under vacuum.
5. *Desiccant drying*. In this process, a desiccant is used to remove moisture from the air to increase its drying potential. The desiccant is then regenerated by solar energy. Sometimes a portion of the product itself (especially grain) might be used as the desiccant. If solar energy is used for drying, grain could be overdried during the summer in a desiccant system. At the time of harvest, a part of the overdried grain is removed from the desiccant bin and blended with wet grain to produce a mixture with the average moisture content around the required value. Low-temperature drying may be used to achieve a uniform value for this mixture (i.e., moving moisture from wet to dry agricultural products to reach the required value).

8. SOLAR DRYING PROCESSES

Using the sun's energy to dry agricultural products (known as sun drying) is the most widely used form of drying because it is cheap, easy, and convenient. Not long ago, sun drying was the only form of agricultural drying, and it is still the most common agricultural process industry. The easiest and simplest way of sun drying is to spread the products such as fruits, vegetables, cereals, tobacco, and so forth on a suitable surface under the sun and turn them regularly until sufficiently dried so that they can be stored safely. Another important application of sun drying is the evaporation of seawater to produce salt. It is obvious that sun drying would work best in a hot and dry climate with gentle breezes but would be difficult in humid areas. Although sun drying requires little capital or expertise, it has many limitations: irregular and slow drying rate, high final

moisture content especially in humid areas, and variable product quality where some of the products may be overdried and others underdried since there is no control on the drying process. Other problems include contamination with dust and insect infestation, and sudden rain storms, which can soak the products. Also, large areas are required because sunlight is not concentrated. Problems associated with sun drying can be reduced by using mechanical dryers and conventional energy sources like electricity, coal, and fossil fuels. Due to the high cost of conventional energy sources and the associated environmental problems, solar agricultural dryers have gained popularity, particularly in developing countries. Many of these countries are located in areas that receive a good amount of solar radiation.

9. SOLAR DRYERS

Solar dryers are special structures that enhance the drying power of the sun and protect the agricultural product from dust, dirt, and insects. Figure 7 shows a block diagram of an active solar drying system, consisting of solar air collectors, a drying unit or chamber, and an air handling unit. An active solar drying system can accommodate the use of a backup heat source when there in not enough solar heat available.

Solar dryers usually employ high airflow rates at low temperatures over long periods of time, whereas fossil fuel dryers usually employ lower airflow rates and higher temperatures for fast drying. Slow drying of fruits and vegetables preserves the flavor and quality of the products much better, which makes solar drying more attractive. Therefore, many commercial solar dryers have already been marketed.

Drying capacity depends on the size of the dryer and varies with the type of the produce and the amount of moisture to be removed. Placing agricultural products on racks above each other limits the area of exposure of the food surfaces to the drying air, which might result in poor drying. Underloading will result in low efficiency because of not fully using the available capacity. The loading density can be assessed based on the following rules of thumb, which were suggested by M. A. Leon, S. Kumar, and S. C. Bhattacharya in 2002.

1. Average dryer load is about 4 kg of fresh produce per square meter of tray area.
2. Solar collector area is about 0.75 times total tray area.
3. Airflow rate is about 0.75 cubic meter per minute per meter square tray area.

There are different types of solar dryers; most of them were developed for specific products or class of products. Selection of a solar dryer represents a compromise between dryer cost, product quality, safety consideration, and installation convenience. Solar dryers may be classified into many categories depending on the mode of heating or operation. According to their operating modes, these can be classified into the following categories:

1. Passive systems: Passive systems use natural forces such as buoyancy and breeze for air flow, therefore, these systems have no external energy input except solar radiation.

a. Direct solar dryers: In such dryers, the agricultural products receive the heat directly from the sun. There are many designs for direct solar dryers, the most important of which are the following:

i. Box solar dryers: These are suitable for arid and semi-arid areas, where the relative humidity is low and the amount of incident solar radiation is high. The low initial cost and easy maintenance are the main advantages of the box dryer. Although box dryers cut the drying period by half in comparison to open sun drying, this period is still very long. Box dryers are usually rectangular, painted black on the inside, and have doors to load and unload the produce. The bottom and sides of the box may be insulated. It has transparent cover on its top. Holes are made at the base and the top of the rear vertical

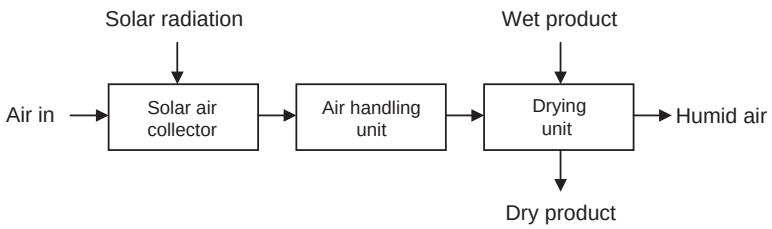

FIGURE 7 Block diagram of a solar dryer.

wall (a few centimeters below the cover) to permit movement of air by natural convection. Ambient air enters through the base holes and leaves through the top holes carrying moisture from the products. The agricultural products to be dried are kept in trays, with perforations allowing air flow through them. The trays are placed so that the product receives solar radiation directly. Heat is absorbed directly by the products themselves as well as by the internal surfaces of the drying chamber. The absorbed heat evaporates moisture from the food and induces natural convection, assisting the drying by air circulation. Figure 8 shows a schematic of a possible arrangement known as the solar box dryer. The box's overall dimensions recommend that the length is at least three times the width to minimize the shading effect. Box solar dryers can be made portable or stationary.

ii. Greenhouse solar system: A greenhouse dryer is usually made from a metallic frame covered by transparent plastic or glass with removable inner chambers, which acts as the absorber. Insulating panels may be used over the glazing at night to reduce heat loss, and a means of storing excess daytime heat is often provided. The system as a whole represents a combination of a solar collector and an integrated energy storage device. Figure 9 shows a greenhouse solar system with tobacco curing and grain drying modes (at the left and right, respectively), with an illustration of typical air flow patterns for solar drying and furnace drying. The incident solar radiation gets absorbed on the moveable black absorber. The useful heat is continuously removed by the slow rotation of the absorber and transferred to the agricultural products. Under such conditions, the dryer will most likely be an active one. For nongrain products, the absorber remains stationary. Such systems are usually of medium capacity.

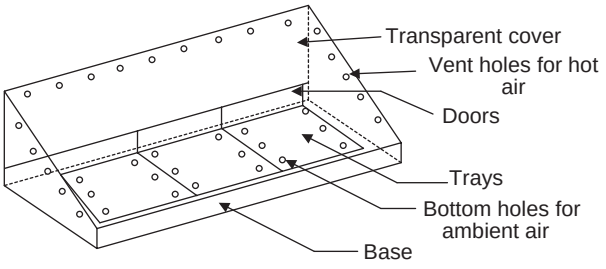

FIGURE 8 Schematic of a box type solar dryer.

iii. Rack type solar dryers: These dryers are mostly used for drying grapes. The dryer usually consists of 6 to 10 racks, each about 50 to 100 m long, 2.5 m high, and 1.5 m wide, with a north-south orientation lengthwise. Each rack is fitted with galvanized wire netting, spaced at about 25 cm from each other. The outside frame can be made of steel or wood. Products are placed or hung from the wire mesh. The whole structure is normally covered with iron sheets, and side curtains are sometimes used for protection from dust, rain, and excessive sunshine. Racks are usually constructed 9 to 12 m apart to ensure that the agricultural products are exposed to sunlight during the morning and afternoon hours. The racks are preferably placed in an exposed area, clear of any obstruction to permit free air flow.

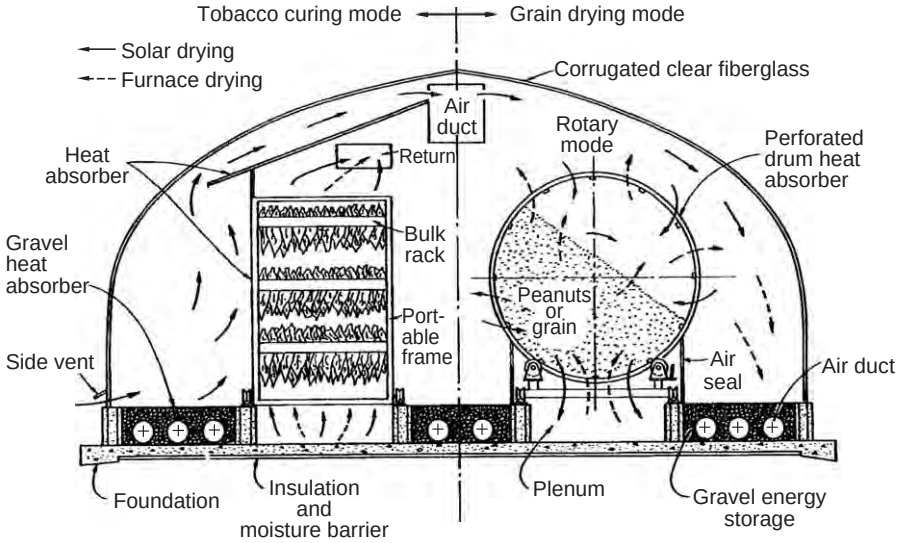

FIGURE 9 Greenhouse solar system.

b. Indirect solar dryers: This mode of drying is important especially when the products must be dried under certain specifications of temperature, humidity, and drying rate. In such dryers, the products are placed inside an opaque drying chamber, and solar collectors, usually air type, provide the hot air. Dryers of this type consist of solar air collectors and a drying chamber. The design of such dryers is the same as the conventional fuel type—the only difference is that the heat source is completely or partially solar energy. Some indirect solar dryers are described next:

i. Solar cabinet dryers: The air is heated in the collector and moves upward toward the bed due to buoyancy forces. The products to be dried are laid on the bed, which usually consists of many trays, placed close to the exit section of the collector. As the air moves across the bed, it picks up moisture from the products. Figure 10 shows one possible design of such systems.

ii. Geodesic dome solar fruit dryers: The dome shape (Fig. 11) of these greenhouse dryers makes them perform better than the conventional gable and semicylindrical shapes because they are able to collect more energy from the sun. The dryers are formed from a dome structure covered from the outside by a transparent cover and from the inside by a black plastic absorber. The transparent cover and the black absorber are separated by a suitable distance, about 1 foot. The drying trays are placed inside the inner dome. Air between the transparent cover and the black absorber is heated up by solar radiation and passed through the drying trays before it leaves the dome. The air flow can be by forced convection (Fig. 12A) or by natural convection (Fig. 12B).

c. Mixed type dryers: In mixed type of dryers, the products are heated by the hot air from the solar collectors and by direct solar radiation absorbed by them. The sides and the top of the drying chamber can be made of a transparent material, where the products absorb the solar radiation directly. Figure 10 is one possible arrangement showing the front and side walls of drying chamber as transparent.

2. Active systems: An electricity-driven blower or fan is used to circulate the air in active systems. These are further classified as follows:

a. Direct solar dryers: These consist of a drying chamber with a transparent cover and a blower. The solar radiation passing through the transparent cover heats the air. The blower forces the air to pass through the products where it picks up the moisture. Figure 8 shows one possible arrangement with a blower or a fan fixed at one side to circulate the air.

b. Indirect solar dryers: In such dryers, the air heated in the solar collectors is ducted to the drying chamber, where it evaporates and removes the moisture. Some of the most important designs of

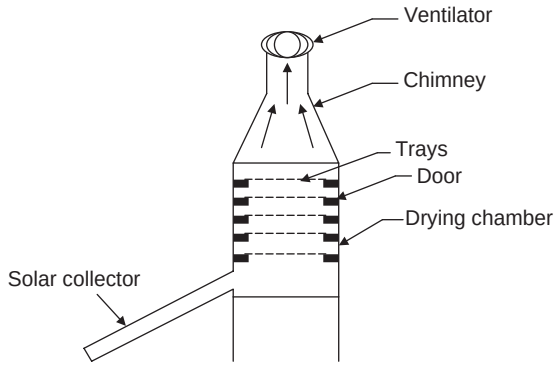

FIGURE 10 Schematic of a cabinet type solar dryer.

FIGURE 11 Structure of a geodesic dome dryer.

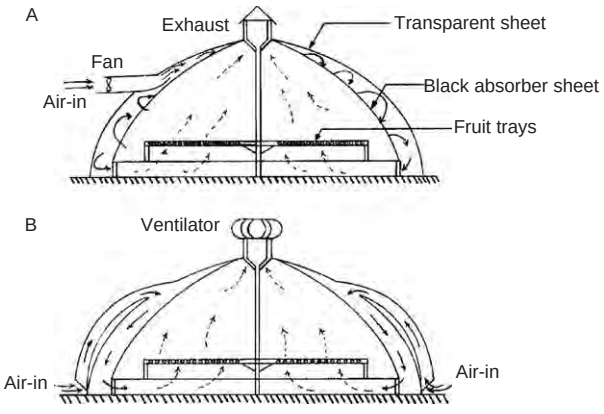

FIGURE 12 Modes of airflow in a geodesic dome dryer. (A) Forced air configuration. (B) Natural air configuration.

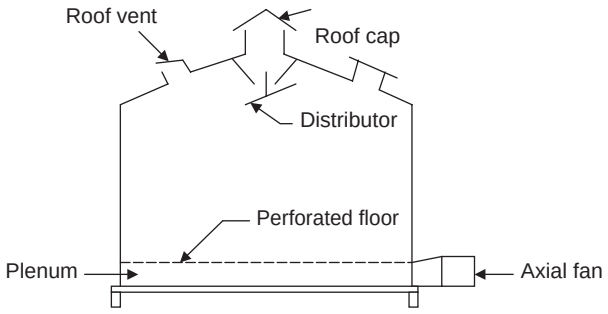

FIGURE 13 Schematic of a bin dryer.

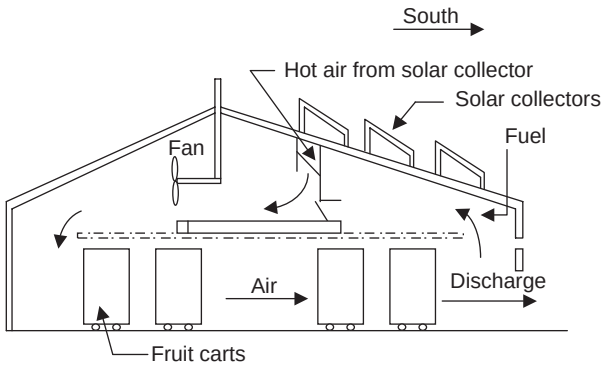

FIGURE 14 Schematic of an industrial dryer.

this type are the following:

i. Bin-type grain dryers: In these dryers, the bin is filled to the top and the hot air from the solar collector is blown from the bottom. Figure 13 shows a schematic diagram of this type.

ii. Shelf-type dryers: The drying chamber consists of many holding trays to increase the capacity of the dryer. The dryer design is similar to that in Fig. 10, but the air is circulated with the help of a blower.

iii. Hybrid or industrial dryers: Such systems use a backup source of conventional energy when solar energy is not sufficient or during off-sun hours. These are usually of a continuous process type and have large capacities. Figure 14 shows a schematic of such dryers.

c. Mixed-type dryers: These are similar to passive dryers, but air is circulated with the help of blowers or fans.

10. DRYER PERFORMANCE

The amount of heat utilized in evaporating the water, q_e, can be calculated as

$$q_e = \dot{m}_e h_{fg},$$

where h_{fg} is the latent heat of evaporation, and $\dot{m}_e$ is the amount of water evaporated in the dryer per unit area perpendicular to the direction of the flow:

$$\begin{aligned}\text{Dryer overall thermal efficiency, } \eta_d(\%) &= \frac{\text{output}}{\text{net input}} * 100 \\ &= \frac{q_e}{q_{input}}.\end{aligned}$$

If a solar collector of efficiency η_c is used to supply the hot air, the overall efficiency of the system will be

$$\eta_{ovetall} = \eta_d \eta_c.$$

In the case of active solar dryers, the energy consumed by the blower or fan is accounted for in the input. Also in the case of hybrid dryers, the amount of conventional energy consumed is added in the solar input.

Glossary

solar architecture The conception, design, and construction of buildings and communities so as to utilize incoming solar radiation.

solar cell A semiconductor material often made of specially treated silicon that converts sunlight directly into electricity.

solar greenhouses Structures used to cultivate plants that are designed and built to utilize solar energy for both heating and lighting.

solar thermal power Systems that capture energy from solar radiation, transform it into heat, and then use it for a variety of applications.

The ancient Greeks began using solar energy 2500 years ago. Since then, people have used the Sun for their benefit.

1. SOLAR ARCHITECTURE AND GREENHOUSES

1.1 Ancient Greece

During the fifth-century BC, the Greeks faced severe fuel shortages. Fortunately, an alternative source of energy was available—the sun (Fig. 1). Archaeological evidence shows that a standard house plan evolved during the fifth century so that every house, whether rural or urban, could make maximum use of the sun's warm rays during winter (Fig. 2). Those living in ancient Greece confirm what archaeologists have found. Aristotle noted that builders made sure to shelter the north side of the house to keep out the cold winter winds. Socrates, who lived in a solar-heated house, observed, "In houses that look toward the south, the sun penetrates the portico in winter," which keeps the house heated. The great playwright Aeschylus went so far as to assert that only primitives and barbarians "lacked knowledge of houses turned to face the winter sun, dwelling beneath the ground like swarming ants in sunless caves." The ancient Greeks planned whole cities in Greece and Asia Minor, such as Colophon, Olynthus, and Priene, to allow every homeowner access to sunlight during winter to warm their homes. By designing the streets in a checkerboard pattern running east–west and north–south, every home faced south, permitting the winter sun to flow into all houses.

1.2 Ancient Rome

Fuel consumption in ancient Rome was even more profligate than in classical Greece. In architecture, the Romans remedied the problem in the same fashion as did the Greeks. Vitruvius, the preeminent Roman architectural writer of the first century BC, advised builders in the Italian peninsula, "Buildings should be thoroughly shut in rather than exposed toward the north, and the main portion should face the warmer south side." Varro, a contemporary of Vitruvius, verified that most houses of at least the Roman upper class followed Vitruvius's advice, stating, "What men of our day aim at is to have their winter rooms face the falling sun [southwest]." The Romans improved on Greek solar architecture by covering south-facing windows with clear materials such as mica or glass.

Such clear coverings let in the light. When the light hit the masonry it converted into heat. The longer heat waves could not easily escape through the glass and the area inside heated to higher temperatures than those of previously unglazed structures. The Romans called these glass-covered structures *heliocamini*,

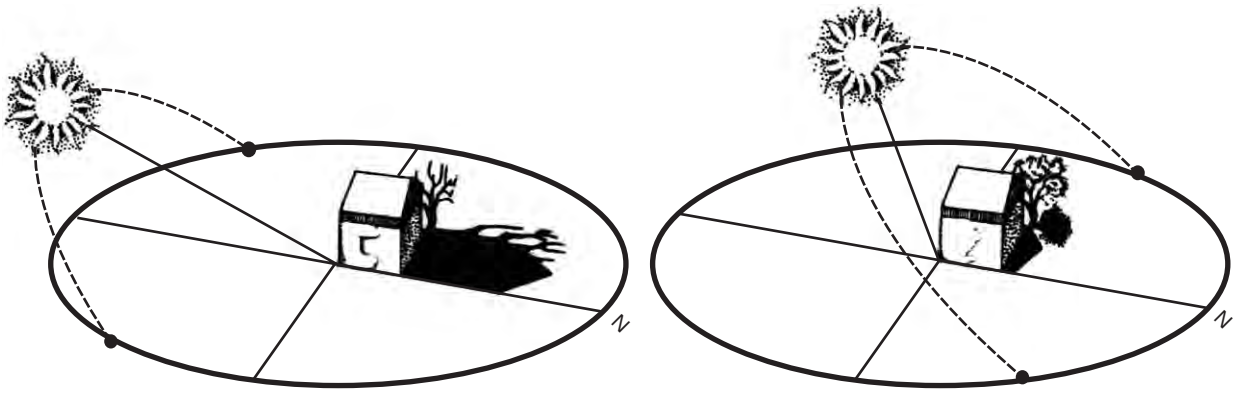

FIGURE 1 In the Northern Hemisphere, the low winter sun rises relative to Earth in the southeast, by noon it is in the south, and it sets in the southwest. During summer, the sun rises in the northeast, by noon it is directly south and very high in the sky, and it sets in the northwest. From Perlin/Butti Solar Archives.

which means "sun furnaces." The Romans used the term to describe their south-facing rooms because they became much hotter in winter than similarly oriented Greek homes, which lacked such coverings.

1.3 Ancient Roman and Renaissance Solar Greenhouses

The ancient Romans not only used window coverings to hold in solar heat for their homes but also relied on such solar heat traps for horticulture. Plants would mature quicker and produce fruits and vegetables out of season and exotic plants from hotter climates could be cultivated at home. With the fall of the Roman Empire, so too came the collapse of glass for either buildings or greenhouses. Only with the revival of trade during the 16th century was there renewed interest in growing in solar-heated greenhouses exotics brought back from the newly discovered lands of the East Indies and the Americas. Trade also created expendable incomes that allowed the freedom to take up such genteel pursuits as horticulture once more. Nineteenth-century architects such as Humphrey Repton brought the sunlit ambiance of the greenhouse into the home by attaching it onto the south side of a living room or library. On sunny winter days, the doors separating the greenhouse and the house were opened to allow the moist, sun-warmed air to freely circulate in the otherwise gloomy, chilly rooms. At night, the doors were shut to keep in as much solar heat as possible. By the late 1800s, the country gentry had become so enamored of attached greenhouses that they became an important architectural fixture of rural estates.

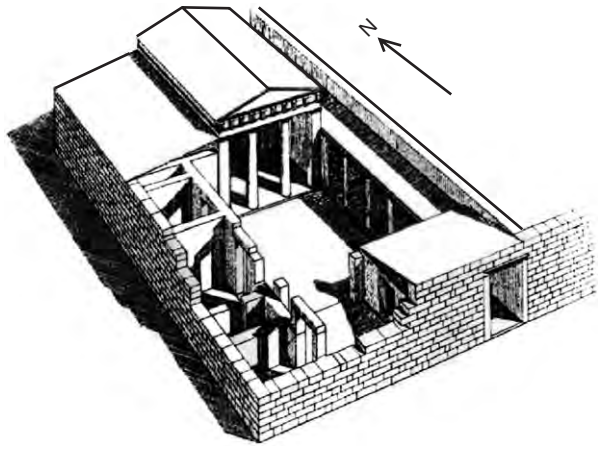

FIGURE 2 The Greeks took advantage of their knowledge of the location of the sun during the year to heat and cool their buildings. They opened their buildings to the south and protected them with a covered porch. The strategy allowed winter sunlight to pour into the house, whereas the roof shaded the house from the high summer sun. From Perlin/Butti Solar Archives.

1.4 Indigenous America

American solar architecture began with its indigenous heritage. Acoma, built by the Pueblo Indians in the 12th century and continuously inhabited since then, serves as an excellent example of their sensitivity to building with the climate in mind. The "sky city," built atop a plateau, consists of three long rows of dwelling units running east to west. Each dwelling unit has two or three tiers stacked one behind the other to allow each one full exposure to the winter sun. Most doors and windows open to the south to catch the warm solar rays of winter. The walls are built of adobe. The sun strikes these heat-absorbing south walls more directly in winter than during summer. The sun's heat travels through the adobe slow enough to reach the interior as night

falls, heating the house through the night. Insulating the ceiling with straw keeps the horizontal roof, vulnerable to the rays of the high summer sun, from allowing too much heat to enter the house.

1.5 Early Euro-Americans

Spaniards who settled in the American southwest often built to take advantage of the winter sun: They aligned their homes east to west so the main portion of the house faced south. Shutters outside the windows were closed at night to help keep the solar heat that had flowed in all day from escaping during wintertime.

Settlers in New England considered the climate when they built their homes. They often chose "saltbox" houses that faced toward the winter sun and away from the cold winds of winter. These structures had two south-facing windowed stories in front where most of the rooms were placed and only one story at the rear of the building. The long roof sloped steeply down from the high front to the lower back side, providing protection from the winter winds. Many saltbox houses had a lattice overhang protruding from the south facade above the doors and windows. Deciduous vines growing over the overhang afforded shade in summer but dropped their leaves in winter, allowing sunlight to pass through and penetrate the house.

1.6 Post-World War I Europe and America

Ameliorating the terrible slums that blighted European cities during the industrial revolution sparked a renewed interest in building with the sun. As one English city planner bent on housing reform urged in the first decade of the 20th century, "Every house should have its face turned to the sun, whence comes light, sweetness, and health." Young architects on the Continent agreed, declaring that their profession should embrace functionalism over anesthetics. To many, functionality meant designing houses that satisfied the basic needs of those living in them. In the relatively chilly European climate, this dictum meant providing dwellers with a warm haven. Therefore, Hannes Meyer, the leader of functional architecture in Germany, argued that an architect wishing to build a useful house must consider its body "to be a storage cell for the heat of the sun." Hence, "maximal use of the sun," as far as Meyer was concerned, was "the best plan for construction." Meyer, who became the director of the highly famous and influential Bauhaus architectural school, told fellow architects that to achieve optimum sunshine in buildings, they must conduct or at least be privy to scientific research into the sun's year-round movement relative to the earth. Germany led a renaissance in solar building during the 1930s that spread throughout Europe only to be stamped out by the Nazis, who condemned functional architecture as Jewish. When they came to power, a good number of German architects who designed solar buildings fled, many to the United States. George Fred Keck, a Chicago architect, befriended some of these expatriates and through their influence began designing homes in the Chicago area according solar building principles: expansive south-facing glass to trap the winter sun; long overhangs to shade the house in summer; minimal east–west exposure to prevent overheating in summer and fall; and the placement of secondary rooms, garages, and storage corridors on the north side to help insulate the living quarters from the cold north winds. Keck had a knack for publicity and called the houses he designed "solar homes." By the mid-1940s, Keck's work caught the attention of the national media. *House Beautiful*, *Reader's Digest*, and *Ladies Home Journal* featured his work. Fuel rationing during the war inclined the American public toward valuing the energy-saving features of solar homes. When war ended, the building market exploded. With the wartime-conservation ethic still imbued in most people's minds, many manufacturers in the prefabricated home industry adopted solar design features for leverage in this highly competitive market.

1.7 Post-World War II America

Studies of houses with large amounts of glass on the south side demonstrated that they experience much greater temperature swings than ordinary homes, warming quickly during the day due to accumulating the sun's heat and cooling off rapidly at night due to large heat losses through the windows. Tucson Architect Arthur Brown eliminated the unwanted fluctuations in temperature by running a thick black wall between the sun porch next to the south-facing glass and the living quarters. During sunny winter days, sunlight struck the black wall and the concrete absorbed the solar heat. Estimating that heat moves through the wall at 1 in. per hour, Brown made the wall 8 in. thick. As evening approached, the solar heat soaked up by the wall began to radiate into the rooms and continued to do so during the night. By

morning, all the solar heat in the wall had dissipated into the living areas, leaving the wall totally cooled down and ready for another heating cycle.

Brown also designed the world's first solar-heated public building in 1948. Since students attended classes between 9 AM and 3 PM, Brown did not have to worry about storing solar energy since no one needed heat at night or in the very early morning. To keep costs down, he used the roofing supports to separate the space between the ceiling and the roof into channels. In this way, the roof served as the solar collector. The school's fan, which had forced gas-heated air through the building, now pushed air through the channels. The sun's energy heated the air and a second fan distributed that heat into the classrooms when needed. The solar system provided the school with 86% of its heat. However, in 1958, when the school district decided to expand the campus, the authorities chose a gas-fired furnace due to cheap energy costs. Cheap energy running highly reliable and easy to use heating and cooling systems led to an almost universal disinterest in solar design. It was only in the 1970s, with the Arab oil embargo and skyrocketing fuel prices, that people became interested in solar architecture again.

2. SOLAR THERMAL POWER

2.1 Ancient Chinese, Greeks, and Romans

Archaeological finds and ancient literature show that solar concave reflectors and convex lenses have a long history. Convex lenses predate concave reflectors by more than 1000 years. People crafted the first convex lenses out of rock crystal. Ancient Chinese and Roman doctors relied on convex lenses to cauterize wounds. The first mention of solar concave reflectors appeared in the third-century BC writings of Euclid. The ancient Chinese and Greeks used solar concave reflectors to light fires for domestic cooking.

2.2 Medieval and Renaissance Europe

Latin translation of Arab writer Al-Hazan introduced Europeans to ancient Greek works on solar concave reflectors and convex lenses. Between the 13th and 16th centuries, many Europeans suggested burning whole armies with huge solar reflectors, but no one could build reflectors or lenses large enough for martial purposes. However, Europeans did use reflectors to ignite fires for cooking meals, to distill perfumes, and to weld metal statuary.

2.3 19th- and Early 20th-Century America, Europe, and Africa

Many in 19th-century Europe worried that the prodigious consumption of coal by industry would eventually lead to coal shortages. Among the concerned, Augustine Mouchot thought that the sun's heat could replace coal to run Europe's many steam engines. Mouchot's work with mirror technology led him to develop the world's first sun motor in the 1870s, which produced sufficient steam to drive machinery (Fig. 3). One journalist described it as a "mammoth lamp shade, with its concavity directed skyward." After 1 year of testing Mouchot's sun machine, the French government concluded,

> *In France, as well as in other temperate regions, the amount of solar radiation is too weak for us to hope to apply it for industrial purpose. Though the results obtained in our temperate and variable climate are not very encouraging, they could be much more so in dry and hot regions where the difficulty of obtaining other fuel adds to the value of solar technologies. [Hence] in certain cases, these solar apparatuses could be called upon to provide useful work.*

An American inventor, Frank Shuman, took his cue from the French report. In 1911, he chose to locate his commercial solar motor in Egypt, where land and labor were cheap, sun was plentiful, and coal was costly. To increase the amount of heat generated by the solar motor, glass-covered pipes were cradled at the focus of a low-lying trough-like reflector. A field of five rows of reflectors was laid out in the Egyptian desert. The solar plant also boasted a storage system that collected excess sun-warmed water in a large insulated tank for use at night and during inclement weather, in contrast to the solar motor designed by Mouchout, which went "into operation only when the sun [came] out from behind a cloud and [went] out of action the instant the sun disappears again." For industrialists, Shuman's solution eliminated a major obstacle to solar's appeal. Shuman's solar plant proved in Egypt to be more economical than a coal-fired plant. Engineers recognized that this plant demonstrated that "solar power was quite within the range of practical matters." However, the hopes and dreams of solar engineering disintegrated with the outbreak of World War I. The staff of the Egyptian plant had to leave for war-related work in their respective homelands. Shuman, the driving force behind large-scale solar developments, died before the war ended. After the war, the world turned to oil to replace coal. Oil and gas reserves were found in sunny and previously

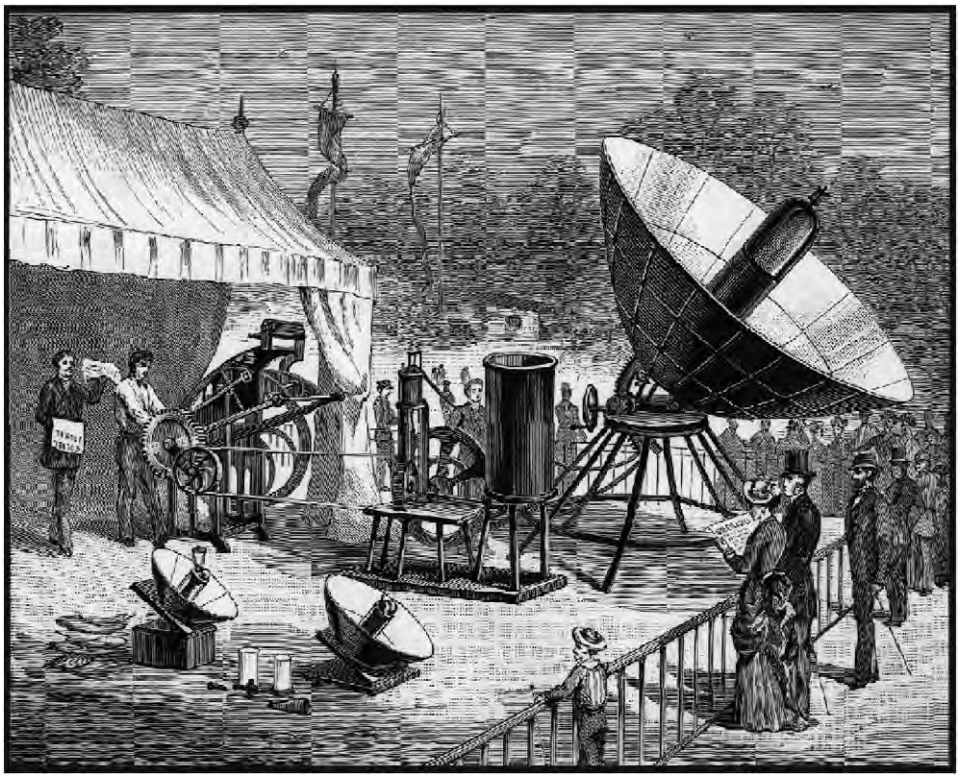

FIGURE 3 A solar-powered machine built by Mouchot's protégé, Pifre, runs a printing press. From Perlin/Butti Solar Archives.

sun-short places that had been targeted as prime locations for solar plats. With oil and gas selling at near-giveaway prices, scientists, government officials, and business people became complacent about the world's energy situation and interest in sun power came to an abrupt end.

3. SOLAR HOT WATER HEATING

3.1 Solar Hot Box

Horace de Saussure, a noted Swiss naturalist, observed in the 1760s, "It is a known fact, and a fact that has probably been known for a long time, that a room, a carriage, or any other place is hotter when the rays of the sun pass through glass." To determine the effectiveness of trapping heat with glass covers, de Saussure built a rectangular box out of half-inch pine, insulated the inside, covered the top with glass, and placed two smaller glass-covered boxes inside. When exposed to the sun, the bottom box heated to 228°F (109°C), or 16°F (9°C) above the boiling point of water. de Saussure was unsure how the sun heated the glass boxes. Today, we can better explain what happened. Sunshine penetrated the glass covers. The black inner lining absorbed the sunlight and converted it into heat. Although clear glass allows the rays of the sun to easily enter through it, it prevents heat from doing the same. As the glass trapped the solar heat in the box, it heated up. Its inventor realized that someday the hot box might have important practical applications because "it is quite small, inexpensive, and easy to make." Indeed, the hot box became the prototype for the solar collectors that have provided sun-heated water to millions since 1891.

3.2 The First Solar Water Heaters

In the 19th century, there was no easy way to heat water. People generally used a cook stove for this purpose. Wood had to be chopped or heavy hods of coal lifted, and then the fuel had to be kindled and the fire periodically stoked. In cities, the wealthier heated their water with gas manufactured from coal. However, the fuel did not burn clean and the heater had to be lit each time someone wanted to heat water. If someone forgot to extinguish the flame, the

tank would blow up. To add to the problem of heating water, in many areas wood or coal or coal gas cost a lot and many times could not be easily obtained. To circumvent these problems, many handy farmers, prospectors, or other outdoorsmen devised a much safer, easier, and cheaper way to heat water: They placed a metal water tank painted black into sunlight to absorb as much solar energy as possible. These were the first solar water heaters on record. The downside was that even on clear, hot days it usually took from morning to early afternoon for the water to get hot. As soon as the sun went down, the tanks rapidly lost heat because they had no protection from the night air.

3.3 The First Commercial Solar Water Heater

The shortcomings of the bare tank solar water heaters came to the attention of Clarence Kemp, who sold the latest home heating equipment in Baltimore, Maryland. In 1891, Kemp patented a way to combine the old practice of exposing metal tanks to the sun with the scientific principle of the hot box, thereby increasing the tanks' capability to collect and retain solar heat. He called his new solar water heater the Climax, the world's first commercial solar water heater (Fig. 4). Kemp originally marketed his invention to eastern gentlemen whose wives had left with their maids to summer resorts, leaving their husbands to fend for themselves. The solar water heater, Kemp advertised, would simplify housekeeping duties for this class of men already burdened by their wives and domestic staffs' absence and unaccustomed to such work as lighting the gas furnace or stove to heat water. In California and other temperate states, having greater amounts of sunshine throughout the year but also higher fuel costs (compared to states such as Maryland) made it essential for residents to take their solar assets seriously and not waste them (Fig. 5). The Climax sold well in such areas. Sixteen hundred had been installed in homes throughout southern California by 1900, including those installed in Pasadena, where one-third of the households heated their water with the sun by 1897.

3.4 The Flat Plate Collector

From the turn of the century to 1911, more than a dozen inventors filed patents that improved on the Climax. However, none changed the fact that the heating unit and the storage unit were one and the same and both laid exposed to the weather and

FIGURE 4 Advertisement for the world's first commercial solar water heater. From Perlin/Butti Solar Archives.

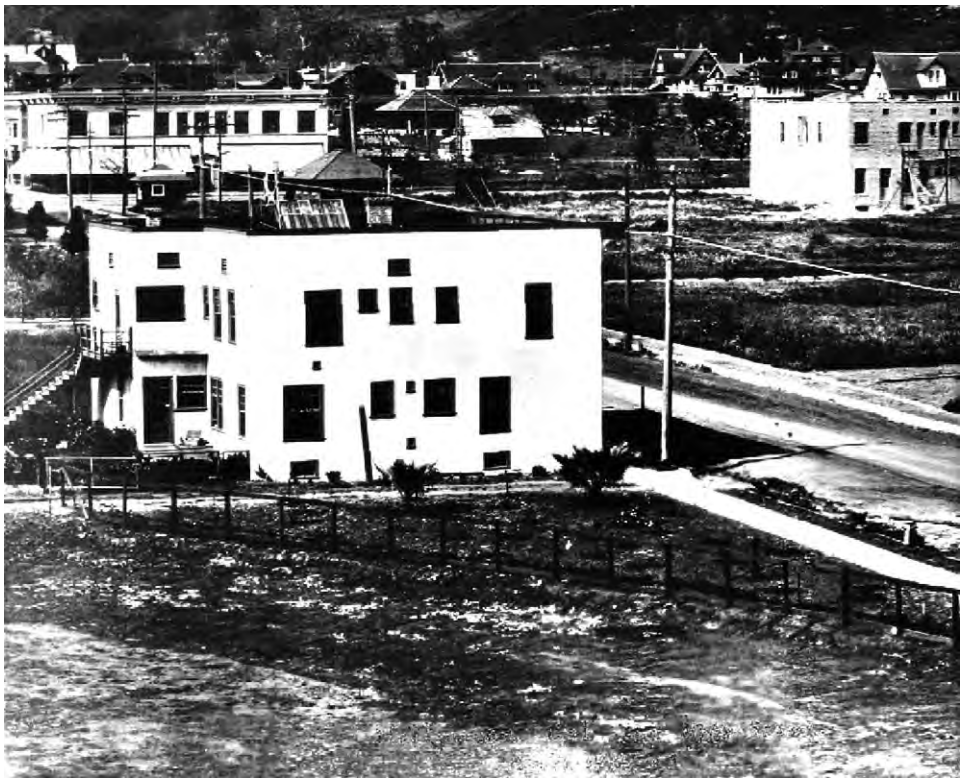

FIGURE 5 Installation of tanks in glass-covered box, Hollywood, California. From Perlin/Butti Solar Archives.

the cold night air. Hence, water heated by the sun the night before never stayed hot enough to do the wash the next morning or to heat the bath. In 1909, William J. Bailey patented a solar water heater that revolutionized the business. He separated the solar water heater into two parts: a heating element exposed to the sun and an insulated storage unit tucked away in the house so families could have sun-heated water day and night. The heating element consisted of pipes attached to a black-painted metal sheet placed in a glass-covered box. Because the water to be heated passed through narrow pipes rather than sitting in a large tank, Bailey reduced the volume of water exposed to the sun at any single moment and therefore the water heated faster. The heated water, which was lighter than the incoming cold water, naturally and immediately rose through the pipes to an insulated storage tank, where the water was kept warm for use both day and night. He also connected the storage tank to the home's furnace, guaranteeing hot water even after several rainy days. Providing hotter water for longer periods put Bailey's solar hot water heater, called the Day and Night (Fig. 6), at a great advantage over the competition. Soon, the Climax company went out of business. From 1909, when Bailey started his business, through 1918, his company sold more than 4000 Day and Night solar hot water heaters (Fig. 7).

3.5 The Demise of the Solar Water Heater in California and Its Success in Florida

The discovery of huge amounts of natural gas in the Los Angeles basin during the 1920s and 1930s killed the local solar water heater industry. Rather than lose money from the energy changes, Bailey applied the innovations he had made in solar to develop thermostatically controlled gas water heaters. His Day and Night gas water heater made him his second fortune. He also sold the patent rights of the Day and Night solar water heater to a Florida firm. A building boom in Florida during the 1920s had tripled the number of houses, but just as in California before the great oil strikes, people had to pay a high price to heat water. The high cost of energy combined with the tropical climate and the great growth in housing stock created a major business for those selling solar water heaters. By 1941, more than half the population heated water with the sun. Declining electric

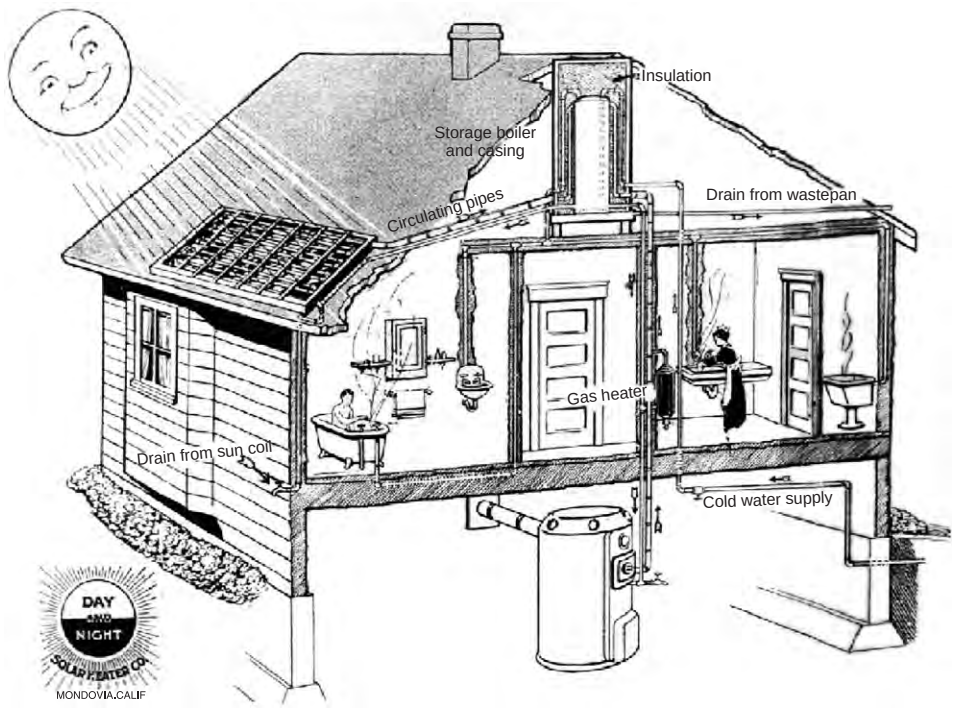

FIGURE 6 Schematic of the first flat plate solar collector with solar heat collection and solar storage separated. From Perlin/Butti Solar Archives.

FIGURE 7 An early flat plate collector installation. From Perlin/Butti Solar Archives.

rates after World War II, in association with an aggressive campaign by Florida Power and Light to increase electrical consumption by offering electric water heaters at bargain prices, brought Florida's once flourishing solar water heater industry to a screeching halt.

3.6 Solar Water Heaters in Japan

Unlike in the United States during the post-World War II years, Japan lacked cheap and abundant energy to supply hot water on demand. Rice farmers in particular yearned for a hot bath after working long hours in the hot, humid patties. To heat water, however, they had to burn rice straw, which they could have otherwise used to feed their cattle or fertilize the earth. A Japanese company began marketing a simple solar water heater consisting of a basin with its top covered by glass, and more than 100,000 were in use by the 1960s. People living in towns and cities bought either a plastic solar water heater that resembled an inflated air mattress with a clear plastic canopy or a more expensive but longer lasting model that resembled the old Climax solar water heaters—cylindrically shaped metal water tanks placed in a glass-covered box. Approximately 4 million of these solar water heaters had been sold by 1969. The advent of huge oil tankers in the 1960s allowed Japan access to new oil fields in the Middle East, supplying it with cheap, abundant fuel. As had happened in California and Florida, the solar water heater industry collapsed, but not for long. The oil embargo of 1973 and the subsequent dramatic increase in the price of petroleum revived the local solar water heater industry. Annual sales of more than 100,000 units continued to hold steady from 1973 until the second oil shock of 1979. Sales then increased to almost 500,000 that year and increased further to nearly 1 million the following year. By this time, the Japanese favored solar water heaters that closely resembled the type introduced in California in 1909 by William J. Bailey with the heating and storage units separated. As the price of oil began to stabilize in 1985 and then decline sharply in subsequent years, so did the sales of solar water heaters; however, the Japanese still purchase approximately 250,000 each year. Today, more than 10 million Japanese households heat water using the sun.

3.7 Solar Water Heating in Australia

From the 1950s to the early 1970s, a few thousand Australians relied on the sun to heat water. The numbers grew as a consequence of the major spikes in oil prices in 1973 and 1979. Interestingly, the purchase of solar water heaters during these years varied from state to state. Whereas 40–50% of those living in Australia's Northern Territory heated water using the sun, approximately 15% in Western Australia did so and less than 5% did so in the more populated eastern states. The major difference had more to do with the cost of electricity than the amount of sun available. People in the Northern Territory and Western Australia bought electricity generated by imported and increasingly costly petroleum, whereas for those in the eastern states of New South Wales, Queensland, and Victoria, electricity was produced by locally mined and very cheap coal. In the late 1980s, the Australian solar water heater market began to stagnate. Pipelines bringing newly discovered natural gas to previously fuel-short regions, such as the Northern Territory and Western Australia, eliminated growth in these once fertile markets for solar water heaters. Exports now account for more than 50% of the sales of Solahart, Australia's leading manufacturer of solar water heaters.

3.8 Solar Hot Water Heaters in Israel

Unlike the United States and much of Europe, Israel, like Japan, found itself without sufficient fuel supplies in the early 1950s. The power situation became so bleak in the early days of the Jewish state that the government had to forbid heating water between 10 PM and 6 AM. Despite mandatory domestic rationing of electricity, power shortages worsened, causing pumping stations to fail and threatening factory closures. A special committee impaneled by the government could only suggest the purchase of more centralized generators to overcome the problem. This conclusion raised the ire of Israeli engineer Levi Yissar, who complained, "How about an already existing energy source which our country has plenty of—the sun. Surely we need to change from electrical energy to solar energy, at least to heat our water." Yissar put his money where his mouth was, becoming Israel's first manufacturer of solar water heaters. His design closely resembled the type introduced in California in the early 20th century with heating and storage separated. By 1967, approximately 1 in 20 households heated water with the sun. However, cheap oil from Iran in the late 1960s as well from oil fields captured during the Six Day War drastically reduced the price of electricity and the number of people purchasing solar water heaters. Israeli success in the Yom Kippur War resulted in the infamous oil boycott of 1973. The Israelis responded by mass purchasing of solar water heaters. By 1983, 60% of the population heated water using the sun. When the price of oil dropped in the mid-1980s, the Israeli government did not want people backsliding in their energy habits as happened throughout the rest of the world. It therefore

required its inhabitants to heat water using the sun. Today, more than 90% of Israeli households own solar water heaters.

3.9 Solar Water Heating for Swimming Pools

Solar swimming pool water heaters rank as the most successful but least heralded commercial solar application. The use of solar energy for pool heating and the equipment and needs of pool owners make a perfect match. The storage unit for the solar heated water already exists—the swimming pool. The pump needed to push water through the solar collectors must be purchased irrespective of the technology used to heat the water. The pool owner merely has to purchase the solar collectors. Since those using the pool generally want the temperature of the pool to be no higher than 80°F (27°C), the solar collectors do not require a costly glass cover or expensive metal sheeting and piping. Climax solar water heaters kept pools warm in the 1890s. Later, collectors resembling those designed by William J. Bailey were put to use for this application. In the 1970s, American Freeman Ford developed low-cost plastic to act as the solar collector. Exposed to the sun, water would pass through narrow ducts in the plastic and carry enough heat to warm the pool. The outdoor swimming season harmoniously coincides with the maximum output of the solar collectors. Even with other forms of energy selling very cheaply, the pool owner who buys a solar unit will start to save money very quickly. In the United States alone, solar swimming pool heaters have produced the energy output equivalent of 10 nuclear power plants.

4. PHOTOVOLTAICS

All the methods discussed in the previous sections change solar energy into heat. In contrast, photovoltaics produces electricity directly from sunlight.

4.1 The First Solid-State Solar Cell

The direct ancestor of solar cells currently in use got its start in the late 19th century with the construction of the world's first seamless communication network—transoceanic telegraph cables. While laying them under water to permit instantaneous communications between continents, engineers experimented with selenium for detecting flaws in the wires as they were submerged. Those working with selenium discovered early on that the material's performance depended on the amount of sunlight falling on it. The influence of sunlight on selenium aroused the interest of scientists throughout Europe, including William Grylls Adams and his student Richard Evans Day. During one of their experiments with selenium, they witnessed something completely new: Light could cause a solid material to generate electricity.

However, with the science of the day not yet sure if atoms were real, scientists could not explain why selenium produced electricity when exposed to light. Most scientists of the day therefore scoffed at Adams and Day's work. It took the discovery and study of electrons and the discovery and acceptance that light contains packets of energy called photons for the field of photovoltaics to gain acceptance in the scientific community. By the mid-1920s, scientists theorized that when light hits materials such as selenium, the more powerful photons pack enough energy to knock poorly bound electrons from their orbits. When wires are attached, the liberated electrons flow through them as electricity. Many envisioned the day when banks of selenium solar cells would power factories and light homes. However, no one could build selenium solar cells efficient enough to convert more than half a percent of the sun's energy into electricity—hardly sufficient to justify their use as a power source.

4.2 The Discovery of the Silicon Solar Cell

An accidental discovery by scientists at Bell Laboratories in 1953 revolutionized solar cell technology. Gerald Pearson and Calvin Fuller led the pioneering effort that took the silicon transistor, now the principal electronic component used in all electrical equipment, from theory to working device. Fuller had devised a way to control the introduction of impurities necessary to transform silicon from a poor to a superior conductor of electricity. He gave Pearson a piece of his intentionally contaminated silicon. Among the experiments Pearson performed using the specially treated silicon was exposing it to the sun while hooked to a device that measured electrical flow. To Pearson's surprise, he observed an electric output almost five times greater than that of the best selenium produced. He ran down the hall to tell his good friend, Daryl Chapin, who had been

trying to improve selenium to provide small amounts of intermittent power for remote locations. He said, "Don't waste another moment on selenium!" and handed him the piece of silicon he had just tested. After a year of painstaking trial-and-error research and development, Bell Laboratories showed the public the first solar cells capable of producing useful amounts of power. Reporting the event on page 1, the *New York Times* stated that the work of Chapin, Fuller, and Pearson "may mark the beginning of a new era, leading eventually to the realization of one of mankind's most cherished dreams—the harnessing of the almost limitless energy of the sun for the uses of civilization."

Few inventions in the history of Bell Laboratories evoked as much media attention and public excitement as its unveiling of the silicon solar cell. Commercial success, however, failed to materialize due to the solar cells' prohibitive costs. Desperate to find marketable products run by solar cells, manufacturers used them to power novelty items such as toys and the newly developed transistor radio. With solar cells powering nothing but playthings, one of the inventors of the solar cell, Daryl Chapin, could not hide his disappointment, wondering, "What to do with our new baby?"

4.3 The First Practical Application of Silicon Solar Cells

Unbeknown to Chapin at the time, powerful backing of the silicon solar cell was developing at the Pentagon. In 1955, the U.S. government announced its intention to launch a satellite. The prototype had silicon solar cells for its power plant. Since power lines could not be strung out to space, satellites needed a reliable, long-lasting autonomous power source. Solar cells proved the perfect answer.

The launching of the Vanguard (Fig. 8), the first satellite equipped with solar cells, demonstrated their value. Preceding satellites, run by batteries, lost power after approximately 1 week, rendering millions of dollars' worth of equipment useless. In contrast, the solar-powered Vanguard continued to communicate with Earth for many years, allowing the completion of many valuable experiments. The success of the Vanguard's solar power pack broke down the existing prejudice at the time toward the use of solar cells in space. As the space race between the United States and the Soviet Union intensified, both adversaries urgently needed solar cells. The demand opened a relatively large business for companies manufacturing them. More important, for the first time in the history of solar power, the sun's energy proved indispensable to society: Without the secure, reliable electricity provided by photovoltaics, the vast majority of space applications so vital to our everyday lives would never have been realized.

FIGURE 8 An engineer holds the Vanguard 1, the first satellite to use photovoltaics. From Perlin/Butti Solar Archives.

4.4 The First Terrestrial Applications

Although things were looking up for solar cells in space in the 1960s and early 1970s, their astronomical price kept them distant from Earth. In 1968, Elliot Berman decided to quit his job as an industrial chemist to develop inexpensive solar cells to bring the technology from space to Earth. Berman prophetically saw that with a major decrease in price photovoltaics could play a significant role in supplying electrical power to locations on Earth where it is difficult to run power lines. After 18 months of searching for venture capital, Exxon executives invited Berman to join their laboratory in late 1969. Dismissing other solar scientists' obsession with efficiency, Berman concentrated on lowering costs by using lower grade and therefore cheaper silicon and less expensive materials for packaging the modules. By decreasing the price from $200 to $20 per watt, solar cells could compete with power equipment needed to generate electricity distant from utility poles.

4.5 Terrestrial Applications

Oil companies were the first major customers of solar modules. They had both the need and the money. Oil rigs in the Gulf of Mexico were required to have warning lights and horns. Most relied on huge flashlight-type batteries to run them. The batteries required heavy maintenance and also had to be replaced approximately every 9 months. This required a large boat with an onboard crane or a helicopter. In contrast, a small skiff could transport the much lighter solar module and accompanying rechargeable battery, resulting in tremendous savings. By 1980, photovoltaics had become the standard power source for warning lights and horns not only on rigs in the Gulf of Mexico but also on those throughout the world.

Oil and gas companies also need small amounts of electricity to protect well casings and pipelines from corroding. Sending a current into the ground electrochemically destroys the offending molecules that cause this problem. However, many oil and gas fields both in the United States and in other areas of the world such as the Middle East and North Africa are far away from power lines but receive plenty of sunshine. In such cases, solar modules have proven the most cost-effective way of providing the needed current to keep pipes and casings corrosion free.

The cost of changing nonrechargeable batteries on the U.S. Coast Guard's buoys exceeded the buoys' original cost. Hence, Lloyd Lomer, at the time a lieutenant commander in the Guard, believed that switching to photovoltaics as a power source for buoys made economic sense. However, his superiors, insulated from competition, balked at the proposed change. Lomer continued his crusade, winning approval to install a test system in the most challenging of environments for sun-run devices—Ketchikan, Alaska. The success of the photovoltaic-powered buoy in Alaska proved Lomer's point. Still, his boss refused to budge. Going to higher authorities in government, Lomer eventually won approval to convert all buoys to photovoltaics. Almost every coast guard service in the world has followed suit.

To solar pioneer Elliot Berman, the railroads seemed to be another natural for photovoltaics. One of his salesmen convinced the Southern Railway (now Norfolk Southern) to try photovoltaics for powering a crossing signal at Rex, Georgia. These seemingly fragile cells did not impress veteran railroad workers as capable of powering much of anything. They therefore put in a utility-tied backup. However, a strange thing happened that turned quite a few heads. That winter, the lines went down on several occasions due to heavy ice buildup on the wires, and the only electricity for miles around came from the solar array. As one skeptic remarked, "Rex, Georgia taught the Southern that solar worked!"

With the experiment at Rex a success, the Southern decided to put photovoltaics to work for the track circuitry, the railroad's equivalent of air-traffic control, keeping trains at a reasonable distance from one another to prevent head-on collisions or backenders. The presence of a train changes the rate of flow of electricity running through the track. A decoder translates that change to throw signals and switches up and down the track to ensure safe passage for all trains in the vicinity. At remote spots along the line, photovoltaics provided the needed electricity.

Other railroads followed the Southern's lead. In the old days, telegraph and then telephone poles ran parallel to most tracks. Messages sent through these wires kept stations abreast of matters paramount to the safe and smooth functioning of a rail line. However, by the mid-1970s, wireless communications could do the same tasks. The poles became a liability and maintenance expense. Railroads started to dismantle poles. Whenever they found their track circuitry devices to be too far away from utility lines, they relied on photovoltaics.

The U.S. Army Signal Corps, which pioneered the use of solar power in space by equipping the solar pack on the Vanguard, was the first to bring photovoltaics down to Earth. In June 1960, the Corps sponsored the first transcontinental radio broadcast generated by the sun's energy to celebrate its 100th anniversary. The Corps, probably photovoltaics' strongest supporter in the late 1950s and the early 1960s, envisioned the solar broadcast would lead others to use photovoltaics to help provide power to run radio and telephone networks in remote locations.

Fourteen years later, GTE John Oades realized the Corps' dream by installing the first photovoltaic-run microwave repeater in the rugged mountains above Monument Valley, Utah. By minimizing the power needs of the microwave repeater, Oades could power the repeater with a small photovoltaic panel, saving all the expenses formerly attributed to them. His invention allowed people living in towns in the rugged American west, hemmed in by mountains, to enjoy the luxury of long-distance phone service that most other Americans took for granted. Prior to the solar-powered repeater, it was too expensive for phone companies to install cable or

lines, forcing people to drive hours, sometimes through blizzards on windy roads, just to make long-distance calls.

Australia had an even more daunting challenge to bring modern telecommunication services to its rural customers. Although approximately the same size as the United States, only 22 million people lived in Australia in the early 1970s when its government mandated Telecom Australia to provide every citizen, no matter how remotely situated, with the same radio, telephone, and television service enjoyed by urban customers living in Sydney or Melbourne.

Telecom Australia tried, without success, traditional stand-alone power systems such as generators, wind machines, and nonrechargeable batteries to run autonomous telephone receivers and transmitters for its rural customers. Fortunately, by 1974, it had another option—relatively cheap solar cells manufactured by Elliot Berman's firm, Solar Power Corporation. The first photovoltaic-run telephone was installed in rural Victoria, after which hundreds of others were installed. By 1976, Telecom Australia judged photovoltaics as the preferred power source for remote telephones. In fact, the solar-powered telephones proved so successful that engineers at Telecom Australia believed they were ready to develop large photovoltaic-run telecommunication networks linking towns such as Devil's Marbles, Tea Tree, and Bullocky Bone to Australia's national telephone and television service. As a result of photovoltaics, people in these and neighboring towns could dial long distance direct instead of having to call the operator and shout into the phone to be understood. Nor did they have to wait for newsreels to be flown to their local station to view news, hours, if not days, old. There were a total of 70 solar-powered microwave repeater networks by the early 1980s, the longest spanning 1500 miles. The American and Australian successes showed the world that solar power worked and benefited hundreds of thousands of people. In fact, by 1985 a consensus in the telecommunications field found photovoltaics to be the power system of choice for remote communications.

A few years earlier, Mali, a country located south of the Sahara desert, along with its neighbors, suffered from drought so devastating that tens of thousands of people and livestock died. The Malian government knew it could not save its population without the help of people like Father Vespieren, a French priest who lived in Mali for decades and had successfully run several agricultural schools. The government asked Vespieren to form a private company to tap the vast aquifers that run underneath the Malian desert. Vespieren saw drilling as the easy part. His challenge was pumping. No power lines ran nearby and generators lay idle for lack of repairs or fuel. Then he heard about a water pump in Corsica that ran without moving parts, without fuel, and without a generating plant: It run simply on energy from the sun. Vespieren rushed to see the pioneering installation. When he saw the photovoltaic pump, he knew that only this technology could save the people of Mali. In the late 1970s, Vespieren dedicated Mali's first photovoltaic-powered water pump with the following words: "What joy, what hope we experience when we see that sun which once dried up our pools now replenishes them with water!" By 1980, Mali, one of the poorest countries in the world, had more photovoltaic water pumps per capita than any other country due to Vespieren's efforts. The priest demonstrated that success required the best equipment, a highly skilled and well-equipped maintenance service, and financial participation by consumers. Investing their own money helped pay the bill for the capital equipment and ongoing maintenance but, more important, the people came to regard the panels and pumps as valued items that they would help care for. Most successful photovoltaic water pump projects in the developing world have followed Vesperien's example. When Vespieren initiated his photovoltaic water-pumping program, less than 10 photovoltaic pumps existed throughout the world. Today, tens of thousands of photovoltaic pumps provide water to people, livestock, and crops.

Despite the success of photovoltaic applications throughout the world in the 1970s and early 1980s, institutions responsible for rural electrification programs in developing countries did not consider installing solar electric panels to power villages distant from urban areas. Working from offices either in the West or in large cities in poorer countries, they only considered central power stations run by nuclear energy, oil, or coal. Not having lived "out in the bush," these "experts" did not realize the huge investment required to string wires from power plants to the multitudes residing in small villages tens of miles away. As a consequence, only large populated areas received electricity, leaving billions in the countryside without. The disparity in energy distribution helped cause the great migration to the cities in Africa, Asia, and Latin America. As a consequence, megalopolises such as Mexico City, Lagos, and Bombay arose with all the ensuing problems, such as crime,

diseases like AIDS, pollution, and poverty. The vast majority still living in the countryside do not have electricity. To have some modicum of lighting, they have had to rely on ad hoc solutions such as kerosene lamps. Those buying radios, tape cassettes, and televisions also must purchase batteries. It has become apparent that mimicking the Western approach to electrification has not worked in the developing world. Instead of trying to install wires and poles, which no utility in these regions can afford, bringing a 20- to 30-year supply of electricity contained in solar modules to consumers by animal or by vehicle makes more sense. Whereas it requires years to construct a centralized power plant and even more time for power lines to be installed to deliver electricity, it takes less than 1 day to install an individual photovoltaic system.

Ironically, the French Atomic Energy Commission pioneered electrifying remote homes in the outlying Tahitian Islands with photovoltaics. The Atomic Energy Commission believed that electrifying Tahiti would mollify the ill feeling in the region created by its testing of nuclear bombs in the South Pacific. The commission considered all stand-alone possibilities, including generators, wind machines, and biogas from the husks of coconut shells, before choosing photovoltaics. In 1983, 20% of the world's production of solar cells went to French Polynesia. By 1987, half of all the homes on these islands received their electricity from the sun.

Rural residents in Kenya believe that if they have to wait for electricity from the national utility, they will be old and gray by the time they receive it. To have electricity now, tens of thousands of Kenyans have bought photovoltaic units. Though relatively small compared to what an American would purchase, the typical modules in Kenya range from 12 to 25 W and are capable of charging a battery with enough electricity to run three low-wattage lights and a television for 3 hours after dark. Electric lighting provided by photovoltaics eliminates the noxious fumes and the threat of fire that people had to contend with when lighting their homes with kerosene lamps. Due to photovoltaics, children can study free from eye strain and tearing and from developing hacking coughs that they formerly experienced when studying by kerosene lamp. Their performance in school has soared with better lighting. Electric lighting also allows women to sew and weave at night products that generate cash. Newly gained economic power gives women more say in matters such as contraception. In fact, solar electricity has proven more effective in lowering fertility rates than have birth control campaigns.

Electricity provided by photovoltaics allows those living in rural areas to enjoy the amenities of urban areas without leaving their traditional homes for the cities. The government of Mongolia, for example, believed that to improve the lot of its nomadic citizens would require herding them into communities so the government could connect them to electricity generated by centralized power. The nomads, however, balked. Photovoltaics allowed the nomadic Mongolians to take part in the government's rural electrification program without giving up their traditional lifestyle. Whenever they move, the solar panels move too, with yurt and yaks and whatever else they value.

With the growing popularity of photovoltaics in the developing world, solar thievery has become common. Perhaps nothing better demonstrates the high value that people living in these countries place on photovoltaics than the drastic increase in solar module thefts during the past few years. Before the market for photovoltaics took off in the developing world, farmers would build an adobe fence around their photovoltaic panels to keep the livestock out. Now, razor wire curls around the top of these enclosures to bar solar outlaws.

As the price of solar cells has continued to decline, devices run by solar cells have seeped into the suburban and urban landscapes of the developed world. For example, when construction crews have to excavate to place underground electrical transmission lines, installing photovoltaics instead makes more economic sense. Economics has guided highway departments throughout the world to use solar cells for emergency call boxes along roads. In California alone, there are more than 30,000. The savings have been immediate. Anaheim, California, would have had to spend approximately $11 million to connect its 11,000 call boxes to the power grid. Choosing photovoltaics instead, the city paid $4.5 million. The city of Las Vegas found it cheaper to install photovoltaics to illuminate its new bus shelters than to have the adjacent street and sidewalk dug up to place new wires.

In the mid-1970s and early 1980s, when governments of developing countries began to fund photovoltaic projects, they copied the way electricity had been traditionally produced and delivered, favoring the construction of large fields of photovoltaic panels far away from where the electricity would be used and delivering the electricity by building miles of transmission lines. Others, however, questioned this

approach. When Charles Fritts built the first selenium photovoltaic module in the 1880s and boldly predicted that it would soon compete with Thomas Edison's generators, he envisioned "each building to have its own power plant." Since the late 1980s, most in the photovoltaic business have come around to Fritts's view. Instead of having to buy a huge amount of land—unthinkable in densely populated Europe and Japan—to place a field of panels, many began to ask why not turn each building into its own power station. Using photovoltaics as building material allows it to double as windows, roofing, skylights, facades, or any type of covering needed on a home or building, and it makes sense since the owner gets both building material and electrical generator in one package. Having the electrical production sited where the electricity will be used offers many advantages: Producing electricity on site eliminates the electricity lost in long-distance transmission, which ranges from approximately 30% in the best maintained lines to approximately 65% in rundown lines prevalent in the developing world; it reduces the danger of power lines being overloaded as demand increases by rerouting additional electricity directly to the users; and occasionally, such as on a hot August afternoon, when peak electrical demand empties the wires, excess electricity produced by photovoltaic-equipped homes and buildings can refill the lines with much needed electricity to prevent brownouts and blackouts.

4.6 The Future of Photovoltaics

Although the photovoltaics industry has experienced a phenomenal 20% annual growth rate during the past decade, it has just started to realize its potential. Although more than 1 million people in the developing world get their electricity from solar cells, more than 1 billion still have no electrical service. The continuing revolution in telecommunications is bringing a greater emphasis on the use of photovoltaics. As with electrical service, the expense of stringing telephone wires keeps most of the developing world without communication services that people in more developed countries take for granted. Photovoltaic-run satellites and cellular sites, or a combination of the two, offer the only hope to bridge the digital divide. Photovoltaics could allow everyone the freedom to dial up at or near home and, of course, hook up to the Internet.

Opportunities for photovoltaics in the developed world also continue to increase. In the United States and Western Europe, hundreds of thousands of permanent or vacation homes are too distant for utility electric service. If people live more that 250 yards from a utility pole, paying the utility to string wires to their houses cost more than supplying their power needs with photovoltaics. Fourteen thousand Swiss Alpine chalets receive electricity from solar electricity, as do tens of thousands of others from Finland to Spain to Colorado.

Many campgrounds now prohibit RV owners from running their engines to power generators for appliances inside. The exhaust gases pollute, and the noise irritates other campers, especially at night. Photovoltaic panels mounted on the roofs of RVs provide the electricity needed without bothering others.

Restricting carbon dioxide emissions to help moderate global warming could result in the flow of large amounts of money from projects in which fossil fuels are burned to photovoltaic projects. The damage wrought by the 1997–1998 El Nino is an indication of the harsher weather expected as the earth warms. The anticipated increase in natural disasters brought on by a more disastrous future climate, as well as the growing number of people living in catastrophic-prone regions, makes early warning systems essential. The ultimate early warning device may consist of pilotless photovoltaic-powered weather surveillance airplanes, of which the *Helios* serves as a prototype. The *Helios* has flown higher than any other aircraft. Solar cells make up the entire top of the aircraft, which is merely a flying wing. Successors to the *Helios* will also have fuel cells on the underside of the wing. They will get their power from the photovoltaic panels throughout the day, extracting hydrogen and oxygen from the water discharged by the fuel cells the night before. When the sun sets, the hydrogen and oxygen will power the fuel cells, generating enough electricity at night to run the aircraft. Water discharged in the process will allow the diurnal cycle to begin the next morning. The tandem use of solar cells and fuel cells will allow the aircraft to stay aloft forever, far above the turbulence, watching for and tracking hurricanes and other potentially dangerous weather and other natural catastrophes.

Revolutionary lighting elements, called light-emitting diodes (LEDs), produce the same quality of illumination as their predecessor with only a fraction of the energy. LEDs therefore significantly reduce the amount of panels and batteries necessary for running lights, making photovoltaic systems less costly and less cumbersome. They have enabled

photovoltaics to replace gasoline generators in mobile warning signs used on roadways that alert motorists of lane closures and other temporary problems that drivers should know about. The eventual replacement of household lighting by LEDs will do the same for photovoltaics in homes.

When Bell Laboratories first unveiled the silicon solar cell, their publicist made a bold prediction: "The ability of transistors to operate on very low power gives solar cells great potential and it seems inevitable that the two Bell inventions will be closely linked in many important future developments that will influence the art of living." Already, the tandem use of transistors and solar cells for running satellites, navigation aids, microwave repeaters, televisions, radios, and cassette players in the developing world and a myriad of other devices has fulfilled the Bell prediction. It takes no great leap of imagination to expect the transistor/solar cell revolution to continue until it encompasses every electrical need from space to earth.

4. Outlook

Glossary

aperture Opening of a solar cavity receiver.
Carnot efficiency Maximum efficiency for converting heat from a high-temperature thermal reservoir at T_H into work in a cyclic process and rejecting heat to a low-temperature thermal reservoir at T_L, given by $1-T_L/T_H$.
exergy efficiency (for a solar thermochemical process) The efficiency for converting solar energy into chemical energy, given by the ratio of the maximum work that may be extracted from a solar fuel to the solar energy input for producing such a fuel.
solar cavity-receiver A well-insulated enclosure, with a small opening to let in concentrated solar energy, that approaches a black-body absorber in its ability to capture solar energy.
solar concentration ratio Nondimensional ratio of the solar flux intensity (e.g., in "suns") achieved after concentration to the incident normal beam insolation.
solar thermochemical process Any endothermic process that uses concentrated solar energy as the source of high-temperature process heat.

This article develops the underlying science of solar thermochemical processes and describes their applications for delivering clean fuels and material commodities. The thermodynamics of solar thermochemical conversion are examined, the most promising solar thermochemical processes are discussed, examples of solar chemical reactors are presented, and the latest technological developments are summarized.

1. INTRODUCTION

Using only 0.1% of the earth's land space with solar collectors that operate with a collection efficiency of merely 20%, one could gather more than enough energy to supply the current yearly energy needs of all inhabitants of the planet ($\sim 1.2 \times 10^{14}$ kWh). Furthermore, the solar energy reserve is essentially unlimited, and its use is ecologically benign. However, solar radiation is dilute (only $\sim 1\,\mathrm{kW/m^2}$), intermittent (available only during daytime and under clear-sky conditions), and unequally distributed (mostly by the equator). These drawbacks can be overcome by converting solar energy into chemical energy carriers—solar fuels—that can be stored long term and transported long range, from the sunny and desert regions to the industrialized and populated centers of the earth, where much of the energy is needed. Solar fuels can be burned to generate heat, further processed into electrical or mechanical work, or used directly to generate electricity in fuel cells and batteries to meet customers' energy demands. Solar process heat can also assist in the processing and recycling of energy-intensive materials, thereby avoiding greenhouse gas emissions and other pollutants derived from the combustion of fossil fuels for heat and electricity generation.

There are basically three pathways for making solar fuels from solar energy:

- *Solar electrochemical path:* solar-made electricity, from photovoltaic or solar thermal systems, followed by an electrolytic process
- *Solar photochemical path:* direct use of the photon energy
- *Solar thermochemical path:* solar-made heat followed by a thermochemical process

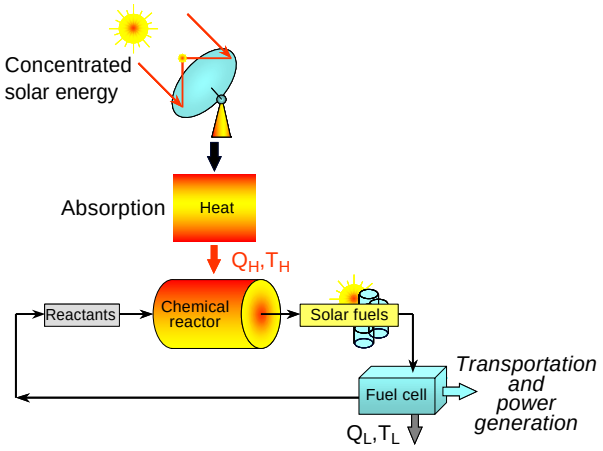

FIGURE 1 Schematic of solar energy conversion into solar fuels. Concentrated solar radiation is used as the energy source for high-temperature process heat to drive endothermic chemical reactions toward the production of storable and transportable fuels.

Combinations of these three pathways are possible, but the thermochemical path offers some intriguing thermodynamic advantages. It is this approach that is the subject of this article, whereas the other two paths are beyond the scope of the article.

Figure 1 illustrates the basic idea of the solar thermochemical path. By concentrating the diluted sunlight over a small area with help of parabolic mirrors and then capturing the radiant energy with help of suitable receivers and reactors, we can obtain heat at high temperatures for carrying out an endothermic chemical transformation and producing storable and transportable fuels. These solar fuels ultimately store solar energy within their chemical bonds. Regardless of the fuel, the higher the temperature of the reaction process, the higher the efficiency of energy conversion. However, higher temperatures also lead to greater losses by reradiation from the solar receiver. The thermodynamic implications of such phenomena are examined in the following section.

2. THERMODYNAMICS OF SOLAR THERMOCHEMICAL CONVERSION

The state-of-the-art technology for large-scale collection and concentration of solar energy is based on three main optical configurations using parabolic-shaped mirrors. These are the trough, tower, and dish systems shown schematically in Fig. 2. Trough

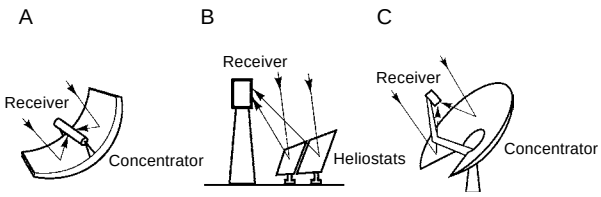

FIGURE 2 Schematic of the three main optical configurations for large-scale collection and concentration of solar energy: (A) the trough system, (B) the tower system, and (C) the dish system.

systems use linear, two-dimensional, parabolic mirrors to focus sunlight onto a solar tubular receiver positioned along their focal line. Tower systems use a field of heliostats (two-axis tracking parabolic mirrors) that focus the sunrays onto a solar receiver mounted on top of a centrally located tower. Dish systems use paraboloidal mirrors to focus sunlight on a solar receiver positioned at their focus. A recently developed Cassegrain optical configuration for the tower system makes use of a hyperboloidal reflector at the top of the tower to redirect sunlight to a receiver located on the ground level. Solar furnaces are concentrating facilities in which high-flux solar intensities are usually obtained at a fixed location inside a housed laboratory. The traditional design consists of using a sun-tracking, flat heliostat on-axis with a stationary primary paraboloidal concentrator; off-axis configurations have also been designed.

The capability of these collection systems to concentrate solar energy is often expressed in terms of their mean flux concentration ratio $\tilde{C}$ over a targeted area A at the focal plane, normalized with respect to the incident normal beam insolation I as follows:

$$\tilde{C} = \frac{Q_{solar}}{I \cdot A}, \tag{1}$$

where Q_{solar} is the solar power input into the target. $\tilde{C}$ is often expressed in units of "suns" when normalized to $1\,kW/m^2$. The solar flux concentration ratio typically obtained at the focal plane varies between 30 and 100 suns for trough systems, between 500 and 5,000 suns for tower systems, and between 1,000 and 10,000 suns for dish systems. Higher concentration ratios imply lower heat losses from smaller receivers and, consequently, higher attainable temperatures at the receiver. To some extent, the flux concentration can be further augmented with the help of a nonimaging secondary concentrator (e.g., a compound parabolic concentrator [CPC]) that is positioned in tandem with the primary concentrating system. The aforementioned

solar concentrating systems have proved to be technically feasible in large-scale experimental demonstrations aimed mainly at the production of solar thermal electricity in which a working fluid (typically air, water, helium, sodium, or molten salt) is solar heated and further used in traditional Rankine, Brayton, and Stirling cycles. Solar thermochemical applications, although not developed to the extent that solar thermal electricity generation has been, employ the same solar concentrating technology.

Solar chemical reactors for highly concentrated solar systems usually feature the use of a cavity receiver-type configuration, that is, a well-insulated enclosure with a small opening (the aperture) to let in concentrated solar radiation. Because of multiple internal reflections, the fraction of the incoming energy absorbed by the cavity greatly exceeds the simple surface absorptance of the inner walls. The larger the ratio of the cavity's characteristic length to the aperture diameter, the closer the cavity receiver approaches a black-body absorber. Smaller apertures also serve to reduce reradiation losses. However, they intercept a reduced fraction of the sunlight reflected from the concentrators. Consequently, the optimum aperture size is a compromise between maximizing radiation capture and minimizing radiation losses.

The solar energy absorption efficiency of a solar reactor, $\eta_{absorption}$, is defined as the net rate at which energy is being absorbed divided by the solar power coming from the concentrator. At temperatures above approximately 1000 K, the net power absorbed is diminished mostly by radiant losses through the aperture. For a perfectly insulated black-body cavity receiver, it is given by

$$\eta_{absorption} = 1 - \left(\frac{\sigma T^4}{I\tilde{C}}\right), \tag{2}$$

where T is the nominal cavity-receiver temperature and σ is the Stefan–Boltzmann constant. The absorbed concentrated solar radiation drives an endothermic chemical reaction. The measure of how well solar energy is converted into chemical energy for a given process is the exergy efficiency, defined as

$$\eta_{exergy} = \frac{-\dot{n}\Delta G|_{298\ K}}{Q_{solar}}, \tag{3}$$

where Q_{solar} is the solar power input, $\dot{n}$ is the products' molar flow rate, and ΔG is the maximum possible amount of work (Gibbs free energy change) that may be extracted from the products as they are transformed back to reactants at 298 K. The second law of thermodynamics is now applied to calculate the theoretical maximum exergy efficiency $\eta_{exergy,ideal}$. Because the conversion of solar process heat to chemical energy is limited by both the solar absorption efficiency and the Carnot efficiency, the maximum ideal exergy efficiency is given by

$$\eta_{exergy,ideal} = \eta_{absorption} \cdot \eta_{Carnot} = \left[1 - \left(\frac{\sigma T_H^4}{I\tilde{C}}\right)\right] \times \left[1 - \left(\frac{T_L}{T_H}\right)\right], \tag{4}$$

where T_H and T_L are the upper and lower operating temperatures of the equivalent Carnot heat engine. $\eta_{exergy,ideal}$ is plotted in Fig. 3 as a function of T_H for $T_L = 298$ K and for various solar flux concentration ratios. Because of the Carnot limit, one should try to operate thermochemical processes at the highest upper temperature possible; however, from a heat transfer perspective, the higher the temperature, the higher the reradiation losses. The highest temperature an ideal solar cavity receiver is capable of achieving, defined as the stagnation temperature $T_{stagnation}$, is calculated by setting $\eta_{exergy,ideal}$ equal to zero, yielding

$$T_{stagnation} = \left(\frac{I\tilde{C}}{\sigma}\right)^{0.25}. \tag{5}$$

At this temperature, energy is being reradiated as fast as it is absorbed. Stagnation temperatures exceeding 3000 K are attainable with solar concentration ratios above 5000 suns. However, an energy-efficient

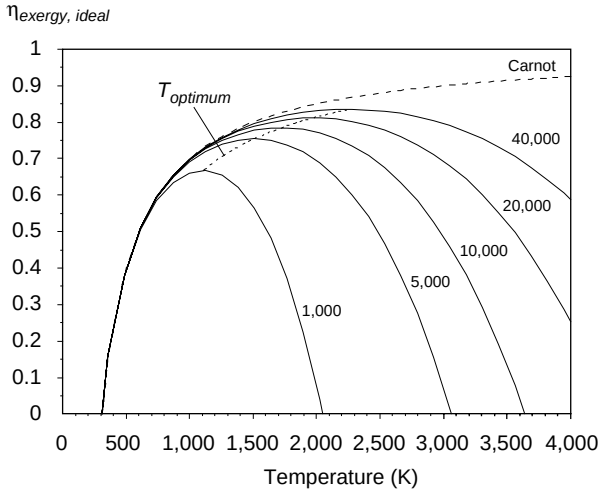

FIGURE 3 Variation of the ideal exergy efficiency $\eta_{exergy,ideal}$ as a function of the operating temperature T_H for a black-body cavity receiver converting concentrated solar energy into chemical energy. The mean solar flux concentration is the parameter: 1,000 … 40,000. Also plotted are the Carnot efficiency and the locus of the optimum cavity temperature $T_{optimum}$.

process must run at temperatures that are substantially below $T_{stagnation}$. There is an optimum temperature $T_{optimum}$ for maximum efficiency obtained by setting

$$\frac{\partial \eta_{exergy,ideal}}{\partial T} = 0. \quad (6)$$

Assuming a uniform power flux distribution, this relation yields the following implicit equation for $T_{optimum}$:

$$T_{optimum}^5 - \frac{3}{4} T_L T_{optimum}^4 - \frac{T_L I\tilde{C}}{4\sigma} = 0. \quad (7)$$

The locus of $T_{optimum}$ is shown in Fig. 3. For example, for a solar concentration ratio of 5000, the optimum temperature of a solar receiver is 1500 K, giving a maximum theoretical efficiency of 75%, that is, the portion of solar energy that could in principle be converted into the chemical energy of fuels. In practice, when considering convection and conduction losses in addition to reradiation losses, the efficiency will peak at a somewhat lower temperature.

The process modeling described in the following paragraphs establishes a base for evaluating and comparing different solar thermochemical processes in terms of their ideal exergy efficiencies. Figure 4 depicts a flow diagram of an ideal cyclic process that leads to a fuel, which uses a solar reactor, a quenching device, and a fuel cell. The complete process is carried out at constant pressure. In practice, pressure drops will occur throughout the system. However, if one assumes frictionless operating conditions, no pumping work is required. The reactants may be preheated in an adiabatic heat exchanger, where some portion of the sensible and latent heat of the products is transferred to the reactants; for simplicity, a heat exchanger has been omitted. The reactor is assumed to be a perfect blackbody cavity receiver. The reactants enter the solar reactor at T_L and are further heated to the reaction temperature T_H. Chemical equilibrium is assumed inside the reactor. The net power absorbed in the solar reactor should match the enthalpy change per unit time of the reaction,

$$Q_{reactor,net} = \dot{n}\Delta H \mid_{\text{Reactants@}T_L \rightarrow \text{Products@}T_H}. \quad (8)$$

Irreversibility in the solar reactor arises from the nonreversible chemical transformation and reradiation losses $Q_{reradiation}$ to the surroundings at T_L. It is found that

$$Irr_{reactor} = \left(\frac{-Q_{solar}}{T_H}\right) + \left(\frac{Q_{reradiation}}{T_L}\right) + \left(\dot{n}\Delta S|_{\text{Reactants@}T_L \rightarrow \text{Products@}T_H}\right). \quad (9)$$

Products exit the solar reactor at T_H and are cooled rapidly to T_L. The amount of power lost during quenching is

$$Q_{quench} = -\dot{n}\Delta H \mid_{\text{Products@}T_H \rightarrow \text{Products@}T_L} \quad (10)$$

The irreversibility associated with quenching is

$$Irr_{quench} = \left(\frac{Q_{quench}}{T_L}\right) + \left(\dot{n}\Delta S|_{Products@T_H \rightarrow Products@T_L}\right). \quad (11)$$

Introducing a reversible ideal fuel cell, in which the products recombine to form the original reactants and thereby generate electrical power, closes the cycle. The maximum amount of work that the products leaving the reactor could produce if they combined at T_L and a total pressure of 1 bar is given by

$$W_{F.C.} = -\dot{n}\Delta G|_{Products@T_L \rightarrow Reactants@T_L}. \quad (12)$$

This work value is also known as the exergy of the products at ambient temperature. The fuel cell operates isothermally; the amount of heat rejected to the surroundings is

$$Q_{F.C.} = -T_L \cdot \dot{n}\Delta S|_{Products@\,T_L \rightarrow Reactants@T_L}. \quad (13)$$

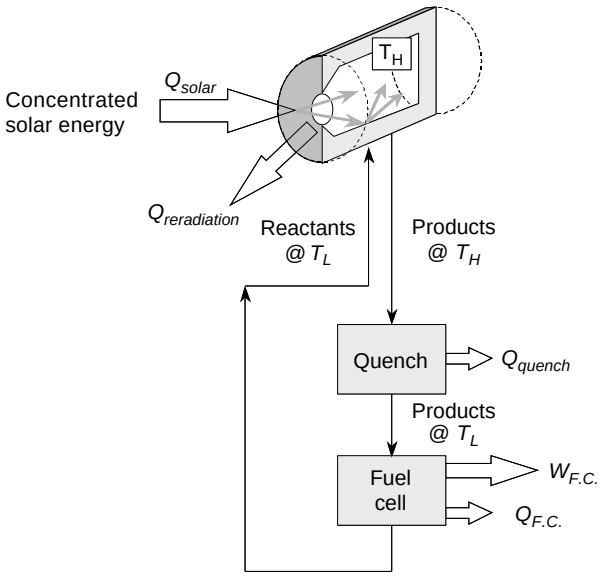

FIGURE 4 Model flow diagram of an ideal cyclic process for calculating the maximum exergy efficiency of a solar thermochemical process.

The exergy system efficiency of the closed cycle is then calculated using Eq. (3) as

$$\eta_{exergy} = \frac{W_{F.C.}}{Q_{solar}}. \quad (14)$$

This thermodynamic analysis can be verified by performing an energy balance and by evaluating the maximum achievable efficiency (Carnot efficiency) from the total available work and from the total power input. The energy balance should satisfy

$$W_{F.C.} = Q_{solar} - \left(Q_{reradiation} + Q_{quench} + Q_{F.C.}\right). \quad (15)$$

The available work is calculated as the sum of the fuel cell work plus the lost work due to the irreversibility associated with the solar reactor and with quenching. Thus,

$$\eta_{max} = \frac{W_{F.C.} + T_L \cdot \left(Irr_{reactor} + Irr_{quench}\right)}{Q_{solar}} = 1 - \frac{T_L}{T_H} = \eta_{Carnot}. \quad (16)$$

Any solar thermochemical processes can be thought of in this manner, and their exergy efficiencies can be compared as one criterion for judging their relative industrial potentials. The higher the exergy efficiency, the lower the required solar collection area for producing a given amount of solar fuel and, consequently, the lower the costs incurred for the solar concentrating system, which usually correspond to half of the total investments for the entire solar chemical plant. Thus, high-exergy efficiency implies favorable competitiveness.

3. SOLAR THERMOCHEMICAL PROCESSES

3.1 Solar Production of Fuels

3.1.1 Solar Hydrogen

Five thermochemical routes for solar hydrogen production are depicted in Fig. 5. Indicated is the chemical source of H_2:water for the solar thermolysis and solar thermochemical cycles, fossil fuels for the solar cracking, and a combination of fossil fuels and H_2O for the solar reforming and solar gasification. All of these routes make use of concentrated solar radiation as the energy source of high-temperature process heat.

3.1.1.1 H_2 from H_2O Although the single-step thermal dissociation of water, known as water thermolysis, is conceptually simple, it has been

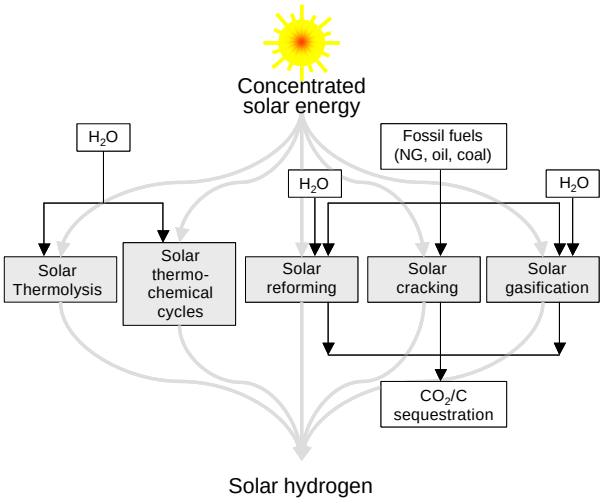

FIGURE 5 Five thermochemical routes for the production of solar hydrogen.

impeded by the need for a high-temperature heat source at above 2500 K to achieve a reasonable degree of dissociation and by the need for an effective technique to separate H_2 and O_2 to avoid recombination or ending up with an explosive mixture. Among the ideas proposed for separating H_2 from the products are effusion and electrolytic separation. Water-splitting thermochemical cycles bypass the H_2/O_2 separation problem and further allow operating at relatively moderate upper temperatures. Previous studies performed on H_2O-splitting thermochemical cycles were characterized mostly by the use of process heat at temperatures below approximately 1300 K, available from nuclear and other thermal sources. These cycles required multiple (more than two) steps and were suffering from inherent inefficiencies associated with heat transfer and product separation at each step. During recent years, significant progress has been made in the development of optical systems for large-scale collection and concentration of solar energy capable of achieving solar concentration ratios of 5000 suns or higher. Such high-radiation fluxes allow the conversion of solar energy to thermal reservoirs at 2000 K and above that are needed for the two-step thermochemical cycles using metal oxide redox reactions:

$$\text{First step (solar):} \quad M_xO_y \rightarrow xM + \frac{y}{2}O_2 \quad (17)$$

$$\text{Second step (nonsolar):} \quad xM + yH_2O \rightarrow M_xO_y + yH_2 \quad (18)$$

Here, M denotes a metal and M_xO_y denotes the corresponding metal oxide. The cycle is represented

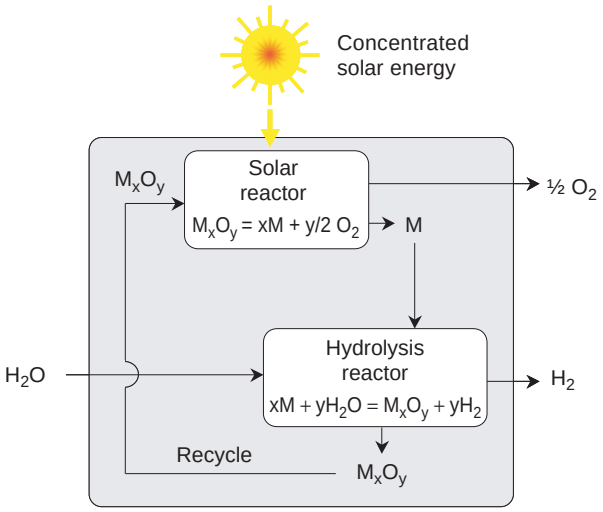

FIGURE 6 Representation of a two-step water-splitting thermochemical cycle using metal oxide redox reactions.

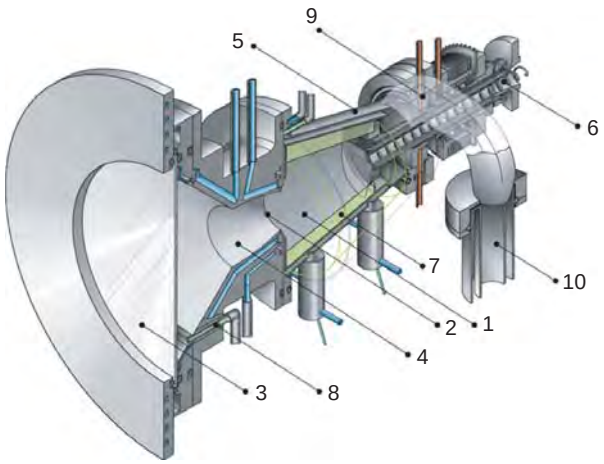

FIGURE 7 Schematic of a "rotating-cavity" solar chemical reactor for the thermal dissociation of ZnO to Zn and O_2 at 2300 K. It consists of a rotating conical cavity receiver (1) that contains an aperture (2) for access of concentrated solar radiation through a quartz window (3). The solar flux concentration is further augmented by incorporating a CPC (4) in front of the aperture. Both the window mount and the CPC are water cooled and integrated into a concentric (nonrotating) conical shell (5). ZnO particles are fed continuously by means of a screw powder feeder located at the rear of the reactor (6). The centripetal acceleration forces the ZnO powder to the wall, where it forms a thick layer of ZnO (7) that insulates and reduces the thermal load on the inner cavity walls. A purge gas flow enters the cavity receiver tangentially at the front (8) and keeps the window cool and clear of particles or condensable gases. The gaseous products Zn and O_2 exit continuously via an outlet port (9) to a quench device (10). Source: Paul Scherrer Institute, Villigen, Switzerland.

in Fig. 6. The first endothermic step is the solar thermal dissociation of the metal oxide to the metal or the lower valence metal oxide. The second, nonsolar exothermic step is the hydrolysis of the metal to form H_2 and the corresponding metal oxide. The net reaction is $H_2O = H_2 + 0.5O_2$, but because H_2 and O_2 are formed in different steps, the need for high-temperature gas separation is thereby eliminated. The most favorable candidate metal oxide redox pairs for this cycle are ZnO/Zn and Fe_3O_4/FeO. In both cases, the minimum temperature requirement for the solar step is 2300 K, and the products need to be either quenched or separated at high temperatures to prevent their recombination. Quenching introduces irreversibility and may be a factor of complexity in large-scale use.

Figure 7 shows a solar chemical reactor concept for performing the thermal dissociation of ZnO that features a windowed rotating cavity receiver lined with ZnO particles that are held by centrifugal force. With this arrangement, ZnO is directly exposed to high-flux solar irradiation and serves the functions of radiant absorber, thermal insulator, and chemical reactant simultaneously. The shell of the cavity is made from conventional steel materials and is lined with the same material as are the reactants themselves. This aspect of the design eliminates the need for using expensive and difficult-to-fabricate ceramic insulating materials for ultra-high temperatures. It also offers excellent resistance to thermal shocks that are intrinsic in short start-up solar applications. The direct absorption of concentrated solar energy by directly irradiated reactants provides efficient radiation heat transfer to the reaction site where the energy is needed, bypassing the limitations imposed by indirect heat transport via heat exchangers.

We illustrate the application of the Second-Law (exergy) analysis, Eqs. (1) to (16), for calculating the theoretical maximum exergy efficiency of the two-step water-splitting solar thermochemical cycle based on the ZnO/Zn redox reaction. Figure 8 depicts the ideal cyclic process. The solar reactor is assumed to be a cavity-receiver operating at 2300 K. The reactant ZnO(s) enters the solar reactor at 298 K and is further heated to the reaction temperature at 2300 K. The molar feed rate of ZnO to the solar reactor, $\dot{n}$, is set to 1 mol/s and is equal to that of H_2O fed to the hydrolyser reactor. After quenching, the products separate naturally (without expending work) into gaseous O_2 and condensed phase Zn. Zinc is sent to the hydrolyser reactor to react exothermally with water and form hydrogen, according to Eq. (18). The heat liberated is assumed

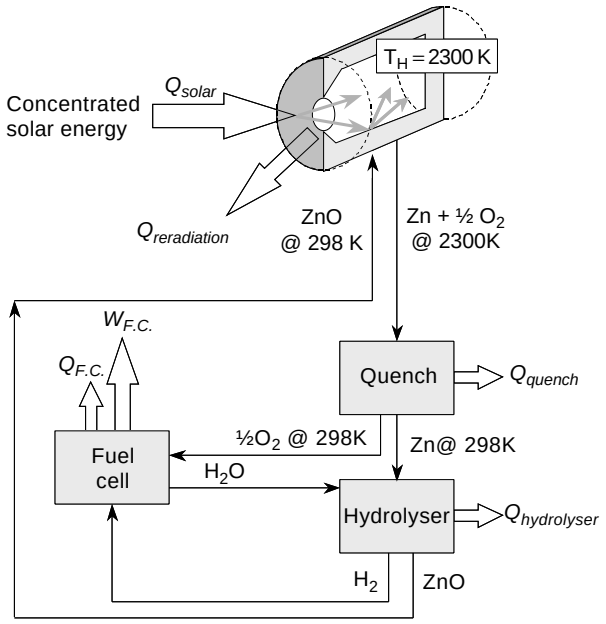

FIGURE 8 Model flow diagram of the two-step water-splitting solar thermochemical cycle used for the exergy analysis.

lost to the surroundings, as given by

$$Q_{hydrolyser} = -\dot{n}\Delta H|_{Zn+H_2O@298\ K \rightarrow ZnO+H_2@298\ K}. \quad (19)$$

Thus, the irreversibility associated with the hydrolyser is

$$Irr_{hydrolyser} = \left(\frac{Q_{hydrolyser}}{298\ K}\right) + \left(\dot{n}\Delta S|_{\ Zn+H_2O@298\ K \rightarrow ZnO+H_2@298\ K}\right). \quad (20)$$

Introducing an H_2/O_2 fuel cell, in which the products recombine to form H_2O and thereby generate electrical power, closes the cycle. $W_{F.C.}$ and $Q_{F.C.}$ are the work output and the heat rejected, respectively, given by

$$W_{F.C.} = -\eta_{F.C.}\dot{n}\Delta G|_{H_2+0.5O_2@298\ K \rightarrow H_2O@298\ K} \quad (21)$$

$$Q_{F.C.} = -T_L\ \dot{n}\Delta S|_{H_2+0.5O_2@298\ K \rightarrow H_2O@298\ K}, \quad (22)$$

where $\eta_{F.C.}$ is the efficiency of the H_2/O_2 fuel cell, assumed to be 100% when based on the maximum work output of H_2 (also known as its exergy). Finally, the exergy efficiency is calculated using Eq. (14). Table I gives the results of the calculation for two values of the solar concentration ratio: 5,000 and 10,000.

TABLE I

Exergy Analysis of the Two-Step Water-Splitting Solar Thermochemical Cycle Using the Process Modeling Depicted in Fig. 8

$\tilde{C}$	5,000	10,000
Q_{solar}	815 kW	662 kW
$Q_{reradiation}$	258 kW	105 kW
$Q_{reactor,net}$	557 kW	
$Irr_{reactor}$	0.81 kW · K^{-1}	
Q_{quench}	209 kW	
Irr_{quench}	0.52 kW · K^{-1}	
$Q_{hydrolyser}$	64 kW	
$Irr_{hydrolyser}$	0.27 kW · K^{-1}	
$Q_{F.C.}$	49 kW	
$W_{F.C.}$	237 kW	
$\eta_{absorption}$	68%	84%
η_{exergy} (without heat recovery)	29%	36%
η_{exergy} (with heat recovery)	69%	84%

Note. The ZnO and H_2O molar rates are set to 1 mol/s.

3.1.1.2 H_2 from Fossil Fuels Three solar thermochemical processes for H_2 production using fossil fuels as the chemical source are considered: cracking, reforming, and gasification. These routes are shown schematically in Fig. 9.

The solar cracking route refers to the thermal decomposition of natural gas (NG), oil, and other hydrocarbons and can be represented by the simplified net reaction:

$$C_xH_y = xC(gr) + \frac{y}{2}H_2. \quad (23)$$

Other compounds may also be formed, depending on the reaction kinetics and on the presence of impurities in the raw materials. The thermal decomposition yields a carbon-rich condensed phase and a hydrogen-rich gas phase. The carbonaceous solid product can either be sequestered without CO_2 release or be used as a material commodity under less severe CO_2 restraints. It can also be applied as a reducing agent in metallurgical processes. The hydrogen-rich gas mixture can be further processed to high-purity hydrogen that is not contaminated with oxides of carbon and, thus, can be used in proton exchange membrane (PEM) fuel cells without inhibiting platinum-made electrodes. From the point of view of carbon sequestration, it is easier to separate, handle, transport, and store solid carbon than gaseous CO_2. Furthermore, while the steam-reforming/gasification method requires additional steps for shifting CO and for separating CO_2, the thermal cracking accomplishes the removal and separation of carbon in a single step. In contrast,

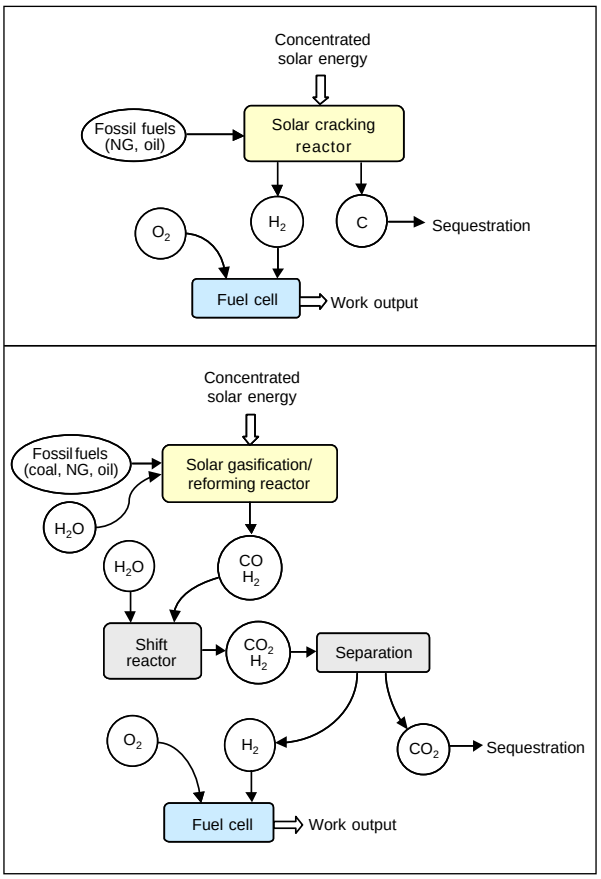

FIGURE 9 Schematic of solar thermochemical routes for H_2 production using fossil fuels and H_2O as the chemical source: solar cracking (upper box) and solar reforming and gasification (lower box).

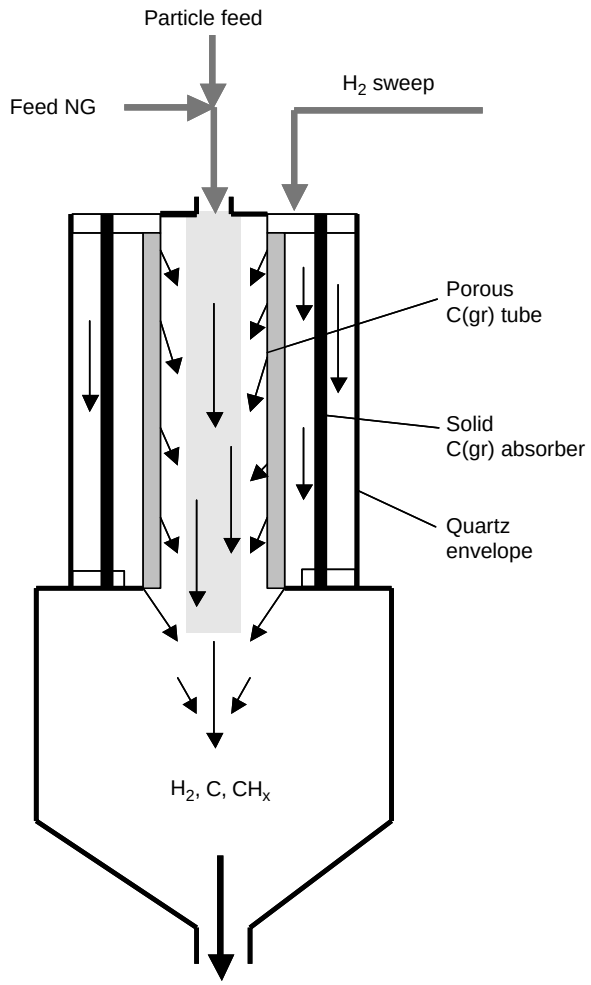

FIGURE 10 Scheme of an "aerosol" solar reactor for cracking NG. Source: National Renewable Energy Laboratory, Golden, CO.

the major drawback of the thermal decomposition method is the energy loss associated with the sequestration of carbon. Thus, the solar cracking may be the preferred option for NG and other hydrocarbons with high H_2/carbon ratios. The exergy efficiency for these routes is defined as the ratio of the work output by the fuel cell to the total thermal energy input by both the solar energy and the heating value of the reactants:

$$\eta_{exergy} = \frac{W_{F.C.}}{Q_{solar} + HHV_{reactant}}. \qquad (24)$$

where $HHV_{reactant}$ is the high heating value of the fossil fuel being processed (e.g., $\sim 890\,\mathrm{kJ \cdot mol^{-1}}$ for NG). Assuming a 65% efficient H_2/O_2 fuel cell, $\eta_{exergy} = 30\%$. This route offers zero CO_2 emissions as a result of carbon sequestration. However, the energy penalty for completely avoiding CO_2 reaches 30% of the electrical output vis-à-vis the direct use of NG for fueling a 55% efficient combined Brayton–Rankine cycle. Figure 10 shows an "aerosol" solar reactor concept for cracking NG that features two concentric graphite tubular reactors, with the outer solid tube serving as the solar absorber and the inner porous tube containing a flow of NG laden with carbon nanoparticles that serve the functions of radiant absorbers.

The steam reforming of NG, oil, and other hydrocarbons, as well as the steam gasification of coal and other carbonaceous materials, can be represented by the simplified net reaction:

$$C_xH_y + xH_2O = \left(\frac{y}{2} + x\right)H_2 + xCO. \qquad (25)$$

Other compounds may also be formed, especially with coal, but some impurities contained in the raw materials are cleaned out prior to the decarbonization process. The principal product is high-quality synthesis gas (syngas), the building block for a wide

variety of synthetic fuels, including Fischer–Tropsch-type chemicals, hydrogen, ammonia, and methanol. Its quality is determined mainly by the H_2/CO and CO_2/CO molar ratios. For example, the solar steam gasification of anthracite coal at above 1500 K yields syngas with an H_2/CO molar ratio of 1.2 and a CO_2/CO molar ratio of 0.01. The CO content in the syngas can be shifted to H_2 via the catalytic water–gas shift reaction ($CO + H_2O = H_2 + CO_2$), and the product CO_2 can be separated from H_2 using, for example, the pressure swing adsorption technique. The exergy efficiency for this route is defined by Eq. (24). Assuming a 65% efficient H_2/O_2 fuel cell and $HHV_{reactant}$ of 35,700 kJ kg^{-1} for anthracite coal, $\eta_{exergy} = 46\%$. This route offers a net gain in the electrical output by a factor varying in the range of 1.7 to 1.8 (depending on the coal type) vis-à-vis the direct use of coal for fueling a 35% efficient Rankine cycle. If CO_2 is not sequestered, specific CO_2 emissions amount to 0.53 to 0.56 kg CO_2/kWh$_e$, approximately half as much as the specific CO_2 emissions discharged by conventional coal-fired power plants.

Some of these processes are practiced at an industrial scale, with the process heat supplied by burning a significant portion of the feedstock. Internal combustion results in the contamination of the gaseous products, whereas external combustion results in a lower thermal efficiency due to the irreversibility associated with indirect heat transfer. Alternatively, using solar energy for process heat offers a threefold advantage: (1) the discharge of pollutants is avoided, (2) the gaseous products are not contaminated, and (3) the calorific value of the fuel is upgraded by adding solar energy in an amount equal to the ΔH of the reaction.

The solar reforming of NG has been studied extensively in solar furnaces with small-scale solar reactor prototypes using Rh-based catalyst. Recently, this solar process has been scaled up to power levels of 300 to 500 kW in a solar tower facility using two solar reactor concepts: indirect irradiation and direct irradiation.

Figure 11 shows a schematic of the indirect-irradiated solar reforming reactor. It consists of a pentagonal cavity receiver, insulated with ceramic fibers, containing a set of Inconel tubes arranged vertically in two banks parallel to the front-side walls. The tubes are filled with a packed bed of catalyst, usually 2% Rh on Al_2O_3 support. The tubular reactors are externally exposed to the concentrated solar radiation entering through the cavity aperture and transfer the absorbed heat to the chemical reactants. The aperture is windowless and tilted from the horizontal axis for an optimal view to the heliostat field. A matching CPC is implemented at the aperture for capturing radiation spillage, augmenting the average solar flux concentration, and providing uniform heating of the tubes. Indirect-irradiated reactors such as this one have the advantage of eliminating the need for a transparent window. The disadvantages are linked to the limitations imposed by the materials of construction of the reactor walls: limitations in the maximum operating temperature, thermal conductivity, radiant absorptance, inertness, resistance to thermal shocks, and suitability for transient operation.

Figure 12 shows a schematic of the direct-irradiated solar reforming reactor, also referred to

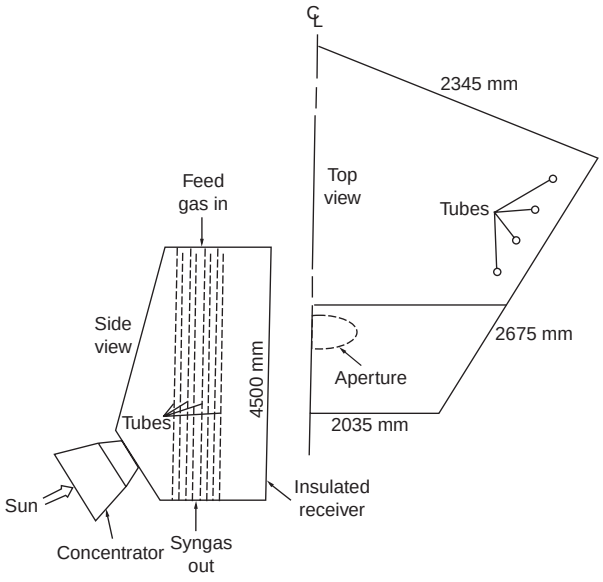

FIGURE 11 Scheme of an indirect-irradiated solar reforming chemical reactor. Source: Weizmann Institute of Science, Rehovot, Israel.

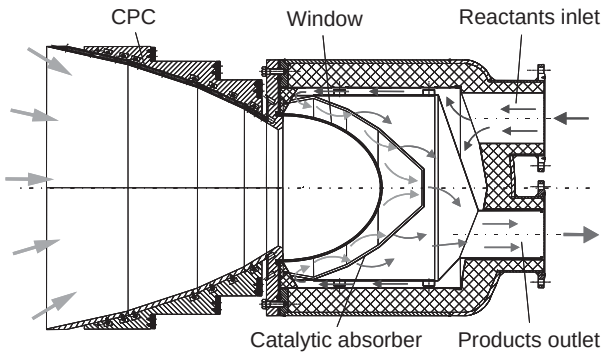

FIGURE 12 Scheme of a direct-irradiated solar reforming chemical reactor. Source: Deutsches Zentrum für Luft- und Raumfahrt, Germany.

as the volumetric reactor. The main component is the porous ceramic absorber, coated with Rh catalyst, that is directly exposed to the concentrated solar radiation. A concave quartz window, mounted at the aperture, minimizes reflection losses and permits operation at high pressures. Similar to the indirect-irradiated reactor, a CPC is implemented at the aperture. Direct-irradiated reactors such as this one have the advantage of providing efficient radiation heat transfer directly to the reaction. Furthermore, under proper conditions, direct irradiation may photochemically enhance the kinetics of the reaction. The major drawback, when working with reducing or inert atmospheres, is the requirement of a transparent window, which is a critical and troublesome component under high-pressure and severe gas environment.

The solar dry reforming of CH_4 (with CO_2) can be applied in a closed-loop chemical heat pipe (Fig. 13). The product of this reversible reaction is syngas that can be stored at ambient temperatures and transported to the site where the energy is needed. By the reverse exothermic reaction, stored solar energy is released in the form of high-temperature heat, which can be used, for example, for generating electricity via a Rankine cycle. The products of this reverse reaction are again recycled to the solar reactor, where the process is repeated. The dissociation/synthesis of NH_3 can also be applied in a chemical heat pipe for storage and transportation of solar energy.

An optional source of H_2 is H_2S, a highly toxic industrial product recovered in large quantities in the sweetening of NG and in the removal of organically

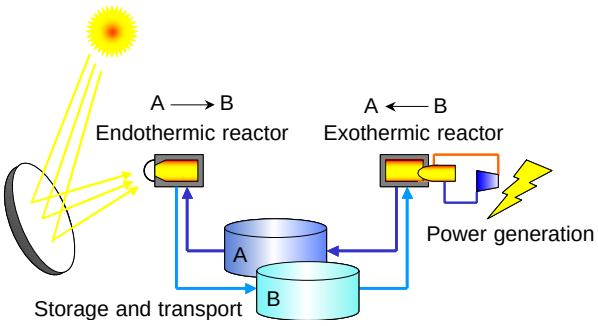

FIGURE 13 Solar chemical heat pipe for the storage and transportation of solar energy. High-temperature solar process heat is used to drive the endothermic reversible reaction $A \rightarrow B$. The product B may be stored long term and transported long range to the site where the energy is needed. At that site, the exothermic reverse reaction $B \rightarrow A$ is effected and yields high-temperature process heat in an amount equal to the stored solar energy $\Delta H_{A \rightarrow B}$. The chemical product A of the reverse reaction is returned to the solar reactor for reuse.

bound sulfur from petroleum and coal. Current industrial practice uses the Claus process to recover the sulfur from H_2S, but the process wastes H_2 to produce low-grade process heat. Alternatively, H_2S can be decomposed to H_2 and S_2 at 1800 K and 0.03 to 0.5 bar. The product gas mixture is quenched, and condensed S_2 is separated from H_2. In contrast to H_2O thermolysis, the quench is relatively easy and the reverse reaction between the products seems to be unimportant at temperatures as high as 1500 K.

3.1.2 Solar Metals

Metals are attractive candidates for storage and transport of solar energy. They may be used to generate either high-temperature heat via combustion or electricity via fuel cells and batteries. Metals can also be used to produce hydrogen from H_2O via hydrolysis, as shown in Eq. (18). The chemical products from any of these power/H_2-generating processes are metal oxides, which in turn need to be recycled. The conventional extraction of metals from their oxides by carbothermic and electrolytic processes is characterized by its high energy consumption and its concomitant environmental pollution. The extractive metallurgical industry discharges vast amounts of greenhouse gases and other pollutants to the environment, derived mainly from the combustion of fossil fuels for heat and electricity generation. These emissions can be reduced substantially, or even eliminated completely, by using concentrated solar energy as the source of high-temperature process heat.

The thermal dissociation and electrothermal reduction of metal oxides proceeds without reducing agents, while the carbothermal reduction of metal oxides uses solid carbon C(gr) or hydrocarbons (e.g., CH_4) as reducing agents. The corresponding overall chemical reactions may be represented as follows:

$$M_xO_y \rightarrow xM + \frac{y}{2}O_2 \qquad (26)$$

$$M_xO_y + yC(gr) \rightarrow xM + yCO \qquad (27)$$

$$M_xO_y + yCH_4 \rightarrow xM + y(2H_2 + CO). \qquad (28)$$

Table II lists the approximate temperatures at which the standard ΔG°_{rxn} for Reactions (26), (27), and (28) equals zero for various metal oxides of interest.

Except for the thermal dissociation of ZnO, the required temperature for effecting Reaction (26) exceeds 3000 K. At temperatures for which ΔG°_{rxn} is positive, solar process heat alone will not make the reaction proceed; some amount of high-quality energy is required in the form of work. It may be

TABLE II

Approximate Temperatures (K) for Which ΔG°_{rxn} of Reactions (26), (27), and (28) Equals Zero

Metal oxide	$\Delta G^{\circ}_{rxn\ 26} = 0$ @	$\Delta G^{\circ}_{rxn\ 27} = 0$ @	$\Delta G^{\circ}_{rxn\ 28} = 0$ @

CaO	>4000	2440	1970

[a] Fe_2O_3, TiO_2, and SiO_2 decompose to lower valence oxides before complete dissociation to the metal.

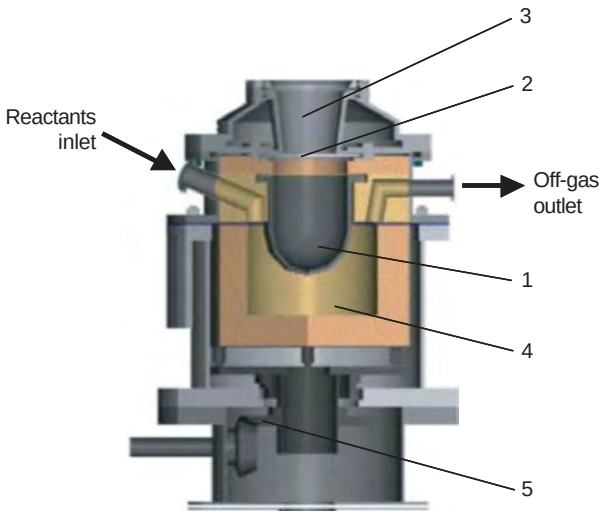

FIGURE 14 Schematic of a "two-cavity" solar chemical reactor concept for the carbothermal reduction of ZnO. It features two cavities in series, with the inner one functioning as the solar absorber and the outer one functioning as the reaction chamber. The inner cavity (1) is made of graphite and contains a windowed aperture (2) to let in concentrated solar radiation. A CPC (3) is implemented at the reactor's aperture. The outer cavity (4) is well insulated and contains the ZnO–carbon mixture that is subjected to irradiation by the graphite absorber separating the two cavities. With this arrangement, the inner cavity protects the window against particles and condensable gases coming from the reaction chamber. Uniform distribution of continuously fed reactants is achieved by rotating the outer cavity (5). The reactor is designed specifically for beam-down incident radiation, as obtained through a Cassegrain optical configuration that makes use of a hyperbolical reflector at the top of the tower to redirect sunlight to a receiver located on the ground level. Source: Paul Scherrer Institute, Villigen, Switzerland.

supplied in the form of electrical energy in electrolytic processes or in the form of chemical energy by introducing a reducing agent in thermochemical processes. An example of a solar electrothermal reduction process that has been demonstrated experimentally is the electrolysis of ZnO using an electrolytic cell housed in a solar cavity-receiver. At 1000 K, up to 30% of the total amount of energy required to produce Zn could be supplied by solar process heat. Other interesting candidates for solar high-temperature electrolysis are MgO and Al_2O_3.

If one wishes to decompose metal oxides thermally into their elements without the application of electrical work, a chemical reducing agent is necessary to lower the dissociation temperature. Coal (as coke) and NG (as methane) are preferred reducing agents in blast furnace processes due to their availability and relatively low price. In the presence of carbon, the uptake of oxygen by the formation of CO brings about a reduction of the oxides at much lower temperatures. Although Reactions (27) and (28) have favorable free energies above the temperatures indicated in Table II, a more detailed calculation of the chemical equilibrium composition shows that only the carbothermic reductions of Fe_2O_3, MgO, and ZnO will result in significant free metal formation. The carbides Al_3C_4, CaC_2, SiC, and TiC are thermodynamically stable in an inert atmosphere; the nitrides AlN, Si_3N_4, and TiN are stable in an N_2 atmosphere.

Using NG as a reducing agent, as indicated in Eq. (28), combines in a single process the reduction of metal oxides with the reforming of NG for the coproduction of metals and syngas. Thus, CH_4 is reformed in the absence of catalysts and, with proper optimizations, may be made to produce high-quality syngas with an H_2/CO molar ratio of 2, which is especially suitable for synthesizing methanol—a potential substitute for petrol. Thermal reductions of Fe_3O_4 and ZnO with C(gr) and CH_4 to produce Fe, Zn, and syngas have been demonstrated in solar furnaces using fluidized bed and vortex-type reactors. These reactions are highly endothermic and proceed to completion at temperatures above approximately 1300 K. Zinc production by solar carbothermic reduction of ZnO offers a CO_2 emission reduction by a factor of 5 vis-à-vis the conventional fossil fuel-based electrolytic or imperial smelting process. Furthermore, the use of solar energy for supplying the enthalpy of the reaction upgrades the calorific value of the initial reactants by 39%.

Two examples of solar chemical reactor concepts for producing Zn by Reactions (27) and (28) are shown in Figs. 14 and 15, respectively: the "two-cavity" solar reactor based on the indirect irradiation

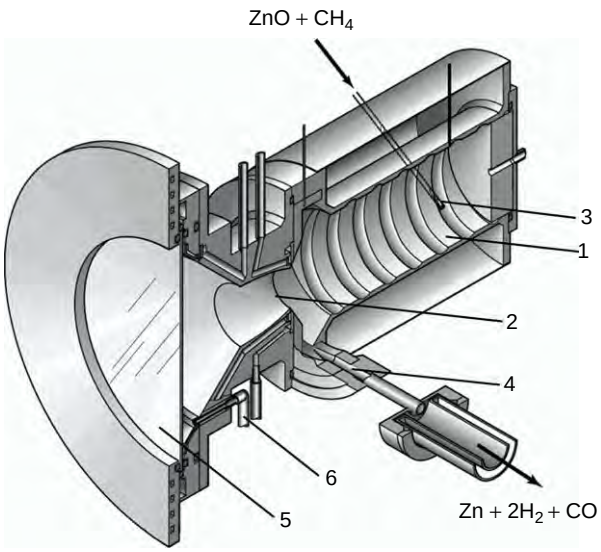

FIGURE 15 Schematic of a "vortex" solar chemical reactor concept for the combined ZnO reduction and CH_4 reforming. It consists of a cylindrical cavity (1) that contains a windowed aperture (2) to let in concentrated solar energy. Particles of ZnO, conveyed in a flow of NG, are continuously injected into the reactor's cavity via a tangential inlet port (3). Inside the reactor's cavity, the gas–particle stream forms a vortex flow that progresses toward the front following a helical path. The chemical products, Zn vapor and syngas, exit the cavity continuously via a tangential outlet port (4) located at the front of the cavity, behind the aperture. The window (5) is actively cooled and kept clear of particles by means of an auxiliary flow of gas (6) that is injected tangentially and radially at the window and aperture planes, respectively. Energy absorbed by the reactants is used to raise their temperature to above approximately 1300 K and to drive Reaction (28). Source: Paul Scherrer Institute, Villigen, Switzerland.

of ZnO + carbon and the "vortex" solar reactor based on the direct irradiation of ZnO + methane.

3.2 Solar Production of Material Commodities

3.2.1 Solar Metals, Metallic Oxides, Carbides, and Nitrides

The extractive metallurgical industry is a major consumer of process heat and electricity and is responsible for approximately 10% of global anthropogenic greenhouse gas emissions. A solar thermal process would drastically reduce these emissions. For example, solar processing of aluminum could reduce the CO_2 emissions per ton of aluminum from 44 to 5. The temperature required to reduce aluminum ores with carbon is in the range of 2400 to 2600 K, that is, at the upper limit for practical process heat addition from a combustion source alone. Preliminary tests performed in a concentrating solar facility suggest two feasible solar thermal routes. First, at approximately 2400 K, a mixture of Al_2O_3, SiO_2, and carbon results in an Al–Si alloy that can be purified after its production. Second, at above 2500 K, Al_2O_3 and carbon results in an Al–Al_3C_4 mixture of varying compositions.

As described in the previous subsection, Zn can be produced from ZnO by a solar thermal, electrothermal, or carbothermal reduction process. Other examples of solar thermal reduction processes that have been demonstrated in solar furnaces' exploratory runs are the production of Zn by dissociation of its natural ore willemite (Zn_2SiO_4), the combined ZnO reduction and biomass pyrolysis, and the production of Mg and Fe by carbothermal reduction of their oxides.

Metallic carbides and nitrides can be produced by the solar carbothermic reduction of metal oxides. The reaction is generally given by

$$M_xO_y + C(gr)\{+N_2\} \rightarrow \{M_{x'}C_{y'}, M_{x''}N_{y''}\} + CO. \quad (29)$$

Exploratory experimental studies were conducted in solar furnaces in which nitrides (AlN, Si_3N_4, TiN, and ZrN) were formed for the systems run in N_2 and carbides (Al_4C_3, CaC_2, SiC, TiC) were formed for the systems run in inert atmosphere. These ceramics are valuable materials for high-temperature applications due to their high hardness, excellent corrosion resistance, high melting points, and low coefficients of thermal expansion. CaC_2 is well known as the feedstock for the production of acetylene. The nitrides and carbides AlN, Fe_3C, and Mn_3C may also be used in cyclic processes as feedstock to produce hydrogen and hydrocarbons or may serve as intermediaries in the production of the metal. The hydrolysis of AlN yields NH_3, the hydrolysis or acidolysis of Fe_3C yields liquid hydrocarbons, and the hydrolysis of the various carbides of manganese yields H_2 and hydrocarbons in different proportions. Thus, Reaction (29) may be incorporated into cyclic processes of the type shown in Fig. 16, in which the metal oxides that result from the hydrolysis are recycled to the solar reactor, and CO from Reaction (29) may be shifted to H_2 via the water–gas shift reaction.

3.2.2 Solar Fullerenes and Carbon Nanotubes

Fullerenes and carbon nanotubes have become a major field in condensed matter physics and chemistry. However, the large-scale production of these materials with high yield and selectivity is still a

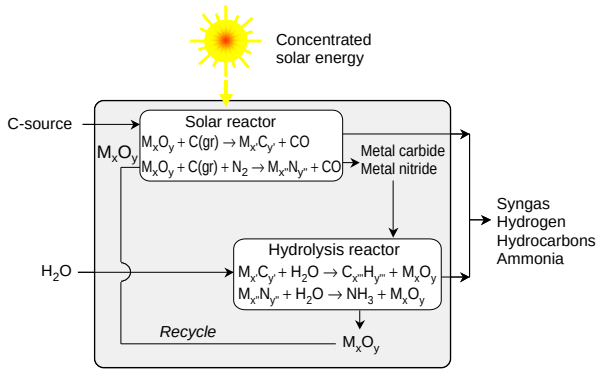

FIGURE 16 Schematic of a two-step thermochemical process for the production of syngas, hydrogen, hydrocarbons, and ammonia using metal oxides and solar energy. In the first (endothermic) step, the metal oxide is carbothermally reduced to a metal carbide or nitride using solar process heat. Subsequently, the carbide or nitride is reacted with water to produce hydrocarbons or ammonia, and CO is water–gas shifted to syngas, whereas the metal oxide is recycled to the solar step. M, metal; M_xO_y, metal oxide; $M_{x'}C_{y'}$, metal carbide; $M_{x''}N_{y''}$, metal nitride.

crucial problem. Conventional methods for the synthesis of fullerenes, such as electric arc discharge and laser ablation, fail when the process is being scaled up to higher power levels. The solar vaporization process seems to be more promising using the solar reactor shown in Fig. 17, in which a graphite rod contained under vacuum pressure behind a hemispherical quartz window is directly irradiated with peak solar concentration ratios exceeding 7000 suns and the vaporized carbon (at temperatures above 3300 K) is swept out by Ar, quenched, and collected in a filter bag. The key parameters characterizing this process are the carbon soot mass flow rate and the desired product yield. The former is a function of the target temperature, whereas the latter is a function of specific reactor variables such as fluid flow patterns, residence times, concentration of the carbon vapor in the carrier gas, target temperature, and temperature distribution in the cooling zone.

Catalytic filamentous carbon (CFC) can be produced by the solar thermal decomposition of hydrocarbons in the presence of small metal catalyst particles. Solar furnace experiments confirmed that nanotubes can be obtained using Co/MgO catalyst for CO and $CH_4 + H_2$ and that nanofibers can be obtained on Ni/Al_2O_3 catalyst for CO, CH_4, $CH_4 + H_2$, and C_4H_{10}. Figure 18 shows a solar chemical reactor used for such experimental runs. It consists of a quartz tube containing a fluidized bed of catalyst and Al_2O_3 grains. A secondary reflector, composed of a two-dimensional CPC

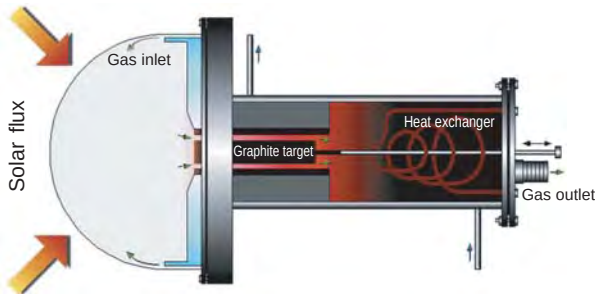

FIGURE 17 Scheme of a solar reactor for fullerene synthesis. Source: Institut de Science et de Génie des Matériaux et Prodédés, Centre National de la Recherche Scientifique, Font-Romeu, France.

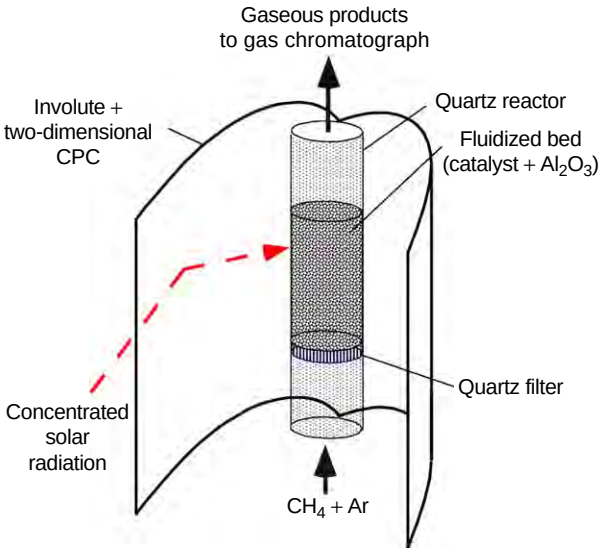

FIGURE 18 Scheme of a solar reactor for CFC production. Source: Paul Scherrer Institute, Villigen, Switzerland.

coupled to an involute, provides uniform irradiation on the tubular reactor. CFC formed typically has the following properties: surface area 100 to 170 m^2/g, pore volume 0.4 to 0.8 cm^3/g, micropore volume 0.004 to 0.008 cm^3/g, and average pore diameter 10 to 40 nm.

3.2.3 Solar Lime and Cement

The thermal decomposition of calcium carbonate (limestone) to calcium oxide (lime),

$$CaCO_3 \rightarrow CaO + CO_2, \qquad (30)$$

is the main endothermic step in the production of lime and cement at 1300 K. Substituting concentrated solar energy in place of carbonaceous fuels, as the source of high-temperature process heat, is a means to reduce the dependence on conventional

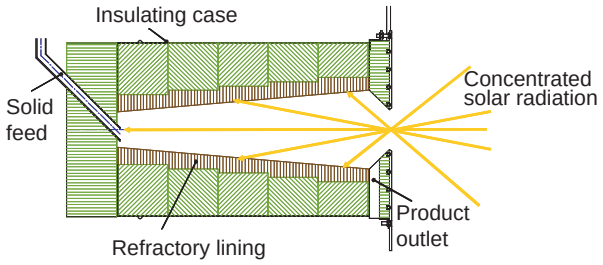

FIGURE 19 Schematic of a direct-irradiated rotary reactor for the solar production of lime. Source: Paul Scherrer Institute, Villigen, Switzerland.

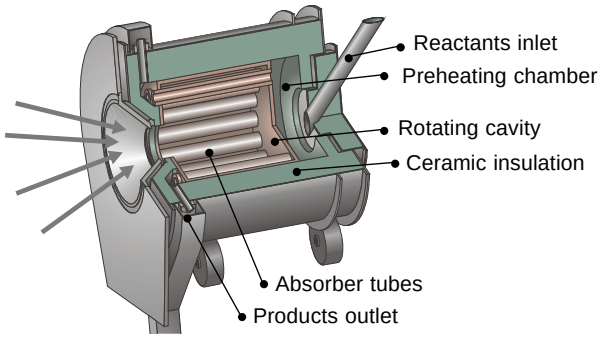

FIGURE 20 Schematic of an indirect-irradiated rotary reactor for the solar production of lime. Source: Paul Scherrer Institute, Villigen, Switzerland.

energy resources and to reduce emissions of CO_2 and other pollutants. Figures 19 and 20 show two solar reactor concepts for the solar calcination process based on direct irradiation and indirect irradiation, respectively. The direct-irradiated solar reactor (Fig. 19) consists of a refractory-lined conical rotary kiln operated in a horizontal position. Because of the rotational movement of the kiln, the reactants are transported within the conical reaction chamber from the preheating zone in the back (feeding side) to the high-temperature zone in the front (discharging side). The indirect-irradiated reactor (Fig. 20) consists of a multiple-tube absorber and a preheating chamber, both made from SiC. The well-insulated rotary reactor is tilted and works in continuous mode of operation.

3.2.4 Solar Thermal Recycling of Hazardous Waste Materials

Solid waste materials from a wide variety of sources (e.g., municipal waste incineration residuals, discharged batteries, dirty scraps, automobile shredded residue, contaminated soil, dusts, and sludge, other by-products from the metallurgical industry) contain hazardous compounds that are usually vitrified in a

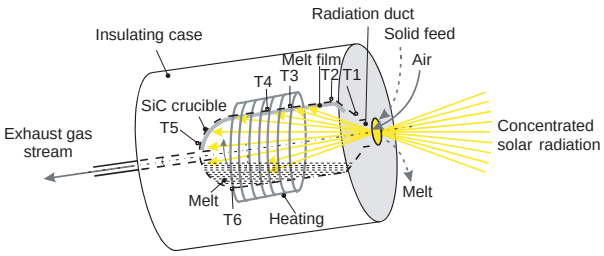

FIGURE 21 Scheme of a rotary kiln for aluminum melting. Source: Deutsches Zentrum für Luft- und Raumfahrt, Germany.

nonleaching slag and are finally disposed of at hazardous waste storage sites. However, limited storage space, increasing storage costs, and environmental regulations have led the need for developing technologies that recycle these toxic materials into useful commodities rather than deposit them in dump sites for an undetermined period of time. Thermal processes are well suited for the treatment of these complex solid waste materials. Waste materials containing carbonaceous compounds can be converted by thermal pyrolysis and gasification into syngas and hydrocarbons that can be further processed into other valuable synthetic chemicals. Those containing metal oxides may be converted by carbothermal reduction into metals, nitrides, carbides, and other metallic compounds. The commercial recycling techniques by blast, induction, arc, and plasma furnaces are major consumers of fossil fuel-based electricity and heat. Concentrated solar energy offers the possibility of converting hazardous solid waste material into valuable commodities for processes in closed and sustainable material cycles. Examples of recycling processes demonstrated in solar furnaces are the processing of electric arc furnace dust using the "two-cavity" reactor depicted in Fig. 14 and the melting of Al scrap using a SiC-lined rotary kiln shown in Fig. 21, which can be tilted for discharging molten metal and slag into molds.

Other recent applications in the area of solar thermal processing of materials that are being explored include hardening of carbon steel, production of expanded natural graphite (ENG) by exfoliation of graphite intercalated compounds, synthesis of advanced ceramics, and purification of metallurgical-grade silicon for photovoltaic applications.

3.2.5 Economics

Economic assessments indicate that solar thermochemical processes for the production of hydrogen and other solar fuels have the potential of becoming economically competitive vis-à-vis alternative paths

for producing solar fuels such as via electrolysis using solar-generated electricity. These studies further indicate that the heliostat field is responsible for approximately half of the total investment costs for the entire chemical plant, whereas the cost of the solar reactor represents 10 to 15%. However, for a fixed product throughput, the solar reactor's efficiency dictates the size of the heliostat field. Thus, reaching high solar reactor efficiencies and reducing the cost of the heliostats per unit area will have a significant impact on reducing the unit cost of the solar fuel. Application of credit for CO_2 mitigation and pollution avoidance will further enable the solar thermochemical technologies to compete favorably with fossil fuel-based processes. The weaknesses of these economic evaluations are related primarily to the uncertainties in the viable efficiencies and investment costs of the various components due to their early stage of development and their economies of scale.

4. OUTLOOK

Solar thermochemical processes have favorable long-term prospects because they avoid or reduce costs for CO_2 mitigation and pollution abatement. The products are renewable fuels and material commodities for delivering clean and sustainable energy services. Further development and large-scale demonstration are warranted.

Glossary

air conditioning The treatment of air temperature, humidity, cleanliness, and circulation so as to achieve a controlled desired result.
coefficient of performance (COP) Ratio of heating capacity to electrical input.
compressor In a vapor compression cycle, the device that increases the pressure and temperature of refrigerant vapor; it continuously draws low-pressure refrigerant vapor from the cooler, adds energy to increase the refrigerant pressure and temperature, and discharges the high-pressure vapor to the condenser.
condenser A heat exchange coil within a mechanical refrigeration system used to reject heat from the system; it is the coil where condensation takes place.
evaporator A heat exchange coil within a mechanical refrigeration system used to absorb heat into the system; it is the coil where evaporation takes place.
heat A form of energy; it is the least organized form of energy and the form of energy into which other forms deteriorate.
heat pump A comfort system in which the refrigeration cycle is reversed by using a four-way valve to supply both heating and cooling.
thermostat A device that connects or disconnects a circuit in response to a change in the ambient temperature.
vapor compression cycle A refrigeration cycle consisting of a cooler, a compressor, a condenser, and an expansion device.

The general term heat pumping technologies is used for processes in which the natural heat flow from a higher temperature level to a lower one is reversed by adding high-value energy, that is, exergy. The term heat pump is used in different ways in various regions of the world. In Japan and the United States, reversible units are called heat pumps; in addition to cooling and dehumidification, they offer the capability of providing useful heat. Most commonly, air-to-air units are used; however, ground-coupled systems have an increasing share. Chillers are more or less always called chillers, even if they are also used for heating purposes, as are heat pump chillers. In Europe, the term heat pump is used for heating-only units, with the heat sources outside air, ground, and groundwater, combined with heat distribution systems.

1. DEVELOPMENTS

Solar energy systems and heat pumps are two promising means of reducing the consumption of fossil energy sources and, potentially, the cost of delivered energy for domestic space heating and cooling with water heating. A logical extension of each is to try to combine the two to further reduce the cost of delivered energy. It is widely believed that solar heat pump combined systems will save energy, but what is not often known is the magnitude of the possible energy savings and the value of such savings relative to the additional expense. So, renewed interest is being directed at solar heat pumps by scientists, architects, engineers, manufacturers, and building owners as well as in the marketplace in general. The principal advantage of employing solar radiation as a heat pump heat source is that, when available, it provides heat at a higher temperature level than do other sources, resulting in an increase in the coefficient of performance (COP). Compared with a solar heating system without a heat pump, the collector efficiency and capacity are materially increased due to the lower collector temperature required.

The combination of a heat pump and solar energy system would appear to alleviate many of the disadvantages that each has when operating separately.

 © 2004 Elsevier Inc. All rights reserved.

During winter, the energy that could be collected by the solar system, but that would be too low in temperature to be useful for direct heating, may be used as a source for the heat pump. Because the solar collector storage system can supply energy at temperatures higher than the ambient outdoor air, the capacity and COP of the heat pump would increase over those for the heat pump alone, the peak auxiliary load requirement would be reduced, and the combined heating system would seem to operate more economically. The operation of the solar system at temperatures near or below room temperature would decrease the collector losses and allow more energy to be collected. The lower collection temperature might allow the use of collectors with one or no covers, and this would reduce the first cost from a conventional two-cover solar system. Finally, for those areas where warm temperatures occur during cloudy periods, the combined system might compensate for the reduced performance of the conventional solar system under cloudy conditions and the low capacity of the heat pump in cold weather.

2. TYPES AND APPLICATIONS

Research and development in the solar-assisted heat pump (SAHP) field has been concerned with two basic types of systems: direct and indirect. In direct systems, refrigerant evaporator tubes are embodied in a solar collector, usually of the flat plate type. Research has shown that when the collector has no glass cover plates, the same collector surface can also function to extract heat from the outdoor air. The same surface may then be employed as a condenser, using outdoor air as a heat sink for cooling.

An indirect system employs another fluid, either water or air, which is circulated through the solar collector. When air is used, an air-to-air heat pump may be employed, with the collector being added in such a way that (1) the collector can serve as an outdoor air preheater, (2) the outdoor air loop can be closed so that all source heat is derived from the sun, or (3) the collector may be disconnected and the outdoor air used as the source or sink. When water is circulated through the collector, the heat pump circuit may be of either the water-to-air or water-to-water type. Heat pumps complement solar collectors and heat storage in SAHP systems in several ways:

- Heat pumps are more efficient and can provide more heat for a given heat pump size if their evaporators can operate from a warm source. Thermal energy storage, heated by solar collectors, can provide that warming.
- Solar collectors operate more efficiently if they collect heat at lower temperatures. If the collected heat can be stored at a lower temperature because it is used to warm the evaporator of a heat pump, the collector is more efficient and, therefore, fewer collectors are needed to collect a required amount of heat.
- Heat pumps are the most efficient way in which to use electricity for backup heat for a solar heating system, even if there is no direct thermal connection of the heat pump with the solar collector and storage system.
- Heat pumps can allow sensible and latent heat storage units (e.g., water, phase change materials [PCMs]) to operate over wide temperature ranges because stored heat down to 5°C can be used in conjunction with heat pumps to heat a building.

Figure 1 shows the SAHP system linked to an energy storage tank for residential heating. In this system, solar collectors were constructed by modifying flat plate water-cooled collectors. Each solar collector had eight 1.25 cm outside diameter copper tubes spaced 10 cm apart and an effective absorber area of 1.66 m^2. The aluminum sheet was 0.55 mm thick. The 18 collectors were connected in parallel series form. The heat pump compressor was a hermetic type. It was driven by a 1490-W electric motor. The heat pump can use air and water as a heat source. The storage tank contained 1500 kg calcium chloride hexahydrate as a PCM for energy storage.

In general, SAHPs can work in three forms: parallel, series, and dual-source systems. A parallel system would use solar energy in the heat exchanger first and then use the air-to-air heat pump when the solar coil is unable to provide the necessary heat. A series system would use the solar energy in the heat exchanger first and then use the water-to-air heat pump when the solar coil is unable to provide the necessary heat. Dual-source heat pumps are currently in the development stage. A dual-source system would have the choice of either an air-heated coil when warm air is available or a water-heated coil when warm water is available. This type of capability would be advantageous in the SAHP, and in applications where well water is available as a source during the heating season. It would also alleviate the need for a cooling tower when the heat pump operates in the cooling mode.

It is not unusual for the SAHP to save up to 20% in operating costs during the heating season compared with an air-to-air heat pump. This represents a

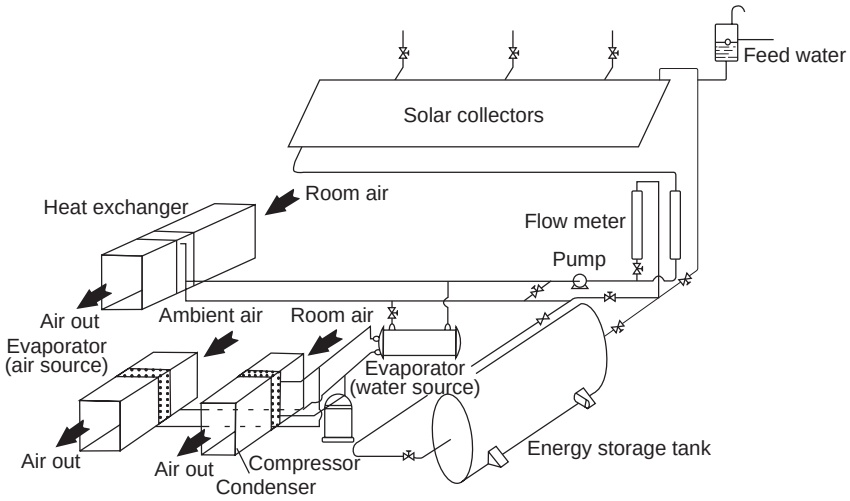

FIGURE 1 Schematic overview of experimental solar-assisted heat pump system. Reprinted from Kaygusuz *et al.* (1993).

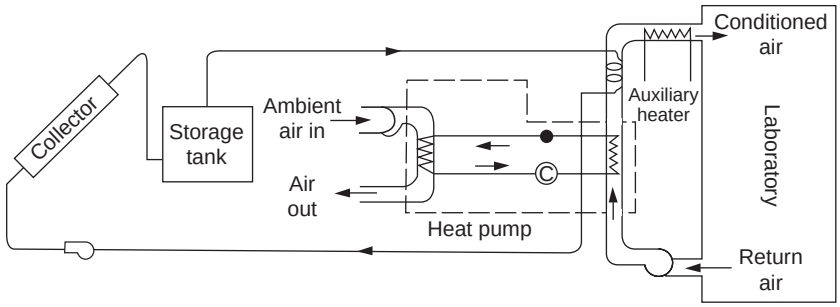

FIGURE 2 Parallel heat pump system. Reprinted from Kaygusuz *et al.* (1993).

heating COP of nearly 3.0. It has been reported that parallel systems can save up to 50% of the energy required when compared with electrical resistance heating, series systems can save up to 60% of the energy normally required, and dual-source systems can save up to 70% of the energy normally required.

A wide variety of options exist to provide air conditioning along with solar heating of buildings. The efficacy of coupling these options with a solar heating system depends strongly on which system is to be used and whether one is considering systems that can already be built reliably or ones that promise optimum performance in the future following extensive development effort. Several SAHP systems are described to illustrate their relationship with air conditioning: the simple parallel system, series system, dual-source system, and cascade system.

2.1 Parallel System

As shown in Fig. 2, the parallel system consists of a solar collector, a water-to-air heat exchanger, an air-sourced heat pump, a water-circulating pump, a storage tank, and other equipment. The parallel SAHP system is combining two main components: the solar system and the parallel heat pump system. In this system, the heat pump uses ambient air as an energy source while the water-to-air heat exchanger uses solar energy as a heat source, and they give their energies to the load one by one. Solar energy is used to meet as much of the heating requirement as possible. Thus, the total available energy of the system is the sum of the extracted energies from two different systems (the solar system and the heat pump).

2.2 Series System

Figure 3 shows a series SAHP system. The solar collector heats water, which is then stored in a tank. The tank provides heat directly to the house if the tank temperature is above 40°C, and the heat pump draws heat from the tank when the tank temperature is between 5 and 40°C. This system has the advantage that the tank can be operated at lower

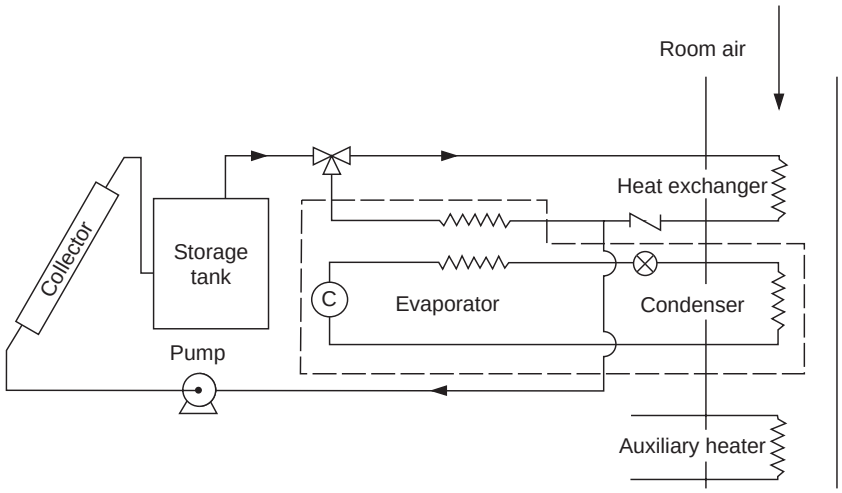

FIGURE 3 Series heat pump system. Reprinted from Kaygusuz *et al.* (1993).

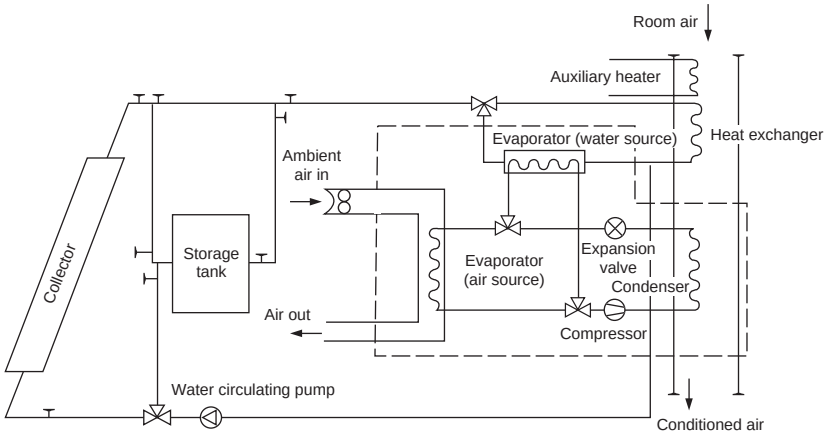

FIGURE 4 Dual-source system. Reprinted from Kaygusuz *et al.* (1993).

temperatures when required, allowing the collector to operate with high efficiency, and the tank heat storage capacity can be increased by the amount of sensible heat stored between 5 and 40°C. The disadvantage of the system is that when the tank temperature finally drops to 5°C, the heat pump cannot be used further without danger of freeze-up in the water tank. The system shown will not provide air conditioning because there is no way in which to exhaust the waste heat to outside air. It would be possible to provide air conditioning if there were another heat exchanger loop between the storage tank and outside air, but this would add to the cost of the heat exchanger and its associated circulating pump. A development effort is required on the heat pump in this system because residential heat pumps are not currently designed to operate efficiently with evaporator temperatures above 20°C, and this one would have to operate at up to 40°C.

2.3 Dual-Source System

The dual-source SAHP system, illustrated in Fig. 4, combines the advantages of the parallel and series systems and overcomes their disadvantages. The solar collector, heat storage, and building heat exchanger all continue to work as a simple solar system so long as the tank temperature remains above 40°C. At temperatures below that, the heat pump system is called on by a microprocessor controller, and a decision is made as to whether it is better to draw the heat pump's heat from the tank or from the outside air. The control strategy options are numerous for this system; it can be operated to optimize savings of electricity or to reduce peak loads. It would be the most efficient of all the systems described here. It has the disadvantage that the required heat pump is complex and will be costly to manufacture. Considerable development work will

be required to ensure that the unit can be operated in all sequences of its modes with full reliability. With this system, air conditioning is accomplished by operating the unit as a simple air-to-air heat pump in the cooling mode, using only the outside heat exchanger as a condenser. So, it is obvious that the dual-source heat pump system takes advantage of the best features of the series and parallel heat pump systems. The system is not capable of using the storage tank to reduce air-conditioning peak loads during the summer because the heat pump cannot be used to cool the tank to the outside air.

2.4 Cascade System

As Fig. 5 shows, the cascade SAHP system allows complete access to the storage tank in both the heating and air-conditioning modes. Two heat pumps are used: one between the outside air and the tank and the other between the tank and the house. The inside heat pump allows the system to operate in the series heat pump mode, providing heat to the house when the tank temperature drops below 40°C. When supplemental heat is required, the outside heat pump charges the tank with heat removed from the outside air. In air conditioning, the inside heat pump cools the house on demand, depositing the heat in storage; the outside heat pump cools the house on demand, depositing the heat in storage; and the outside heat pump then removes heat from the tank to outside air during off-peak periods. Both of the heat pumps used in the cascade system require some development effort. The outside heat pump must be optimized for operation between outside air temperatures and the cool water temperatures of the storage tank. The inside heat pump is the same as the series unit described previously except that it must include the ability to air condition as well as heat. The required development effort would probably be less than that for a three-coil unit. This system is probably the most expensive of those described here due to the cost of heat pump equipment. When operating with the outside heat pump as a supplementary heat source, it will be less efficient than the three-coil or parallel system because the heat must go through a second heat pump in heating the house. On the other hand, it is the most flexible system, allowing full heating and air conditioning as well as the use of the storage tank to store heat for off-peak use (solar or electrical utility) during the heating season and to reduce air-conditioning peak loads during the cooling season. Today, a number of solar-assisted heat pumps are commercially available either as complete systems or as component packages, as shown in Figs 6, 7, and 8.

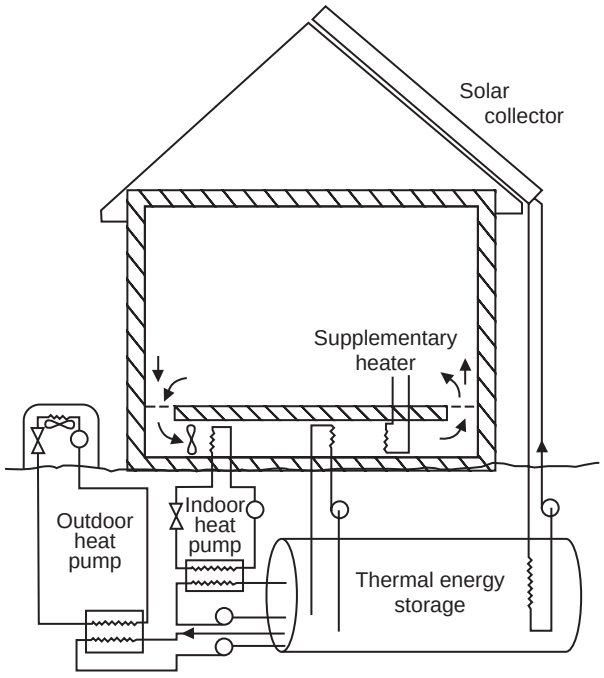

FIGURE 5 Cascade system. Courtesy of General Electric Company (reprinted from Sauer and Howell, 1991).

It is possible to view much of the work of the past few years on SAHP systems as an attempt to address a single fundamental question: what does one do when the sun is not shining and storage is depleted? Studies based on the assumption that electrical resistance is used as the backup heat source have generally concluded that the SAHP is not a good idea. However, it is now possible to identify two general paths that have been taken to avoid this difficulty: direct expansion SAHP systems and ground-coupled SAHP systems. Each type of system has its own special characteristics. These are described in what follows.

2.4.1 Direct Expansion SAHP

Refrigerant-filled, two-phase solar collectors have been used during recent years as alternatives to conventional air or water collectors. The working fluid in these collectors undergoes a liquid-to-vapor transformation, and the absorbed solar energy is manifested as the latent heat of vaporization. Two-phase collectors are usually employed in direct expansion solar-assisted heat pump (DX-SAHP) cycles. The primary objective in these cycles is to raise the evaporator temperature through solar energy input, which in turn translates into improvement in the thermal performance of the heat pump.

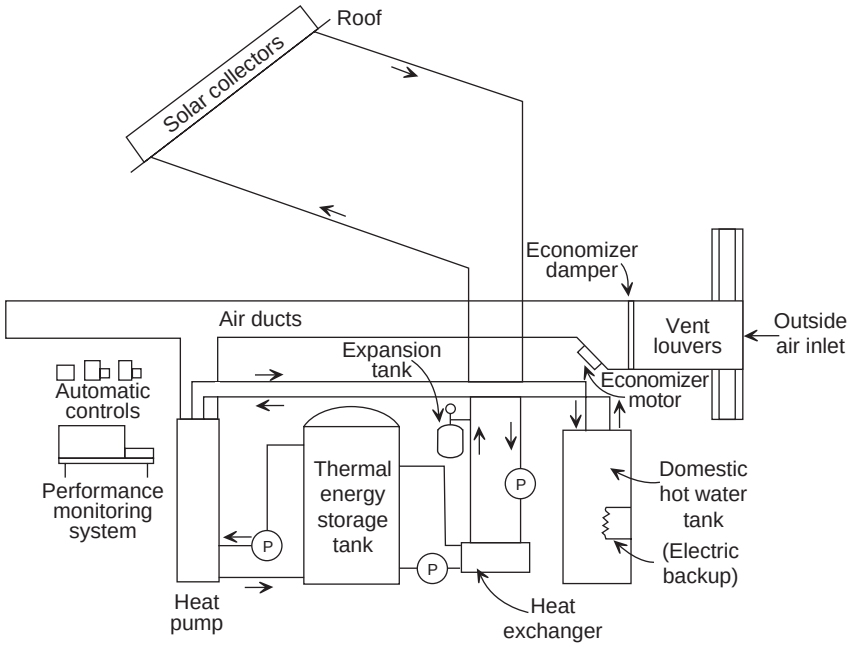

FIGURE 6 Residential dual-source heat pump system. Courtesy of Daystar Corporation–Exxon Enterprises (reprinted from Sauer and Howell, 1991).

Courtesy of General Electric Company (reprinted from Sauer and Howell, 1991).

The DX-SAHP system offers several advantages over the conventional SAHP systems. Because the collector also acts as the evaporator, the number of components in the system is reduced. For example, instead of using a collector, an evaporator, and an intermediate heat exchanger in a conventional SAHP system, only a collector panel is required in the DX-SAHP system. Circulation of refrigerant in the collector tubes also prolongs the system life because corrosion and nighttime freeze-up problems encountered in water collectors are virtually eliminated.

2.4.2 Ground-Coupled SAHP

Ground source heat pumps (GSHPs) were originally developed in the residential arena and are now being applied in the commercial sector. Many of the installation recommendations, design guides, and rules of thumb appropriate to residential design must be amended for large buildings. The term "ground source heat pump" is applied to a variety of systems that use the ground, groundwater, and surface water as a heat source and sink. Included under the general term are ground-coupled (GCHP), groundwater (GWHP), and surface water (SWHP) heat pump systems.

GCHPs are a subset of GSHPs and are often referred to as closed-loop GSHPs. A GCHP is a system that consists of a reversible vapor compression cycle linked to a closed ground heat exchanger buried in soil. The most widely used unit is the water-to-air heat pump, which circulates water or a water–antifreeze solution through a liquid-to-refrigerant heat exchanger and a buried thermoplastic piping network. A second type of GCHP is the direct expansion ground-coupled heat pump (DX-GCHP),

which uses a buried copper piping network through which refrigerant is circulated. To distinguish them from DX-GCHPs, systems using water-to-air and water-to-water heat pumps are often referred to as GCHPs with secondary solution loops.

GCHPs are further subdivided according to ground heat exchanger design: vertical and horizontal. Vertical GCHPs generally consist of two small-diameter, high-density polyethylene (PE) tubes in a vertical borehole. The tubes are thermally fused at the bottom of the bore to a close return U-bend. The nominal diameter of vertical tubes ranges from 20 to 40 mm. Bore depths range from 15 to 185 m depending on local drilling conditions and available equipment.

The advantages of vertical GCHPs are that they (1) require relatively small plots of ground, (2) are in contact with soil that varies very little in temperature and thermal properties, (3) require the smallest amount of pipe and pumping energy, and (4) can yield the most efficient GCHP system performance. The disadvantage is that they are typically higher in cost due to the limited availability of appropriate equipment and installation personnel.

Horizontal GCHPs can be divided into three subgroups: single pipe, multiple pipe, and spiral. Single-pipe horizontal GCHPs were initially placed in narrow trenches at least four deep. These designs require the greatest amount of ground area. Multiple pipes (usually two or four) placed in a single trench can reduce the required amount of ground area. With multiple-pipe GCHPs, if trench length is reduced, total pipe length must be increased to overcome thermal interference with adjacent pipes. The spiral coil is reported to further reduce the required ground area. These horizontal ground heat exchangers are made by stretching small-diameter PE tubing from the tight coil in which it is shipped into an extended coil that can be placed vertically in a narrow trench or laid flat at the bottom of a wide trench. Required trench lengths are only 20 to 30% those for single-pipe horizontal GCHPs, but pipe lengths may be double for equivalent thermal performance.

The advantages of horizontal GCHPs are that (1) they are typically less expensive than vertical GCHPs because appropriate installation equipment is widely available, (2) many residential applications have adequate ground area, and (3) trained equipment operators are more widely available. Disadvantages include (1) the larger ground area requirement; (2) greater adverse variations in performance because ground temperatures and thermal properties fluctuate with season, rainfall, and burial depth; (3) slightly higher pumping energy requirements; and (4) lower system efficiencies.

3. PERFORMANCE AND ECONOMICS

The important quantities for the evaluation of the systems are the seasonal energy flows. For space and service hot water heating, these are the sum of the house space and water heating loads (q_{load}), the heat collected by solar energy system (q_{solar}), the heat

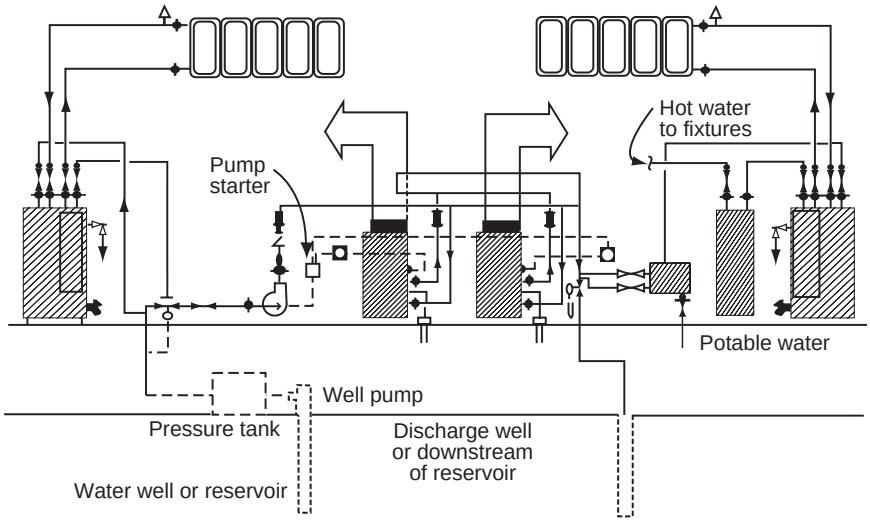

FIGURE 8 Northrup solar-assisted heat pump system and components. Courtesy of Northrup Inc. (reprinted from Sauer and Howell, 1991).

extracted by the heat pump from the ambient air (q_{air}), the electricity required by the heat pump compressor and fans (W_{hp}), and the auxiliary energy required to meet the hot water and space heating loads (E_{aux}). Here, E_{aux} is the delivered energy and is less than the purchased fuel energy due to furnace and water heater inefficiencies. Over the course of a year, there is a negligible change in the amount of energy in the storage tank, and the system energy balance is

$$q_{solar} + q_{air} + W_{hp} + E_{aux} = q_{load}.$$

The first two terms are free energy, whereas the second two terms represent purchased energy. A measure of the thermal performance of combined solar heat pump systems is the fraction (F) of the total load that is met by nonpurchased energy, defined as

$$F = (q_{air} + q_{solar})/q_{load} = 1 - (W_{hp} + E_{aux})/q_{load}.$$

The auxiliary energy may be supplied by gas, oil, electricity, or a combination, whereas the heat pump work is nearly always electricity. The thermal performance fraction does not distinguish among the different kinds and prices of fuels; rather, it reflects only energy requirements.

The fraction, F, is shown in Fig. 9 for Madison as a function of collector area for the conventional furnace, conventional heat pump, parallel, series, dual-source, and conventional single-cover solar system. For a house with neither a solar energy system nor a heat pump, F equals zero. For a house with only a heat pump, the fraction of the heating requirement supplied by nonpurchased energy is q_{air} divided by the total heating requirement and equals 36%. Because the heat pump does not contribute to the domestic hot water system, the value of F depends on the COP and the relative sizes of the space and water heating loads and is usually between 0.2 and 0.4. For a house with a conventional solar system, F depends on collector area. As collector area increases, F increases from zero asymptotically toward 1.0.

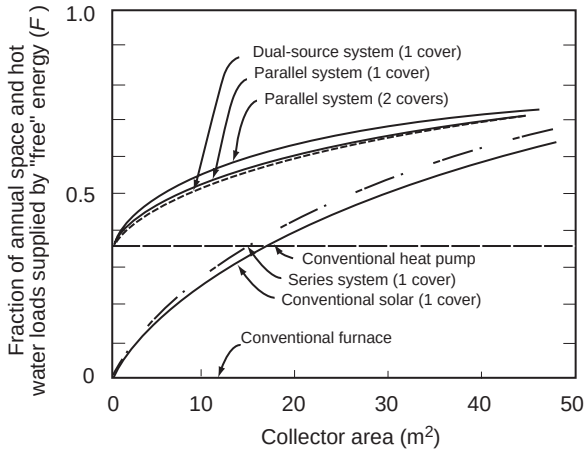

FIGURE 9 The fraction of energy from nonpurchased source (F) for series, parallel, dual-source, heat pump-only, and standard solar energy systems as a function of collector area, based on simulations of the systems on a residential building in the Madison climate. Reprinted from Freeman *et al.* (1979).

The results of the simulations done using the program TRNSYS show that with the same collector area, the parallel system is substantially better than the series system and slightly better than the dual-source system in all collector sizes in that it delivers a greater fraction of the loads from nonpurchased sources. This arises because the heat pumps in the series and dual-source systems must operate to deliver all solar energy stored below 20°C. The extra electrical energy required to deliver this energy more than compensates for the combined advantages of higher collector efficiency and higher heat pump COP. The temperature of storage in the series system (and in the dual-source system) in these simulations is rarely high enough to permit direct solar heating.

Improved collector performance and higher q_{solar} not only are the direct consequences of adding the solar source capability but also are the only benefits to system performance during the heating season. However, the improved collector performance is achieved at the expense of heat pump electrical power input that usually displaces a cheaper fuel. The annual energy balance requires that the sum of all energy supplied equals the load given as

$$q_{load} = q_{solar} + q_{air} + W_{hp} + E_{aux}.$$

The relative contributions from each of these four heat sources are shown in the bar graphs in Fig. 10. The combined height of the q_{solar} and q_{air} bars in the figure represents the percentage of the total heating requirement supplied by free energy and, therefore, is equivalent to F. The systems are ranked from left to right in order of decreasing savings of purchase energy that is decreasing F.

On the other hand, the experimental heat pump seasonal COP (i.e., ratio of rejected heat to work input) varies among the systems. The use of a solar source for the heat pump raises the seasonal COP over that of the conventional heat pump and parallel systems. As shown in Fig. 10 for Trabzon, Turkey, the annual heat pump heating COPs for the parallel, series, and dual-source systems are 3.0, 4.0, and 3.5, respectively. The relative COP values for the

conventional heat pump and the parallel system heat pump result from the fact that the heat pump is forced to operate less often but under generally more unfavorable conditions when used as an auxiliary to a solar system. As expected, the COP for the series and dual-source heat pumps are substantially higher because they use the solar-heated storage tank as a source. Table I shows the experimental performance of the SAHP system for residential heating in Trabzon.

Two configurations of series SAHPs were evaluated experimentally in TECH House I on the University of Tennessee campus in Knoxville. During the 1979–1980 heating season, a 4.2-m^3 insulated above-ground storage tank was used. During the 1980–1981 heating season, the storage system consisted of an uninsulated 7.6-m^3 steel tank buried 2.1 m in the ground. For 1979–1980, the heating season system performance factor was 2.42 and the system's maximum peak electric demand was 11.20 kW. For 1980–1981, the heating season performance factor increased to 3.16, whereas the maximum peak electric demand decreased to 4.33 kW. On the other hand, a parallel SAHP system was evaluated experimentally in TECH House IV for three heating seasons between the fall of 1979 and the spring of 1982. The seasonal performance factors (SPFs) for the 1980–1981 and 1981–1982 seasons were measured to be 2.56 and 2.11, respectively.

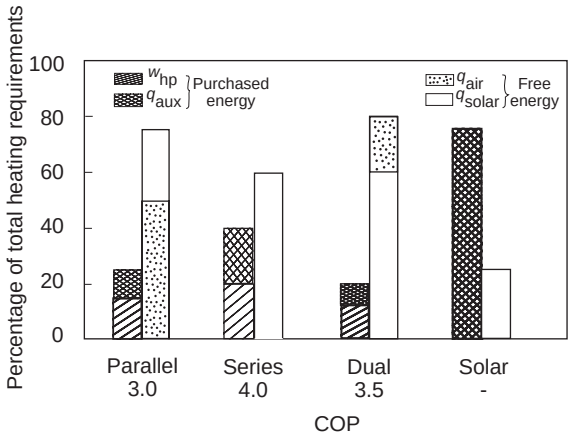

FIGURE 10 Heating contributions from all possible sources for Trabzon, Turkey. Reprinted from Kaygusuz (1995).

In the competition for commercial viability, all solar heating systems must compete for some version of life cycle economic advantage with alternative nonsolar heating systems. In going to solar heating, an economic trade-off is made between the high first cost of solar heating or cooling equipment and the cost savings realized by reduced use of fuel or electricity. One way in which to compare nonsolar and solar heating systems is to determine the cost of electricity at which they have the same overall life cycle cost. A rough comparison of this break-even cost of electricity shows that many solar-assisted systems will be more cost effective than the conventional air-to-air heat pump available in the United States today only when electricity costs become greater than 10 to 12 cents/kWh. The current national average cost of residential electricity is approximately 4 cents/kWh, with a range of up to approximately 10 cents/kWh in some major urban utility systems.

The feasibility of SAHP systems for space heating and domestic hot water preheating in Canada is

examined by simulating the performance of these systems on a computer using the program WATSUN. Simulations are carried out using meteorological data for seven representative Canadian cities, two different building types, and six types of system configurations. For the SAHP system, 20-year life cycle cost comparisons are made with two reference systems, a conventional resistance heating system and an air-to-air heat pump system, based on current economic parameters and projected escalation scenarios for electricity rates.

Results of the study show that the SAHP systems conserve significant amounts of energy over resistance heating and heat pump systems. On the life cycle unit cost basis, SAHP system costs are relatively insensitive to location, but the dependence on building types is substantial, with multiplex dwellings showing the least cost. Liquid-based, dual-source SAHP systems are found to be cost-effective over resistance heating at some of the locations for multiplex units. They are not cost-effective for single-family dwellings at the current time.

4. ENVIRONMENTAL BENEFITS

Energy efficiency and environmental benefit are the key drivers for heat pump application and further research and development. A simple projection of world energy consumption and dwindling energy sources during the coming decades shows that society faces a major challenge. There is a general awareness of this rapidly approaching problem, but society as a whole does not seem to be responding accordingly, assuming that there is sufficient time to find solutions. However, it is encouraging to see that there is a growing interest in applying energy-efficient technology in developing countries and economies in transition. Although costs are an obstacle for applying modern technology, the industrialized world seems increasingly prepared to look for new ways of information and technology transfer to these developing parts of the world.

How important are heat pumps in relation to the environment? Any thermodynamic specialist or heating/cooling engineer will have no problem in quickly answering this question. The numbers on COPs and SPFs, as well as on specific carbon dioxide (CO_2) emission levels, are available and can lead to only one conclusion: an increasing application of heat pumps without delay is very important. On the other hand, it is frequently argued that the refrigerants used in heat pumps today are safe and that their impact on the environment during the equipment life cycle is negligible. That may be true and significant as well, but the fact remains that a much better job can be done. There is significant scope for improved performance and initial cost reduction. Both will lead to a better environment and decreased energy consumption.

In Fig. 11, various systems for the supply with electricity and heat are compared with regard to their CO_2 emissions. The various lines in the figure represent standard systems that are already installed or at least are obtainable in Turkey. The figure shows the CO_2 emissions in kilograms for the supply with 1 kWh power plus heat (in kilowatt-hours). On the other hand, in the case of a conventional coal-fired power plant with an electrical efficiency of 0.40 and a distribution efficiency of 0.95, 0.9 kg CO_2 is emitted for each kilowatt-hour of power delivered to the user. All systems in the figure use this power plant, so all curves intersect at the same point on the ordinate. The steepest line represents a system combining this coal power plant with an oil furnace for heating. For example, for the supply with 1 kWh power from the power plant and 2 kWh heat from the furnace, we get CO_2 emissions of 1.7 kg. When we change the fuel for the furnace from oil to natural gas, we get a 12% reduction in CO_2, from 1.7 to 1.5 kg, for this example. If we further improve the boiler efficiency up to 1.0, which is the value for modern condensing furnaces, we obtain a reduction of the CO_2 emissions of 24%.

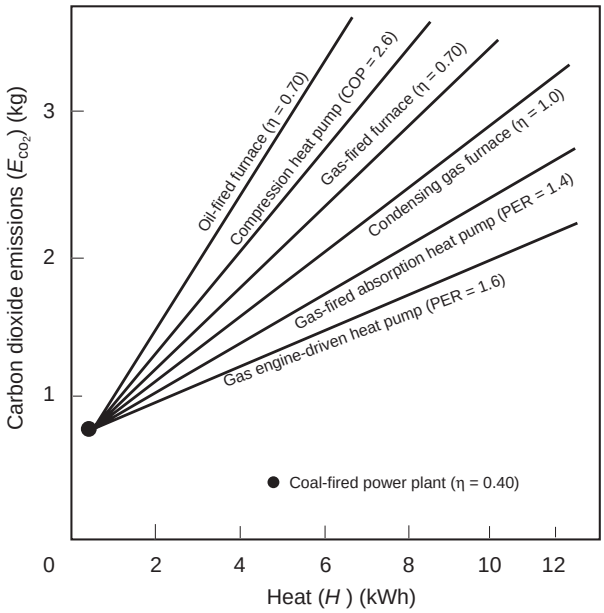

FIGURE 11 Carbon dioxide (CO_2) emissions for systems with a coal-fired power plant. Reprinted from Kaygusuz (2003).

Compression heat pumps with a COP of 2.5, operated with electric power from coal power stations, show only slightly less emissions than do oil furnaces and are even worse than standard gas furnaces and especially condensing gas furnaces. On the other hand, for a larger heating demand, only gas engine-driven compression heat pumps, with a primary energy rate (PER) of 1.5, or direct gas-fired absorption heat pumps (PER = 1.3) show a similarly high reduction in CO_2 emissions. The efficiencies assumed in Fig. 11 are not the best values for available compression heat pumps. Modern systems reach a COP of 3.0 and sometimes 4.0. Modern power stations with a combined gas-and-steam turbine cycle (CC) reach electrical efficiencies of up to 0.53.

In Fig. 12, the CO_2 emissions are plotted for these systems. The striped areas indicate the range of COPs of the advanced heat pumps. As can be clearly seen, heat pumps driven by electricity from conventional coal power stations cannot reduce the CO_2 emissions in comparison with condensing gas furnaces in spite of the COP improvement from 2.5 to 4.0. The situation changes appreciably with modern CC power plants with an efficiency of 0.53. In such a system, even heat pumps with a rather poor COP of 2.5 have lower emission ratios than do the best furnaces. Of course, much better results are achieved with COPs of up to 4.0, which are also shown in the figure.

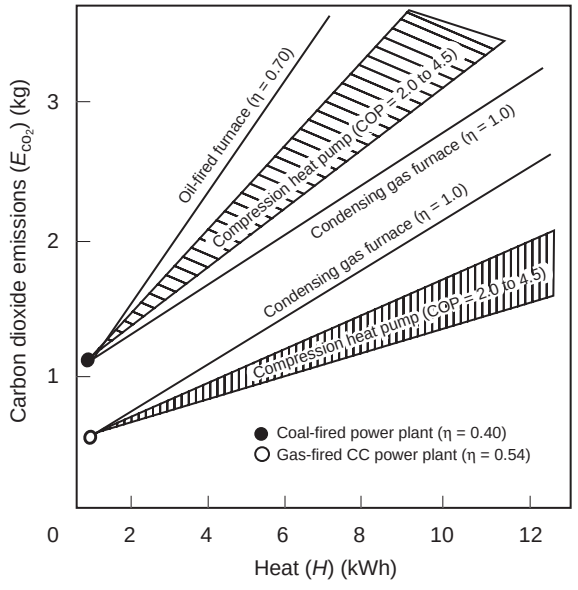

FIGURE 12 Carbon dioxide (CO_2) emissions for systems with advanced compression heat pumps. Reprinted from Kaygusuz (2003).

Worldwide, more than 100 million heat pumps are now installed. Their total annual thermal output is approximately 1300 TWh. This represents an annual equivalent CO_2 emissions reduction of 0.13 billion tons (0.6%), against the backdrop of annual global emissions of CO_2 of more than 22 billion tons. However, the current reduction potential of heat pumps is 6% of global CO_2 emissions, and improved technology could increase this to 16% in the future.

5. CONCLUSION

Heat pumps use mechanical energy to transfer thermal energy from a source at a lower temperature to a sink at a higher temperature. Electrically driven heat pump heating systems have attracted wide interest as an alternative to electric resistance heating or expensive fuels. They have two advantages: a COP greater than unity for heating (thereby saving on purchase of energy) and usefulness for air conditioning during the summer. Heat pumps may use air or water sources for energy, and dual-source machines that can use either are under development.

SAHPs for residential applications have received a great deal of attention since 1975. They combine a solar heating system with a heat pump to provide the necessary heating and cooling requirements. Both air-to-air and water-to-air heat pumps can be used in this system. The solar system basically collects the energy for the heating requirements, and the heat pump supplies this energy at the proper time and temperature and also helps to improve the efficiency of the solar collector in the water-to-air operating mode.

On the other hand, heat pump systems have other advantages for commercial buildings besides their low operating costs. They offer improved comfort due to on-demand, year-round heating or cooling. Greater flexibility in the interior layout of the building is also possible, particularly where a distributed water loop configuration is adopted. In addition, more exterior architectural freedom is possible with the adoption of GSHP systems due to the absence of any need for external equipment such as cooling towers. Because of their use of electric power, heat pumps can also provide a convenient way in which to heat a building in a remote location to which fossil fuel is not economically transportable.

In the past, heat pumps have often been a tool of government policy. For example, during the oil crises of the mid-1970s and early 1980s, governments in some cold climate countries encouraged the use of heat pumps through financial incentives to reduce

their dependence on oil and as part of their energy conservation programs. This may happen again as countries sign on to the Kyoto Protocol and as governments implement measures to reduce greenhouse gas emissions.

As a result, heat pumps are capital intensive, as are solar energy systems. Consideration of the economics of SAHP systems indicates that it may be difficult to justify the investment in a heat pump to improve solar energy system performance unless the cost of the heat pump can be justified on the basis of its use for air conditioning or unless the use of the heat pump would reduce collector costs to a small fraction of their current levels. Today, the most popular commercial heat pump configuration in the United States, Japan, and other countries such as Turkey is the single-packaged air source unit. This is followed by the packaged terminal heat pump and the water source heat pump.

Glossary

aquifer A layer of soil or rock that can hold water.
double-diffusive fluid A fluid embodying the density gradients of two constituents.
nonconvective layer A fluid layer in which natural convection is suppressed.
permeable Allows liquid or gas to pass through.
solar pond Body of still water that collects solar energy and stores it as thermal energy.
thermohaline system Solar thermal system.
transparent insulation layer A layer that is transparent for solar (optical) radiations and is opaque for infrared (heat) radiations.

The solar pond represents a low-cost option among other solar systems. It possesses thermal storage capability spanning seasons and is the only viable system with 100% solar fraction. Solar pond heat can be used for a variety of applications, including generation of electricity, industrial process heating, desalination, and greenhouse heating.

1. INTRODUCTION

Solar radiant energy is characterized by low-energy density and its practical utilization involves large-area solar collectors. A solar pond is a unique large-area solar collector that uses a body of still water to collect solar energy and stores it as thermal energy. As a practical matter, all ponds, lakes, oceans, and other expanses of water in nature collect solar energy and convert it to thermal energy, but their heat retention efficiency is poor because the water near the surface is quickly cooled as the heat is rapidly dissipated to the environment. The warmer and more buoyant water in the lower region rises to the surface; this movement of water is called natural convection. Therefore, a water–pond system will be more effective in the collection and storage of solar energy if the thermal losses to the environment are reduced either by suppressing the natural convection of water in the pond or by covering the pond surface with a partially transparent insulation. The term solar pond is therefore used for a water pool with reduced heat losses. It can collect solar energy, concentrate and store it as heat up to approximately 100°C (higher temperature restricted by the boiling point of water). The solar pond involves simple technology and uses water as working material for three functions: collection of solar radiant energy and its conversion into heat, storage of heat, and transport of thermal energy out of the system.

2. SOLAR POND TAXONOMY

The first recorded use of solar energy for heating a water pool was made approximately 2500 years ago when great Roman baths were heated by the sun. Von Kalecsinsky, who reported that the bottom of Madve lagoon in Transylvania in summer had a temperature of approximately 70°C, discovered the phenomenon of the solar pond in 1902. In this lake, salt concentration was also observed to increase with depth. The downward increase in salt concentration prevents the convection and renders the upper region of the lake a partially transparent insulator trapping solar heat in the bottom region. The

 © 2004 Elsevier Inc. All rights reserved.

conceptual design of the first artificial "sun pool" was given by Tabor and Bloch in 1958. The proposed system was an artificial pond (approximately 1 m deep) with a black bottom and salt gradient with a maximum concentration at the bottom obtained by filling the pond with progressively less dense brine layers. The name salt gradient solar pond or solar pond was coined for such a system. The term solar pond has since been applied to a variety of water pool solar collector/storage systems. These may be broadly classified as shown in Fig. 1.

In nonconvective solar ponds, the basic principle is that heat loss to the environment is reduced by the suppression of natural convection in the upper layer (transparent insulation layer) of water or air medium. The most documented type of nonconvective solar pond is the salt gradient solar pond. It uses such salts as NaCl, $MgCl_2$, and bitterns. It is referred to as an unsaturated salt-stabilized pond to distinguish it from the saturated salt-stabilized pond based on the Soret effect. The latter uses salt such as KNO_3, whose solubility increases dramatically with temperature; in the pond, saturation of the salt concentration is maintained at all depths. The pond is hotter in the bottom region than at the top. Thus, a progressively larger amount of salt is dissolved toward the bottom. Owing to saturation at each level, the vertical diffusion of salt is checked and the density gradient is stable. This provides for the possibility of a maintenance-free solar pond. Alternative methods of suppressing convection have also been investigated and several solar pond systems have been proposed and tested, including the gel- or viscosity-stabilized pond, the membrane pond, and the honeycomb-stabilized solar pond. These are referred to as saltless nonconvective solar ponds.

In convective solar ponds, heat loss to the environment is reduced by covering the pond surface. The cover is transparent and the pond is often of shallow depth; it is thus referred to as a shallow solar pond. In practice, it is a water-filled plastic bag glazed at the top with a blackened bottom insulated by foam. These ponds are used for producing hot water at medium temperature (40–60°C) for industrial applications as well as for boiler preheating. Figure 2 provides a schematic of solar pond concepts.

Earliest theoretical as well as experimental studies of solar ponds predicted solar heat collection efficiencies of approximately 20% and thermal storage capability spanning seasons. Several countries have since built and operated salt gradient solar ponds. The technology of salt gradient ponds is inherently simple. However, for a solar pond energy system of good thermodynamic efficiency, a variety of factors must be considered and quantified. Therefore, the physics and engineering aspects of salt gradient solar ponds and the conceptual outline of other ponds are presented in the following sections.

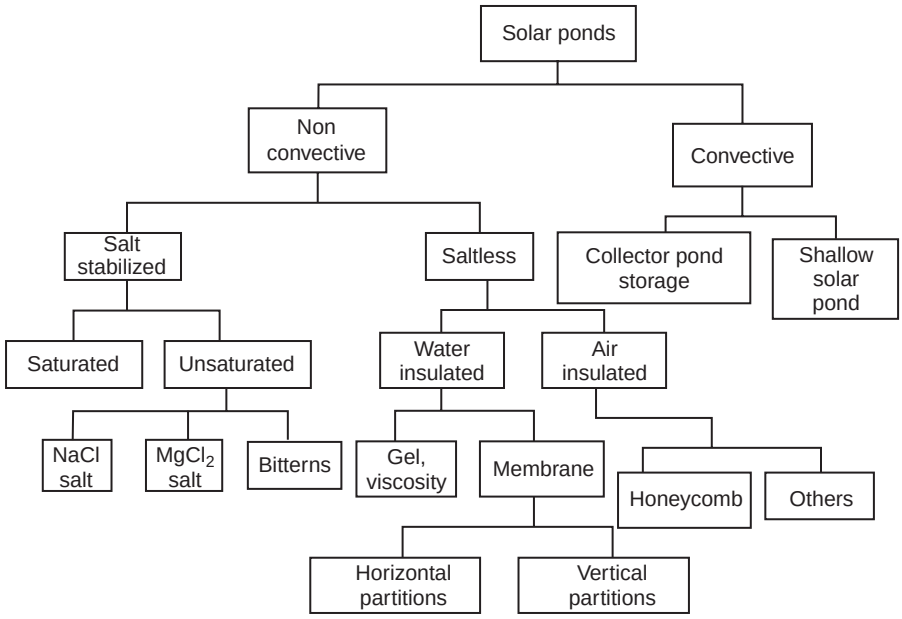

FIGURE 1 Classification of solar ponds.

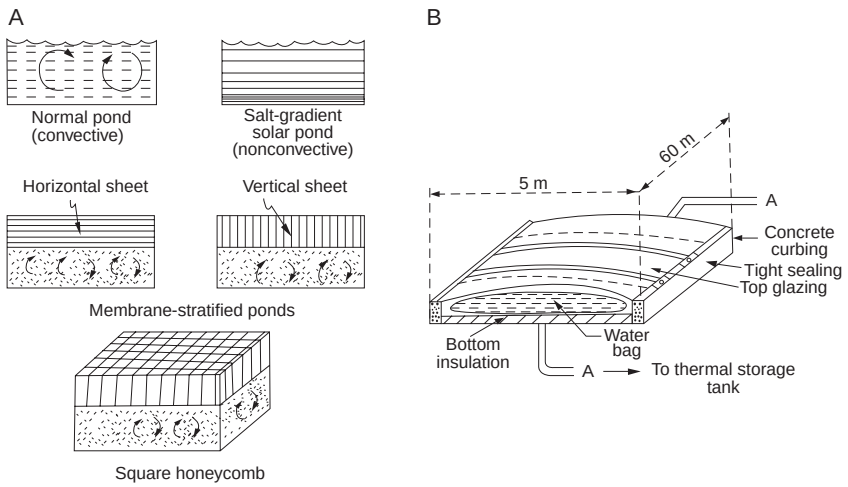

FIGURE 2 (A) Schematics of nonconvective solar pond concepts. (B) Illustration of shallow (convective) solar pond.

3. SALT GRADIENT SOLAR POND

3.1 Containment

Solar pond containment involves trade-offs between several strategies related to the location of the pond, earth excavation, the lining, insulation, and pond shape. Local geology is critically important in site selection; care must be taken to avoid underground aquifers. The pond is usually contained in earth excavated to 3 or 4 m depth. The excavation may be minimized by stacking earth to make a wall around the pond. Leakage effects from the pond can cause considerable loss of salt solution as well as stored heat. In case of permeable soil, these effects may be quite severe; care must be taken when lining the bottom and sides. A membrane liner of butynol, nylex solid vinyl, ethylene propylene diene monomer, or other suitable synthetic materials may be used. An alternative to liner is to treat the soil in such a way as to make it impermeable to hot brine solution. For example, an inexpensive liner may be buried under a layer of compacted earth.

Thermal insulation in the pond bottom and sides may be used to reduce heat losses; it may speed up pond heating but at excessive cost. Pond shape is also an important consideration. Circular surface shapes provide a minimum perimeter for a given pond surface area, involve minimum heat losses to ground, and hence are thermally the most efficient. Rectangular shapes do not have this advantage but are usually less expensive to construct. Slopping sidewalls are very effective in reducing heat loss. Sloppy walls are also desirable from the standpoint of structural stability of banks and edges; a gradient of 45° has generally been used.

3.2 Establishment and Control of Gradient

Three methods have been adopted for the establishment of initial salt density gradient in solar ponds: natural diffusion, stacking, and redistribution. The first method relies on the natural diffusion between a freshwater layer and the layer of saturated salt solution. The pond is half filled with each layer and the surface and bottom concentrations are maintained constant. Stacking involves the filling of a pond with layers of progressively changing concentrations. The redistribution method is considered to be most convenient and expedient for large-area solar ponds. In practice, the redistribution method involves filling the pond with brine of near-saturation concentration (S_c) to half of its total depth (L); the fresh water is then fed into the pond through the diffuser, which is initially placed at the bottom in the brine. The water will stir and uniformly dilute the pond brine above the diffuser. The pond surface level will start rising, and the diffuser is simultaneously raised upward in a continuous motion or in discrete steps of up to 5 cm. The timing of diffuser movement is adjusted so that the diffuser as well as the brine surface reach the final level at the same line. Consequently, in the pond region progressively diluted brine layers are generated and a constant (S_c/L) density gradient, positive downward, is established.

The mathematical expression for the rate of diffuser movement was derived by Zangrando as follows: If $x_s(t)$ and $x_d(t)$ represent the height of the pond surface and the diffuser with reference to the pond bottom at any time t, then in accordance with the proportionality criteria, we have

$$x_d(t) = b_1 x_s(t) + b_2, \tag{1}$$

where b_1 and b_2 are constants:

$$\text{At } t = 0,\ x_d(t) = 0 \text{ and } x_s(t) = 1/2 \tag{2}$$

$$\text{At } t = t_f,\ x_d(t) \text{ and } x_s(t) = 1. \tag{3}$$

Equation (1) in combination with Eqs. (2) and (3) yields

$$x_d(t) = 2x_s(t) - 1$$

or

$$\dot{x}_d(t) = 2\dot{x}_s(t). \tag{4}$$

Equation (4) implies that the rate of diffuser motion should be twice that of the surface motion.

The solar pond may be considered as a horizontal layer of incompressible fluid of depth l and infinite horizontal dimension (y,z plane); the x-axis is taken along the vertical direction and positive downward. The layer embodies the gradients of temperature and salinity corresponding to cold water at the top and hot brine at the bottom. Owing to gradients, diffusion of heat and salt occurs continuously. The solar pond may therefore be considered a thermohaline double-diffusive fluid system, and its physical behavior may be described by the following equations of fluid mechanics and salt diffusion:

1. Conservation of mass (continuity equation):

$$\frac{\partial \rho}{\partial t} + \nabla(\rho \vec{V}) = 0$$

or

$$\frac{D\rho}{Dt} + \rho \nabla \vec{V} = 0$$

2. Conservation of momentum (Navier–Strokes equation):

$$\rho \frac{D\vec{V}}{Dt} = -\nabla p + F + \mu \nabla^2 V + \left(\xi + \frac{\mu}{3}\right)\left(\nabla \vec{V}\right)$$

3. Conservation of energy (heat conduction equation):

$$\frac{DT}{Dt} = \alpha_T \nabla^2 T + Q_T$$

4. Conservation of salt:

$$\frac{DS}{Dt} = \alpha_S \nabla^2 S + Q_S,$$

where Q_T is the heat source term resulting from the absorption of solar radiation in the pond, Q_S is the salt source term resulting from the process of salt replenishment in the pond,

$$\vec{V} = \begin{bmatrix} u \\ v \\ w \end{bmatrix}$$

is the convective velocity vector, $\frac{D}{Dt}$ is the convective derivative given by

$$\frac{D}{Dt} = \frac{\partial}{\partial t} + \vec{v}\nabla,$$

μ is the coefficient of viscosity, F is the external force, and ξ is the viscosity coefficient.

Due to thermal expansion, the fluid of the bottom region tends to be lighter than the fluid at the top. Thus, the system has a top-heavy configuration, which is potentially unstable. The stability criteria in such a situation have been obtained as follows:

$$\left(\frac{\partial S}{\partial X}\right)_{\min} = \frac{\nu + \alpha_T}{\nu + \alpha_S} \times \frac{\alpha_c}{\beta_c}\left(\frac{\partial T}{\partial X}\right)$$

or

$$\left(\frac{\partial S}{\partial X}\right)_{\min} = \frac{p_r + 1}{p_r + \tau_s} \times \frac{\alpha_c}{\beta_c}\left(\frac{\partial T}{\partial X}\right), \tag{5}$$

where $p_r = \nu/\alpha_T$ is the Prandtl number, and $\tau_S = \alpha_S/\alpha_T$ is the ratio of diffusivities and referred to as the Schmidt number. Equation (5) gives the minimum salt gradient requirement corresponding to a given temperature gradient in the double-diffusive solar pond. This equation is often referred to as the hydrodynamic stability criterion in the context of static stability criteria based on a simple buoyancy model given as

$$\left(\frac{\partial S}{\partial X}\right)_{\min} = \frac{\alpha_c}{\beta_c}\left(\frac{\partial T}{\partial X}\right), \tag{6}$$

where α_c is thermal expansion coefficient, and β_c is the salt expansion coefficient.

For dilute solutions at ambient air temperature, $\nu = 7\alpha_T \approx 10^3 \alpha_S$. Therefore,

$$\frac{p_r + 1}{p_r + \tau_S} \approx 1.14.$$

This implies that a concentration gradient approximately 14% greater than the static stability is required by the hydrodynamic stability criterion.

The vertical gradient of density causes an upward diffusion of salt in the pond. For a typical sodium chloride solar pond, the amount of upward diffusion of salt is 60–80 g/m^2 day. The tendency of salt diffusion is to destroy the gradient. One gradient

control approach is to remove salt from the surface and inject it back into the bottom. For this approach, an evaporation pond is required. However, a more practical approach, which does not require the continual addition of salt, is the "falling pond" concept. A schematic of the falling pond technique is shown in Fig. 3. Hot brine is withdrawn from the bottom layer without disturbing the layers above. This is possible since in a fluid system stratified with a density gradient, selective flow of the bottom layer can be accomplished in the same manner as the withdrawal of a single card from the deck. The hot brine withdrawn from the solar pond is passed through the flash evaporator to remove some of its water. The solution, which now has a higher concentration and a smaller volume, is reinserted into the pond bottom. Consequently, the concentration gradient is maintained. The decrease in surface level is restored by the addition of fresh water to keep both the pond depth and the surface concentration constant. In the preceding process, the gradient tends to be displaced downward, hence the name falling pond technique. Following Tabor, if v_0 is the vertical velocity (measured positively downward) of the mass of the brine in the pond, V_1 and V_2 are values of volume flow rates at input and output, and A is the horizontal area of the pond (assumed to be uniform vertically), then

$$v_0 A = V_2 - V_1.$$

The resultant downward flux of salt is given by

$$v_0 S = (V_2 - V_1)S/A.$$

The condition for the maintenance of the gradient may be written as

$$(V_2 - V_1)S/A = \alpha_S(\partial S/\partial x),$$

where α_S is the coefficient of salt diffusion.

3.3 Wind and Precipitation Effects

Wind interaction with a solar pond generates waves and currents in the surface layer. Waves cascade energy through a wave spectrum that results in turbulence, which in turn depletes the salt concentration gradient and can promote complete convection in the surface region. The surface currents interact with banks and edges and create circulations in the vertical plane and cause layer mixing. The raindrops also considerably influence the dynamics of gradient erosion in the pond surface region. The wind flow over the pond surface increases the convective as well as evaporative heat losses. Suppression of wind effects is therefore very important for increasing the operating efficiency of solar ponds. Various methods of limiting the wind mixing have been tested or proposed, including floating plastic pipes, floating plastic nets, floating

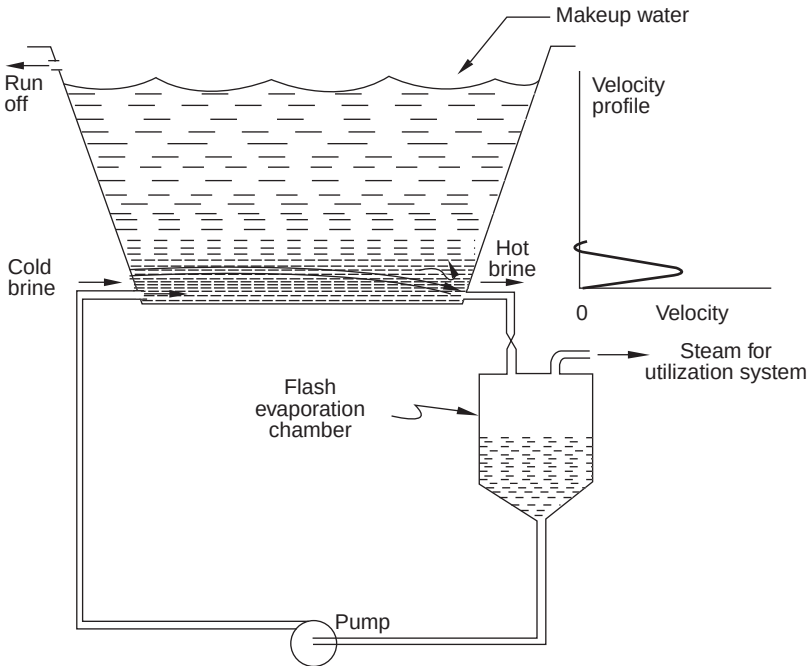

FIGURE 3 Schematic of falling pond technique of gradient control and heat removal.

plastic rings, wind baffles, and an immiscible liquid (amyl acetate and silicone oil) surface layer.

3.4 Fouling and Corrosion

Fouling and corrosion are inherent problems in solar ponds. Fouling may be caused by the falling of wind-blown material such as dirt and leaves as well as by the growth of algae or bacteria in the body of the pond. Heavy wind-blown debris normally settles to the pond bottom, where its effect on pond performance is not significant. The material of low-specific gravity is usually confined to the convective layer at the pond surface and can be removed by filtering and skimming the layer Biological growth can be checked by adding a biocide such as copper sulfate with salt at the time of filling the pond. A hot and saline environment is usually the cause of corrosion, which is often encountered in feed water pumps and heat exchangers. Careful material selection can help. Bronze, ceramic, stainless steel, and plastics (polypropylene) are well suited for saline and hot water.

3.5 Thermal Performance

In practice, a salt gradient solar pond is a three-zone configuration. The temperature gradients are relatively large in the surface region where most of the infrared portion of the solar spectrum is absorbed; the gradient induces instabilities and results in the formation of the surface convective zone. Various processes, including wind mixing, penetrative convection, and diffusive action of salt and heat, also contribute to the formation of this zone. In normal conditions, its depth ranges between 0.2 and 0.5 m. This layer is a liability on solar pond heat collection and storage since in a pond of fixed depth the growth of the mixed surface layer takes place at the expense of the thickness of the insulating gradient layer. The mixed surface layer does not provide thermal insulation to the storage layer and absorbs a considerable portion of incident solar energy. Similarly, the excessive absorption (up to 30%) of radiation by the pond floor induces thermohydrodynamic instabilities in the bottom region and makes it convective and isothermal. The bottom convective zone provides thermal storage. A convective storage layer is therefore placed in the bottom of all modern solar ponds. The minimum depth of this zone should be 0.5 m, which is sufficient to level the diurnal fluctuations in the storage zone temperature. Depths of more than 1.25 m are very effective in leveling the seasonal fluctuations, and at a depth of 10 m no seasonal variation is observed. A storage layer 1.2 m deep is usually considered appropriate. The optimum depth of the nonconvective zone is a function of collection temperature, which seems to favor a depth of approximately 1.25 m for this zone.

The following are typical thermal performance efficiencies of solar ponds:

Predicted: 20–30% at a collection temperature of 70–90°C

Achieved: 15% (Israel ponds) and 9–12% (U.S. ponds)

4. SALTLESS NONCONVECTIVE SOLAR PONDS

A saltless nonconvective solar pond was conceived primarily to overcome numerous problems encountered with conventional salt gradient solar pond. It consists of a convective water reservoir insulated on the bottom and sides. The surface insulation to the water is provided by a nonconvective layer of transparent fluid such as ethanol and silicone oil. The convective stability of the insulation layer is characterized by the stability of the fluid layer with adverse temperature gradient. In hydrodynamics, this problem is referred to as the Rayleigh–Bennard problem. The maximum stable temperature gradient across the layer is given by

$$(dT/dx)_{\max} = \frac{R_c K v}{g\beta D^4},$$

where g is acceleration due to gravity, β is the coefficient of volumetric expansion, dT/dx is the adverse temperature gradient, D is the depth of the layer, K is the thermometric conductivity or thermal diffusivity of fluid, v is the kinematic viscosity of the fluid, and R_c is the critical Rayleigh number.

The insulation layer is nonconvective if its characteristics (v, D, and R_c) are matched to the temperature difference between its bottom and top surfaces. Shaffer suggested that the insulation layer could be stabilized against convection by using viscous fluids such as silicon oil and water syrups. The control of convection by an array of horizontal membranes has been investigated by Hull. It has been shown that the separation of membranes (D) must be approximately 3–5 mm for convection to be suppressed; hence, to minimize the reflection losses at the interface, it is necessary to match the refractive index of fluid to that of the membrane. Water and ethanol are recommended as liquids for the surface

insulation zone. Teflon film seems to be an appropriate membrane. Ethanol is preferable since it can float on the hot water reservoir.

Another method of convection suppression in the insulation layer (air) involves the use of honeycomb panels. It consists of a sealed air-filled honeycomb panel floating over the hot water reservoir. It is predicted to be an attractive alternative, giving solar efficiencies of 40–60% at collection temperatures of 70–90°C. This is approximately double the efficiency of conventional salt gradient ponds.

5. APPLICATIONS

5.1 Electric Power Conversion

The Solar pond is ideal for electricity generation. One remarkable advantage is that its upper surface is cool due to evaporation and can be used for cooling the condenser. Thus, a power-generation application pond can accomplish three functions: radiant energy collection, thermal energy concentration and storage, and heat rejection. The heat available from salt gradient solar ponds is at temperatures of 50–100°C. Thus, the basic element involved in electricity generation is the low-temperature turbine. Based on the nature of the turbine, two plant types are possible: flashed steam plants and binary (organic) fluid cycle plants. Commercial turbines that operate with flashed steam cycle conditions are not available. However, binary fluid cycle turbines are commercially available. These turbines are similar to steam turbines and are based on the Rankine power cycle. Their working fluid is not steam but an organic fluid, such as freons, toluene, chlorinated hydrocarbon, or hydrocarbons with a low boiling temperature. These are high-molecular-weight fluids and so the turbine is smaller than the corresponding steam turbine. These turbines obtain 0.4–0.7 Carnot efficiency. A conceptual schematic of a binary fluid cycle-based solar pond power plant is shown in Fig. 4. Israel is the world leader in the operation of such plants. A 150-kW electric power plant was put into operation at Ein Bokek, Israel, in 1979.

5.2 Process Heating

Solar pond heat holds great promise for application for process heating. Salt production is one of the earliest applications of the solar pond. Any of the following industries and industrial processes may be supplied heat from a solar pond; salt and mineral production; drying and curing of timber; milk pasteurization; concentration and separation by evaporation; cleaning and washing in the food industry; tanning of skins; textile processing, such as wool scouring, carbonizing, and dyeing; industrial laundry; and the paper industry for preheating. Solar pond heat has been demonstrated to be applicable to the social sectors of both the developed and the developing world. Specific applications

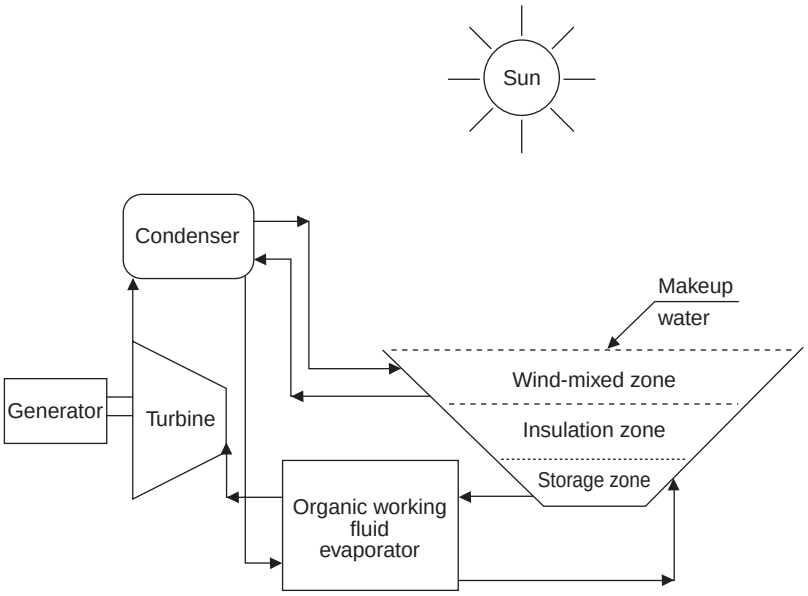

FIGURE 4 Solar pond power system.

include heating swimming pools, low-temperature cooking in southern India and western Africa, and desalinating water in outback Australia. The solar pond heat has multiple applications in the agricultural industry. At the Ohio Agricultural Research and Development Center (OARDC), a solar pond ($18.5 \times 8.5 \times 3.0$ m) has been constructed to supply the winter heat requirements of a single-family residence and partial needs of an adjacent greenhouse. In this system, hot brine is extracted from the pond and passed through shell and tube heat exchangers. If the pond temperature is higher than 40°C, the extracted heat is supplied to a water-to-air discharge heat exchanger in the green house; if the pond temperature is less than 40°C, extracted heat is first upgraded by a heat pump and then supplied for the heating of greenhouse. The method is quite suitable for this application and has good thermodynamic efficiency.

6. ECONOMICS

The major cost factors of a solar pond system are the earthwork (excavation, leveling, and compaction), the synthetic lining, the salt, the water, the land, and other miscellaneous supplies. These factors vary considerably with the location and the size of the system. Consequently, small ponds are considerably more expensive than large ponds, and there is a wide variability in the per unit area cost estimates of solar ponds operated at different locations throughout the world. Installation costs of two small-size solar ponds are provided in Table I. These estimates exclude all expenses related to the heat recovery systems.

TABLE I

Cost of Small-Size Pond Installation

Item	Australian pond ($/m^2)[a]	American pond ($/m^2)[b]
Earth work	9.81	5.00
Liner	2.79	11.00
Salt	1.91	9.70
Water	0.025	—
Land	—	—
Miscellaneous	0.52	5.90
Total	15.06	31.60

[a] Location: Alice Springs (Sheridan, 1982).
[b] Location: Miamisburg (Wittenberg and Harris, 1981).

7. ENVIRONMENTAL IMPACT

Stabilization of the greenhouse effect is the focus of global environmental concerns. The carbon dioxide emissions resulting from the use of fossil fuels must be reduced by more than 60% to stabilize the greenhouse gases at present concentrations. Stabilization cannot be achieved simply by improving fossil fuel technologies and demand management. The world, in which process heat and electricity are the major needs, has therefore pinned its hopes on the introduction of renewable energy systems. The solar pond is an inherently simple and inexpensive renewable energy means of heat and electricity. It therefore has the greatest potential for cost-effective implementation of renewable energy in the short term and long term. However, in a salt gradient pond approximately one-third of a ton of salt per unit area is used and at certain locations salt contamination may cause serious environmental hazards, such as the detrimental effect of salt in drinking water and toxicity to the vegetation surface by saline soil. The development of the honeycomb solar pond eliminates the expense of large quantities of salt and the potential problems of degrading the aquifer with salt. Fouling resulting from the falling of wind-blown debris is another inherent problem in solar ponds.

Glossary

concentrator A solar collector that uses optical methods to concentrate solar radiation before absorption.
flat plate collector A solar collector that uses a flat plate geometry as the absorbing surface.
insolation A term that stands for incident solar radiation.
PTC Abbreviation for parabolic trough collector.
solar industrial process heat (SIPH) Process heat supplied using solar energy.
solar load fraction The fraction of the thermal load that is met by the solar system.
TRNSYS (Transient System Simulation) A widely used transient system simulation program developed at the University of Wisconsin.
utilizability Fraction of solar flux absorbed by the collector that is delivered to the working fluid.

Heat energy forms a large fraction of the total energy consumption in the industrial sector. For example, processes such as boiling, distillation, and polymerization that require heat input are common in chemical industries. Some other examples include cleaning and sterilization operations in the food industry, processes involving drying of materials, and the production and purification of metals and alloys. Heat is often supplied in the form of hot water and steam, or hot air, and sometimes involves the direct heating of the components in the process. All heat energy used in this fashion is referred to as industrial process heat (IPH). Most of the IPH demand today is met by burning fuels such as natural gas, oil, and coal or by using electric heating. Solar energy can be used to supply the heat input required in IPH systems. Several such systems have been designed and constructed all over the world. With the proper choice of collection system, solar systems can be built to meet any temperature level that is required by an industrial process.

1. SOLAR THERMAL COLLECTION SYSTEMS

1.1 Solar Collectors

The simplest version of a solar collector is the flat plate collector. A typical flat plate collector consists of an absorber plate that absorbs well over the range of the solar radiation spectrum. Glazing is used to reduce heat losses by thermal convection and radiation while keeping the absorber plate transparent to solar radiation. Thermal insulation is also used to reduce losses. Flat plate collectors have a working temperature of less than 70°C. To achieve higher temperatures, evacuated tube collectors, which essentially have a vacuum between the absorber and glazing tube, can be used. Because of the very reduced conduction and convection losses across the vacuum, these collectors yield higher efficiency at lower temperatures.

Concentrating collectors use optical concentration to increase the intensity of solar radiation and, thereby, achieve higher temperatures. The simplest concentrating collector can be made by using flat wall reflectors to concentrate solar radiation on a flat plate collector. Concentrating collectors can be of tracking and nontracking types. A tracking concentrator has its orientation adjusted to account for the variation in

 © 2004 Elsevier Inc. All rights reserved.

the position of the sun in the sky with time. For temperatures up to 350°C, parabolic trough collectors (PTCs) are used. These collectors focus solar radiation on a line focus where the absorber is located. A reflecting spherical or paraboloidal bowl is used when temperatures on the order of 250 to 500°C are needed. For extremely high temperatures, a large field of tracking mirrors (called heliostats) is used to concentrate solar radiation on a receiver that is located on top of a central tower.

1.2 Solar Ponds

A solar pond combines collector and energy storage in one unit. Solar radiation entering a pond travels some distance before it is absorbed in the water, increasing the temperature of the water at that depth. In a salt gradient solar pond, the density of water is increased at the lower section of the pond by the addition of a salt into the pond. Although the temperature of the lower section is increased by the absorption of solar radiation, the convection of warmer water to the surface of the pond is suppressed due to the density gradient imposed by the added salt. Salts such as magnesium chloride ($MgCl_2$) and sodium chloride (NaCl) are commonly used in solar pond applications. Bottom-layer temperatures on the order of 70 to 80°C are achievable.

1.3 Thermal Storage

Solar energy is a resource that is not available during the night and is only intermittently available on cloudy or overcast days. Many solar systems incorporate thermal storage to compensate for the intermittent nature of the solar resource. Thermal energy is normally stored as sensible heat, latent heat, or the heat of chemical reaction. In sensible heat storage, the energy is used to raise the temperature of a storage medium. Commonly used sensible heat storage materials include water, organic oils, molten salts, ceramics, and rocks. Latent heat storage takes advantage of the large amount of energy required to effect phase transformations in materials. Phase change occurs at a fixed temperature called the transition temperature or over a very small temperature range. Materials such as paraffin waxes, inorganic salts, and eutectics of organic and/or inorganic compounds are used as phase change materials. Thermal energy can also be stored as the heat of reaction in a reversible chemical reaction. The amount of energy stored depends on the heat of reaction and the extent of conversion achieved. An advantage of thermochemical energy storage is that the products of reaction can be stored at room temperature. Examples of reactions include decomposition of metal hydrides, oxides, peroxides, and ammoniated salts.

2. SOLAR INDUSTRIAL PROCESS HEAT OVERVIEW

It is estimated that solar thermal technology could theoretically supply 51% of the U.S. industrial process heating needs. Process heat solar collectors could be used throughout the year, and each system could be designed to fit the temperature level required for its specific applications (this is particularly important in the use of process heat). Table I shows the heat energy consumption by various SIC (Standard Industrial Classification) categories for selected industries in the United States. A majority

TABLE I

Summary of U.S. Industrial Heat Use by SIC Category for 1971 and 1994

	Quantity in 10^{12} kJ	
SIC group	1971	1994
20 Food and kindred products	779	1254
21 Tobacco products	14	W
22 Textile mills	268	327
23 Apparel	22	W
24 Lumber and wood products	188	518
25 Furniture	37	73
26 Paper and allied products	2006	2812

37 Transportation	310	383
38 Instruments	53	113
39 Miscellaneous	72	W
Total	14,854	22,854

Note. W, withheld to avoid disclosing data for individual establishments.

of the heat is used in mining, food, textiles, lumber, paper, chemicals, petroleum products, stone–clay–glass, and primary metals industries. In addition to the quantity of heat, the quality (i.e., temperature) is very important to match the proper collection system to the application.

Solar collection and concentrator technologies are capable of providing a broad range of temperatures to match the demand of various processes. Fig. 1 gives the distribution of the U.S. process heat requirements based on the required temperature level. Note that approximately 60% of all U.S. process heat requirements fall below 370°C. This temperature is easily achievable by using PTCs. It is estimated that energy demand in the European Union for processes at a temperature below 250°C is 1080×10^{12} kJ. Table II shows the temperatures that can be achieved with low- and medium-temperature collectors and lists a few examples of potential applications.

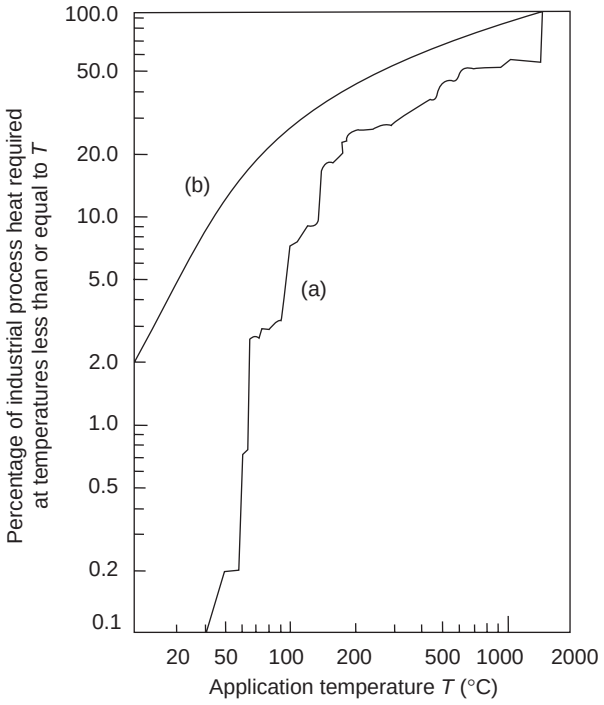

FIGURE 1 Distribution of U.S. process heat use by required temperature level: (a) heat requirements; (b) IPH requirements plus preheat from 15°C.

An example of a solar industrial process heat (SIPH) system for providing process hot water or steam is shown in Fig. 2. Solar energy is collected by circulating a heating fluid (e.g., oil, water) through the solar collectors. The choice of the collector type is strongly influenced by the temperature requirements of the process and the choices made at the time of design. For instance, in the Gould solar system (described later), parabolic troughs were used to collect solar energy, with oil circulated inside the collectors to remove the heat. Because the cost per unit collector area is very dependent on the optics used in the collection process, matching the collector characteristics to temperature requirements is very important.

The hot fluid leaving the collector is stored in a storage tank. This hot fluid can then be used to supply heat to the industrial process by exchanging heat with the process fluid. Because solar energy is an intermittent resource, most applications require a backup energy source to ensure that the requirements of the industry are met even on cloudy days and days with insufficient sunshine.

Another way in which to compensate for the intermittent nature of the solar resource is to use a storage subsystem. Using storage is particularly useful if the load is of an intermittent nature as well given

TABLE II

List of Some Low- and Medium-Temperature Solar Collector Geometries and Potential Industrial Applications

		Example applications	
Type of collector	**Typical working temperature range (°C)**	**Industry**	**Use, energy form**
Flat plate collector	≤ 70	Food industry	Washing, hot water
		Automobile manufacturing	Paint drying, hot air
		Chemicals	Borax drying, hot air
High-efficiency flat plate collector	60–120	Lumber	Log conditioning, hot water
			Kiln drying, hot air
		Dairy	Sterilization, steam
Parabolic trough collector	150–350	Textiles	Finishing, steam
		Paper and pulp	Kraft pulping, steam

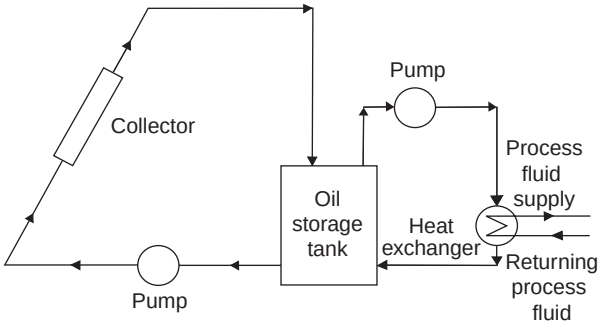

FIGURE 2 Simplified schematic of a process fluid supply system.

that the stored energy can be used to ensure that the solar system is used better. Typically, industrial process heat (IPH) systems tend not to use large storage. Instead, the solar system meets a fraction of the load, and the difference is made up using a backup source. Some SIPH systems are intentionally designed to meet only part of the load of the application. They may simply serve as the preheating arrangement so that the load on the conventional system may be reduced, thereby saving energy.

3. EXAMPLES OF SIPH SYSTEMS

Most of the IPH systems below 200°C require hot water, steam, or hot air. If the heat is needed in process air, water heating collectors along with water to air heat exchangers may be used or air heating collectors and rock storage may be used. Hot air typically is needed in agricultural drying, which may be provided by passive solar air heaters. If a large body of water is available, solar ponds may be used for low-temperature applications.

A high-temperature SIPH system may be designed to use low-, medium-, and high-temperature collectors in stages so as to minimize the cost and maximize the efficiency. A schematic of such a system designed for textile dyeing process is shown in Fig. 3.

3.1 SIPH for Textile Industries

Of all the energy used in the textile industry, 60 to 65% is used in wet processing, including dyeing, finishing, drying, and curing. The energy for wet processing is used as hot water and steam. The textile industry in the United States uses approximately 500 billion L of water per day, and approximately 25% of this water is used at an average temperature of 60°C.

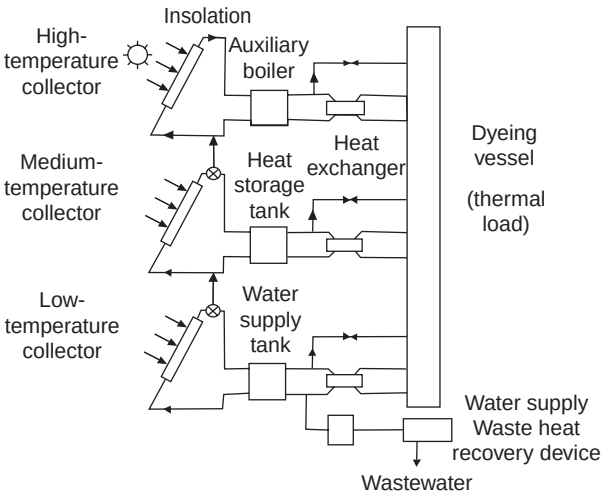

FIGURE 3 Schematic of a SIPH system for a high-temperature dyeing process.

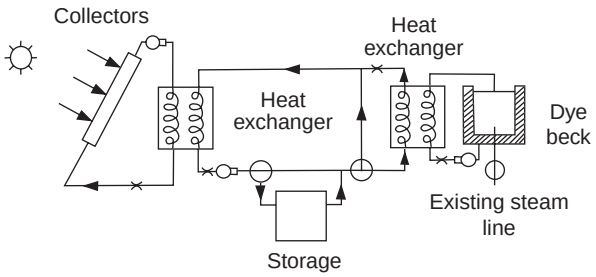

FIGURE 4 Schematic of solar energy system at Riegel Textile Corporation plant in LaFrance, South Carolina.

There are a number of examples of SIPH for textile dyeing. One of those is for a dyeing operation at the Riegel Textile Corporation plant in LaFrance, South Carolina. Figure 4 shows a schematic of the system. Because the dyeing process uses water at a temperature of 70°C, flat plate solar collectors are used in this system. The system has 621 m^2 of collector area.

The dyeing process at this plant is an atmospheric dye beck batch process at a maximum temperature of 90°C, and this is also typical of the textile industry in the United States. The batch dyeing process involves heating approximately 4500 L of inlet water between 10–25 and 90°C. The typical dye cycle is shown in Table III. The SIPH system at the Riegel Textile plant has been operating successfully. The system was simulated using the TRNSYS (Transient System Simulation) computer model. Figure 5 shows the actual performance of the system and that predicted by TRNSYS. According to measured performance of the system from August 14 to October 8, 1983, the system operated with an efficiency of 46%.

3.2 SIPH System for Milk Processing

The food system uses approximately 17% of the U.S. energy, nearly 50% of which is for food processing as hot water (<100°C) or hot air. Proctor and Morse showed that more than 40% of the energy demand in the beverage industry in Australia was in the form of hot water between 60 and 80°C. Considering the temperature and heat requirements of food processing, one would be tempted to conclude that SIPH would be ideal. However, many food processing requirements are seasonal, and this might not be economical considering the prices of conventional fuels unless the SIPH system can be used for a majority of the year. One application that is year-round is milk processing. An example of a TRNSYS simulation of a SIPH system for milk processing in the United States obtained from the literature, with the unit operations (and their respective temperatures) for this plant compatible with solar thermal energy, is as follows:

- Boiler feed makeup water (100°C)
- Pasteurizer makeup water (21°C)

TABLE III

Typical Dye Beck Heat Requirements

Dye process operation	Temperature of dye beck (°C)	Time interval of cycle (h)	Percentage of total process energy
Heat the initial load	16–32	0.5	7
Dyeing preparation	32–88	0.5	22
Dye period	88	7–9	68
Cool and reheat for dye fixation	32–43	1.0	3

- Case washer and rinsing (49°C)
- Cleanup (71°C)
- High-temperature short-time cleanup (79°C)
- Bottled water (93°C)

It was estimated that for a plant producing 170,000 kg/week of milk and 98,000 kg/week of orange juice, a total of 621.3 GJ (or 80%) of energy demand was compatible with solar energy during the summer and 724.9 GJ (or 93%) of energy demand was compatible during the winter. A 4000-m^2 flat plate collector area could provide approximately 30 to 35% solar fraction for the milk processing plant in Madison, Wisconsin; Fresno, California; or Charleston, South Carolina.

3.3 SIPH Systems for Electronic Processing

Gould Electronics, a leading U.S. electronic circuit board manufacturer, uses an SIPH system to provide the process hot water requirement in its foil division manufacturing facility in Chandler, Arizona. The SIPH system was built when Arizona had a moratorium on natural gas systems in new buildings. The SIPH system uses PTCs, through which oil is heated and stored in two 30,000-gallon (113,000-L) storage tanks. The collector field has a total aperture of 60,480 square feet (5600 m^2). The plant has a hot water requirement of 265 gallons/min (1000 L/min) at 196°F (91°C). The hot oil is used to heat up this water, with electric induction heaters serving as backup for the times when the solar system is not able to meet the full load. The field operated successfully from 1983 to 1987, but by 1990 many

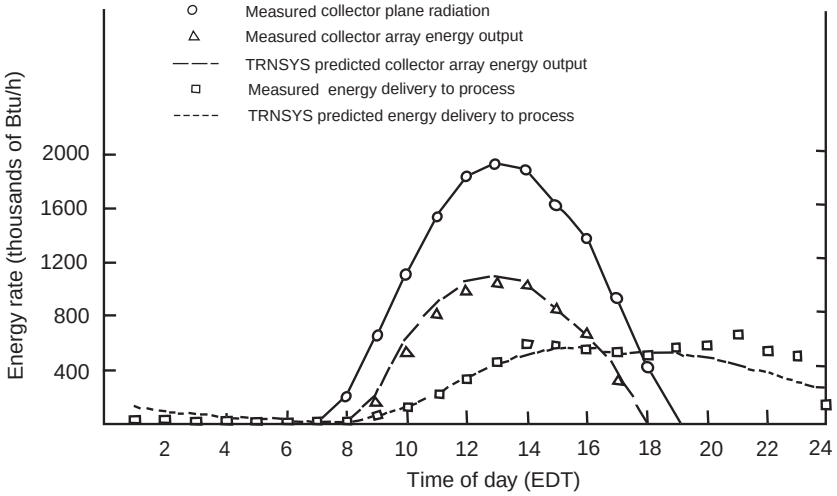

FIGURE 5 Actual and predicted system operation: August 16, 1983.

small problems had resulted in a substantial decrease in field performance. Gould engineers worked with Sandia National Laboratories to solve these problems between 1991 and 1992, restoring system availability to 90%. Based on actual operational data, it was estimated that an average saving of $7800 per month was achieved by using the solar system.

3.4 Direct Process Heat

Solar energy, with the appropriate choice of collection and concentration technology, can be used to deliver a range of temperatures, from very low to extremely high values. This allows SIPH systems to be designed to provide direct heat to a variety of processes. SIPH systems can be designed to provide temperatures that can exceed values achieved using practical combustion processes.

The use of SIPH has been proposed for various processes, including high-temperature detoxification and recycling of hazardous waste; production of fuels such as hydrogen and syngas through thermochemical cycles; production of metals such as aluminum, iron, zinc, and magnesium; and production of other materials such as silicon nitride and silicon carbide in solar furnaces. The use of concentrated solar radiation has also been proposed for the heat treatment of materials. Although several SIPH systems have been proposed for direct process heat applications, there are no known commercial systems that currently operate using these technologies. Nevertheless, research in this direction has progressed, and several laboratory and pilot plant scale demonstrations of these technologies have been completed.

4. DESIGN AND PERFORMANCE OF SIPH SYSTEMS

To assess the economic viability of any solar process, its cumulative energy delivery over its economic life on the order of years or decades must be known. It is very difficult to calculate this number accurately because (1) solar systems and their energy delivery are subject to the vagaries of local microclimates (which can change on a time scale on the order of hours) and (2) future weather cannot be predicted at this level of detail. The standard approach used to estimate future performance of a solar system is to use a typical year of past weather data and assume that it will represent the future on the average, for purposes of engineering accuracy. Two common methods used to predict long-term performance of SIPH systems are the utilizability method and TRNSYS. These methods can also be used for the design of SIPH systems. This section describes the utilizability method and the TRNSYS method.

4.1 The Utilizability Method

Utilizability, ϕ, has been used to describe the fraction of solar flux absorbed by a collector that is delivered to the working fluid. On a monthly time scale,

$$\bar{\phi} = Q_u / F\bar{\eta}_o \bar{I}_c < 1.0.$$

Here, the overbar is used to indicate monthly average values, Q_u is the monthly averaged daily total useful energy delivery, F is a heat exchanger transfer factor, $\bar{\eta}_o$ is the daily averaged optical efficiency of the collector, and I_c is the monthly averaged daily solar radiation incident on the collectors. $\bar{\phi}$ is the fraction of the absorbed solar flux that is delivered to the fluid in a collector operating at a fixed temperature T_c. The $\bar{\phi}$ concept does not apply to a system composed of collectors, storage, and other components where the value of T_c varies continuously. However, with most concentrators for concentration ratios greater than 10, the collector is relatively insensitive to a small range of operating temperatures. To check this assumption for a particular process, values of $\bar{\phi}$ at the extremes of the expected temperature excursion can be compared.

The value of $\bar{\phi}$ depends on many system and climatic parameters. Collares-Pereira and Rabl showed that only three are of the first order: the clearness index $\bar{K}_T$, the critical intensity ratio $\bar{X}$, and the ratio r_d/r_T. The first is related to insolation statistics, the second to collector parameters and operating conditions, and the third to collector tracking and solar geometry.

Empirical expressions for $\bar{\phi}$ have been developed for several collector types.

For example, for nontracking collectors,

$$\bar{\phi} = \exp\{-[\bar{X} - (0.337 - 1.76\bar{K}_T + 0.55 r_d/r_T)\bar{X}^2]\}$$

$$for\ \bar{\phi} > 0.4, \bar{K}_T = [0.3 - 0.5], \text{and } \bar{X} = [0 - 1.2].$$

Here, $\bar{X}$ is the monthly average daily critical intensity ratio, defined as the ratio of collector heat loss to absorbed solar flux at the "no net energy delivery" condition. The monthly averaged clearness index $\bar{K}_T$ is defined as the ratio of the monthly averaged daily total radiation on a horizontal surface to that on a corresponding surface outside the earth's atmosphere.

The ratio r_d/r_T is a factor that depends on solar geometry and collector tracking. Expressions are available and tabulated for various collector types.

Similar equations are available for other collector types and other clearness index values. In some cases, the collection time Δt_c might need to be determined for nontracking, low-concentration collectors.

A well-known method to calculate the long-term performance of collector systems with storage is using the "f-Chart" method developed by Klein and Beckman The f-Chart method can be used for estimating the fraction of the load that will be met by the solar thermal system. The method uses the utilizability (defined differently from the method given previously) and a few other nondimensional parameters to predict the monthly solar load fraction f_s. Predictions are based on the results of simulations for various climatic conditions by an hourly time scale computer model.

4.2 TRNSYS Computer Simulation Program

TRNSYS is a sequential–modular transient simulation program developed at the Solar Energy Laboratory of the University of Wisconsin. It is a widely used, detailed design tool involving hourly simulations of a solar energy system over an entire year. The TRNSYS computer program contains FORTRAN subroutines of nearly all the components necessary to build a solar energy system. The component models, which are either empirical or analytical, describe the component performance with algebraic and/or differential equations. A system simulation model is created by interconnecting the models of individual components. The resulting set of simultaneous algebraic and/or differential equations is solved by TRNSYS. This software is constantly being upgraded and is backed by technical support.

5. ECONOMICS OF SIPH

The commercialization of SIPH systems did not take off as was expected during the late 1970s and early 1980s. One reason why was the low price of natural gas in the market. Carwile and Hewett analyzed 15 proposed SIPH systems that were never built and the examined reasons why. It was seen that the payback period was too large when compared with industry standards for many of these projects. An additional hurdle that had to be overcome was investors' lack of confidence in this unconventional method of providing IPH. The small number of existing SIPH systems in the market made it difficult to convince investors to allocate money for the solar systems, even though the economics were favorable. Studies have been performed on the future prospects of SIPH, particularly systems using PTC for collecting solar radiation. As per the analysis, it was forecast that there was considerable potential to reduce the cost of such systems. If costs could be brought down by research and development (R&D) and by larger production volumes, a bigger market share would result in the future. Some studies estimated that with cost reductions through R&D, SIPH could have as much as 35% of the projected market by 2030.

In conclusion, SIPH systems are technically capable of meeting the IPH needs of many of today's industries. However, the higher costs of SIPH systems and the availability of cheaper alternatives have resulted in only few SIPH systems being built and still being in operation.

Glossary

conduction band Excited electronic status of semiconductor materials, with readiness for electron transport.
heliostats Plane mirrors that continuously adjust in angle according to the sun's position, so as to reflect a beam of solar radiation to some fixed point in space.
kilowatt (kW) A unit of power equal to 1 kJ of energy applied per second. Addition of a subscript "e" indicates electrical energy, subscript "th" indicates thermal energy.
kilowatt-hour (kWh) A unit of energy equal to the power of 1 kW applied over the duration of 1 h. Addition of a subscript "e" indicates electrical energy, subscript "th" indicates thermal energy.
megawatt (MW) A unit of energy equal to 1000 kW.
nanometer A very small unit of length, equal to one one-millionth of a millimeter.
photovoltaics (PV) The science behind semiconductor-based solar energy conversion systems.
pyranometer An instrument that measures the intensity of total solar radiation.
pyrheliometer An instrument that measures the intensity of direct beam solar radiation.
receiver A device that intercepts concentrated solar radiation and transforms it into another form of energy.
secondary concentrator An arrangement of mirrors to form a light funnel to further concentrate preconcentrated solar radiation that is incident on a receiver.
stagnation temperature The equilibrium temperature a solar receiver will reach if the process that normally removes energy is turned off.
thermal loss Undesirable transfer of heat away from a solar receiver to the environment.
valence band Relaxed electronic status of semiconductor materials.

Solar thermal power generation systems capture energy from solar radiation, transform it into heat, and then use an engine cycle to generate electricity. The majority of electricity generated around the world comes from thermally driven steam-based systems. The heat for these systems is largely provided by the combustion of coal, oil, or natural gas or by nuclear fission. The concept of substituting solar radiation for these thermal inputs leads to the consideration of solar thermal power generation. The second law of thermodynamics expresses the empirically observed fact that the potential conversion efficiency from heat to electricity (work) increases with the temperature of the thermal input available. For solar systems, this naturally leads to the consideration of methods for concentrating solar radiation to achieve high temperatures. Small-scale solar thermal power generation systems were demonstrated as early as the 1860s, mainly in France and the United States. In 2003, the largest examples of solar thermal power plants are the 80 megawatt electric (MW_e) parabolic trough systems that have been operating in southern California since the late 1980s. There are nine such power plants with variable sizes that have a combined nominal capacity of 354 MW_e and generate approximately 800,000 MWh (megawatt-hour) of electricity every year. This is sufficient to service a medium-sized city of approximately 200,000 people. These power plants generate electricity on a competitive basis thanks to previous tax incentives, long-term amortization, green-power credits, some natural gas back-up, and expert operation and maintenance.

1. THE SOLAR RESOURCE

The sun is approximately 1.4 million km in diameter and approximately 150 million km from the earth. It is close to 5500°C at its surface and emits radiation

 © 2004 Elsevier Inc. All rights reserved.

at a rate of 3.8×10^{23} kW. This energy is supplied by nuclear fusion reactions near its core, which are estimated to continue for several billion years.

The major part (70%) of the solar radiation received on the earth's surface is within the visible spectrum, with a maximum intensity at approximately 500 nm. This is consistent with a "black body" radiating at 5500°C. The intensity of solar radiation reaching the surface of the earth is typically between 900 and 1000 Wm^{-2} on a clear sunny day at noon.

Only a tiny fraction (4.5×10^{-8} percent) of the total energy radiated by the sun reaches the outer surface of the earth's atmosphere, but this is still equal to approximately 1.6×10^{14} kW. Putting this in perspective, the total annual world electricity generation of approximately 1.5×10^{13} kWh could be met with a hypothetical solar thermal power generation system (using technology discussed in this article) covering an area of approximately 30,000 km^2, which is approximately equal to the size of Belgium or Taiwan, for example. The total or "global" solar radiation reaching the earth's surface is made up of "direct" and "diffuse" components. Direct radiation can be concentrated with mirrors or lenses that point directly at the sun. It is measured with a pyrheliometer. Diffuse radiation is that fraction that has been scattered by water vapor, particles, or molecules within the atmosphere. It cannot easily be concentrated and makes up approximately 15% or more of the total radiation, depending on the clarity of the sky. Diffuse radiation levels are measured with a pyranometer fitted with a shading device to exclude direct radiation. Together the diffuse and direct components combine to make up the global total and this can be measured with an unshaded pyranometer.

However, there are challenges associated with turning this solar energy source into continuous electrical power:

- The solar radiation reaching the surface of the earth is diffuse ($\sim$1000 Wm^{-2} maximum) compared to other sources of energy, such as fossil fuel flames (megawatts/m^2);
- The sun shines intermittently in a daily cycle, which in turn follows a seasonal variation and is also heavily influenced by local weather conditions;
- The position (azimuth and elevation) of the sun in the sky and hence the angle of incidence of direct beam radiation vary continuously;
- Solar radiation cannot be stored directly, but must be immediately converted into heat, electricity, or chemical energy.

Technological solutions that allow these challenges to be met do exist.

2. MAIN SOLAR COLLECTOR SYSTEMS

Various devices for collecting solar radiation thermally have been devised. At the simplest level, a flat metal plate, painted black and placed in the sun, will heat up until it reaches a temperature where the amount of heat that it radiates and loses to the air around it exactly balances the amount of energy it receives from the sun. This "stagnation temperature" occurs at approximately 80°C for a simple flat-plate solar collector. If water, for example, is passed through passages in the plate collector, then it will stabilize at a lower temperature and the water will extract some of the energy in being usefully heated up. This is the essence of solar thermal energy collection.

Greater levels of sophistication are aimed at reducing the amount of "thermal loss" from the collector surface at a given temperature. This allows energy to be collected more efficiently and at higher temperatures. The thermal efficiency of a solar collector can be defined as:

$$\text{Thermal efficiency} = \text{Energy converted/Solar energy intercepted.}$$

Starting with the flat-plate solar collector, a cover layer of glass helps by cutting down the energy lost by the circulation of cold air across the collector. If metal tubes and glass cylinders are used as collectors instead of plates, then the space can be evacuated, so that air convection losses are largely eliminated. The smart use of coating materials to produce an optically selective surface helps to reduce radiation losses. Such coatings absorb as much as possible of the high-energy (ultraviolet and visible) solar wavelengths while they emit as little thermal radiation (infrared) as possible from the plate. Various combinations of these measures are used in the design of systems for the production of solar hot water that are used around the world for domestic and industrial applications. In principle, solar collectors of this nature could be used for electricity production. However, the comparably low temperatures that are achievable limit the conversion efficiencies that are possible to low levels.

Further increasing the temperature at which energy can usefully be recovered requires some

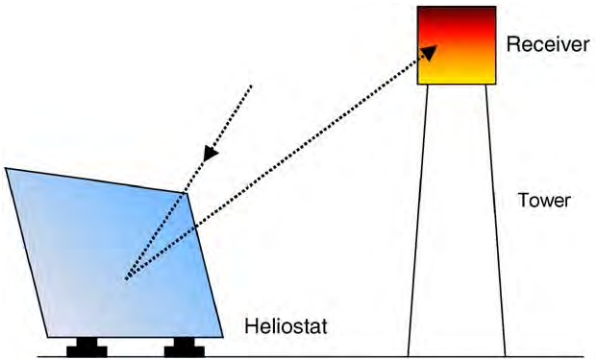

FIGURE 1 The central receiver concept; a field of plane mirror heliostats all move independently to one another to keep a beam of solar radiation focused on a single central receiver.

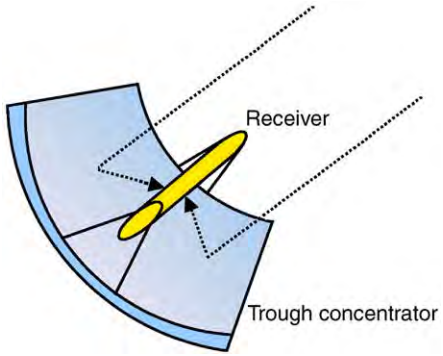

FIGURE 2 A parabolic trough concentrator focuses solar radiation onto a linear receiver when faced directly toward the sun.

method of optically concentrating the radiation so that the size of the absorbing surface and hence its thermal loss is reduced. The conceptually simplest approach is to employ a series of flat mirrors, called heliostats, that are continuously adjusted to direct solar radiation onto the absorbing surface. This is illustrated conceptually in Fig. 1. Large plants called "central receiver systems" or "power towers" have been built based on this principle and are discussed in detail in Section 4.1. The concept can also be adapted to linear absorbers and long strips of flat mirrors to create a "linear Fresnel" concentrator.

Alternatively, the mathematical properties of a parabola can be exploited for solar energy concentration. The equation for a parabola in the x–y plane is:

$$y = x^2/4f.$$

Rays of light parallel to the y axis of a mirrored parabola will all be reflected and focused at the focal point at a distance f from the vertex. As illustrated in Fig. 2, this effect can be used in a linear arrangement, where a mirrored "trough" with a parabolic cross section will concentrate solar radiation onto a line-focus when it is pointed directly at the sun. The largest solar thermal power plants thus far constructed employ this principle. They are discussed in Section 4.2. Alternatively, a mirrored dish with a parabolic cross section (a paraboloid) will focus solar radiation to a point focus (see Fig. 3). Paraboloidal dish systems are discussed in Section 4.3. Both dishes and troughs require continuous adjustment of position (or at least frequent readjustment) to maintain the focus as the sun moves through the sky.

Similar focusing effects can obviously be achieved with lenses of various kinds, but this has not been employed on the scales needed for solar thermal power systems.

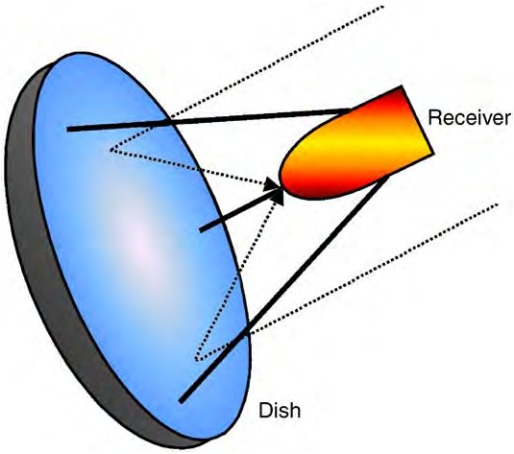

FIGURE 3 A paraboloidal dish concentrator focuses solar radiation onto a point focus receiver.

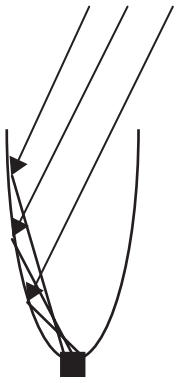

FIGURE 4 A nonimaging concentrator concentrates solar radiation without the need to track the sun.

Another alternative, which potentially avoids the need to track the sun, is to employ "nonimaging" concentration. As illustrated in Fig. 4, this involves the construction of a mirrored "light funnel" of some

TABLE I

Typical Operating Temperature and Concentration Range of the Various Solar Thermal Collector Technologies

Solar collector technology	Typical operating temperature (°C)	Concentration ratio	Tracking	Maximum conversion efficiency (Carnot)
Flat-plate collector	30–100	1	—	21%
Evacuated-tube collector	90–160	1	—	38%
Solar pond	70–90	1	—	19%
Solar chimney	20–80	1	—	17%
Linear Fresnel reflector technology	260–400	8–80	One-axis	56%
Parabolic trough collectors	260–400	8–80	One-axis	56%
Heliostat field + central receiver	500–800	600–1000	Two-axes	73%
Paraboloidal dish concentrators	500–1200	800–8000	Two-axes	80%

kind. Such a device will be able to collect rays into its aperture over a range of incidence angles and cause them to exit through a smaller aperture via multiple reflections. Nonimaging concentrators have thus far not found application as the "primary" means of concentration for solar thermal power systems but they are frequently applied as "secondary concentrators" at the focus of central receivers, dishes or troughs, where they serve to further reduce the size of the focal region.

The rays of light from the sun are not exactly parallel. This means that even a perfect optical system will produce an image of finite size, with an intensity distribution that is a maximum in the center and tapers off to zero at the edges. Imperfections in mirror shape and tracking accuracy have the effect of further spreading out the sun's image.

Each of these approaches to solar energy collection has a typical ratio of collected radiation intensity to incident solar radiation intensity, termed the "concentration ratio." Table I summarizes the options discussed and lists typical concentration ratios, the resultant operating temperatures, and the consequent thermodynamic limiting efficiency with which electricity could be produced. The limiting conversion efficiency arises from the second law of thermodynamics. The maximum efficiency for conversion of heat from a constant high temperature source is given by:

$$\text{Maximum conversion efficiency} = 1 - T_{\text{cold}}/T_{\text{hot}}.$$

This is the "Carnot limit." (Note that "absolute" temperatures must be used in the equation, usually degrees Kelvin, equal to °C + 273.15.) Real solar thermal power generation systems typically achieve approximately one-third or less of the ideal maximum Carnot efficiency.

Although higher concentration ratios give higher efficiency, they also lead to potentially higher complexity and cost. The ultimate challenge with solar thermal power systems is to produce the desired output as economically as possible. This invariably means that a tradeoff between system efficiency and capital investment drives the design process.

The three main solar thermal concentrating technologies are discussed in detail in this article as they constitute the bulk of the commercial development efforts undertaken in the area of solar thermal power generation.

3. ENERGY COLLECTION AND CONVERSION

A solar thermal power system can be presented schematically as shown in Fig. 5.

All systems begin with a concentrator, followed by a receiver that catches the concentrated radiation and converts it to another form (typically thermal energy). At this point there are two options: either the energy is further converted to the final form desired (i.e., electricity) or it is transported to another location for final conversion. The choice of the transport path provides the option of storage in the intermediate form before going to final conversion. There is also the option of designing an energy storage system after final conversion.

3.1 Receiver Types

Receivers are often built with a cavity geometry; this gives a higher effective "absorbtivity," maximizing the amount of radiation absorbed and also reducing the surface area susceptible to radiation and

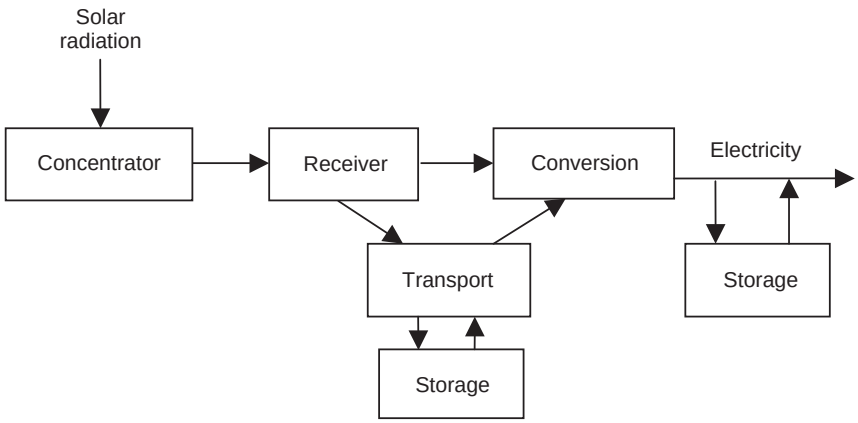

FIGURE 5 Schematic representation of the component parts of a solar thermal power system.

convection losses. Notable exceptions include the single-tube receivers with evacuated insulation used on the Californian parabolic trough power plants and the cylindrical externally irradiated receivers used on power tower systems with a completely surrounding heliostat field. There are several methods for construction. Four of the commonly used approaches are discussed here.

3.1.1 Tubular Receivers

The conceptually simplest thermal receiver type involves circulating the working fluid or heat transfer fluid through directly irradiated tubes. The tubes can be arranged to form a cavity by winding a single tube to form a helical cylinder. An alternative is arranging a number of parallel straight tubes around the outside.

Tube receivers provide a simple and reliable way of designing for high system pressures. There are issues associated with thermal cycling (particularly for steam receivers) and flow balancing in multiple parallel tube receivers.

3.1.2 Volumetric Receivers

Volumetric or direct absorption receivers aim to have the radiation absorbed by surfaces directly in contact with the working fluid. This is often achieved by having a window in front of a cavity receiver that contains an absorbing matrix, over which a fluid passes. Windows are generally made of quartz because of its superior ability to handle thermal gradients. Matrices are often ceramic (such as a foam or ceramic formed into spikes). Such receivers have been used for chemical reactors, with a catalyst impregnated in ceramic foam, and for heating air. If air is being used at atmospheric pressure, then the window is not essential.

3.1.3 Heat-Pipe Receivers

A major issue with receivers is matching the incident flux to the requirements of the energy conversion system. A very effective approach to this is the "heat pipe" receiver. The idea is to use a container with a liquid/vapor mixture. The container will be essentially all at the boiling temperature corresponding to the pressure. In regions where heat is added, liquid will evaporate, whereas it will condense where heat is extracted. The result is a "black box" of extremely high effective conductivity. Sodium (boiling point 883°C at atmospheric pressure) is favored for solar applications. This approach has been used with central receiver systems, Stirling engines, and chemical reactor receivers.

3.1.4 Solid-State Receivers

Solid-state receivers are based on the application of semiconductor materials that are designed as directly irradiated photovoltaic or thermoelectric devices. These systems produce low-voltage direct current electric power that is then transformed to higher voltage alternative current for use.

3.2 Heat Transport Mechanisms

Various methods are employed for the task of energy transport within solar thermal power plants. Five major heat transfer mechanisms for solar application are discussed here.

3.2.1 Oil

The Californian parabolic trough power plants employ a synthetic heat transfer oil. The oil is circulated through the receivers and brought back to the centrally located power plant where a heat exchanger is used to raise steam for power

generation. It has the advantage of providing stable and predictable receiver operation. Oils, however, have the disadvantages of slowly decomposing when operated at high temperatures and of environmental as well as fire hazards when leaking. The oil lines must be adequately insulated and design allowance must be made for adequate pipe expansion.

3.2.2 Steam

If the final conversion process is based on a steam Rankine cycle, then it makes sense to collect the energy as steam in the first place. The major challenge with direct steam generation, however, is the rapid thermal cycling that can occur in tubular receivers. At the point in the receiver where the tubes "dry out," the internal convective heat transfer coefficient is much less than in the regions where tubes are in contact with water. Problems arise because some sections of the tubing are exposed to rapidly alternating exposure to vapor and liquid. This causes localized thermal cycling and leads to fatigue of the metal. Insulation of pipe work and allowance for expansion is needed, as are sophisticated rotary joints to allow for solar concentrator tracking.

3.2.3 Air

Central receiver systems have been designed, among other options, to use air as heat transfer fluid either in pressurized tubular systems or in atmospherically open volumetric receivers. Systems with air temperatures of up to 1000°C have been extensively tested. Whereas tubular receivers allow for high-pressure operation with associated potential for conversion efficiency gains in gas turbines, the volumetric air receiver concept achieves very effective heat transfer from sunlight to air with minimized thermal gradients. Metallic mesh receivers have been used for temperatures of up to approximately 700°C and ceramic matrix elements for higher temperatures. Hot air from volumetric receivers can be used to heat chemical reactor tubes or boiler tubes in exactly the same way as if they were fired with fossil fuels. This provides for a uniform and controllable method for heating.

3.2.4 Molten Salt

A direct competitor to the air-based system for central receivers is molten salt. It offers the advantages of a high-specific-heat, single-phase fluid in the receiver and can also provide effective energy storage using insulated tanks. A disadvantage is that all pipes must have a provision for external heating to keep the system warm overnight and to facilitate cold starts (melting point of typical nitrate salts vary between approximately 140 and 260°C). Molten salts are corrosive and react with air and water if leaks occur. The usual nitrate salts employed, though, are environmentally benign fertilizer salts.

3.2.5 Chemical

Thermochemical cycles with fluid reactants can provide energy transport and storage. If energy is converted chemically at the receiver, then the use of counterflow heat exchangers means that reactants to and from the receiver are at ambient temperature. Hence, chemical systems not only provide an elegant way of storing energy, they also provide simple heat-loss-free energy transport. Pipes no longer need insulating, they neither expand nor contract, and much simpler mechanisms such as flexible joints are able to get through the axes of rotation.

3.3 Conversion Systems

There are three main thermo-mechanical conversion systems that are being applied with solar thermal power technologies. These are Rankine cycle, Stirling engine, and Brayton cycle systems.

3.3.1 Rankine Cycle

Steam-based Rankine cycles are responsible for the majority of electric power generation in the world. The technology is readily applicable to solar thermal systems as long as the energy collected can be transported to a central power block. Water is first compressed by a feed-water pump and then boiled and superheated (up to approximately 500°C) before being expanded through a turbine that turns an electric generator. The low-pressure steam is then condensed in a heat exchanger and fed back to the feed-water pump to be reused. Steam Rankine cycles have been, and continue to be, employed with parabolic trough, paraboloidal dish and central receiver solar thermal power plants.

Organic Rankine cycles are identical to steam-based Rankine cycles with the exception that organic fluids are employed. Organic fluids such as toluene have a lower liquid-to-gas phase change temperature than water/steam and therefore employ a lower-temperature heat input of typically between 80 and 280°C. Flat-plate, trough, dish, and solar pond systems have all been demonstrated to be suitable solar collector systems for organic Rankine cycle power generation.

3.3.2 Stirling Engines

The most extensive development of engine systems for direct solar operation has been based on the Stirling cycle, invented in 1816. The Stirling cycle employs external heating and cooling of its working fluid. The ideal cycle is made up of a constant-volume heating step from a sink temperature to a source temperature, augmented by isothermal heating, followed by a constant-volume cooling step to a sink temperature, and finished by further isothermal cooling. Dish/Stirling systems achieve very high net solar-to-electric conversion efficiencies, with the solar power world record for a precommercial 25 kilowatt electric (kW_e) unit being 29.4%.

In solar applications, Stirling engines commonly use helium or hydrogen as the working fluid. Kinematic (crankshaft-coupled) and "free-piston" engine versions are the two main concept variants developed worldwide. In a free piston engine, a floating-drive piston bounces back and forth between gas volumes at either end of a single cylinder. The piston itself serves as a linear generator. The result is a minimum number of moving parts. Solar receiver designs for Stirling engines have employed either directly irradiated fine-tubing for heating the working fluid or heat transfer heating via sodium heat pipe systems. Hybridization with fossil-fuel firing for 24 h operation has been demonstrated.

3.3.3 Brayton Cycle

The Brayton cycle is the basis of the conventional gas turbine. The cycle involves adiabatic (i.e., insulated) compression of a gas by a compressor turbine, constant pressure addition of heat, and adiabatic expansion in an expansion turbine (usually attached to the same shaft as the compressor), followed by constant pressure cooling. In a fuel-fired system, the heat addition is carried out in a combustion chamber and gases are exhausted after expansion, either with or without heat recuperation. For solar applications, heat recuperation is economically warranted for efficiency gains and gas fuel back-up advised for system control purposes as well as on-demand operation regardless of time of day.

3.3.4 Others

There are many other ways to convert thermal energy into work, many of which can potentially be applied to solar thermal power generation systems. They include, for example, the following:

- Thermoelectric converters produce electricity directly from heat. Semiconductor-based systems work in an analogous way to photovoltaic (PV) cells. Excitation of electrons from the valence band into the conduction band of the semiconductor material occurs via thermal excitation rather than individual photon absorption;
- Thermo-photovoltaics use PV cells tailored to infrared thermal radiation wavelengths to convert the radiation re-emitted from heated surfaces; and
- Magneto-hydrodynamic converters use the expansion of heated, ionized gas through a magnetic field to generate a potential difference.

4. DEVELOPMENTS OF CONCENTRATOR SYSTEMS

The three major solar thermal concentrating technologies, central receivers, parabolic troughs, and paraboloidal dishes, are discussed in more detail in this section.

4.1 Central Receiver Systems

The central receiver (or power tower) concept was first proposed by scientists in the U.S.S.R. in the mid-1950s. The first experiment was established in Sant' Ilario near Genoa, Italy, in 1965 by Professor Giovanni Francia. He installed 120 round mirrors, each the size of a "tea table," focusing on a small steam generator on top of a steel frame. The product was superheated steam (500°C, 10 MPa).

Central receivers have the advantages that large-area radiation collection to a central point occurs optically and that all the energy conversion takes place at this single fixed point. This avoids the need for energy transport networks and allows investment to improve the efficiency and sophistication of the energy conversion process to be made more cost-effectively. Associated disadvantages are that they must be built as single large systems, without the modularity benefits of distributed systems, such as troughs or dishes. The fixed position of the receiver also means that heliostats do not point directly at the sun for the majority of the time. The amount of collected solar radiation per unit area of mirror is therefore less than with the other solar concentrating technologies.

Major investigations during the past 20 years have focused on four heat transfer fluid systems. They are water/steam, sodium, molten salt, and air (see Section 3.2). An overview of the main grid-connected central receiver research facilities and demonstration

TABLE II

Summary of Grid-Connected Central Receiver Research Facilities and Demonstration Power Plants Built over the Past 20 years

	Net electric power	Total reflector area	Heat transfer fluid	Effective storage capacity (electrical or thermal)	Period of service
Eurelios (Italy)	1 MW	6216 m^2	Water/steam	0.5 MWh_e	1980–1984[a]
Sunshine (Japan)	1 MW	12,912 m^2	Water/steam	3 MWh_e	1981–1984[a]
IEA-CRS (Spain)	0.5 MW	3655 m^2	Sodium	1.0 MWh_e	1981–1985[b]
Solar One (United States)	10 MW	71,447 m^2	Water/steam	28 MWh_e	1982–1988[c]
Solar Two (United States)	10 MW	81,344 m^2	Molten salt	107 MWh_{th}	1996–1999[d]
CESA-1 (Spain)	1.2 MW	11,880 m^2	Water/steam	3.5 MWh_e	1983–1984[b]
Themis (France)	2.5 MW	10,794 m^2	Molten salt	12.5 MWh_e	1983–1986[b]
MSEE (United States)	0.75 MW	7845 m^2	Molten salt	2.5 MWh_e	1984–1985[b]
SES-5 (former Soviet Union)	5 MW	40,584 m^2	Water/steam	1.5 MWh_e	1985–1988[b]
Weizmann (Israel)	0.5 MW (since 2001)	3472 m^2	Beam-down concept	None	1988–today[b]

power plants built over the past 20 years is given in Table II.

Thus far, power generation has been via conventional steam Rankine cycles at the base of the tower. In early systems, tubular receivers were built to produce superheated steam directly. Thermal problems associated with the unsteady boundary between liquid water and steam in the tubes, however, motivated a move to secondary heat transfer fluids, such as sodium, molten salt, or air. Liquid sodium provides good heat transfer behavior, but carries the disadvantage that all the transport piping must be heated above sodium's melting point (close to 100°C). The possibility of leaks also poses a significant fire risk. The use of molten salt avoids the fire risk but is well suited to storage in tanks to allow power generation when there is no sun. As a downside, the nitrate salt mixtures commonly used have a melting point of between 140 and 260°C and corrosion challenges arise if leaks occur. Being the most environmentally friendly heat transfer fluid, air has been extensively and successfully tested at scales of up to 3 megawatt thermal (MW_{th}).

Heliostat fields can either surround the tower or be spread out on the shadow side of the tower. Whereas externally irradiated cylindrical receivers are predominantly employed for surround fields, cavity receivers are used with one-sided heliostat fields. System designers have developed optimization strategies that determine the best arrangement for a given number of heliostats. These take into account the effects of shading between heliostats during the course of the day, the spread of the field, and the optical inefficiency that increases as heliostats are further from the tower.

Two generic approaches to heliostat design have been used. The most obvious is a plane structure with rigid mirror facets mounted on it. The structure sits on top of a pedestal with a drive arrangement that allows for two-axes tracking of the sun. The other alternative is termed the "stretched-membrane" approach. As the name implies, membranes are stretched across a circular frame in a manner similar to a drum skin. Thin stainless steel sheets covered with thin-glass mirror tiles are used successfully. A variety of reflective polymer films have also been tested over the years, but face issues of limited

durability. Focusing of this heliostat concept is achieved by applying a small vacuum inside the drum. In this way heliostats can focus their own sun image onto the tower receiver rather than directing a plane beam at it. Figure 6 illustrates an example of a rigid mirror facet heliostat design. Development trends have suggested that larger heliostats might be more cost-effective. Current optima are between 100 and 150 m^2.

The largest central receiver solar thermal power plant demonstrated thus far is the "Solar Two" plant in southern California. This plant is an updated version of the previously operated "Solar One" system. Extra heliostats were added and the receiver was converted from direct steam generation to molten salt. Figure 7 shows the Solar Two plant in operation and Fig. 8 is a schematic illustrating the operating principles. When the solar field is operating, the molten nitrate salt moves from a "cold" (288°C) storage tank via the receiver at the top of the tower, where it is heated, to the hot storage tank (566°C). Independently of the solar energy collection process, salt from the hot tank is passed through a heat exchanger where heat is transferred to produce superheated steam, with the salt passing back to the cold storage tank. The steam is used in a conventional steam turbine power plant for electricity generation.

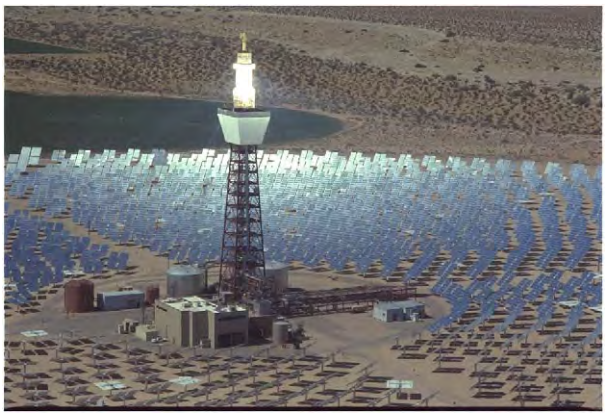

FIGURE 7 The "Solar Two" (previously "Solar One") central receiver power plant in operation. Source: Sandia National Laboratories.

The Solar Two plant has 1018 heliostats of 39.1 m^2 plus a further 108 heliostats of 95 m^2. Under nominal conditions, 48 MW_{th} is concentrated onto the receiver that sits at the top of a 91 m high tower. Steam is produced in the heat exchangers at 10 MPa and 538°C and the net electrical output is 10.4 MW_e.

One of the newest developments in the central receiver area is the "beam-down" concept proposed and tested in part by the Weizmann Institute of Science in Israel. Rather than converting the concentrated solar energy at the top of the tower in a receiver, a hyperbolically shaped secondary mirror directs the converging radiation vertically downward to a focal point at the bottom of the tower. On the ground, an additional nonimaging mirror concentrates the radiation further before the concentrated sunlight is captured by a volumetric receiver. This receiver is capable of reaching very high air temperatures to power, for instance, a Brayton cycle gas turbine.

4.2 Trough Systems

Solar thermal power in the form of mechanical energy for water pumping was established for the

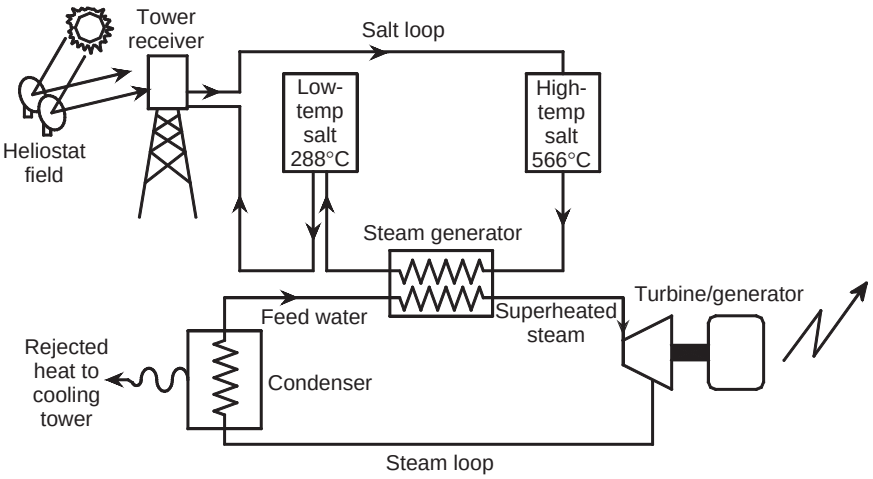

FIGURE 8 Schematic of "Solar Two" operation.

first time by Frank Shuman near Cairo in 1913 ($\sim$40 kW). It incorporated a water/steam operated parabolic trough array (five units, 4 m $\times$ 62 m each) and a low-pressure condensing steam engine. Solar electric trough development was continued in the mid-1970s by the U.S. Department of Energy. The first experimental system started operation in 1979. At the same time, a private research and development company from Israel decided to design and commercialize parabolic trough "solar electric generating systems" (SEGS) in southern California. This decision was strongly motivated by favorable power purchase agreements and tax credits offered in the state of California.

Nine SEGS power plants were built between 1984 and 1989, with a combined capacity of 354 MW_e. These investor-owned, natural gas-assisted power plants have not only been operating on a fully commercial basis ever since, but have also been continuously improved. They operate beyond their nameplate capacity, generating important solar peaking power for the southern California grid, at the world's most competitive solar power prices.

During the early 1980s, small, trough-based solar thermal demonstration power systems were constructed in the United States, Japan, Spain, and Australia. Table III lists the details of these plants. Specifications for the nine SEGS plants are given in Table IV.

Figure 9 shows one of the SEGS plants and Fig. 10 illustrates the operating principles schematically. A synthetic heat transfer oil is pumped through the trough solar collector array and heated to 400°C. This oil is then used to produce steam in heat exchangers before being circulated back to the array. The steam is used in a conventional steam turbine-based electricity-generating plant. Although some hot oil-based energy storage was provided in the first plant, the SEGS systems overall rely on natural gas firing to provide continuous operation when the sun is not available. The special tax law for these power plants limits the fossil-fuel cofiring to a maximum of 25% per annum of the total heat energy supplied to the boilers.

The SEGS troughs are built using a galvanized steel space frame. This frame supports 4 mm thick toughened glass mirror facets that are shaped by heating and molding the raw glass to match the parabolic profile, before silvering. Each mirror facet is supported at four attachment points. The most

TABLE III

Details of the Main Small, Trough-Based Solar Thermal Demonstration Power Plants

	Net electric power	Total aperture area	Heat transfer fluid	Effective storage capacity (electrical or thermal)	Duration of service
Coolidge (United States)	0.15 Mw	2140 m^2	Synthetic oil	5 MW_{th}	1980–1982
Sunshine (Japan)	1 Mw	12,856 m^2	Water/steam	3 MW_e	1981–1984
IEA-DCS (Spain)	0.5 Mw	7622 m^2	Synthetic oil	0.8 MW_e	1981–1985
STEP-100 (Australia)	0.1 Mw	920 m^2	Synthetic oil	117 MW_{th}	1982–1985

TABLE IV

Details of the Californian Parabolic Trough "SEGS" Solar Thermal Power Plants

	Net electric power	Total aperture area	Duration of service
SEGS I	13.8 MW	83,000 m^2	1984–present
SEGS II	30 MW	19,000 m^2	1985–present
SEGS III	30 MW	230,000 m^2	1986–present
SEGS IV	30 MW	230,000 m^2	1986–present
SEGS V	30 MW	251,000 m^2	1987–present
SEGS VI	30 MW	188,000 m^2	1988–present
SEGS VII	30 MW	194,000 m^2	1988–present
SEGS VIII	80 MW	464,000 m^2	1989–present
SEGS IX	80 MW	484,000 m^2	1989–present

recently constructed systems (termed LS-3) are 5.76 m wide and 95 m long, resulting in a total aperture of 545 m^2 each. Two hundred twenty-four glass mirror facets are used and a geometric concentration ratio of up to 80:1 is achieved. The trough units are lined up in north–south rows and track the sun from east to west during the course of the day. Each parabolic trough has its own positioning and local control system.

FIGURE 9 View of SEGS trough-based solar thermal power plant in southern California. Source: Kramer Junction Operating Company.

The receiver units of the SEGS troughs consist of a stainless steel tube 70 mm in diameter, covered by a Pyrex glass envelope that is sealed to the tube via metal bellows at each end. The space between the steel and glass is evacuated to minimize thermal losses. The surface of the stainless steel absorber tubes is coated with a selective surface that absorbs up to 97% of the incident solar radiation while minimizing the amount that is radiated at thermal (infrared) wavelengths. The combination of trough and receiver is capable of operating at temperatures in excess of 400°C. However, the synthetic heat transfer oil becomes chemically unstable and begins to break down at temperatures above 300°C. Approximately 350 m^3 of oil circulates in each of the 30 MW_e plants. Depending on the operating regime, this oil may need to be replaced at rates of up to 6% per year as a result of thermochemical breakdown.

Each of the latest SEGS plants employs a steam turbine with a reheat cycle and multiple extractions. With steam inlet conditions of 10 MPa and 370°C, thermal-to-electric conversion efficiencies of approximately 37% are achieved, giving overall peak solar-to-electric conversion efficiencies of up to 24%.

Regular maintenance is required for all solar thermal power plant systems. For the SEGS plants, routine cleaning and replacement of broken mirror facets and receiver modules forms a major part of the maintenance program. Major improvements have been realized over time.

Research and development on parabolic trough systems has continued since the SEGS plants were completed. A major area of investigation has targeted the replacement of the heat transfer oil with direct

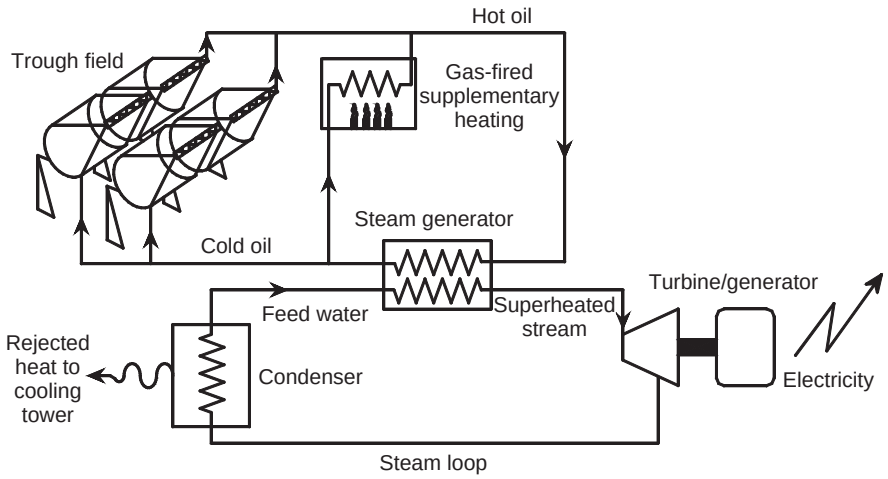

FIGURE 10 Schematic representation of SEGS plant operation.

generation of steam in the receivers. Direct steam generation allows collection of energy at higher temperatures as well as elimination of one heat-exchange step and thus improves the efficiency of the steam turbine. It also avoids the need to replace the costly oil and eliminate the inherent fire risk. When attempting once-through-to-superheat boiling, the challenge is in managing the rapidly changing thermal stresses induced in the receiver tube by the unsteady, localized movement of the liquid/vapor phase boundary when boiling is occurring.

In a variation of linear focusing technology, compact Fresnel-type concentrator systems are being developed at various places around the world. This concept dates back to the 1950s and is much like a linear version of a central receiver system. Fixed linear receivers are illuminated by a series of long, narrow mirrors that track the sun individually in a single axis. If several receiver rows are installed side by side, then the individual mirror units can switch from one receiver to another depending on the relative optical efficiencies at different times of the day. Alternatively, a secondary concentration of the reflected light near the receiver can be used to ease precision and costs of the linear primary solar concentrator.

4.3 Paraboloidal Dishes

The first realization of a solar dish concentrator/engine system design dates back to 1864. The Frenchman Augustin Mouchot built a variety of "thermo-piles" and "solar engines" using conical mirrors. There are many designs and states of development of paraboloidal dishes.

Paraboloidal dish concentrators must point directly at the sun for proper operation. This necessitates two-axes tracking mechanisms. There are two main approaches to this: "altitude/azimuth" tracking or "polar/equatorial" tracking. In the first approach, the dish is mounted with a horizontal axis pivot (to allow altitude adjustment) plus a vertical axis pivot (to allow azimuth adjustment). A polar/equatorial system has a main axis of rotation, the angle of which is adjusted on a daily basis so that it is at a right angle to the sun's noon elevation. With the polar axis correctly adjusted, tracking during the day involves following the sun from sunrise to sunset on a constant basis with a single axis of movement. Altitude/azimuth arrangements have the disadvantage that both actuators must work throughout the day and the azimuth adjustment must be relatively rapid near midday for high sun elevations. Despite this, it is sometimes used for pragmatic structural design reasons.

Dish-based solar thermal power systems can be divided into two groups: those that generate electricity with engines at the focus of each dish and those that use some mechanism to transport heat from an array of dishes to a single central power-generating block. From a research and development perspective, dish systems have two major advantages over central receivers in particular, in that a single dish prototype can be constructed and tested relatively economically. Furthermore, for the dish/engine approach, a single module on its own can demonstrate the operation of the full system. Consequently, there have been well over 40 different dish prototypes developed thus far, by both research institutes and private engineering companies.

The variations in structural design of dish concentrators are very similar to the different types of heliostats used with central receivers. Possible different approaches include the following:

- A space frame structure that supports a number of rigid mirror elements held in a paraboloidal orientation;
- A single rigid paraboloidal surface covered with mirror elements;
- A single, mirrored, stretched-membrane that is pulled into a near-paraboloidal shape on a drum-like structure; and
- A space frame supporting a series of small stretched membrane mirror facet elements.

The high concentration ratios achievable with dish concentrators allow for efficient operation at high temperatures. Stirling cycle engines are well suited to construction at the size needed for operation on single-dish systems and they function with good efficiency, with receiver operating temperatures in the range of 650 to 800°C. To achieve good power-to-weight ratios, working gas pressures in the range 5–20 MPa are employed and the use of high-conductivity gases, such as hydrogen or helium, gives improved heat transfer. Dish/Stirling units of 25 kW_e have achieved solar-to-electric conversion efficiencies of close to 30%. This represents the maximum net solar-to-electric conversion efficiency yet achieved by any nonlaboratory solar energy conversion technology.

Figure 11 shows two dish/Stirling system operating in southern Spain. The dish is fitted with a 10 kW_e two-cylinder kinematic Stirling engine. One-millimeter-thick, back-silvered glass mirror facets are employed to achieve very high focusing accuracy.

FIGURE 11 Paraboloidal dish solar concentrator with a receiver-mounted Stirling engine operating in southern Spain. Source: Schlaich, Bergermann, and Partner.

FIGURE 12 Seven hundred dishes producing steam for a central turbine system. Source: LaJet.

Including various alternative versions of the generic system, over 80,000 h of cumulative on-sun operating time have thus far been clocked with dish/Stirling systems.

The largest distributed array/central plant solar thermal power system that has yet been demonstrated is the "Solarplant-1" system built in southern California in 1983–1984. A photograph of this system is shown in Fig. 12. It consisted of 700 dishes with a total collecting area of 30,590 m^2. The dishes generated steam in their cavity receivers, with 600 of the dishes producing saturated steam at approximately 6 MPa (275°C) and the remainder taking the saturated steam to a superheat of 460°C. The steam was transported through an insulated pipe network to a central steam turbine-based generating plant that produced a nominal output of 4.9 MW_e. The dishes were constructed with multiple stretched-membrane mirror elements. The plant ceased operation in 1990.

The world's largest solar dish, with an aperture of 400 m^2, is shown in Fig. 13. It was developed for use in distributed systems similar to Solarplant-1. Two prototypes are in operation: one at the Australian National University in Canberra, Australia and the other at the Sde Boquer Desert Research Centre of the Ben Gurion University in Israel. These dishes have triangular mirror panels supported on a hexagonal aperture space frame structure. Altitude–azimuth tracking is employed, with the horizontal axis near the base of the dish so that it can be parked in a horizontal position relatively close to the ground. This helps to reduce wind resistance and thus improve storm survivability. The Canberra dish has a cavity receiver based on a single helical winding of tubing to serve as a once-through-to-superheat boiler producing superheated steam at 5 MPa and

FIGURE 13 The world's largest 400 m^2 solar dish system. Source: Australian National University.

500°C. Although intended for operation in large arrays, the prototype system is connected to a small reciprocating steam engine that is capable of generating up to 45 kW_e for the local electricity grid. The thermal efficiency from sun to steam is between 85 and 90% and, in a large steam turbine-based system, production of electricity at a rate of approximately 100 kW_e per dish would be expected.

Research and development on paraboloidal dish systems around the world strive to improve and develop dish designs to reduce the costs and to optimize the reliability and efficiency of conversion systems. A number of groups are investigating the use of small solar-driven gas turbines at the focus of dishes (dish/Brayton systems). Such systems offer the potential for high-efficiency operation and moderate maintenance requirements.

Chemical conversion systems are also investigated using paraboloidal dish concentrators. High-temperature reversible chemical reactions, such as

methane re-formation (up to 900°C) or ammonia dissociation (up to 700°C), can be used to store heat energy in chemical form. The resulting chemical products, such as hydrogen and carbon dioxide, are stored and transported at ambient temperature and thereafter recombined in an exothermic reaction to provide the heat for power generation on a continuous, 24 h basis.

5. ECONOMICS

Solar thermal power generation technologies have achieved impressive development progress over the past two decades. Some of this progress, most notably with parabolic troughs, has resulted in successful technology commercialization, delivering the lowest-cost solar power yet achieved.

Given the very many different technology routes, development status, application options, and project sizes, solar thermal power generation technologies cannot be compared, let alone summarized, on a one-line economic basis. It is, however, valuable to look at the achievements, status, and trends of capital costs, operation and maintenance costs, and levelized electricity costs. These costs are strongly dependent on the country and on site-specific labor-rate structures. Although some general observations can be made, it is not necessarily valid to translate costs experienced with a particular project in one country to operation in another by a simple exchange-rate conversion.

5.1 Capital Costs

Capital costs arise for land, site preparation, construction work, solar collectors, power conversion units, the balance of plant including controls, and infrastructure as well as services such as engineering, project management, and commissioning.

Depending on the plant capacity, its technical complexity, the chosen location (geophysics, climate, access, water, etc.), and the choice of storage and/or fuel hybridization or back-up, solar thermal power plant capital costs over the past two decades have varied greatly between approximately U.S. $3000 and U.S. $9000 per kilowatt of nominal plant capacity.

Economies-of-scale progress with the Californian SEGS parabolic trough plants has shown that a cost reduction of typically between 12 and 16% has been achieved on doubling of the plant capacity.

In 2003, 10 to 50 MW_e power plants are offered for approximately U.S. $2500–$3000 per kilowatt, whereas 0.5 MW_e to 10 MW_e power plants require investment capital of U.S. $3000–$5000 per kilowatt of nominal plant capacity. Smaller projects, such as one-off 10–25 kW_e dish/Stirling units, cost approximately U.S. $6000–$7000 per kilowatt.

Given that solar thermal power generation technologies are comparably "low-tech" offerings based primarily on structural and civil engineering skills and efforts, cost reduction curves are quite predictable. Performance improvement, manufacturing progress, economies-of-scale, and options of hybridization as well as energy storage dominate cost reductions, indicating trends toward capital costs of approximately U.S. $1500–$2500 per kilowatt.

5.2 Operation and Maintenance Costs

Operation and maintenance (O&M) costs are composed of labor and materials costs. The split between these two varies according to technology choice, remoteness of location, labor rates, and water costs, with typical ratios of approximately 1:2 for large power plants and 2:1 for small power plants.

Whereas current commercial solar thermal power plants have typical O&M costs in the range of U.S. $0.025–$0.035 per net kilowatt-hour of power generated, continuous optimization efforts indicate a strong trend toward U.S. $0.01–$0.015 per kilowatt-hour for utility-scale power stations in the range of 50–100 MW_e over the next decade.

5.3 Levelized Electricity Costs

Levelized electricity costs (LECs) are averaged electricity costs calculated on a simple basis of fixed economic parameters and a straight-line depreciation of capital cost over the duration of the project life. Technologies as well as projects are difficult to compare due to the large variety of design- and finance-specific parameters chosen.

Nevertheless, when analyzing well-demonstrated, megawatt-scale projects on a comparative basis of 30 years of project life, 8% real discount rate, 1% insurance rate, straight-line depreciation, and 0% income tax rate, typical LECs of U.S. $0.12–$0.16 per kilowatt-hour result. Small-scale, one-off projects, such as dish/Stirling systems, are likely to achieve LECs of U.S. $0.20–$0.30 per kilowatt-hour once technically matured and commercially operated. Following the ongoing efforts and predictions of major project developers, megawatt-scale solar thermal power plants are likely to ultimately generate LECs of U.S. $0.05–0.1 per kilowatt-hour.

6. OUTLOOK

The future of solar thermal power generation holds great commercial promise and a broad spectrum of interesting new opportunities. Among these possibilities are 24 h solar-only power generation thanks to thermal and/or thermochemical energy storage, the re-formation and synthesis of high-value fuels and fine chemicals, the thermal and/or thermochemical production of hydrogen, and the detoxification of hazardous waste.

Glossary

electrodialysis Desalination method using membranes to separate anions and cations from water by applying an electric field to the membranes.

evacuated tube collectors Medium-temperature solar radiation collectors (up to 250°C) using selective absorption surfaces into the vacuum tubes.

flat-plate collectors Devices that absorb solar radiation on black surfaces and transfer the thermal energy to a fluid. They are low-temperature devices up to 95°C.

focusing collectors Devices that focus solar radiation on a surface or a point. The high-temperature thermal energy is transmitted to pressurized water or it produces vapor.

photovoltaic Devices that transform solar radiation into electricity by the use of semiconductors.

renewable energies Inexhaustible natural energy resources (solar, wind, geothermal, tidal, wave, and biomass), replaceable as they are consumed. These exist in huge amounts worldwide.

reverse osmosis Pressure-driven desalination method using semipermeable membranes that permit only water to be transferred through the membrane, and the solutes are retained.

solar collectors Devices that absorb solar radiation in select black surfaces and transform it to thermal energy, which is transferred to a suitable fluid.

solar ponds Small artificial lakes with salt gradient water that absorb solar radiation and act as storage devices for hot water and as devices supplying hot water with a temperatures up to 90°C.

Solar energy desalination is a method by which the sun's energy is used to desalinate brackish or seawater to produce fresh drinkable water. There are two methods for using solar energy: directly by heating and evaporating the brackish or seawater in a solar still (this method is called solar distillation) and indirectly by capturing solar energy using one of the techniques that transform solar radiation into thermal or electrical energy to drive a conventional desalination method (the indirect method is called solar-assisted or solar-driven desalination). Indirect thermal solar desalination methods are the multistage-flash thermal distillation method, the multiple-effect thermal distillation method, and the thermal vapor compression method. Electrical power generated from the sun's energy is used to drive reverse osmosis, electrodialysis, or mechanical vapor compression desalination methods. Theoretically, solar energy can replace any other energy source, but from a practical standpoint this is not yet technically feasible, especially for large-capacity solar desalination plants. This is due to the spreading and very low concentration of solar radiation falling on the earth's surface and variations in solar incident radiation. Solar energy depends on local insolation rates, which vary depending on location, the hour of the day, the day of the month, and the month of the year. These conditions result in an unsteady state diurnal operation. On the other hand, because solar radiation is very diluted, large surface areas are needed to capture the necessary amount of energy. Storage of heat or electricity could be a solution for smooth 24-h operation, but it adds to the capital cost, which in many cases is prohibiting. Thus, solar desalination installations are of small- or medium-size capacity, ranging from a few to 100 m^3/day, and in some cases up to 300 m^3/day (26,420–79,260 gallons per day) for

 © 2004 Elsevier Inc. All rights reserved.

indirect methods. They can supply with fresh water remote, arid, or semiarid regions that have high intensity solar radiation.

1. HISTORICAL BACKGROUND

Solar-driven desalination was developed mainly in the second half of the 20th century, although solar conversion systems have been known since antiquity. It was developed mainly during the energy crisis in the 1970s. Intensive studies led to the construction of compact, small- and medium-capacity conventional desalination plants that could be driven by solar energy. However, solar distillation has been known since antiquity but only as theory or as a very primitive application. Aristotle described the "water cycle" in nature, which is an immense solar distillation procedure, concluding that this procedure may be used to produce sweet water from salt water. He explained, "as the vapors formed by the evaporation from the surface of seas and lakes rise to the atmosphere and condense again, they give sweet water." Later, there were some practical applications and references about the production of drinkable water from sea water using solar radiation. The first practical application of solar distillation was the American patent issued in the 19th century to N. M. Wheeler and W. W. Evans. The patent describes a solar still and is a complete scientific source about production of fresh water by distillation using solar energy. No significant changes have been made to this theory.

The first large solar distillation plant was built in Las Salinas, Chile, to provide fresh water from mine brackish water with 140 g/kg total dissolved solids (TDS) (140,000 ppm). The plant had a surface area of 4450 m^2 (48,000 ft^2), produced 22.7 m^3/day [$\sim$6000 gallons per day (GPD)] of fresh water for the mine and the people working in it, and was in operation for approximately 40 years until the mine was closed.

Until the early 1960s, no other large-scale application of solar distillation was reported. Nevertheless, during World War II distillation gained interest due to the lack of fresh water for troops of Africa and the islands of the Pacific region. In 1945, at the Massachusetts Institute of Technology (MIT), Maria Telkes invented individual inflatable solar stills that saved many lives. After World War II, the MIT team developed various solar still configurations, which have been studied at the office of saline water (OSW) demonstration plant in Daytona Beach, Florida. Some commercial installations have been erected in St. John, Virgin Islands, and Australia. In the 1960s, the Church World Service erected two distillation plants in the Greek Islands, where four additional solar distillation plants have been built that produce fresh water for the local communities..

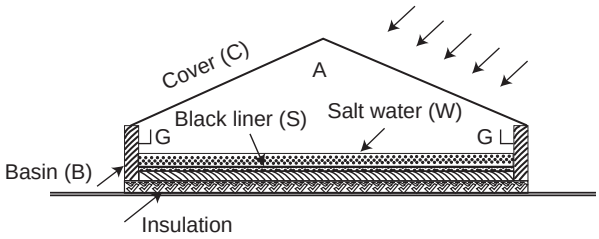

FIGURE 1 The greenhouse symmetrical-type solar still.

2. SOLAR STILLS

Since the 1980s, no large-capacity solar distillation plants have been built, mainly for the following reasons: Large installation areas are needed, solar distillation plants have low efficiencies, and solar-driven desalination has been developed, which in some cases can replace solar distillation (e.g., for medium-size communities).

A solar still is composed of simple equipment, which acts simultaneously as a converter of solar radiation into thermal energy and provides storage for the heat. There are two types of solar stills: single- and multiple-effect stills. For both types, a large variety of configurations have been studied, but most have no practical applications. Studies have focused mainly on increasing output by various means, but this leads to an increase in capital or operation costs. Thus, simple, single-effect stills are the only ones used for large-scale applications. They can be easily constructed from local materials and easily operated without skilled personnel.

There are two types of single-effect solar stills (called greenhouse solar stills): symmetrical (Fig. 1) and asymmetrical (Fig. 4). These types have many configurations depending on the geometry of the still and the type of cover (glass or plastic). Figure 2 show some of the single-effect solar still designs used to construct solar distillation plants.

3. PRINCIPLES OF SOLAR STILLS

A solar still consists of the following:

A well-insulated basin (Fig. 1B), which may be made from metal, plastic, treated wood, concrete, or

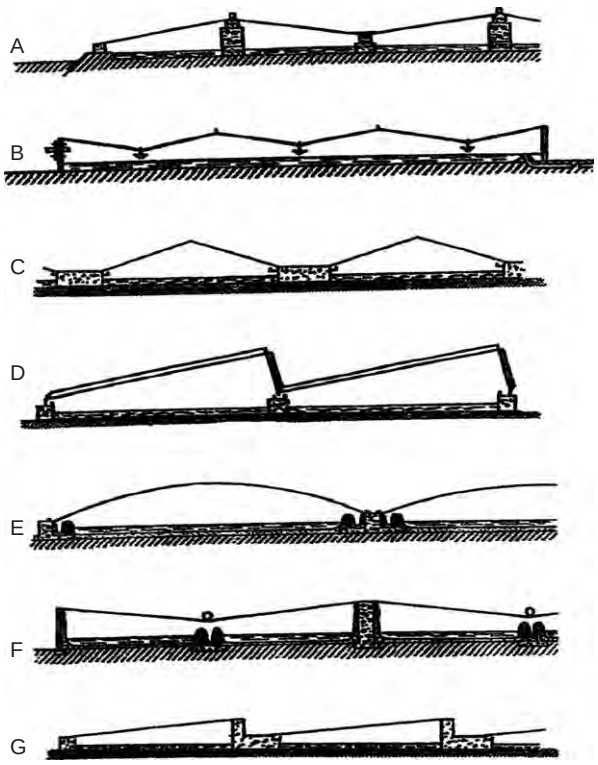

FIGURE 2 Various configurations of single-effect solar tills used to construct solar distillation plants: (A) Battele–Loef glass-covered type; (B) Howe University glass-covered type; (C) CSIRO Australian glass-covered type; (D) Technical University, Athens, glass-covered type; (E) Inflated, tedlar plastic film type; (F) V-shaped plastic cover design; and (G) stretched-inclined plastic cover type.

any material that withstands temperatures of 90–100°C, according to the local availability.

A black sheet (Fig. 1S) that covers the inside of the bottom of the basin to avoid leakage of hot water. The basin can be deep or shallow and contains the water to be heated by solar radiation. The black liner absorbs the incident radiation.

A frame that supports the transparent cover. The frame can be made of metal (e.g., aluminum), treated wood, concrete, or plastic material.

A tilted transparent cover (Fig. 1C) made from either glass or a plastic sheet that withstands ultraviolet radiation and is not easily deteriorated by heat.

Collecting canals, the gathers (Fig. 1G), placed inside the still walls to collect the condensate of fresh water, running along the transparent cover.

Various auxiliaries, such as tubes for loading the still with salt water and for unloading to drain the brine, water storage tanks, and distilled water pumps.

Solar radiation penetrates through the tilted transparent cover into the airtight space (Fig. 1A) and is partially absorbed by the salt water in the basin, which is heated to a temperature higher than that of the cover but lower than boiling point of salt water. The air–vapor mixture leaving the saltwater surface has a higher temperature and lower density than the air–vapor mixture directly beneath the cover. Thus, a convection current is formed and the saturated air–vapor mixture from the water surface moves upward, is cooled by contact with the colder cover, becomes saturated, and is partially condensed, forming a thin film that slides along the inside cover surface by gravity. The uncondensed air–vapor mixture moves back to the water surface. The process takes place in narrow layers between the two surfaces, but the bulk of the air mass does not participate because diffusion and heat conductance are low. The mechanism of the vapor flow in the space takes place by convection and the optimum space is the one that enhances conduction. Therefore, it is advantageous to keep the distance between the water surface and the cover, as well as the angle between the cover and horizontal, as small as possible to achieve good convection (normally, the lowest angle is 15°). It is obvious that the productivity of the still depends on the proper sliding of the condensate on the inner surface of the cover and the temperature difference between the saltwater surface and the cover. The larger the difference, the more intense the circulation of the air–vapor mixture becomes and consequently the vapor condensation. Thus, for a greenhouse-type solar still, it is essential to understand the convection phenomena inside the still. Flow patterns and isotherms are given in Fig. 3 for a single solar still with a 15° angle of inclination and an Ra number of 10^{10}.

4. HEAT AND MASS BALANCE IN THE STILL

Mathematical calculations and models for unsteady state conditions in a solar still are very complicated. There are numerous relations and models for heat and mass transfer coefficients to predict the output of a still—almost as many as still designs. Most of them are empirical or semiempirical and are applied only to the specific design of the still. For the single, greenhouse type, the most common is that by Dunkle. Under the assumption that the temperature of the transparent cover T_c and that of the surroundings T_a are uniform, the thermal network in the basin describing the fluxes in a

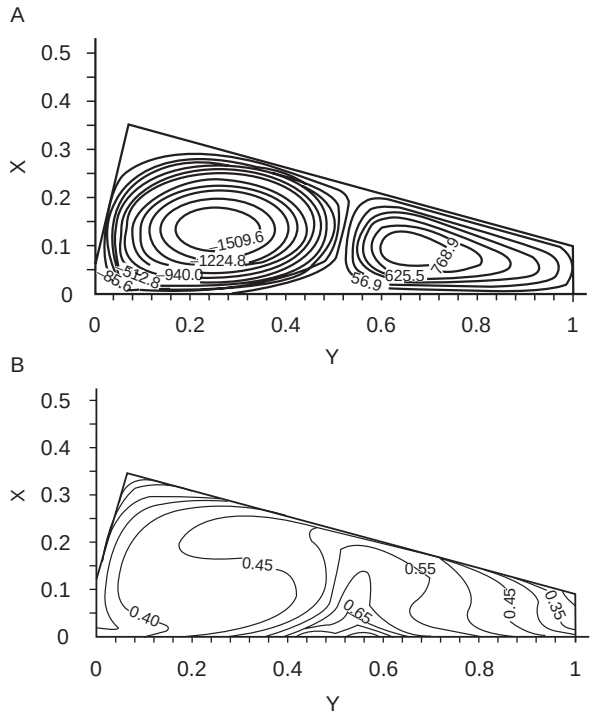

FIGURE 3 Computed streamline (A) and isotherms (B) for an asymmetrical single solar still.

greenhouse-type solar still is presented in Fig. 4. According to the figure, the energy balance for a surface area of the cover A_c and solar radiation intensity I, is

$$\text{Around the cover}: \quad A_g I + q_{rwg} + q_{ewg} = q_{cgs} + q_{rgs} \tag{1}$$

Around the bottom of the still :

$$I\tau_g A_w = q_{rwg} + q_{ewg} + q_b + \frac{C_w \times \partial T_w}{\partial t}, \tag{2}$$

where the last term is the thermal lag for unsteady state operation and is of significance only if the water in the basin is deep. Heat transfer coefficients for radiative heat transfer h_{rwg}, for convective heat transfer h_{cwg}, and for evaporative heat transfer h_{ewg} from the water surface to the cover, as well as radiative heat transfer from the cover to the sky h_{rgs}, for the previous equations are given (in W/m^{2}K) as follows:

For radiation :

$$h_{rwg} = 0.9 \cdot \sigma\left(T_w^2 + T_g^2\right) \cdot \left(T_w + T_g\right) \tag{3}$$

For convection :

$$h_{cwg} = \left[\left(T_w - T_g\right) + \left(\frac{p_w - p_g}{268.9 \times 10^3 - p_w}\right) \cdot T_w\right]^{1/3} \tag{4}$$

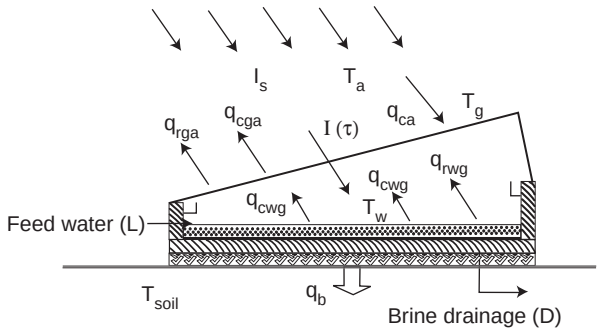

FIGURE 4 Energy balance in a solar still of the asymmetrical type.

For evaporation :

$$h_{cwg} = \frac{9.15 \times 10^{-7} \cdot h_{cwg} \cdot \left(p_w - p_g\right) \cdot \Delta h_v}{\left(T_w - T_g\right)}. \tag{5}$$

The radiative heat transfer between the cover (T_g) and the sky (T_s), which is intensive at night, is given as

$$h_{rgs} = \varepsilon_g \cdot \sigma \cdot \left(T_g^2 + T_s^2\right) \cdot \left(T_g + T_s\right), \tag{6}$$

where Δh_v is the enthalpy of evaporation, and the sky temperature T_s is given as $T_s = 0.0552 \times T_a^{1.5}$. The overall heat transfer coefficient for the upward heat flow for a solar still is given as

$$U_t = \left[(1/U_i) + (1/A_r \cdot U_o)\right]^{-1}, \tag{7}$$

where U_i is the overall heat transfer coefficient between the water surface and the cover given as

$$U_i = h_{rwg} + h_{cwg} + h_{ewg} \tag{8}$$

U_o is the overall heat transfer coefficient between the water surface and the environment given as

$$U_o = \left[h_w \cdot \left(T_g - T_a\right)/\left(T_g - T_s\right)\right] + h_{rgs} \tag{9}$$

and the surface area A_r is the ratio of cover area A_g to the free horizontal surface area of the salt water in the basin A_w:

$$A_r = A_g/A_w. \tag{10}$$

The heat balance within the solar still is thus given by the following equation:

$$\frac{C_w}{A_w} \cdot \frac{dT_w}{dt} = \theta(t) \cdot \eta_0 \cdot I(t) - U_t[T_w(t) - T_a(t)] - U_b[T_w(t) - T_a(t)] \tag{11}$$

5. PREDICTION OF DAILY OUTPUT

Operating efficiencies of solar stills in general are low and do not exceed 35%. This is due mainly to the low incident solar radiation per square meter and to the rejection to the atmosphere of the condensation

enthalpy. Consequently, single-effect solar stills have daily output ranging from approximately 2 in wintertime to 5 or 6 liters/m^{-2}/day in summertime. Double- or multiple-effect stills have efficiencies up to 46%. Many attempts have been made to increase the output of the stills, including

- Coupling the stills to solar collectors to increase feed water temperature.
- Use of a double glass cover (Fig. 5) with running water inside the cover to increase the temperature difference between the water surface and the cover.
- Trickle feeding of salt water by using wicks or using multiple-effect stills to win condensation enthalpy.
- Use of storage incorporated to the still or in connection with solar collectors to extend operation during nighttime and/or cloudy days.
- In places where rainfall occurs during wintertime, rain may be collected by outside canals. Thus, the output of distilled water may be doubled.

Nevertheless, the output by these means is not always sufficiently high to offset additional capital and operating expenses, and the single-effect, greenhouse-type solar stills remain the most simple and low cost for large-scale applications.

The daily output of a solar still is a function of solar radiation intensity, the duration of daily radiation, and heat fluxes within the still, which in turn depend on the design characteristics of the still. Solar radiation for a bright, cloudless day is given by the curve of daily incident radiation. It can be divided into three phases: phase 1, the early morning start of operation; phase 2, the main operation period called the pseudo-steady state; and phase 3, the saturation of the still at the end of the day during sunset. The mean daily output can be calculated from the following equation, which may be applied to many still configurations if parameters f_1–f_3 are known:

$$M_{m-d} = f_{1-d} \cdot H_d + f_{2-d} \cdot (\bar{T}_{w-d} - \bar{T}_{a-d}) + f_{3-d}, \quad (12)$$

where H_d is the daily solar radiation (MJ/day); T_w and T_a are the daily mean temperatures of salt water and the environment, respectively; and f_1–f_3 are characteristic parameters of the still. f_3 concerns the energy state of the still during phase 1 and represents the inertia of the still. Parameters f are functions of the characteristics of the still and of the heat fluxes. They are given as

$$f_1 = \overline{\theta} \cdot n_0 \cdot \frac{A_g \cdot A_w}{C_w} \cdot \frac{h_{ewg}}{\Delta h_v} \cdot \frac{U_t}{U_i} \cdot \Delta t \quad (13)$$

$$f_2 = (U_t - U_b) \cdot \frac{A_g \cdot A_w}{C_w} \cdot \frac{h_{ewg}}{\Delta h_v} \cdot \frac{U_t}{U_i} \cdot (\Delta t)^2 \quad (14)$$

$$f_3 = A_g \cdot \frac{h_{ewg}}{\Delta h_v} \cdot \frac{U_t}{U_i} \cdot (\Delta t)_I \cdot (T_{w-in} - T_{a-in}), \quad (15)$$

where θ is the mean radiation incident inclination angle.

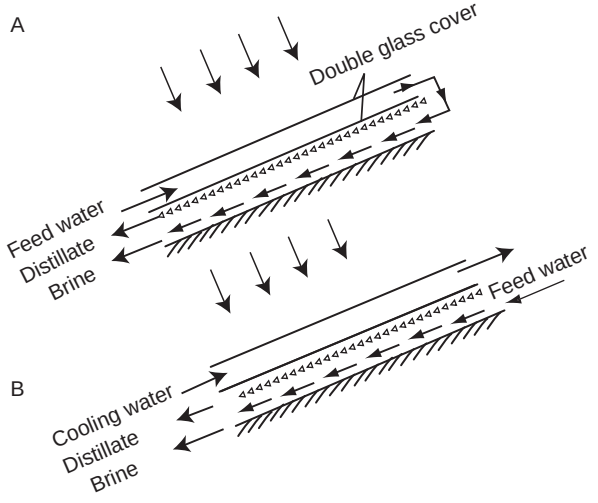

FIGURE 5 Double glass cover solar stills using (A) feedback flow and (B) counter flow.

6. MATERIALS OF CONSTRUCTION

To achieve long life and good operation conditions, the construction materials are important. Good maintenance is also important. Thus, the material used must be of good quality, low cost, and, if possible, available in local markets. Small poor communities cannot afford the high capital cost of special materials and long-distance transport expenses. Local inexpensive materials were used to construct solar distillation plants in the Caribbean Islands and India. Thus, from an economic standpoint, solar distillation plants are not comparable from place to place because cost varies according to the materials used. Nevertheless, there are some basic requirements for achieving a long life of operation and the best possible daily output:

- The parts of the still must be precut and easily assembled at the site.
- Maintenance and proper operation must be supervised continuously to achieve an effective lifetime of the plant of approximately 15–20 years.

• The system must withstand severe weather conditions, such as hale, hurricanes, and sand and wind storms. Thus, it has to be well anchored in the soil or pavement.
• Construction materials that come in contact with fresh or salt water must not be toxic and in general not contaminate the water produced.
• The still parts must be easily bound in compact packages in case transportation to the site is necessary.

The parts of the still must have the following characteristics:

1. Transparent cover, usually made from glass and, less often, from plastic sheet material:
   - The material must withstand wind, sunlight, rain, dust, hail, and/or the wind. Plastic material may be easily deteriorated by sunlight or damaged by hale or wind.
   - It must have high transmissibility (more than 90%), low absorptivity, and low reflectivity.
   - The properties of the material must not alter with time and exposure to sunlight and environmental effects and must withstand temperatures up to 90°C.
   - Especially plastic material should not have electrostatic properties. Electrostatic properties facilitate the accumulation of dust particles, thus decreasing solar radiation absorption inside the still.
2. Solar still frame and basin material, which in most cases are made from the same material. Concrete, wood impregnated with a protective coating, hard plastic material, or any metallic material (e.g., aluminum–magnesium alloy) that is not corroded by distilled or seawater may be used.
   - The material must withstand corrosion of distilled and seawater, inside and outside of the still.
   - The frames must be anchored, especially in places with strong winds.
   - They have to be easily removed or permit access for cleaning and maintenance.
3. The liner of the basin: The black sheet liner acts as an absorber surface for the solar radiation. A variety of materials have been used, including black paints resistant to seawater, butyl rubber sheets, and jute impregnated with tar. In general, the liner must have the following properties:
   - It must have absorptivity >0.95 and be impervious to water.
   - The sheet surface must be smooth. Rough surfaces facilitate scale deposition and are more difficult to clean.
   - It must not deteriorate by solar radiation and must not release toxic substances.

Some auxiliary materials are used, such as pumps, piping systems for drainage and for freshwater transportation, freshwater reservoirs, and sealants. These materials are available commercially. They must be resistant to fresh and seawater and must be cleaned often to avoid algae formation. Formation of algae is dangerous because it results in decreased efficiency and may contaminate fresh water. In stagnant conditions, even inside the still algae are deposited.

7. MULTISTAGE SOLAR STILLS

Recovery and utilization of condensation enthalpy are achieved in multiple-effect solar distillation systems. There are a variety of configurations for double- and multiple-effect solar stills. None have found practical application in large-scale solar distillation plants. Figure 6 demonstrates a two-effect still, and Fig. 7 shows the multieffect wick. A special type is the multieffect diffusion still. In this type, the gap between the cover and saltwater surface is reduced and evaporation occurs only by molecular

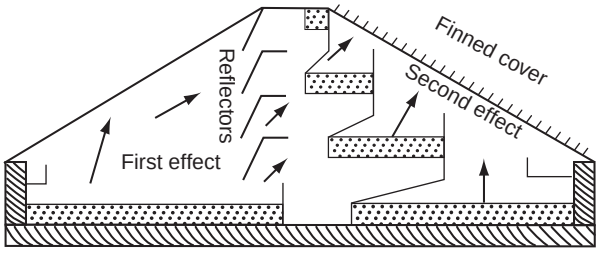

FIGURE 6 A two-effect solar desalination still.

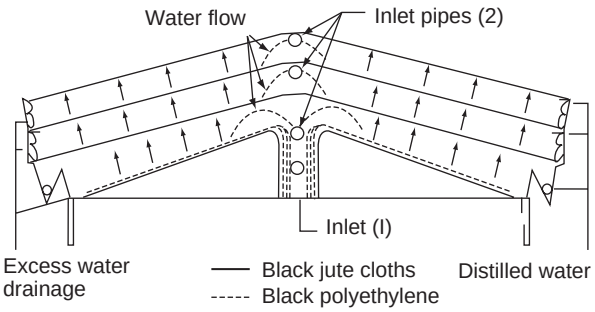

FIGURE 7 Multiple-effect wick solar still.

diffusion and not by natural convection. To determine whether to use a single- or a multieffect still, one must calculate the increase in output and the additional costs in construction and operation.

8. SOLAR-DRIVEN DESALINATION

For medium-size communities, water demand may be for households, agriculture needs, and small industries. These regions may also be remote without energy supply. In this case the solution is solar-driven desalination plant. Capacities range from 10 to 100 m^3/day (2642–26,420 GPD).

Solar-driven desalination plants combine two different technologies: thermal or electrical techniques and conventional desalination methods. Desalination methods are considered mature and commercially available, with a variety of procedures, equipment, and capacities. Solar thermal and electrical transformation methods are more or less mature and in some cases commercially available. In comparison to solar distillation plants, both are capital- and operation-intensive enterprises, but costs decrease as technology improves. In general, they are more complicated to operate than plants driven by conventional energy sources. This is due mainly to the unsteady-state solar incident radiation.

9. ENERGY CONVERSION SYSTEMS

Energy conversion systems must be chosen according to the morphology of the site, the desalination method, the availability of salty water, and the freshwater output needed. Wind energy may be included as an energy transformation source because it is an indirect solar energy source. Energy conversion systems include

- Flat-plate collectors, which supply hot water up to $\sim 95^{\circ}$C.
- Solar ponds, which produce hot water up to 90°C.
- Evacuated tube collectors, which reach temperatures up to 200°C and are more suitable for conventional distillation plants, such as multiple-effect thermal distillation (MED) and thermal vapor compression (TVC). They have been proven to be very effective in combination with MED.
- Focusing collectors, which produce high-temperature vapor and/or electricity. They are suitable for large-scale dual-desalination plants and for electricity and freshwater production. Thus, small remote regions are excluded.

Flat-plate collectors and solar ponds require large installation areas (either flat or cascading for flat-plate collectors), but if available, capital and operation costs are low. Not all solar conversion systems are suitable for each desalination method. The combined technologies have to be carefully designed to give the highest possible efficiency for the morphology and environment of the site. Flat-plate collectors, solar ponds, and evacuated tubes are coupled with MED, TVC distillation equipment, focusing collectors, and evacuated tubes for multi-stage-flash thermal distillation plants.

10. CONVERSION TO ELECTRICITY

Solar energy conversion to electricity includes wind energy, which is an indirect solar energy source. The conversion systems comprise photovoltaic devices that directly transform solar energy into electricity and wind turbines that indirectly produce electricity. The electrical energy produced is used to operate seawater and/or brackish water reverse osmosis units, electrodialysis and electrodialysis reversal units, and mechanical vapor compression distillation units. Electrical energy is also used to run auxiliary equipment, such as pumps, fans, and control devices, and to provide the site with electricity. In the case of thermal conversion systems, small photovoltaic installation may help provide the necessary electricity to the system.

Solar-driven desalination plants are unsteady-state systems. Solar energy can be stored as: sensible heat in water tanks, in phase change material, and in batteries as electrical energy to smooth diurnal operation during night and/or cloudy days.

11. SIZING A SOLAR-DRIVEN SYSTEM

For remote and arid locations, solar energy and desalination technology systems have to be as simple as possible, controlled and maintained by skilled personnel. This facilitates good operation conditions and minimal maintenance. Generally, an overcapacity design is recommended for desalination plants and freshwater storage tanks. For small- and medium-size plants, a water storage tank three to six times the daily water consumption and an overcapacity design of approximately 50% are sufficient. Conventional desalination plants are energy-intensive enterprises.

TABLE I

Indicative Typical Energy Inputs for Solar Desalination[a]

Process	PR (kg/2326 kJ)	kJ/kg of fresh water	Production rate (liters/m^2)	Form of energy	Suitable energy technology
Stills	0.53	4259	4	50–80°C	Ponds, flat-plate
MED	8	294–296	8	~71°C	Ponds, flat-plate
	15	159–161	13	~120°C	Evacuation-concentrating
MSF	8	298–300	9.5	~90°C	Ponds, evacuated
	12	199–201	14	~120°C	Concentrating
MVC	58	61	50	17 kWh m^{-3}	Solar electric, PV
SWRO	54	43	100	12 kWh m^{-3}	PV, wind
BWRO	200	12	75	3 kWh m^{-3}	PV, wind
BWED	200	12	30	3 kWh m^{-3}	PV, wind

[a] Abbreviations used: MED, multiple-effect distillation; MSF, multistage flash distillation; MVC, mechanical vapor compression distillation; SWRO, sea water reverse osmosis; BWRO, brackish water reverse osmosis; BWED, brackish water electrodialysis; PV, photovoltaic.

TABLE II

Solar Drive Desalination Plants Worldwide[a]

Plant location	Desalination process	m^3/day	Solar energy conversion plant
Abu-Dhabi, UAE	MEB, 18 effects	120	Evacuated tubes
Al-Ain, UAE	MED, 55 effects, MSF, 75 stages	500	Parabolic trough
Borkum Island, Germany	MVC	5–12.5 m^3/h	Wind, 300 kW
Cabo Verde	MSF, auto flash	300	Solar pond
El Paso, Texas	MSF	19	Solar pond
Gran Canaria, Spain	MSF	10	
Hzag area, Tunisia		0.1–0.35	Flat-plate collectors
La Desire Island, French Caribbean	MED, 14 effects	40	Evacuated tube
Lampedusa Island, Italy	RO	16	100 kWp
Margerita di Savoya, Italy	MSF	50–60	Solar ponds
Platforma Solar, Almeria, Spain	MED, 14 effects	72	Parabolic trough
Safat, Kuwait	MSF	10	Solar collectors
Takami Island, Japan	MED, 16 effects	16	Flat-plate collectors
University of Ancona, Italy	MED	30	Solar pond

[a] Abbreviations used: MEB, multiple-effect boiling; MED, multiple-effect distillation; MSF, multistage flash distillation; MVC, mechanical vapor compression distillation; RO, reverse osmosis.

Thus, energy needs are the most important factor in determining the size of a solar conversion system. For multieffect stack (MES) evaporators, which are the most preferable to combine with high-performance flat-plate and evacuated tube collectors, thermal energy requirements depend on performance and capacity:

$$Q_{ev} = M_d \cdot \frac{\Delta h_v}{R}, \qquad (16)$$

where M_d is the daily rated capacity, and R is the performance ration of the MES unit, which depends on the number of effects and is given as

$$R = -0809 + 0.93N - 0.0091N^2. \qquad (17)$$

In addition, electrical energy is provided by either diesel or photovoltaic arrays to drive the pumps. Table I gives prices of energy

consumption for solar distillation and solar-driven systems.

12. CONCLUSION

Solar distillation systems are suitable for remote, arid, or semiarid regions for small capacities. Simple designs are preferred because they are cost-effective and easier to operate and maintain. Low-cost, locally available materials can be used, taking into consideration safety and lifetime of the installation. Although some solar distillation plants with capacities of 1–40 m^3/day (in Greece, India, the Caribbean islands, and other places) are in operation, the interest currently has turned to solar-driven systems. Solar-driven desalination is suitable for small- to medium-size capacities. As these systems combine, different technologies must be carefully selected and coupled to achieve high efficiencies, simple operation, and easy maintenance. Most plants are pilot plants used to study and improve design, operation, and cost. They do not exceed 0.1% of the capacity of desalination plants driven by conventional energy sources and require further study to improve technologies and lower cost. Table II lists some of the most important solar-driven desalination plants.

Glossary

calcination A process of oxidation (here of lime in iron making).
charge Load of a furnace with the usual materials.
coke rate Amount of coke used per ton of iron or steel product.
energy efficiency Amount of output produced per unit of energy input.
energy intensity Amount of energy used per ton of product.
oxidation Chemical process by which oxygen is added to a reactant.
reduction Chemical process by which oxygen is removed from a reactant.

Iron and steel-based products lay the footprint for industrialization, and thus energy consumption in the transportation, commercial, industrial, and end-use sectors of an economy. Their manufacturing itself is highly energy intensive and often accounts for a significant share of a country's energy use. This article concentrates on the uses of energy for steel production.

1. BACKGROUND

Since the construction of the great Iron Bridge in England during the 1770s, the use of iron and steel-based products has come to be associated with the industrialization of economies. Iron and steel are used in such diverse applications as railroads and skyscrapers, automobiles and other durable consumer products, as well as many infrastructure systems of modern society. To this day, iron and steel are among the least expensive and most widely used metals.

As economies industrialized and grew in size, world production of steel has increased (Fig. 1). By early 1900, the United States led the world in steel production, contributing about 36% of the world's output, followed by the German Empire (23%), the United Kingdom (17%), and Russia (10%). In 2000, the three largest steel producers were China (15% of world output), Japan (13%), and the United States (12%). With the boom in its economy, China's demand for finished steel increased more than 40-fold from the early 1950s to the mid-1990s, and its production rose by more than 10% per year. However, production increases in China were less rapid than the growth of the Japanese steel industry during that time period or the Korean steel industry since the mid-1970s.

This article explores the uses of energy for steel production. The first section describes key processes for raw steel production. The second section addresses iron and steel casting, finishing and forming processes used to produce semifinished or finished products. The third section describes processes that are not always carried out by the iron and steel industry itself, such as beneficiation of ores, but that significantly influence the industry's energy use profiles. The fourth section investigates various drivers behind technology change in the industry and their influences on energy use. The chapter closes with a brief summary and conclusions.

2. IRON AND STEEL PRODUCTION

Iron is made from ores by removing oxygen and impurities from the iron oxides in ores. Chemical reduction is achieved with the help of coke, lime, or

Permission granted.

other reduction agents. The molten iron typically contains from 3 to 5% carbon and other impurities. It is usually produced with blast furnaces and passed on in a molten state as input in steel-making processes.

Steel making involves reducing carbon content to about 1%. Various steel-making processes exist. The crucible, bessemer, open hearth, and basic oxygen processes start with iron as their primary material input to which in some cases iron and steel scraps are added. In contrast, the electric arc process starts with up to 100% scrap as its material input and uses electricity to melt the furnace charge. Through history, each of these processes accounted for varying contributions to overall iron and steel production (Fig. 2). By early 1900 the crucible, bessemer, and open hearth furnaces were used in the United States for 67%, 32%, and 1% of steel production, respectively. By 2000, these furnaces were replaced in the U.S. steel-making process by the basic oxygen and electric arc furnaces, which produced 53% and 46% of steel, respectively.

Basic oxygen furnaces are typically part of vertically integrated operations that produce ores, a variety of intermediate products such as coke and pig iron, and raw and finished steels. While basic oxygen furnaces were replaced gradually in the United States and many other countries as the technology matured, furnaces aged, and new technologies became available, Japanese and European competitors had to rebuild most of their production facilities after the war. Only a small fraction of the furnaces they lost were replaced by the traditional open hearth technology. Most new capacity was added in the form of basic oxygen furnaces, which reduced the time it took to produce steel from longer than 6 hours to less than 40 minutes.

No new basic oxygen furnace capacity has been added since the 1960s in vertically integrated mills in the United States, capacity fell by over 50%, and no new future capacity additions are expected, in part because of large capital requirements to build furnaces that must operate at 1.5 to 3 million tons per year in order to be economically viable. Concomitant with these trends, the share of output from electric arc furnaces has steadily increased since the 1970s (Fig. 2), and the energy use profiles of the industry as a whole have changed.

Each iron and steel-making process has characteristic energy use profiles. However, in the thermodynamic ideal only iron making requires substantial energy consumption. The theoretical minimum energy requirement to reduce ore is given by the physical and chemical properties of ore. At room temperature, the theoretical minimum energy requirement to melt Hermatite, the main ore type, is 6.9 GJ per ton of steel. This thermodynamic minimum does not change with time and establishes a lower bound on the energy necessary for steel production from ore. In practice, energy consumption for primary steel production is two to three

times the thermodynamic minimum. Consequently, energy use by the industry could, in principle, be reduced significantly.

2.1 Blast Furnace Production

Blast furnaces are the largest consumers of materials and energy in the iron and steel-making process. They are relatively flexible in their ability to use different metal charges, such as pellets, sinter, or scrap, with little change in performance. Other inputs include coke to produce carbon monoxide for the reduction of iron ore to iron, and other energy sources for various stages of the production process, such as preheating of air up to 1100°C for injection into blast furnaces. Since blast furnaces require significant quantities of coke, they are often operated in close conjunction with coke ovens, creating opportunities for joint use of byproducts, such as coke oven gas as well (Fig. 3).

The main outputs of blast furnaces includes pig iron and slag, which is formed by combination of limestone with sulfur and other impurities. Pig iron is typically tapped every 3 to 5 hours in quantities of 300 to 600 tons. After tapping, the pig iron is transported, typically in liquid form, to steel-making operations.

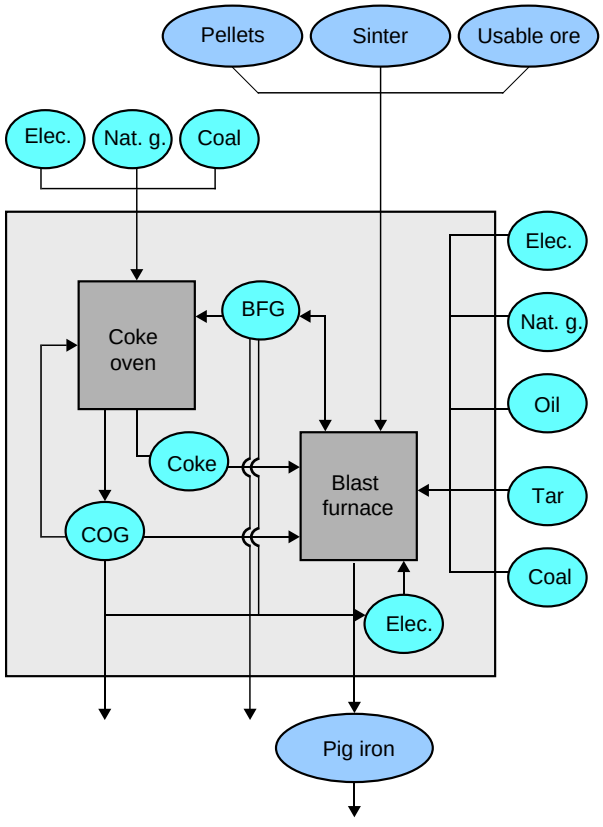

FIGURE 3 Main material and energy flows of blast furnace and coking operations. BFG = Blast furnace gas, COG, coke oven gas; Nat. G., natural gas; Elec., electricity.

Other outputs from blast furnaces include blast furnace gas, an off-gas with a heating value of 3 MJ per m^3, which is approximately one-tenth of the energy content of natural gas. This heating value has been dropping as a result of reduced coke rates and better burden preparation. The gas quality is insufficient to allow high-efficiency conversion to electricity in gas turbines. To increase heating values, blast furnace gas is often mixed with other gases such as coke oven gas and natural gas, which have higher energy content. This mixture can be converted into electricity with efficiencies of 41 to 42% in combined cycle plants. Much of that conversion takes place onsite at steel plants for electricity used in steel making and in some instances for sale into the electricity grid. A portion of the off-gas is consumed in boilers that produce compressed air via steam-powered or electric blowers. Funneling that air through hot blast stoves provides the heat required in the blast.

With the price of coke rising, steel makers have sought to reduce their dependence on coke, for example, by installing pulverized coal injection into their blast furnaces as a partial substitute for coke. A few use natural gas for the same purpose. The need for greater efficiency in blast furnaces has also focused attention on the efficiency of oxygen use so that combining coal injection and large amounts of oxygen can further diminish the need for coke.

2.2 Crucible Steel Production

The crucible process for steel making was introduced in the 1740s in England. It used iron, frequently in solid form, which was molten with the aid of coke fires (Fig. 4). Melting took place in clay crucibles to which other materials were added to achieve desired properties of the steel they produced. Production was typically small-scale (approximately 50 kg per batch) and took roughly 4 to 6 hours per batch. Both the small batch sizes and relatively long heating times meant that the crucible process was highly energy inefficient and did not yield steel at rates necessary to meet rapidly growing demand.

2.3 Bessemer Steel Production

The bessemer process reduces molten pig iron in so-called bessemer converters—egg-shaped, silica, clay,

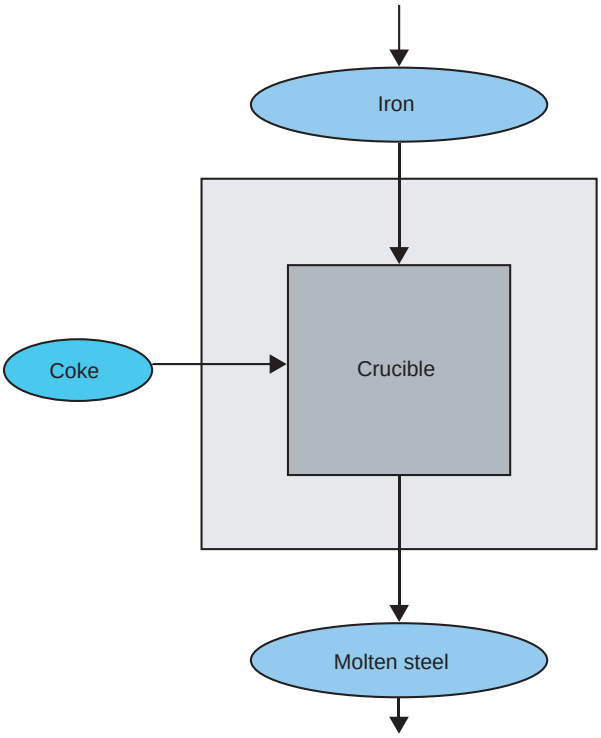

FIGURE 4 Main material and energy flows of crucible steel production.

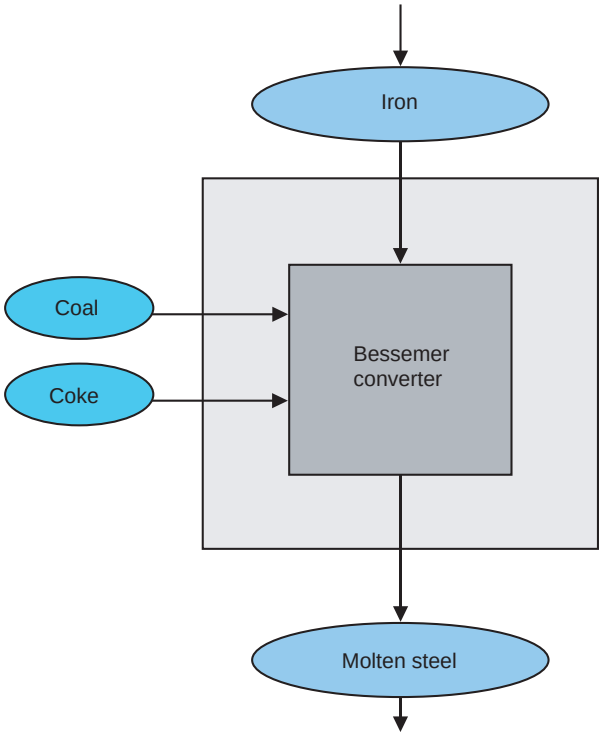

FIGURE 5 Main material and energy flows of bessemer steel production.

or dolomite-lined containers with capacities of 5 to 30 tons of molten iron. An opening at the narrow upper portion of the bessemer converter allows iron to be introduced and the finished product to be poured out. Melting of metal typically is accomplished with coal and coke fires (Fig. 5). Air is forced upward through perforations at the wide bottom-end of the converter. As the air passes upward through the molten pig iron, impurities such as silicon, manganese, and carbon oxidize. Different property steels are produced by introducing additional elements, such as spiegeleisen—an iron-carbon-manganese alloy—into the molten metal after the oxidation is completed. The converter is then emptied into ladles from which the steel is poured into molds. Since the whole process could be completed typically in well under 1 hour and for significantly larger quantities than with crucibles, bessemer steel production significantly helped meet steel demands during the onset of the industrial revolution. As steel production increased, demand for coal and coke increased in lockstep.

2.4 Open Hearth Production

Open hearth furnaces are first charged with scrap and a small amount of limestone. Limestone is used as a reduction agent. Then the fuel—typically oil, natural gas, coal, tar and pitch, or a combination of these—is ignited to melt the charge (Fig. 6). As the charge melts, proportioned amounts of molten pig iron are added to the furnace and high-purity oxygen is blown in. After various minor operations, the molten steel is trapped for approximately 8 hours to further chemically reduce the iron.

Between 1910 and 1970, open hearth furnaces were the predominant technology for steel production in much of the industrialized world. Their flexibility in using a wide range of hot metal and scrap charges added versatility to the production process. However, their long cycle times also meant significant energy use per ton of steel produced. With the onset of the energy crises of the 1970s and 1980s, the newer, more efficient technology of basic oxygen production became increasingly economically viable.

2.5 Basic Oxygen Furnace Production

Basic oxygen furnaces use pig iron and small amounts of scrap as their primary material inputs and typically melt the furnace charge with coke oven, blast furnace, and natural gas. Electricity and fuel oils are used to drive ancillary processes (Fig. 7).

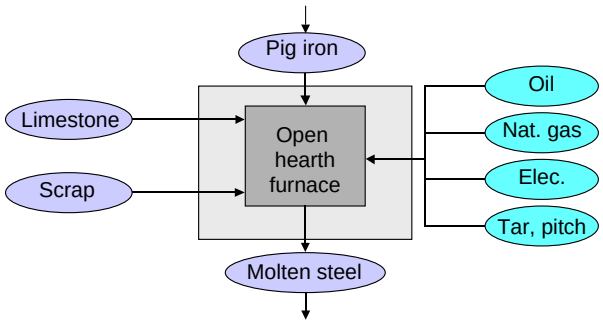

FIGURE 6 Main material and energy flows of open hearth steel production. Nat. G., natural gas; Elec., electricity.

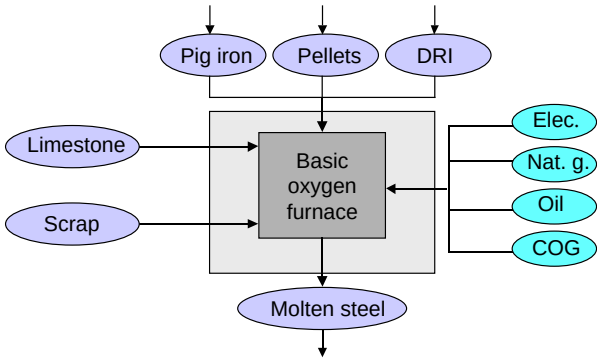

FIGURE 7 Main material and energy flows of basic oxygen production. DRI, direct reduced iron; COG, coke oven gas; Nat. G., natural gas; Elec., electricity.

Basic oxygen furnaces have the ability to cut total cycle time to less than a tenth of the cycle time of open hearth furnaces, thus enabling significant savings of energy for a given metal mix, and substantial total cost savings even though material costs themselves may be higher. However, their reduced flexibility in use of scraps, compared to the flexibility of basic oxygen furnaces, meant temporary scrap surpluses in the economy, reduced scrap prices, and opportunities for growth of yet another new technology—electric arc furnaces. At first, electric arc furnaces were predominantly used in integrated plants as the "swing" facility when scrap was scarce or plentiful. To a significant extent, this combination of versatile electric arc and efficient basic oxygen furnaces soon spelled the end for the open hearth as a major steel making technology.

2.6 Electric Arc Furnace Production

As output from integrated steel producers declined and electric arc technology improved, smaller-scale

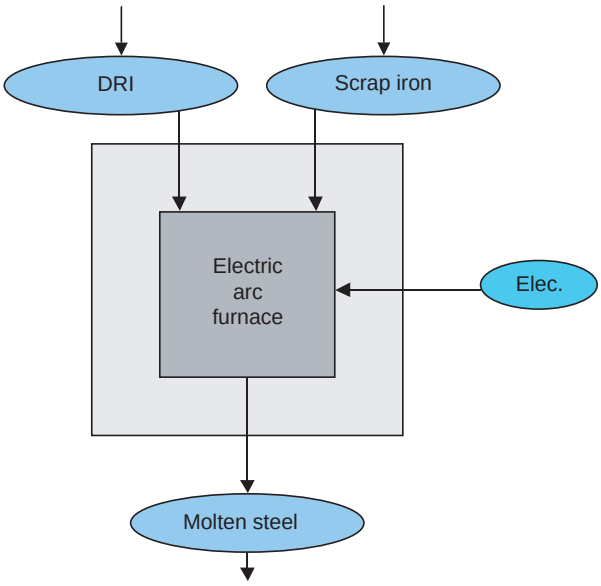

FIGURE 8 Main material and energy flows of electric arc furnace production. DRI, direct reduced iron; Elec., electricity.

electric arc furnaces quickly became an economically attractive alternative to integrated mills—compared, for example, to blast furnaces, which cost around $1 billion and usually operate at scales between 1.5 and 3 million tons per year, as noted by Crandall in 1996.

Electric arc furnaces melt metal by passing a large electric current through the charge (Fig. 8). Since it takes approximately one-third to one-half of the energy to produce steel from scrap than from ore (because it takes considerably more energy to reduce iron oxides than simply melt scrap), energy savings and onsite emissions reductions are substantial when steel made from scrap is substituted for steel made from iron ore. Their relatively smaller scale, predominant use of scrap, and cleaner production enabled electric arc furnaces to be located in large urban areas and steel fabrication centers where the supply of steel scrap is high.

However, several limitations exist to reduce energy use in steel production by expanding electric arc furnace output. First, an increase of the amount of scrap that is recycled without some decrease in the amount of hot metal production will increase, not decrease, energy use. To reduce overall energy consumption for steel production requires substitution of either scrap for hot metal in existing furnaces, or of new, scrap-based furnaces for ore-based furnaces, not just simply an increase in scrap recycling. Second, actual energy savings depend on (1) how much energy is required to collect, sort, process, and deliver scrap and (2) how much energy

is consumed by hot metal production. Considering both the direct and indirect energy requirements, some studies have found that even if all the steel were made from scrap, the total energy intensity of U.S. steel production would be reduced by only 6%, saving less than 1% of total annual U.S. energy use. However, increases in scrap use may be pursued for other reasons, such as relative rises in labor costs and relatively high ore taxes. Other constraints on increasing the market share of electric arc furnace output depend on environmental cost, scrap availability and prices, and product quality.

3. CASTING, FORMING, AND FINISHING

A series of casting, forming, and finishing processes are used to change the shape and other physical and chemical characteristics of raw steel products. Each of these requires a specific set of steps with distinct efficiencies and energy use profiles. The general pattern of energy use of casting, forming, and finishing is shown in Fig. 9. Details are provided next.

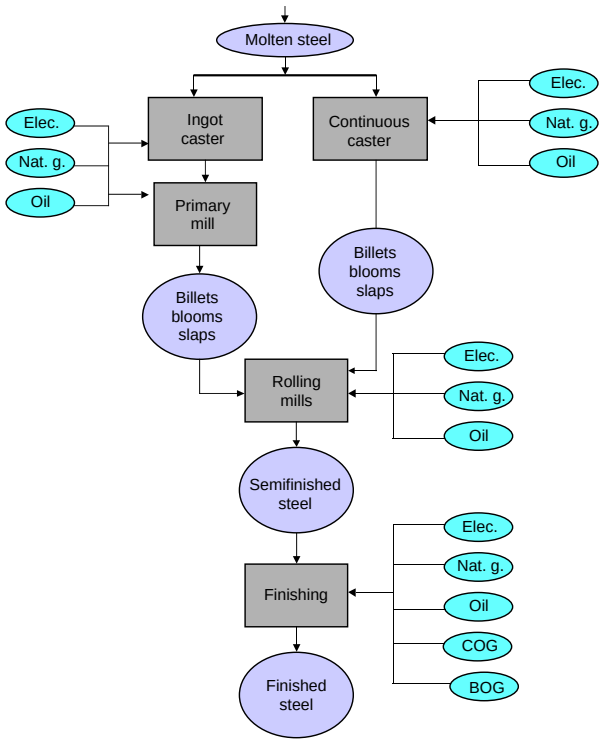

FIGURE 9 Main material and energy flows for pellet and sinter production. Nat. G., natural gas; Elec., electricity.

3.1 Casting

Most of the raw steel produced by the industry is cast either continuously or into ingots or strips. In ingot casting, which in the United States and other industrialized countries is mostly used for small batch sizes for specialty steels or for end products with certain shape specifications, the molten steel is teemed into a series of molds and allowed to solidify to form ingots. After the molds are stripped away, the ingots are heated to uniform temperature in soaking pits to prepare them for rolling. Subsequently, heated ingots are removed from the pits and rolled into slabs, blooms, or billets.

In continuous casting, the molten steel is delivered in ladles and poured into a reservoir from which it is released into a mold. The steel cools as it passes through the mold and forms a solid outer skin. As the steel proceeds onto a runout table, the center of the steel also solidifies, yielding a semifinished shape at a specified width and thickness. Depending on the type of caster used, various shapes are produced. The melting, casting, and rolling processes have been linked with each other to produce shapes that substantially conform to the desired shape of the finished product.

Continuous casting eliminates the need for teeming into ingots, mold stripping, reheating, and primary hot-rolling into semifinished shapes. As a consequence, the continuous process has higher yields compared to the ingot process and is roughly 10 times as energy efficient as continuous casting. Continuous casting also offers important benefits in product quality for most products because of the uniformity with which products are cast and the reduction of defects during solidification of the molten steel. Ultimately, the main benefit of continuous casting and direct rolling—both from an energy and overall economic perspective—may be the rapid feedback, which could eventually enable the elimination of most production errors that now result in substantial rejection of finished and semifinished products.

The choice of casting technology is closely related to existing melting technology. For example, in the United States in the 1970s, when open hearth and basic oxygen furnaces dominated steel production, less than 10% of steel was continuously cast. Similarly, in China and India where open hearth furnaces have still been widely used at the turn of the 21st century, the share of continuous casting was relatively low. In contrast, in the United States, approximately 96% of all steel produced at the turn

of the 21st century was continuously cast, the remaining 4% was ingot cast.

3.2 Forming

The slabs, billets, and blooms produced in casting operations are further processed to produce strips, sheets, plates, bars, rods, and other structural shapes through various hot forming operations, which are sometimes followed by cold forming operations. The exact sequence and temperatures of forming operations not only help generate desired shapes but also impart particular physical and chemical properties of the semifinished product. Prior to hot forming, semifinished shapes must be heated to rolling temperatures of about 1000 to 1200°C in a reheat furnace. Upon exiting the furnace, slabs may undergo a surface preparation step, which removes defects prior to entering a rolling mill.

The most common hot forming process is hot-rolling where a heated steel slab is passed between two rolls revolving in opposite direction. Each set of rolls produces an incremental reduction in the thickness of the slab. The final shape and characteristics of a hot formed piece depend on the rolling temperature, the roll profile, and the cooling process used after rolling. Rolling and reheating require considerable amounts of energy. The more the size of the cast steel resembles the size of the finished product, the less energy is required for finishing.

3.3 Finishing

Finishing processes are used to clean the surface of the semifinished hot-rolled steel products prior to cold-rolling or forming or coating operations. Rust and other oxides, oil and grease, and other impurities and contaminations of the steel are physically and chemically removed from the surface with help of solvent cleaners, pressurized water, abrasives, alkaline agents, salt baths, or acid pickling processes. The latter utilize steam generated from fuel to heat the pickling bath and preheat the incoming strip. Electricity is used to power various ancillary equipment, such as extraction fans and acid recovery. Acid recovery plants also use either steam or gas as primary energy inputs, depending on the type of acid employed.

Steel that has been hot-rolled and pickled may be cold-rolled to make a product thinner and smoother so that it is suitable for a variety of uses, such as car bodies, tin cans, pipes, and tubes. Energy requirements for rolling and finishing processes include fuels used for slab reheating and heat treatment, and electricity used by rolling mills and cooling beds. The electricity requirement for rolling is determined by the initial and final gauges and quality of the steel. For hot-rolling it typically ranges from 600 to 1000 MJ per ton steel.

Reheat furnaces are fired with a variety of fuels, including natural gas, coke oven gas, basic oxygen furnace gas, and fuel oil. Modern, efficient reheating furnaces in hot strip mills use about 1400 MJ per ton of steel from cold start to heat slab, whereas older furnaces typically require around 1800 MJ per ton steel and most efficient technologies currently have energy intensities around 1000 MJ per ton.

In some flat-rolled electric arc furnace facilities, thin slabs are sheared and fed directly from the caster to an inline tunnel furnace that acts as a buffer ahead of the hot strip mill. These tunnel furnaces have energy intensities in the range of 500 to 800 MJ per ton steel.

The energy intensity of heat treating furnaces in plate mills is in the order of 400 MJ per ton. However, since not all plate steel is typically heat treated, the specific energy consumption of treated plates can be much higher.

Both electricity and fuel are consumed in cleaning and annealing. Modern hydrogen atmosphere annealing furnaces use 600 MJ per ton of product, while the energy intensity of older furnaces may be 50% or more higher.

4. ANCILLARY PROCESSES

4.1 Mining, Beneficiation, and Agglomeration

Since extraction and some preparation of ores are carried out at the mine site, not at the steel mill, they are typically considered outside the scope of steel making. However, considerable energy is expended in ore preparation processes (Fig. 10), and use of variously prepared ores can significantly reduce energy expenditures at the steel mill.

Crude ores are sold as usable ore by mine operations after some processing and beneficiation. One such form of usable ores are pellets. Pellets usually contain between 60 and 70% iron, with the remainder being binder and substances contained in the original ore. Their surface geometry enables more efficient heat and air fluxes through blast furnaces and thus more uniform reduction of iron oxides and higher efficiency in material (iron, coke) and energy

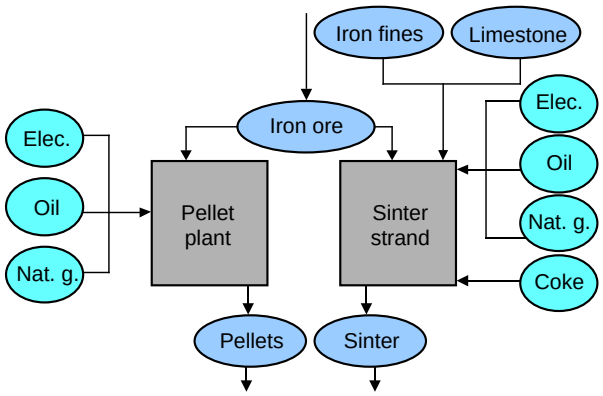

FIGURE 10 Casting, forming, and finishing processes. BOG, basic oxygen gas; COG, coke oven gas; Nat. G., natural gas; Elec., electricity.

use. Their production requires around 1000 MJ per ton of product, depending on the type of ore used, in addition to crushing, screening and washing of ores.

Other types of usable ores are distinguished, for example, as sinter and briquettes, depending on the process used. While pellet production typically occurs at the mine site or shipping port, sinter production usually occurs at the mill. A sintering plant provides a means of recycling many of the iron-bearing fines generated by iron making and steel making. In sinter strands, materials such as scale, sludge, and slag are added to ore fines and agglomerated into a suitable material. Flux, in the form of dolomite or limestone, is added to the sinter burden and calcined during the process, decreasing the energy requirements of the blast furnace process. The sinter, usually 50 to 60% iron, is easily reducible, since its high surface to volume ratio permits high contact of gases and solids. With energy intensities between 10,000 and 20,000 MJ per ton of product, sinter production is an order of magnitude more intensive than pellet production.

4.2 Coke Production

Coals suitable for coking are ground and blended before use as charge in so-called by-product coke ovens, which derive their name from the fact that during the coking process byproducts, such as light oils, tar, ammonia, and coke oven gas, are recovered for use elsewhere in the operation (see Fig. 3). Several of the byproduct fuels are mixed with combustion air for burning in combustion chambers. Under normal operating conditions, the charge is heated for 16 to 20 hours (14 or less with preheated coal—the latter makes the process approximately 10% more efficient). Then the coke is forced into waiting cars where it is water quenched to prevent combustion. After cooling, the coke is crushed and screened. Most of it is then transported to blast furnaces and the remaining coke dust is conveyed to reclamation plants and used either in sintering plants or sold. The entire process requires upward of 20,000 MJ per net ton of coke.

Form coking, a complete substitute for the conventional slot oven coke process, involves grinding and preforming the coal, which is then binded, pelletized, cured to a char, and completely devolatized to develop the necessary strength, a major problem in coke manufacture. Since briquettes are the final product, their uniform size and shape will improve blast furnace productivity. In addition, the process is enclosed, reducing emission problems. The process is not necessarily more energy efficient, although form coaking is a resource-saving technology.

Preheating of coal prior to use in the coking process may enable direct energy savings achieved in coke manufacture, improvements in the quality of the coke produced, and a consequent reduction in coke charged to the blast furnace. Alternatively, poorer quality coals may be used to produce coke equal in quality to that made from high-grade coals.

Because of high replacement costs, regionally declining supplies of low-sulfur coal and tightened emissions standards, coking capacity in the United States and many other industrialized countries has decreased significantly. Of the existing coke batteries, some are operated by iron and steel companies that produce coke mainly for their blast furnaces. The remainder is held by merchant companies that generally sell their product on the open market.

4.3 Scrap Preparation

Iron and steel scraps are used in many stages of iron and steel making. Some of the scraps (prompt scrap) accrue in production itself and are directly fed back into production, others (obsolete scrap) are returned to the industry from other industries or after use of iron and steel containing end use products. Typically, prompt scrap is of a more uniform quality and more readily available than obsolete scrap which often contains larger amounts of impurities and accrues after significant time lags between production and return to the industry.

Scrap quality is a limiting factor for increased scrap use. Certain types of scrap contain high

quantities of trace elements. High-quality steel requires a low trace element content. In the current practice, scrap is used for lower quality steel grades, such as reinforcement bars. However, electric arc furnace steel producers are gradually moving toward the production of higher quality products. In the longer run, declining steel scrap quality and increasing steel quality may pose serious challenges for recycling.

The lower the scrap quality, the lower the yield, and thus the higher the energy requirement per ton of desired output. Since prompt scrap is a waste product of the industry itself and does not replace raw material inputs, increases in prompt scrap use or quality will not noticeably improve energy efficiency. Only expansion of obsolete scrap use can lead to an overall reduction of energy requirements to the extent that obsolete scrap substitutes for steel production from ores. To increase productivity when using scrap and to replace high-cost electric energy with lower cost fuels, some basic oxygen furnaces and electric arc furnaces preheat scrap.

4.4 Direct Reduction

Direct reduced iron is iron ore in the form of lumps, fines or pellets that have had the oxygen removed by using hydrogen and carbon monoxide. Typical sources of carbon monoxide are natural gas, coal gas, and coal. Other energy inputs into the production process often include oil and electricity. Since much of the energy used is in the form of natural gas (e.g., Mexico produces virtually all its direct reduced iron with natural gas), most direct reduced iron is produced where low cost natural gas is available and where adequate capacities exist to access iron ore shipments. Use of natural gas not only reduces the need for coal and coke, but also reduces the associated emissions, such as sulfur oxides and carbon dioxide into the atmosphere.

In direct reduction the ore is heated to temperatures below its melting point. Direct energy requirements per net ton of direct reduced iron are in the order of 10,000 MJ. The product is 90 to 95% metallized and hence is suitable as a charge in blast, basic oxygen, and electric arc furnaces.

By using direct reduced iron, steel makers can dilute lower grade ores and lower cost ferrous scrap to attain acceptable levels of contamination in the mix. If direct reduced iron pellets are substituted for pelletized ores in blast furnaces, the amount of coke per ton of pig iron would be cut. However, reductions in the coke rate could result in shortages of coke byproducts, while natural gas requirements would increase considerably.

5. DRIVERS FOR CHANGE OF ENERGY USE IN IRON AND STEEL MAKING

Changes in iron- and steel-making technology, capacity utilization and production quantities all influence energy use by the steel industry. These changes are often the result of a multitude of interrelated factors, including technological changes in steel production, changes in national and international markets of iron and steel and their substitutes, changes in availability and prices of inputs, as well as environmental regulation. As the industry meets the challenges associated with technology change, product market dynamics, changes in input prices, and environmental regulation, it tends to create savings in all factors of production: labor, capital, materials, and energy.

5.1 Technology Change

Among the most notable changes that occurred in the iron and steel industry of many industrialized countries since World War II are the transition from open hearth to basic oxygen and electric arc furnaces and the use of continuous casting methods instead of ingots. Many new steel-producing countries are following these trends as their industries expand, and technologies change. Further changes in the industry are expected as product quality from electric arc furnaces continues to improve and as newer technologies such as direct reduced iron provide increasingly cost-effective alternatives to the energy intensive basic oxygen route.

The extent to which iron and steel firms adopt new technology depends in part on previous successful experience with the technology, which makes innovation less of a gamble, and on the speed at which technologies change. Firms are likely to delay adoption of technologies that are improving rapidly and tend to adopt a technology after a slowdown in technical progress, either with the furnace the firm is choosing or the competing one. Since many improvements in technology are very costly, long-lived, and once implemented determine a firm's long-term material, energy, and emissions profiles, the industry's aggregate performance changes only slowly relative to the rate at which individual technologies change.

5.2 Market Dynamics

Prior to the 1970s, the industry experienced steady growth and sustained profitability. Since furnaces with higher capacity utilization have lower heat loss per ton of furnace charge and thus higher energy efficiencies and lower emissions per ton of product, overall energy efficiencies in the industry were relatively high during years of high production and capacity utilization rates.

The recession that followed the 1970s oil price crisis has led to overcapacity and resulted in pessimistic forecasts of future demand. Nevertheless, by the beginning of the 21st century, steel makers could produce 15% more steel than the world market demanded, but they were adding 2% more capacity each year.

Since the 1970s, many traditional steel firms have shed unprofitable operations, reorganized production to eliminate waste, and focused their resources both in terms of product lines and of the geographic markets they serve. However, U.S. integrated producers and in some cases minimills were slower than their European and Japanese competitors in implementing improvements.

Integrated steel producers were more likely to close plants that had comparably small output, competed with minimills or sold to contracting industries, and plants that did not use electric arc furnaces. As a consequence, the firms that remained in the market tended to be large, and the probability of exit fell as firm size increased. As the industry consolidated, far-reaching changes in technology required larger capital investments, and as market exit of firms decreased, rates of improvements in aggregate efficiencies from factors other than economies of scale slowed down.

Other reasons for delays in technology change included a lack of profits and access to capital at sufficiently low interest rates to make the necessary large investments in new steel-making technology. The situation was exacerbated by failures to anticipate changes in product needs in the rest of the economy and underestimates of the potentials of new technologies to reduce cost and increase product quality.

5.3 Changes in Material and Energy Prices

Changes in quality of material inputs into steel making are closely related to changes in energy requirements to process furnace charge. As a consequence, the material and energy costs of steel production are related to each other as well as to other technological variables and firm experience.

For example, availability and quality of iron ores influence energy and material efficiencies. Iron ores used in China are mainly of low grade with an average iron content of 34%. Iron ores are beneficiated before they are put into blast furnaces, but because of limits to which the quality of ores can be improved through beneficiation, the Chinese steel industry historically had high coke rates and high iron-to-steel ratios. In contrast, in the 1970s and 1980s, Japanese firms have secured high-quality ore at favorable prices by engaging in long-term contracts with Brazilian and Australian ore development projects. During that time, the price of ore had dropped on the international markets to the point where Japanese firms could secure ores at prices well below the cost incurred, for example, by American firms to get ore from domestic sources, even though shipping cost for Japanese firms were substantial. The resulting cost savings helped Japanese firms to increase their market shares and profitability and thus afforded capital for investment in new capacity and improved technologies.

Improvements in competitiveness and technology also occur in response to changes in energy prices, although influences of energy prices—and for that matter any other single driver—may have be lower than often suspected. Empirical results show that even though energy is a large cost component, energy prices are not a central criterion by which integrated or minimills decide about major process changes. Other determinants include prices and quality of reduction agents. For example, for the U.S. iron and steel industry as a whole, higher coke prices are correlated with later adoption of basic oxygen furnaces and earlier adoption of electric arc furnaces.

Further influences on technology choice and energy efficiency may come from investments into a more diversified and reliable energy system, demand side management, and technology-specific investments. For example, improvements in natural gas infrastructure and technology, power recovery, and direct coal injection at the blast furnace have increased energy efficiency in the steel industry of China and its economy as a whole. Potential improvements in minimills' electricity use indicate that minimills may be a particularly good target for energy demand policies. They are large single users of electricity with a demonstrated engineering potential for efficiency improvements. Encouraging

more rapid upgrading or replacement of older capacity is one effective way to improve aggregate energy efficiency.

5.4 Environmental Regulation

Many energy intensive industries like steel are under increasing pressure to reduce their energy consumption for at least the following two key reasons. First, improving the efficiency with which energy along with other inputs is used can help realize operating cost savings and thus contribute to the industry's competitiveness. Second, reductions in energy use may occur for environmental reasons because environmental impact may reduce the appeal of steel relative to competing materials or because the need to comply with environmental regulation may increase the cost of production.

Focus on local and regional water and air quality has led to the closure of many coke ovens and smelters whose needs for cooling water and emissions of sulfur oxides resulted in significant environmental impacts. In many industrialized countries, blast furnaces continue to face closure and steel makers are increasingly reluctant to make long-term maintenance expenditures on blast furnaces and their associated technologies.

Environmental concerns have shifted to emissions of carbon dioxide and other greenhouse gases influencing global climate. With its use of large quantities of fossil fuels, the iron and steel industry accounts for about 7% of total anthropogenic carbon dioxide emissions. Efforts to reduce carbon dioxide emissions through fuel switching and efficiency improvements typically also address other inefficiencies in the industry.

A number of fuel alternatives exist for coal, the predominant source of carbon dioxide emissions by the industry. The most relevant ones from a carbon dioxide reduction perspective are natural gas, charcoal from renewable wood biomass, waste plastic, hydrogen, and electricity.

Natural gas can be injected into blast furnaces and with proper oxygen enrichment can boost hot-metal output by up to 40%, compared to about 10% in the case of coal injection. Up to 125 kg of natural gas can be injected per ton of hot metal (in energy terms equivalent to about 210 kg coal injection). The potential for carbon dioxide emission reductions amounts to 100 Mt (compared to coal injection) or about 135 Mt compared to coke use. Low carbon dioxide emissions from Mexican steel producers have in part been achieved by using a larger proportion of natural gas in the steel-making process compared to more carbon-rich fuels.

Charcoal, if produced from wood can be considered a renewable carbon source. Part of Brazilian iron production is based on the use of charcoal. Charcoal lacks the mechanical stability of coke, but it is possible to substitute blast furnace coal injection with charcoal injection. Traditional charcoal production is a very polluting activity. New, modern shaft kilns have been developed with much lower emissions compared to traditional charcoal making, but production costs are significantly higher.

Plastic wastes can be added to coke ovens to reduce coal requirements or injected into blast furnaces to substitute for coke and coal. An advantage of use in coke ovens over injection into blast furnaces lies in the possibility to generate higher value products and reduced interference with the sensitive blast furnace operation. However, byproducts from incineration of plastics, most notably gaseous emissions and generation of toxic ash, may limit overall use of plastic wastes by the steel industry.

Not all changes in fuel mix reduce overall carbon dioxide emissions. As firms in different countries undertake fuel substitution in efforts to reduce operating costs, some increases in carbon dioxide emissions may result. For example, the fuel mix in Brazil's steel industry is less carbon dioxide–intensive than in other major steel producing countries because the share of coal is low. The observed increases in net carbon dioxide emissions from Brazilian steel making have been triggered, in part, by the privatization of the steel industry in Brazil which led to a trend away from wood-based charcoal and capital-intensive hydropower generation to fossil-based electricity.

6. CONCLUSIONS

Iron and steel production is among the most energy-intensive industrial activities. Significant changes occurred in the dominant technologies used to produce steel, as well as the fuel mix of the industry and the efficiency of each technology. Several technologies widely used at the beginning of the past century—open hearth and basic oxygen furnaces—now account for only small market shares.

As technology mix in the iron and steel industry changed, upstream and downstream processes had to

adjust. Pelletization of ores and preheating of scraps, for example, are increasingly widely used methods to improve furnace performance, material and energy efficiency, and product quality. New casting and rolling technologies similarly help improve overall industry performance. For example, thin-slab casting in minimills eliminates the need for traditional hot-rolling facilities to reduce slap to hot-rolled sheet. Similarly, newly developing thin-strip casting may produce light-gauge sheet steel without several hot and cold reduction steps.

New technologies will continue to enable minimills to enter new markets. Minimills will also increase the usage of some form of iron—direct reduced iron, pig iron, hot metal—with the scrap charge to improve the quality of the steel they produce to serve even broader markets.

As the industry responds to changes in energy and material prices, changes in the cost of capital, market dynamics, and environmental regulation, the ratio of energy consumption by the steel industry to gross national product declines. For example, in constant-dollar terms, that decline was 32% in the United States between 1973 and 1984. In western Europe and Japan, input prices have risen even more sharply and even more energy conservation has been carried out.

Further improvements in technologies undoubtedly will continue to help maintain steel's competitiveness and energy and environmental performances. Many of these improvements will support the transition from aging furnaces in integrated mills to modern, smaller, more efficient operations. These changes may be most striking in China, India, and other developing countries with significant steel-production capacities and rising demand for iron- and steel-based products.

Glossary

arbitrage pricing theory (APT) A theoretical development in corporate finance that yields a model for pricing risk. The APT model linearly relates stock returns to several risk factors.
autoregressive conditional heteroskedasticity (ARCH) A statistical modeling technique that takes into account volatility clustering.
backwardation A pricing structure in which futures prices are lower than spot prices or when the near futures price exceeds the distant futures price.
contango A pricing structure in which futures prices are higher than spot prices.
forward contract A contract for the purchase or sale of a commodity for future delivery, given by a specific delivery date, and not traded on an organized market.
futures contract Standardized contract for the purchase or sale of a commodity for future delivery, given by a specific delivery date, and traded on an organized futures markets.
heteroskedasticity The variances of a set of random variables are not constant.
ordinary least squares (OLS) A statistical modeling technique that posits a linear relationship between a set of drivers and a dependent variable.
risk A source of randomness that can be quantified.
uncertainty A source of randomness that cannot be quantified.
vector autoregression (VAR) A statistical modeling technique in which each variable of interest is explained by lagged values of itself and the lagged values of other variables in the system of equations.
volatility A tendency for prices to fluctuate widely.
volatility clustering A tendency for large movements in prices to be followed by large movements in prices in either direction.

The interaction between changes in energy prices and economic performance has been of interest for a long time. For example, in the 1890s J. D. Rockefeller publicly expressed concern over rapidly fluctuating oil prices and advocated controlling oil prices in order to stabilize oil company profits and economic activity. Conversely, the relationship between stock markets and energy prices is a relatively new and emerging field of energy economics and finance that sprung to life after the two oil price shocks of the 1970s and the development of the oil futures market in the 1980s. Serious study of the relationship between stock markets and energy prices, and energy and the macroeconomy, has only occurred during the past 20 years.

1. DEFINITION AND ECONOMIC IMPORTANCE

Higher energy prices, mostly through higher oil prices, act like an inflation tax on consumers and producers. Higher oil prices raise the cost of production for non-oil-producing companies and, in the absence of fully passing these costs on to consumers, reduce profits and dividends. Profits and dividends are included in the income side of a country's national accounts. Consequently, sharp reductions in profits and dividends reduce gross

 © 2004 Elsevier Inc. All rights reserved.

domestic product (GDP). Reduced profits dampen the future outlook for corporate earnings, a major driver of stock prices, and decrease stock returns. Steel mills, paper mills, sawmills, airlines, trucking firms, and other companies lay off workers and close plants when faced with steadily increasing fuel bills. Higher oil prices impact consumers directly via increases in the price of gasoline. This reduces the amount of disposable income consumers have left for purchasing other goods and services. Firms selling nonessential goods and services experience a decrease in business activity, which in turn results in lower profits, corporate earnings, and dividends and feeds back into the economy and the stock market.

With the U.S. Federal Reserve moving to an ever more transparent monetary policy, oil price changes have the potential to have a larger impact on stock prices than interest rate changes. This is because oil prices fluctuate more than interest rates do, and oil price changes embody more uncertainty regarding oil demand and supply imbalance, geopolitical, and institutional factors than do interest rates.

2. RELATIONSHIP BETWEEN STOCK MARKETS, ENERGY PRICES, AND THE ECONOMY

Real crude oil prices were highest in two distinct periods: 1861–1869 and 1974–1981. Real oil prices in the period 1861–1869 were very volatile and this is historically identified as the period with the highest real oil prices and the most amount of oil price volatility. Russian oil exports began in the 1880s and this helped to lower oil prices. After the discovery of oil at Spindletop, Texas, at the turn of the 20th century, real oil prices tended to stay fairly constant for long periods of time, particularly between the 1930s (at approximately the time that the East Texas oil field was discovered) and the early 1970s. Price changes did occur, but these changes were few and far between. After the oil price shocks of 1973 and 1979, the underlying structure of the world oil market changed and oil price volatility increased considerably. In fact, oil price volatility in the late 1970s was almost as high as that during the 1860s. Increased oil price volatility created a need for risk management tools and the development of forward and futures markets for crude oil followed. Futures markets for natural gas and electricity are also important, but most of the attention regarding stock markets and energy prices is focused on the crude oil futures market. Today, it is the interaction between oil futures markets and the stock market that financial managers watch closely for signs of pricing pressure on the economy. In the future, with deregulated natural gas and electricity markets, the prices of natural gas and electricity will have a much larger impact on financial markets and the economy.

Since World War II, almost every recession in the United States has been preceded by a large increase in oil prices. Generally, the negative correlation between oil prices and GDP is taken as an empirical fact. During the four quarters preceding the onset of the 1948–1949, 1953–1954, 1957–1958, 1960–1961, and 1969–1970 contractions, the real price of energy increased on average 1.5%. The average increase in real energy prices prior to the onset of the four recessions during the periods 1973–1975 (called the U-shaped recession because real GDP growth during this period resembled the letter U), 1980, 1981–1982 (the W-shaped recession), and 1990–1991 (the V-shaped recession) was 17.5%. This increase in real oil prices was much greater than in earlier recessions. The economic downturns in the United States during the 1970s and 1980s were the largest since the Great Depression. The impact of oil price shocks on the U.S. economy became more pronounced after 1970. This was the time when U.S. demand for imported oil increased and the Organization of Petroleum Exporting Countries (OPEC) cartel began to exert their influence on the world oil market. The 1970s and early 1980 were also turbulent times for world equity markets. Oil price shocks can also occur from large decreases in oil prices. Large decreases in oil prices in 1986 and 1998 are two such examples.

Until the early 1970s, the price of internationally traded oil was set by a group of major oil companies (know as the seven sisters). During this time, the major oil companies set the price of oil on a reference barrel of oil (Arabian Light 34 API) so that the price remained constant in nominal dollars. OPEC basically inherited this pricing regime with some modifications. It was not until 1987 that OPEC adopted the current pricing regime whereby the price of internationally traded oil is determined by a pricing formula based on a reference basket of crude oils.

To understand the relationship between stock markets and energy prices, it is useful to use an equity pricing model. In such a model, the price of equity at any point in time is equal to the expected present value of discounted future cash flows. A firm's cash flow can be affected by economy-wide

factors as well as firm-specific factors. Approximately 60–80% of stock price movements result from broad-based market and industry sector factors and only 20–40% are related to company-specific factors. Cash flows are affected by business cycle conditions, and business cycle conditions can be represented by several key macroeconomic variables, such as industrial production, crude oil prices, interest rates, consumer prices, and possibly currency exchange rates. The ability to manage firm-specific and economy-wide risks determines the economic evolution of a firm.

Oil prices can affect the expected present value of cash flows in several ways. Oil is a resource and essential input into the production process. The basic production function requires inputs on capital (K), labor (L), energy (E), and materials (M): This is the basis for the KLEM model. Increases in energy costs, with the prices of other inputs held constant, will increase the cost of production and, without any offsetting effects, will reduce company profits and dividends. More generally, energy price increases can be mitigated by substitution effects among the other factor inputs. The impact on stock prices depends on whether the company is a net producer or consumer of energy. Increases in energy prices lower (raise) the stock prices of energy-consuming (producing) companies.

The net effect of higher energy prices on the stock market depends on how many firms are net users of oil. Given that there are more firms using oil than producing oil, oil is an input to the global economy. As a result, increases in oil prices lead to decreases in stock prices.

Future oil price changes can also impact stock prices through the discount rate. The expected discount rate is composed of a real interest rate component and an expected inflation component. Higher oil prices put upward pressure on the general price level, thereby raising the aggregate supply curve for a country that is a net user of oil and oil-related products. Higher oil prices can lead to increases in expected inflation and higher nominal interest rates. Since interest rates are negatively correlated with stock prices, increases in interest rates depress stock prices.

Economic growth leads to feedback effects between the economy, energy prices, and the stock market. Increasing industrial production generates a stronger economy and, as a consequence, higher profits and dividends. Higher profits and dividends raise stock prices. A stronger economy also raises the demand for oil and oil-related products. An increased demand for oil and oil-related products puts upward pressure on aggregate prices and interest rates, and the reaction of the Central Bank becomes critical to the movement of the stock market. The Central Bank can either accommodate or dampen the increased economic activity via expansionary or contractionary monetary policy, respectively. Which path the Central Bank takes directly impacts stock returns.

Interest rates can impact stock prices in three ways. First, changes in interest rates are changes in the price charged for credit. The price of credit affects both firms and consumers. Firms seeking to expand existing operations or build new ones need to borrow money. Consequently, the price charged for credit is an important influence on the level of corporate profits and changes in corporate profits are a major driver of stock prices. The price of credit, through its impact on corporate profits, affects the price that investors are willing to pay for equities. Companies prefer to borrow money or issue debt when interest rates are low. In addition, a higher interest rate makes it less likely for consumers to purchase big ticket items, such as houses, automobiles, furniture, and appliances. Second, higher interest rates alter the relationship between competing financial assets. As interest rates rise, fixed-income securities become more attractive relative to equities and investors rebalance their portfolios to take this into account. Third, some stocks are purchased on margin and changes in interest rates impact the cost of carrying margin debt. Higher margin debt limits the ability of investors to participate in the stock market.

Inflation, a sustained rise in the general price level, erodes the real value of investments. This was particularly evident in the high-inflation period of the 1970s and early 1980s. As an example, consider the case of person A loaning $100 to person B for 1 year. Person A would like to earn a 3% real rate of return. Suppose that the current inflation rate is 2% per year and this is expected to be the inflation rate in the following year. Person A will then loan person B $100 at an interest rate of 5%. At the end of 1 year, person B agrees to pay person A $105. Now suppose that the inflation rate over the coming year is not 2% but instead 4%. In this case, person A's real return on his or her investment is 1% (5%−4%). Inflation (unexpected) has lowered the return on person A's investment.

Furthermore, inflationary pressures tend to lead to higher interest rates and a slowing economy, which lessens the ability of growth companies to meet revenue and earnings targets, causing stock prices to

fall. Oil price increases are one of the most likely sources of inflation and oil is a raw material used in almost everything that is made. Crude oil and natural gas are required to produce 98% of North American manufactured products. Oil price increases usually impact the transportation sector first through higher prices for fuel (gasoline, diesel, and jet fuel), with initial price hikes being absorbed by this sector. Airlines are particularly susceptible to higher oil prices because jet fuel represents a major cost of doing business in the airline industry. Persistent oil price increases lead to higher producer prices and eventually, after 6–9 months, inflation. Inflation, which erodes the real value of investments, leads to higher interest rates as contractionary monetary policy is used to bring economy-wide price increases down. Crude oil price increases in 1973, 1979, and 1990 were followed by stock market downturns.

Although oil price increases are not very good for the performance of the economy as a whole, oil price increases are very beneficial to companies engaged in the oil and gas industry. Consequently, oil price risk is a major concern for oil and gas companies. Higher oil prices lead to increased profits and spending on capital budgets, whereas lower oil prices lead to lower cash flows and reduced spending patterns of oil producers. Annualized oil price volatility is approximately 25% per year and annualized natural gas price volatility is approximately 40%. Hence, price variability is a major impact on the stock returns of oil and gas companies. There are three ways in which crude oil prices affect oil company stock prices. First, investors in oil stocks are usually only concerned about the flow of profits from their stock investment and future profits are determined by the expected average price of oil over a particular period. If investors expect the average price of oil to fall (rise), then they will sell (buy) shares in oil companies. Second, oil company stocks are more leveraged than crude oil. Oil exploration, development, and production is a capital-intensive business and oil and gas companies often borrow large amounts of money to go into production. The capital costs of exploration, development, and production depend on several factors, including whether the deposit is underground, under the ocean, or open pit; the type of plant required for oil extraction; and the location of the plant. As oil prices rise or fall, marginal oil deposits become profitable or unprofitable, which in turn changes the value of the company by more than the change in the actual price of crude oil. Third, the profits of oil companies, as for other companies, are a function of production costs and production costs are influenced by the economic business cycle, which in turn is affected by energy prices. In the usual case, rising energy prices contribute more to the revenue side of an energy company's profits than to the cost side.

3. OIL MARKETS AND OIL PRICES

The global oil and gas industry is a mature industry that has prospects for growth as long as global demand for oil and gas products continues to grow. Oil and gas product demand is difficult to predict but is generally highly correlated with worldwide industrial production. In 2000, world oil consumption was 73,905 thousand barrels of oil per day (b/d). The United States accounted for 25.6% of this world total, whereas Europe accounted for 21.4%. During the period 1990–2000, world oil consumption increased 12.9%. World demand for oil is expected to grow 2% per year during the next decade. United States energy demand sensitivities indicate that a 1% increase in real U.S. GDP raises U.S. petroleum demand by approximately 0.6% and U.S. natural gas demand by approximately 1.1%. A 10% increase in crude oil prices, assuming no price response from nonpetroleum energy sources, reduces U.S. petroleum demand by 0.3%. These data were obtained from the U.S. Energy Information Administration Short-Term Energy Outlook (www.eia.doe.gov/emeu/steo/pub/sensitivities.html). The oil and gas industry, however, is very sensitive to business cycle conditions.

In 2000, world oil production was 74,510 thousand b/d. The five largest producing countries were Saudi Arabia (12.3% of world production), the United States (9.8%), the Russian Federation (9.0%), Iran (5.2%), and Mexico (4.8%). In 2000, OPEC accounted for 41% of world production. When OPEC member countries act in unison, they command monopoly power over approximately one-third of the world's oil production. During the period 1990–2000, world oil production increased by 13.9%.

Of course, future oil production depends on where the oil reserves are located. This is where it becomes interesting because most of the world's consumption of oil (62.4% of the world total) occurs in the Organization of Economic Cooperation and Development (OECD) countries, whereas most of the world's oil reserves are located outside of OECD countries. In fact, OECD countries only account for 8.1% of the world's oil reserves. For example, the United States, the world's largest consumer of oil,

currently imports approximately 60% of its crude oil. During 2001, approximately 48% of U.S. crude oil imports came from the Western Hemisphere (19% from South America, 15% from Mexico, and 14% from Canada), whereas 30% came from the Persian Gulf region (18% from Saudi Arabia, 9% from Iraq, and 3% from Kuwait). Since 1960, U.S. petroleum imports have increased more than sixfold.

In 2000, total world proven oil reserves were estimated at 1046.4 thousand million barrels of oil. At current production rates, this implies that there are 39.9 years of oil remaining in the world. Saudi Arabia has the most proven oil reserves with 261.7 thousand million barrels of oil. This equals 25% of the world total. OPEC countries own 77.8% of the world's proven oil reserves. In comparison, the United States and Mexico have proven oil reserves numbering 29.7 (2.8% of the world total) and 28.3 (2.7%) thousand million barrels of oil, respectively. Plentiful cheap oil is found mostly in OPEC countries. The wild card is the Russian Federation, which, in the interim, can rival Saudi Arabia in terms of crude oil production.

In a competitive well-functioning market, the price of oil would be determined by the intersection of demand and supply. An increase in demand (assuming supply does not change) would increase oil prices and an increase in supply (assuming demand does not change) would decrease oil prices. The actual mechanics of the world oil market, however, are much more complicated and are heavily influenced by global politics, institutions, and futures markets.

Political factors are important determinants in oil policy in both the oil-exporting countries (historically OPEC) and the oil-importing countries. The oil-exporting countries tend to intervene in the oil market when prices are too low. Low oil prices reduce the revenue of oil-exporting countries, dampening their economic growth and prosperity. OPEC sells oil in international markets on the basis of price formulae that use as a reference the spot or futures prices of certain important crude oil prices, such as West Texas Intermediate, Brent, or Dubai. Oil-importing countries often enact oil-directed energy policies when oil prices become too high. Higher oil prices tend to be followed by inflation, which erodes the real value of investments and slows economic growth and well-being. Oil-exporting countries can also use oil as a strategic weapon in response to U.S. foreign policy. The world oil market is populated by many consumers and many suppliers, which by itself suggests a competitive market for crude oil. The reality is that the world oil market is very much influenced by institutional factors such as OPEC, strategic oil reserves in OECD countries, and the role that the large multinational oil companies play.

Generally, the difference between oil that is produced and oil that is consumed, if positive, goes into oil inventory stocks. Short-term supply disruptions can be met with a drawdown of oil stocks. Obtaining reliable estimates on oil stocks, however, is difficult because different countries use different reporting systems. Moreover, there is the issue of oil tanker traffic, which plays a major role in getting oil out of the producing countries in the Middle East and into the OECD consuming nations. Supply bottlenecks caused by oil tanker traffic can have a huge impact on gasoline prices in oil-importing countries.

Trade on the marginal barrel of oil sets the price of crude oil. The 11 members of OPEC (Algeria, Indonesia, Iran, Iraq, Kuwait, Libya, Nigeria, Qatar, Saudi Arabia, United Arab Emirates, and Venezuela) are the marginal producers. The near-term outlook for the oil market can be determined be matching data on future consumption, OPEC oil being transported by tanker, and oil inventories. The problem is that OPEC members are very secretive about how much oil they are actually exporting at any given time—so secretive, in fact, that they do not even reveal their oil exports to each other. Tracking the amount of oil in transit is difficult but essential to understanding the world oil market.

The bulk of OPEC oil moves from Quoin Island in the Persian Gulf to ports in New York, Gibraltar (via the Suez Canal), New Orleans, Montevideo, Uruguay, Fremantle, Australia, and Yokohama, Japan. It can take several days to fully load an oil tanker at Quoin Island. Once an oil tanker is loaded, it sails to its destination. Sailing time depends on the distance traveled. The shortest trips of 12 or 13 sailing days are from Quoin Island to Gibraltar and Fremantle. The longest trip takes 31 days to New Orleans. Once the crude oil arrives at its destination, it is unloaded and piped to refineries to be turned into refined products such as gasoline, heating oil, and jet fuel. The refined products are then moved in pipelines and trucks to consumer outlets. This process takes approximately 2 months. In total, it can take 3 or 4 months for crude oil from the Persian Gulf to reach gasoline stations in the United States. Consequently, knowing the amount of oil in transit is essential to knowing the amount of oil available for supply in the next 3 or 4 months. The oil futures markets react quickly to expectations about differences in oil supply.

4. FUTURES MARKETS, OIL PRICE VOLATILITY, AND STOCK MARKETS

Oil is a commodity that is traded in both the spot and the futures markets. The spot market reflects trading for oil delivered today. The futures market reflects trading for oil delivered at some specified time in the future. The futures market provides an essential ingredient to risk management. In the oil market, futures prices tend to be followed more closely than spot prices because futures prices are not as affected by the short-term supply disruptions that affect spot prices. Futures markets for petroleum products are located in New York, London, and Singapore. The three major energy futures exchanges are the New York Mercantile Exchange (NYMEX), the International Petroleum Exchange (IPE), and the Singapore International Monetary Exchange (SIMEX). The NYMEX launched the futures contract on heating oil No. 2 in November 1978. In April 1983, NYMEX introduced the popular futures contract on crude oil. A futures contract on unleaded gasoline followed a few years later. The natural gas contract has only traded since April 1990. The NYMEX natural gas contract size is 10,000 million British thermal units of natural gas deliverable to Henry Hub, Louisiana.

The deregulation of the natural gas industry began in 1978 and was completed in November 1993. As deregulation evolved, the marketplace changed from one dominated by fixed long-term contracts (provided by the pipeline companies) to a spot market, followed by a forward market, and finally a futures market. The success of the natural gas futures contract in the 1990s enabled the natural gas industry to more efficiently manage risk through hedging strategies. In turn, the natural gas futures market has become the foundation for other types of derivatives and now forms the basis for financial engineering in the natural gas industry. Since its introduction in April 1990, the NYMEX natural gas contract has increased in importance as an effective financial instrument for natural gas price discovery.

In 1996, NYMEX launched two futures contracts on electricity. Trading in electricity futures is likely to increase in importance as North America experiments with energy market deregulation. NYMEX also trades options on futures for crude oil, New York Harbor unleaded gasoline, heating oil No. 2, natural gas, and electricity. Options on futures contracts are very useful for risk management.

The IPE trades two popular petroleum futures contracts in Brent crude oil and gasoil. Gasoil can be either heating oil or diesel fuel. Gasoil is the largest single product market in Western Europe. The IPE also trades futures in natural gas. The SIMEX trades residual fuel oil and the market is relatively small compared to NYMEX and IPE.

The West Texas Intermediate (WTI) crude oil futures contract traded on NYMEX is the most closely watched oil price in the world. One contract of WTI crude oil is for 1000 barrels. The NYMEX crude oil market is the largest market (in terms of volume traded) outside of the financial futures market. The WTI crude oil futures market is clearly important to the United States. Moreover, the physical market underlying WTI crude oil is of particular importance to those interested in the demand and supply relationships that reflect the flow of oil from the Gulf of Mexico into the Chicago region. In a broader sense, the WTI crude oil futures contract has become a benchmark for the global oil industry. Reliable fundamental information on global demand and supply in the oil market is often difficult to obtain. Production estimates for some countries, for example, tend to be higher than actual production, and consumption data tend to be made available after some lag time. In contrast, reliable data on oil demand and supply in the United States are often easily accessible and very reliable. Given that United States oil consumption is approximately 25% of world consumption and the fact that the United States accounts for approximately 31% of global GDP, it is natural to use the U.S. data as a proxy for unobservable global fundamentals.

In some instances, futures prices can be used to provide a reasonably good forecast of future spot prices. In other cases, futures prices may provide poor forecasts of future spot prices. The key to determining when futures prices might reasonably be expected to forecast spot prices is to understand the role that storage plays in commodity markets.

Nonstorable commodities are those that are perishable and cannot be stored. Examples include agricultural products such as dairy products. For nonstorable commodities, futures prices reflect the relationship between demand and supply for commodities to be delivered in the future. Small changes in anticipated supply and demand conditions are immediately reflected in futures prices. In this case, futures prices can be used to forecast future spot prices.

Some commodities can be stored and have large inventories. For these commodities, futures prices are equal to the spot price plus the carrying costs associated with storage. In this case, futures prices provide little guidance to future spot prices. Examples include agricultural products such as corn and wheat and also metal products.

Some commodities, such as crude oil, can be characterized as storable commodities with modest inventory levels. In general, consumption is high relative to inventory levels. If futures prices are lower than spot prices, then the pricing structure is called backwardation. In this case, oil can be characterized as a nonstorable commodity. If oil supplies are expected to increase in the future, then the futures price would decrease relative to the spot price. This difference in price creates an apparent arbitrage possibility but low inventory levels prevent the actual collection of arbitrage profits. When commodity markets are in backwardation, futures prices are useful in predicting future spot prices.

If futures prices are higher than spot prices, then the pricing structure is called contango. In this case, oil can be characterized as a storable commodity with large inventory. If the supply of oil is expected to decrease in the future, then futures prices will be higher than spot prices. The difference between futures prices and spot prices reflects carrying costs associated with storage. When commodity markets are in contango, futures prices are of little use in predicting future spot prices.

Futures markets respond to news on four factors: demand and supply fundamentals, geopolitics, institutional arrangements, and the dynamics of the futures market. Whereas some of the spot markets for crude oil tend to be thinly traded, the futures markets (or markets for paper barrels) tend to be very liquid. Futures markets respond not just to facts about the demand and supply balance but also to rumors. In fact, some of these rumors can impact trader sentiment, which may be unrelated to the actual mechanics of the physical market for crude oil. Unanticipated changes in these factors, be it fact or rumor, can create volatility in oil futures prices.

Volatility in the oil futures market leads to uncertainty and this affects the decision making of consumers, producers, investors, and governments. Economic uncertainty creates situations in which planned spending on consumption and investment is postponed or canceled. This economic uncertainty affects the consumption, investment, and government spending categories of the expenditure side of a country's national accounts. Oil price uncertainty impacts the profits of firms, which in turn creates more uncertainty in the stock markets. Uncertainty in the stock markets usually translates into stock price declines, which further affect the economy either through reductions in consumer wealth or postponed investment by business. Volatility in oil prices makes short-term oil price forecasting very difficult. In the long term, oil price fundamentals should dominate, making it easier, at least conceptually, to forecast the price of oil. Forecasting oil prices and oil price volatility, in general, is very difficult, but progress has been made in recent years by using new statistical techniques in modeling and simulation.

5. OIL PRICES AND CURRENCY EXCHANGE RATE RISK

There is evidence that currency exchange rates impact the movement of commodity prices. Since commodities are homogeneous and traded internationally, it is very likely that they are subject to the law of one price. This means that commodities have similar prices in each country's home currency. Thus, as the U.S. dollar weakens relative to other currencies (ceteris paribus), commodity consumers outside the United States should be willing to pay more dollars for commodity inputs priced in U.S. dollars. A strengthening U.S. dollar relative to other currencies (ceteris paribus) increases the price to commodity consumers outside the United States resulting in lower demand for the commodity. Most internationally traded commodities, including crude oil, are priced in U.S. dollars. Consequently, currency exchange rate movements may be an important stimulus for energy price changes. In particular, currency exchange rate movements impact crude oil prices and crude oil prices affect the prices of derivative products, such as heating oil and unleaded gasoline. Crude oil price changes also affect the price of natural gas. Thus, changes in crude oil prices create a ripple effect throughout the pricing structure of petroleum products. The dominance of the U.S. dollar may be challenged in the future as European countries make more use of the Euro currency in their business transactions. Already, some European countries prefer to price oil in Euros and measure oil in metric tonnes. Thus, there are times when the price of crude oil changes not so much from changes in the demand and supply balance in the global oil market or changes in OPEC pricing structure but instead from changes in currency exchange rates.

6. TECHNOLOGY STOCK PRICES AND ENERGY PRICES IN THE NEW ECONOMY

There are two views on the relationship between oil price movements and technology stock prices. The

first view is that oil price changes have very little impact on technology stock prices because technology companies engage in business activities that are not very energy intensive. The second view is that oil price changes do have an impact on technology stock prices because oil price increases fuel inflation and inflation leads to economic downturns. High-technology companies are very sensitive to the overall business cycle. Both views deserve further discussion.

The basis for the first view is the fact that technology companies produce products or services that are less energy intensive than products produced in other sectors of the economy. For example, it takes less energy per unit of output to produce telecommunications equipment than it does to produce steel beams. Manufacturing, in general, has also become less energy intensive. In the United States, it takes 45% less energy to produce one dollar of GDP today than it did in 1973. Automobiles built today are 50% more fuel efficient than automobiles built in the 1970s. The combination of less energy-intensive manufacturing and energy efficiency suggests that technology stock prices are relatively unaffected by oil price movements.

The second view is that oil price movements have a major impact on technology stock prices. Technology stocks, especially prices of Internet stocks, tend to be valued at very high price earnings multiples and stock price movements are linked to expected earnings. These stocks are highly vulnerable to market cycles. In particular, technology stocks, like other growth stocks, are very susceptible to inflation because inflation reduces corporate earnings. Furthermore, inflationary pressures tend to lead to higher interest rates and a slowing economy, which lessens the ability of growth companies to meet revenue and earnings targets, causing stock prices to decline.

Oil price increases are one of the most likely sources of inflation. Oil price increases usually impact the transportation sector first, with initial price hikes being absorbed by this sector. Persistent oil price increases lead to higher producer prices and eventually, after 6–9 months, inflation. Inflation, which erodes the real value of investments, leads to higher interest rates as contractionary monetary policy is used to bring economy-wide price increases down. In the high-technology sector, oil price increases can directly impact technology stock returns by raising the costs of the transportation component of e-business. When a customer places an order for a product online, the product still needs to be shipped from the warehouse to the customer's doorstep. Higher interest rates also create competition for equity financing, and equity financing is more important than debt financing in the high-technology sector. In March 2000, for example, the debt equity ratio for NASDAQ listed stocks was 16.6%, whereas that for the rest of the U.S. stock market was 85.2%. Moreover, some large technology companies such as Cisco Systems have no debt. As interest rates rise, private investors may choose to buy fixed-income securities rather than invest in venture capital pools to finance the startup of new technology companies.

7. MODELING APPROACH AND QUANTITATIVE METHODS

There are three main ways to empirically investigate the interaction between stock prices and energy prices. The first approach uses arbitrage pricing theory (APT), the second approach uses a discounted cash flow model, and the third approach uses unrestricted vector autoregressions.

The APT approach uses an arbitrage pricing argument to relate priced risk factors to required rates of return in assets (securities):

$$R_t = \alpha + \sum_{j=1}^{k} \beta_j F_{jt} + \varepsilon_t, \qquad (1)$$

where R_t is the expected excess return on an asset or stock market index, β_j are the factor loadings or systematic risks, and F_{jt} are the risk factors. The variable ε_t is a random error term. The APT assumes that the total variability of an asset's returns can be attributed to market-wide risk factors that affect all assets and other risks that are firm specific. Market-wide risk factors are known as systematic or non-diversifiable risks, and firm-specific risk factors are known as unsystematic or diversifiable risks. A widely diversified portfolio of equities can reduce or eliminate unsystematic risks, but systematic risk cannot be diversified. Thus, an investor must be compensated for systematic risk. In APT models, assets can have exposure to a number of different risks, including market risk, inflation risk, default risk, exchange rate risk, and oil price risk. Equation (1) can be estimated by ordinary least squares (OLS) regression using a time series data set on a single asset or as a cross section for one particular point in time with many assets. Model adequacy can be checked using regression diagnostic tests. More sophisticated models may involve many assets or classes of assets.

In this case, a system of equations estimation approach would be used. There is considerable evidence that asset prices display time-varying risk premiums and volatility clustering. Time-varying risk premiums can result from time variation in the risk sensitivities (factor loadings) or time variation in the market premiums (factors). Volatility clustering means that major stock price changes follow major stock price changes but the direction of the change is not known. As a result, time-varying autoregressive conditional heteroskedasticity models are often used in the estimation of Eq. (1).

The second approach uses a discounted cash flow model to test whether stock prices react rationally to changes in oil prices:

$$RS_t = E_{t-1}(RS_t) + (E_t - E_{t-1}) \sum_{j=0}^{\infty} \rho^j \Delta C_{t+j} - (E_t - E_{t-1}) \sum_{j=1}^{\infty} RS_{t+j} + \sum_{s=0}^{k} \theta_s OIL_{t-s} + \eta_t, \quad (2)$$

where RS_t is the log real return on a stock in period t, E_t is the mathematical expectation operator, C_t is the log of real cash flow in period t, ρ is a parameter close to but not equal to 1, OIL_t is the percentage change in oil prices, and η_t is a random error term. The model can be estimated by OLS. If the stock market is rational, then the coefficients on the OIL variables should be statistically insignificant from zero. At the economy-wide level, aggregate future cash flows can be approximated by future industrial production.

The third approach uses an unrestricted vector autoregression (VAR). This approach is intentionally unrestricted and useful for determining or confirming patterns between economic variables. Many interesting dynamic relationships can be captured using multiequation regression models such as VARs. Moreover, the VAR is very useful for performing policy simulations. The basic form of the VAR treats all variables symmetrically. No reference is made to distinguish which variables are independent and which variables are dependent. Consider a congruent statistical system of unrestricted forms represented by Eq. (3):

$$\mathbf{x_t} = \sum_{\tau=1}^{p} \Pi_\tau \mathbf{x}_{t-\tau} + \varepsilon_t, \;\; \varepsilon_t \sim \text{iid}(0, \Omega), \; t = 1, \ldots, T, \quad (3)$$

where $\mathbf{x_t}$ is a (nx1) vector of variables, and the error term ε_t is independent and identically distributed with mean zero and variance Ω. Economic theory guides the choice of variables. Typical variables used in studying the relationship between stock prices and energy prices include industrial production, interest rates, stock prices, oil prices, consumer prices, and, possibly, exchange rates. The variables in the vector $\mathbf{x_t}$ might also be transformed into growth rates or may be estimates of volatility. In the latter case, the VAR would be used to investigate the dynamic relationship between oil price volatility and stock market volatility. Basic research questions include the following: What are the determinants of stock market volatility? Has stock market volatility increased over time? Has international financial integration led to faster transmission of volatility across international stock markets?

8. EMPIRICAL EVIDENCE ON THE RELATIONSHIP BETWEEN OIL PRICE MOVEMENTS AND STOCK PRICE MOVEMENTS

The empirical evidence on the relationship between oil price movements and stock price movements is mixed. Empirical models can be estimated using daily, monthly, quarterly, or annual data, and the analysis can be conducted at the firm, industry, or economy-wide level.

Empirical models using the APT model generally use monthly data to investigate the relationship between oil price movements and stock price movements across industry sectors or at the economy-wide level. Generally, the empirical results indicate that an oil price factor is an important driver behind stock price movements. At the economy-wide level, an oil price risk factor is important but it does not have the same impact on all countries' stock markets. Countries that are net importers (exporters) of oil and gas tend to have a negative (positive) correlation between oil price changes and stock returns. The Group of Seven (G7) economies (Canada, the United States, England, France, Germany, Italy, and Japan) is adversely affected by oil price increases. This effect is muted in Canada since it is a net exporter of energy products.

Industries are not all the same and different risk factors can have different effects across different industries. Empirical results suggest that factor sensitivities vary across industries. At the industry level, oil price risk factors have a positive and significant impact on oil company stock returns. For Canadian and U.S. oil and gas companies, market

betas are typically approximately 0.7 and oil price betas are typically approximately 0.3. For industries that are net users of oil and gas, such as airlines and trucking companies, oil betas have a significant negative impact on stock prices.

Empirical results from a discounted cash flow model to test whether stock prices react rationally to changes in oil prices are mixed. The reaction of Canadian and U.S. stock markets to oil price shocks can be completely accounted for by the impact of oil price shocks on real cash flows. The results for the United Kingdom and Japan are not very strong. For these countries, their respective stock markets seem to overreact to oil price shocks.

The VAR approach has been widely used in studies investigating the relationship between oil price movements and stock price movements. This approach, which is generally applied at the economy-wide level using monthly or quarterly data, has provided evidence across a variety of developed and emerging economies showing that oil price changes do impact stock returns. One of the more interesting discoveries from these studies is that oil price changes have asymmetric effects on economies and the stock market. Positive oil price changes exert a much larger impact on economies and stock markets than do negative oil price shocks. This is because positive oil price shocks are associated with an increase in uncertainty. In periods of high uncertainty, firms postpone their hiring and investment decisions. This slows GDP growth. Negative oil prices shocks tend to be viewed as temporary and unlikely to affect the investment and hiring decisions of firms. Any benefits of lower oil prices are usually seen in increased profits for energy-consuming companies.

The VAR approach applied at the industry or firm level using daily data to investigate the lead–lag relationship between oil futures prices and stock prices during the day has provided little evidence of a relationship between broad-based stock prices and oil prices. This is probably because oil price changes take several months to impact the non-oil-related sectors of an economy. As expected, there is strong evidence to support the hypothesis that daily oil company stock prices respond quickly to daily oil price movements.

The VAR approach is also useful for studying the relationship between stock market volatility and the volatility of oil prices. Empirical results indicate that the conditional volatilities of oil prices, interest rates, and U.S. inflation rates each have a significant impact on the conditional volatility of equity markets.

9. ENERGY PRICE RISK MANAGEMENT

Fluctuating energy prices create uncertainty for both consumers and producers of energy products. Energy consumers prefer low and stable energy prices, whereas energy producers prefer higher energy prices. This situation creates a demand for risk management practices. There are a number of risk management tools, including forward contracts, futures contracts, options on futures contracts, and other derivative products (some traded and others not traded).

A typical example is an electricity power generator that needs to buy a known amount of natural gas 6 months in the future. The power generator is a heavy user of energy products and is concerned that natural gas prices will increase in the future. Rising natural gas prices will increase costs and lower profits, possibly resulting in declining earnings, a cut in dividends, and declining share prices. A useful risk management strategy is to employ a hedging strategy. The power generator could buy a forward contract for delivery of the natural gas in 6 months. In this case, the power generator buys the required amount of natural gas from a seller at a price negotiated today. This locks in the price at today's forward prices. The power generator could also use the futures markets for natural gas to buy the appropriate number of natural gas futures contracts on the NYMEX for delivery of natural gas 6 months in the future. Provided that the price of natural gas increases enough in the 6-month period, the forward or futures contracts will have provided the power generator with an effective hedge against rising natural gas prices. Hedging strategies that use forward or futures contracts eliminate the upside risk by locking in the price for natural gas. This eliminates the company's exposure to rising natural gas prices but, unfortunately, also gives away all or part of the company's exposure to declining natural gas prices.

Buying options on natural gas futures contracts is another form of risk management available to the power generator. In this case, the power generator pays the premium to purchase the options. The options premium is a form of insurance against rising natural gas prices. The power generator has the right but not the obligation to purchase the underlying futures contracts. The options will be exercised if natural gas spot prices rise high enough relative to the futures prices specified in the options contract.

If spot natural gas prices decline, then the options expire worthless. The company loses the premium paid on the options but can still buy natural gas in the spot market at a lower price than would have been available under the forward or futures contract.

Glossary

aquifer thermal energy storage (ATES) ATES systems store thermal energy in aquifers (natural groundwater basins or layers at different depth). The system consists of two groups of wells with hydraulic coupling, one cold and the other warm. In winter, ambient air or surface water can be preheated before use by a heat exchanger circulating water from the warm well to the cold. In the summer, excess heat, solar energy, or waste heat can be stored by reversing the process.

compressed air energy storage (CAES) Off-peak electrical energy is used to compress air into underground storage reservoirs until times of peak or intermediate electricity demand. To generate power, the compressed air is heated and then passed through turbines.

duct/borehole thermal energy storage (DTES) DTES systems store thermal energy using vertical ground heat exchangers in drilling boreholes. The thermal energy is transferred via plastic tubes in boreholes typically of 50–200 m depth. A heat carrier fluid is circulated through the tubes to transfer the energy between source and sink.

final storage The storage of final energy such as heat, which is used by the customer to sustain continuous energy services.

grid-level power storage Consists of small and high-power storage systems with the capability to improve reliability, flexibility, and quality of electricity services.

latent heat storage Storage of the energy in special materials such as phase change materials (PCMs). The energy required to change the state of a unit mass of material from solid to liquid or liquid to gas is stored without changes in temperature. This energy is then released when the material reverts from gas to liquid or from liquid to solid.

mechanical storage Energy storage by mechanical processes such as rotation.

secondary storage Storage of secondary energy.

thermal energy storage Storage of heat or cold in different medias, such as PCMs, thermo-oils, or water kept in insulated tanks, caverns, pipes, or underground. Heat storage is a secondary storage type (tertiary, if heat is generated by electricity).

underground thermal energy storage (UTES) Storage of thermal energy underground using either underground storage tubes, aquifers with reduced storage volume needs, or man-made cavern storage systems with sealed storage volumes.

uninterruptible power supply (UPS) systems Combination of high-power, high-energy-capacity storage components that work together to ascertain supply and quality for a specific application.

Energy supply is an intricate task that provides reliable energy service to consumers throughout the year. Import dependencies, seasonal differences in energy supply and use, and daily fluctuations in consumption require sophisticated management of energy resources and conversion, or energy distribution and resource intermittency, in order to guarantee continuous energy services throughout all sectors. Energy storage thus plays a critical role.

Energy is mostly stored in between conversion steps from primary to secondary energy and secondary to final energy. Often, rechargeable systems are used to refill the storage capacity when energy demand is low and energy services are not needed. Primary storage, such as large crude oil and natural gas storage tanks, is essential for the proper functioning of a country's energy system. Water stored in reservoirs behind dams is valuable for selling hydropower electricity at the right time or during seasons of increased demand. Secondary or final storage systems, such as in tanks or in batteries, are crucial for emergency situations, uninterrupted industrial production, long-distance mobility, or to secure energy services at home.

 © 2004 Elsevier Inc. All rights reserved.

Storage systems are engineered to hold adequate amounts of mechanical, thermophysical, electrochemical, or chemical energy for prolonged periods of time. Energy storage systems should be quickly chargeable and should have a large energy storage capacity, but at the same time they should also have high rates of recovery and high yields of energy regain.

Final energy in factories or households is often stored in tanks as chemical energy in the form of heating oil or natural gas or as thermophysical energy in the form of steam, hot or cold water, or thermo-oils. For special applications or for safety reasons, energy may be stored electrochemically in batteries or physically in the form of pressurized air. Other storage systems are related to electricity and apply mechanical storage in the form of spinning turbines or flywheels, physical storage in the form of water in reservoirs in highland terrains, or electrostatic storage in supercapacitors.

1. INTRODUCTION

Several different types of energy storage systems are used for primary, secondary, and final energy. Primary energy is predominantly stored chemically in oil or gas tanks or in piles of specific energy carriers, such as biomass or coal. Secondary and final storage involve silos or piles of briquettes or biomass chips or storage tanks for refined petroleum oils, fuels, and gases. The conversion of these forms of energy into useful end-user energy provides for immediate energy services. If the demand or system status changes, useful energy can also be stored using mechanical or physical storage systems, thermophysical or thermochemical systems, electrochemical and electrostatic systems, or chemical storage systems.

For proper functioning of energy supply chains, storage concepts must be well developed to appropriately incorporate the storage technology into the energy system. Imbalances in a domestic energy system for heat, gas, and electricity can result in a country's increasing dependence on foreign gas and oil companies and expensive transboundary high-voltage electricity transmission lines. The development of inexpensive storage options may enable a country to cope with imbalances between demand and capacity and variable prices in energy markets. Uninterrupted availability of affordable clean energy products for both private and industrial consumers is important for society.

Energy systems rapidly change under the influence of energy policies. The ongoing liberalization or deregulation of energy markets may make small-scale and large-scale storage capabilities increasingly beneficial because of emerging competition in the energy market. However, increasing oil prices indicate structural weaknesses, with the increasing energy dependence on oil playing a major role in fuel consumption. Strategic petroleum reserves are still an important regulatory aspect of energy supply systems and compulsory storage ratios are negotiated between importing companies and the government. Adequate storage facilities must be available not only for crude oil but also for natural gas, which is expected to largely substitute oil in the near future.

Electricity and renewable energy technologies, increase variations in the grid and must be integrated properly into the existing electricity system. This involves local storage of electricity, which may require, among other things, installation of grid-level power storage capabilities.

Industrial and commercial customers increasingly demand power quality and reliability for functioning microprocessor systems. The spread of information technology brings new requirements for the transmission and distribution of electricity.

Uncertainties in grid reliabilities shift the emphasis in energy storage to guarantee energy service from producers to distributors. Distributed power generation and storage interconnected with the distribution grid can provide the needed power quality. In addition to energy supply reliability, incentives for energy storage include the moderation of increasingly volatile energy prices. Real-time pricing in liberalized energy markets is expected to result in additional local storage within buildings and "intelligent" household appliances.

To achieve full potential, both independent and grid-based power distribution systems rely on the availability of different storage technologies. These include safe on-vehicle storage and infrastructure components to ensure fuel availability at filling stations. Other examples are hybrid systems that combine microturbines, photovoltaic panels, or fuel cells for diverse industrial, commercial, or residential applications. These custom power systems must be electronically controlled within a complex grid containing multiple generating units. They require additional storage systems, such as batteries, superconducting magnetic energy storage (SMES), and flywheel energy storage, for power quality and reliability. In both small uninterruptible power supply (UPS) systems for personal computers and

large pumped storage projects, energy storage will increase system reliability. At utility sites, however, storage capabilities that provide large-scale instantaneous response are required. In the future, underground storage technologies including SMES may be possible. Innovations for storing hydrogen, recharging batteries or fuel cells, and facilitating high-temperature superconductivity have great potential to satisfy future heat and electricity storage requirements. In addition, new regulatory standards for efficiency and environmental compatibility require faster technical or technological innovations, such as heat-, corrosion-, abrasion-, and impact-resistant materials or thermal and chemical functional materials for thermal storage, insulation, and cooling media.

In the following sections, the basics of different types of energy storage systems are discussed for electricity, thermal, and chemical storage.

2. ELECTRICITY STORAGE

Apart from the use of secondary batteries, electricity storage is predominantly in the form of mechanical energy. Large-scale electricity storage systems are suitable to balance differences between power supply and demand. Power must be deliverable in time frames of hours and days or months to balance seasonal changes. Large-scale electricity storage systems supply peak-load power using previously stored baseload electricity or make it possible to integrate renewable energy technologies characterized by intermittent resource availability (e.g., solar and wind). In addition, they can supply regulating power for proper transmission and distribution of electricity through the grid. As part of the ancillary services, minimal power must be available within seconds or minutes. Sometimes, power levels must be sustained for hours. The following storage technologies are often used for large-scale electricity storage systems: pumped storage hydropower reservoirs, compressed air energy storage, and large-scale secondary batteries and large fuel cells.

Smaller scale applications of electricity storage provide power for mobile systems or upgrade power quality and reliability (including emergency supply). Electricity storage for these applications has varied capacity and timescale characteristics. The following technologies are applicable: batteries and fuel cells, SMES, supercapacitors and ultracapacitors, and flywheel energy storage.

Batteries are often used in mobile applications and systems in which reliability with low maintenance is important. Their release of power is instantaneous. Batteries can provide relatively prolonged power compared to capacitor and flywheel energy storage, which have different discharge characteristics, releasing high power in a short time frame. Capacitors and flywheels are suitable for improving power quality, integration into emergency backup systems, and peaking in mobile systems. Although in the testing phase, fuel cells are suitable for providing power over long periods of time and for continuous operation at various power ranges.

The capital costs of both power and energy are important in evaluating the economics of storage systems. Typically, the capital cost component of power is related to the output capacity, whereas the cost of energy is related to the storage capacity of the system (Table I).

2.1 Mechanical Systems

2.1.1 Hydropower Storage

An important application of hydropower storage plants is to balance seasonal differences in electricity demand. The reservoir stores excess water from water-rich, lower demand seasons and generates electricity during water-poor, higher demand periods. Pumped-storage hydropower plants follow a different strategy. Extra water is pumped back up to the reservoir using baseload electricity when electricity demand is low, usually at night, and is used for electricity generation during peak-load periods. The

TABLE I

Estimates of Power Capacity Cost and Energy Capacity Cost for Different Storage Systems[a]

Electricity storage system	Power capacity costs ($/kW/a)	Energy capacity costs ($/kWh/a)
Compressed air energy storage in tanks	120	100–1500
Underground compressed air energy storage	90	5–100
Large-scale batteries	70	10–700
Pumped storage hydropower	50	3–90
Superconducting magnetic energy storage	40	9–150
Flywheel energy storage	30	80–1200

Annual costs assume a discount rate of 9% and a 10-year life cycle.

[a] *Source*. EESAT (1998).

increase in electricity generation from renewable energy sources, such as wind and solar, requires additional storage due to its intermittent generation.

2.1.1.1 Hydropower Storage Plants Hydropower storage plants accumulate the natural inflow of water into reservoirs (i.e., dammed lakes) in the upper reaches of a river where steep inclines favor the utilization of the water heads between the reservoir intake and the powerhouse to generate electricity. This efficient storage of potential energy allows hydropower storage schemes a broader range of energy benefits than pure run-of-river schemes. Reservoirs at the upper watershed regulate the river downstream, which typically flows more evenly throughout the year, and the run-of-river power generated downstream utilizes part of the same water used upstream for the hydropower storage plant. Reservoirs can provide a seasonal, annual, or multi-annual storage capacity. Often several hydropower plants form larger hydropower schemes to follow demand along the load curves. Hydropower produces electricity preferentially during periods of higher load. The use of large storage volumes is often controversial because of considerable environmental impact, including the issue of pumping water from distant catchment areas to enhance inflow to the reservoir.

2.1.1.2 Pumped Storage Hydropower The most widespread large-scale electricity storage technology is pumped storage hydropower. A pumped storage plant uses two reservoirs—an upper storage basin providing the head to drive the hydropower turbines and another to collect water back into the upper basin using surplus baseload electricity during off-peak hours. The stored energy is only utilized for electricity generation during daily peak load. By International Energy Agency definition, a pure pumped storage plant uses less than 5% of inflow from upper watersheds and is therefore an energy system storage component, not a renewable energy source. Using "green electricity" (e.g., from surplus wind power) for pumping and using the additional storage volume for grid regulation and balancing are interesting possibilities for a future sustainable energy system.

Hydraulic turbines have a very high efficiency of more than 95%, whereas pumps are less efficient. The result is a maximum efficiency of approximately 85% for pumped storage hydropower plants. The effective efficiency is determined by the roundtrip cycle efficiency, which calculates the cycle with the turbine operated both as a generator and as a pump. Designs of pumped storage are optimized for overall efficiency and dynamic response. The effective efficiency is 65–70%, and for each kilowatt-hour (kWh) of electricity produced, approximately 1.4 kWh of energy is necessary for pumping, assuming the same architecture for both operation modes. Pumped storage is one of the most efficient ways to store electricity.

Economic performance is highly dependent on the price of the cheapest electricity produced by other plants and the variation in daily load. A pumped storage project will provide the most efficient and cheapest operation when it can provide a high water head and volume between its two reservoirs. This will allow the greatest amount of energy to be stored in the smallest volume of water, resulting in smaller pumps and turbine, thus reducing capital costs.

Appropriate location, equipment, and construction are particularly important in view of the high costs associated with pumped storage systems. In general, pumped storage sites with high heads and short water passages are more desirable (i.e., cost-effective sites with higher water head ranges between 300 and 800 m with relatively steep topography). Shorter water passages reduce the need for surge tanks to control transient flow conditions. With higher heads, smaller volumes of water provide the same level of energy storage, and smaller size water passages can be used for the same level of power generation.

The global pumped storage hydropower capacity is estimated to be 82,800 MW. Capital costs are likely to be in line with those for a conventional project (i.e., $1000–3000/kW). The payback time depends on the difference in value of peak and off-peak power. The availability of suitable sites in the future will limit growth in pumped hydrocapacity, with initial capital costs for construction increasing due to environmental obligations. In the longer term, the role of pumped storage plants is likely to increase to cope with intermittency of renewables.

2.1.2 Flywheels

Flywheel energy storage systems provide highly reliable, high-quality, uninterruptible electric power for communications networks, computers, the Internet, industrial manufacturing, commercial facilities, and distributed generation applications. Very heavy flywheel systems have been used for many years in electricity plants and smaller test systems have been used for mobile units.

The charging of a flywheel occurs when heavy symmetrical circumferential masses are rotated. The masses can rotate at approximately 50,000 revolutions per minute almost without friction around a titanium axle using magnetic bearings. The rotating masses are used in conjunction with a dynamo to generate electricity on demand.

The higher the angular velocity of rotation (ω radians per second) and the further away from the center the flywheel masses are placed, the more energy is stored. The relationship is $1/2I\omega^2$, where I, the moment of inertia of the flywheel, is the product of the total masses M and the square of their mean distance r from the center. Since the centrifugal forces are equal to $M\omega^2 r = I\omega^2/r$, for a given flywheel diameter and thickness, higher stored energy requires stronger flywheel materials to withstand the rotational forces. For materials such as fused silica, the specific energy stored in watt-hours per kilogram (Wh/kg) is more than 20 times better than that of steel-based flywheels and approximately 40 times better than that of lead–acid electric vehicle batteries (Table II).

Modern flywheel energy storage systems make use of advanced composite materials and state-of-the-art active bearing technologies. Single flywheel units are typically 5–100 kWh and can be cascaded to achieve utility-scale power and energy ratings with much larger systems being developed in various research laboratories. A 2-kWh composite flywheel system has been introduced and flywheels with an increased energy of up to 4 kWh are available. Plans include production of an 8-kWh model, which is to be followed by a 20-kWh unit. Medium-scale storage (0.1–10.0 MWh) has some unsolved technological problems. Experiments pairing microturbines with a fuel cell or flywheel system as a complete hybrid backup power system are under way.

TABLE II

Energy Densities of Storage Media[a]

Media	Wh/kg[b]
Hydrogen	38,000
Gasoline	13,000
Flywheel, fused silica	870
Flywheel, carbon fiber	215
Flywheel, steel	48
Lead–acid battery	25

[a] *Source*. Ristinen and Kraushaar (1999).

[b] Weight of motor and generator and conversion efficiency not included.

Ceramic superconducting materials may also be applied—for example, a flywheel running on frictionless bearings by means of magnetic fields generated by the superconducting materials.

2.1.2.1 Flywheels for Vehicles Electric buses or trains could use rapidly rotating flywheels for energy storage instead of secondary batteries. Urban transit buses and military vehicles have used stored inertial energy since the 1970s. Some impractical aspects, including a short range of only approximately 10 km, have limited their applicability.

Modern flywheels can store much more electricity than contemporary metal hydride or lead–acid batteries of similar weight or volume. Flywheels are environmentally friendly and have a much longer lifetime than electrochemical systems. High-performance materials enable the design of electric vehicles with flywheel systems comparable to petroleum-powered vehicles. Similar acceleration, speed, and range per unit weight of energy stored, including regenerative braking, are achieved. Hybrid vehicles using flywheel energy storage performed similarly to electric vehicles with supercapacitor or battery systems. One goal is to develop a zero-emission vehicle combining hydrogen lean-burn spark-ignited engines with high fuel economy or hydrogen fuel cells, with both incorporating flywheels or supercapacitors as acceleration and braking energy recovery systems.

2.1.3 Compressed Air

In compressed air energy storage (CAES), the release of stored pressurized air is used to generate electricity, most efficiently in conjunction with a gas turbine. In a CAES plant, compressed air is used to drive the compressor of the gas turbine, which uses 50–60% of the total energy consumed by the gas turbine system. The most important part of the CAES plant is the storage facility for compressed air. Usually, a man-made rock, salt, or porous rock cavern, created either by water-bearing aquifers or as a result of oil and gas extraction, is used. In contrast to the other systems, aquifers can be very attractive because the compressed air will displace the water, setting up a constant pressure storage system.

CAES plants show very high availability and reliability. CAES technology in the range of 25–290 MW has been achieved throughout the industrialized world, and there are proposed projects for an installed power of up to 1050 MW. The estimated annual investment costs for a CAES are $90–120/kW/year

(i.e., uniform cash flow), depending on air storage type.

The development of large-scale CAES is limited by the availability of suitable sites, with current research focusing on the development of systems with man-made storage tanks.

2.2 Electrochemical Systems

Electrochemical storage is characterized as the ability to convert chemical binding energy directly to electricity. The process can be reversed in secondary (rechargeable) batteries or accumulators to recharge the storage media. Only recently have large-scale applications of battery storage become of interest. Utility electricity storage requires a large battery system that can be repeatedly charged and discharged. Battery systems can release power virtually instantaneously, significantly improving the stability of an electricity network. Because of slow self-discharge and the aging processes, battery cells exhibit a decreasing capacity and recharging ability, which results in electricity storage for limited periods of time only. The potential advantages of battery systems are quietness, freedom from maintenance, reduction of gaseous emissions, and their independence of the primary energy carrier. Electric batteries also store direct current (DC) and can be easily integrated into domestic DC networks. An important system parameter is the charging (or load) factor, which relates to the necessary quantity of electricity in Ampere-hours for the batteries to become fully charged to the corresponding quantity released in the previous cycle.

The secondary battery is well suited for applications involving instant, relatively low-voltage power. Battery operation must be designed to be application specific and must consider factors influencing cost, which often limit energy and power per unit weight and volume (energy and power density, specific energy, and specific power) or durability (cycle lifetime and maintenance). Costs and performance of larger systems must be competitive with those of common mechanical storage systems (Table I).

2.2.1 Energy Storage in Batteries

The performance of a battery is characterized by thermodynamic and kinetic parameters that depend on the materials and media used and on battery design. Thermodynamically, large chemical-binding energy differences between the reaction partners, represented by a difference in Gibbs reaction energy, appear as cell voltage. To achieve a high specific energy (Wh/kg), the electrochemical reaction partners or electrodes should be as light as possible. Conventional lead–(sulfuric) acid batteries store approximately 200–500 times less enthalpy than petroleum fuel. Significant improvements have been achieved with nickel–metal hydride and lithium–ion batteries compared to older lead and nickel–cadmium batteries (Table III). The main requirements are improved lifetimes and replacement of heavy metals such as lead with much lighter and nontoxic materials. In addition to the energy storage capacity of a cell, the speed and quality of recharge are often important for efficient and attractive applications of battery systems. The time required to recharge a battery is strongly dependent on operating temperatures. Based on the solubility of reaction products or possible side reactions inside the cell, the recharging process can be inhibited or stopped completely after a few recharge cycles.

2.2.1.1 High-Energy Density Batteries Electrochemical power sources can be classified as accumulators (secondary cells), which store all corresponding reactive components inside, or as fuel cells with reactants stored outside that are fed to the cell stack when power is needed. The systems are also distinguished according to their operating temperature and electrolyte. The most important high-energy density battery systems are summarized in Table IV.

High-temperature secondary batteries and fuel cells compete to claim the electric vehicle markets. In recent years, the fuel cell has received a great deal of attention since it offers good performance in lower temperature operation and allows greatly improved electric vehicle ranges.

Regenerative fuel cells can be used to store electricity in chemical form and convert the stored energy back into electricity when needed. A regenerative fuel cell plant could store more than 100 MWh of energy and provide power for hours to several thousand homes. The development of regenerative fuel cells faces many challenges, particularly regarding pole reversal and recharging cycles. A new regenerative fuel cell design, the redox-flow battery, stores electricity in liquid (dissolved) form, allowing the maximum storage capacity to be easily increased by adjusting the electrolyte volume. The energy density is 20–30 Wh/liter, which is approximately 30% of a normal lead–acid battery. Redox-flow batteries are relatively large and heavy, which makes them suitable only for stationary applications. A large-scale application with a capacity of 15 MW/120 MWh has been built based on the Regenesys

TABLE III

Battery Systems Used in Applications[a]

System	Electrolyte	Type	Storage capacity (Wh/kg)[b]	Application
Lead–acid	Aqueous electrolyte (sulfuric acid), mostly immobilized	Often sealed (valve regulated), works at low temperatures, rechargeable	20–50	Starter battery for cars, batteries for forklifts, electric vehicles, submarines, and ships (also unsealed non-maintenance-free)
Nickel–hydroxide cadmium	Aqueous electrolyte, mostly immobilized	Sealed (valve regulated) rechargeable	20–55	Battery system mostly for small equipment and some for propulsion, on-board electronics, and on-site applications
Nickel–hydroxide hydrogen gas	Aqueous electrolyte, immobilized	Sealed, pressurized, rechargeable	50–60	Battery system for many satellites
Nickel–hydroxide metal hydrides[c]	Aqueous electrolyte, immobilized	Sealed (valve regulated), relatively high load capacity, rechargeable	50–80	Can replace nickel cadmium batteries
Sodium sulfur[d]	Solid electrolyte (β-alumina) at temperatures of 300–400°C	High-temperature system, rechargeable	90–120	Electric vehicles, trams, buses
Sodium nickel–chloride[d]	Solid electrolyte (β-alumina) at temperatures of 300–400°C	High-temperature system, rechargeable	90–100	Electric vehicles, trams, buses
Lithium–ion polymer, lithium cobalt oxide, lithium manganese oxide, iron, or aluminum disulfide	Organic electrolyte at room temperature	Relatively high voltage (4V), relatively high load capacity, rechargeable	~100	Battery system for small applications, tests for some electric vehicles
Zinc bromine[e]	Aqueous electrolyte	Rechargeable	65–70	Tests for some electric vehicles
Zinc air (oxygen from air)[e]	Alkaline or neutral electrolyte	Mechanically rechargeable (i.e., exchange of zinc electrode after a few cycles)	~170	Tests for some electric vehicles

regenerative fuel cell employing the bromide/tribromide and the polysulfide/sulfide couples in aqueous solution. Technical and economic data, according to National Power PLC, are given in Table V.

2.2.1.2 Battery Systems for Different Applications Although the end use of electricity is efficient when compared to the low energy conversion efficiency of gasoline, batteries still severely limit electric vehicle range. No battery has the energy density of gasoline, and battery recharging takes longer than refueling. Nonetheless, by providing a low-emission, low-noise, and clean mobility environment, battery-powered automotive systems for indoor use are increasingly being applied in organized transport systems in automated industries.

Electric buses for public transport and electric cars are becoming more popular for environmental

TABLE IV

Properties of Secondary Batteries and Fuel Cells[a]

Class	System	Type	Operating temperature (°C)	Electrolyte	Energy density (Wh/kg)[b]	Power density (W/kg)[c]	Lifetime charging cycles/years charged
Accumulators	Lead–lead oxide system	Pb/PbO_2	<45	H_2SO_4	161/35	80/160	750/>3
	Lithium–metal sulfide (oxide) system[d]	Li/TiS_2	Ambient	Polymer	473/100	35/400	300/1
	Lithium–iron sulfide system	Li/FeS_2	400	Salt melt	650/180	30/400	1000/0.9
	Zinc–bromine system	Zn/Br_2	60	$ZnBr_2 + H_2O$	430/55	70/80	400/2
	Sodium–sulfur system	Na/S	320	Ceramics	758/110	95/150	4000/4
	Sodium–nickel chloride system	$Na/NiCl_2$	300–400	Ceramics	650/82	60/140	2000/—
					Fuel	**Maximum power (W/cm^2)**	**Maximum operation time (h)**
Fuel cells	Low-temperature fuel cells	H_2/air	<100	Polymer	H_2 or MeOH	1500	1200 (1-kW module)
	Mid-temperature fuel cells	H_2/air	>100–200	H_3PO_4	Natural gas	150	16000 (several MW)
	High-temperature fuel cells	H_2/air	600	Carbonate melt	Natural gas, gasification	150	5000 (3-kW module)
	High-temperature fuel cells	H_2/CO/air	1000	Ceramics	Natural gas, gasification	300	40000 (cell)

[a] *Source*. Kiehne, H. A., Berndt, D., Fischer, W., Franke, H., König, W., Köthe, K. H., Preuss, P., Sassmannshausen, G., Stahl, U.-C., Wehrle, E., Will, G., and Willmes, H. (2000). "*Batterien: Grundlagen und Theorie aktueller technischer Stand und Entwicklungstendenzen.*" Expert Verlag, Renningen.

[b] Theoretical/experimental: The theoretical value accounts only for the weights of the reaction substrates. The experimental value accounts for a 5-h discharging time, except for the sodium–sulfur system, which has 1 h.

[c] Continuous operation/pulse operation (30 s).

[d] Other combinations include MoS_2, NbSe, V_2O_5, and CO_2.

reasons. As Lindly and Haskew note, complete electrification of the vehicle fleet of gasoline-fueled, light-duty, internal combustion (IC) engines, including the complete fuel cycle and based on 1997 Alabama electricity generation mix, would provide a 44% decrease in nitrous oxide (NO_x) emissions, an 18% decrease in CO_2 emissions, but a 14% increase in sulfur dioxide (SO_2).

In contrast to fuel cells, research and development of electrical vehicles with lead–acid, nickel–cadmium, nickel–metal hydride, or molten salt sodium β-alumina batteries has not achieved the required reduction in weight and volume to compete with conventional IC engines. An innovative concept is the hybrid vehicle with a small, efficient IC engine to drive the vehicle after the electric motor has accelerated the vehicle and to recharge its electrochemical system when idling. Recapture braking energy adds to the recharge, and with the reserve electric motor the idle time of the IC engine can be minimized, resulting in improved fuel efficiency.

Stationary fuel cells can also be used for public mobility as centralized electrical energy supply for trams and trolleys, underground (subway), light and conventional rail, and high-speed trains if combined with high-power storage systems such as superconducting magnetic energy systems (SMES) and ultracapacitors.

For large on-site immobile battery systems, mostly lead–acid- or nickel-based batteries are used in power plants and solar installations, signal transmission (telecommunications and radio) and UPS systems, backup systems, switchgear installations, annunciator and traffic lights, safety or emergency lighting, and air-conditioning installations. Because of the nature of the applications, high reliability is required. Less than a 0.25% failure rate has been observed with lead–acid and nickel–cadmium batteries in such systems.

TABLE V

Characteristics of Regenesys[a]

Power	15-MW maximum
Storage capacity	120 MWh
Footprint	<5000 m2
Storage tanks	Two tanks, 1800 m3 each
Total installed costs	$22 million
Lifetime	15 years
O&M costs	Relatively small (unmanned facility)
Storage time	10 h
Capital costs	$185/kWh, $50/kWh (mature technology)
Overall efficiency[b]	70%

For telecommunication equipment, batteries need long operating times to balance electricity supply outages of several hours. For UPS systems, batteries must be able to instantaneously release very high currents over short time periods (minutes) until the backup system responds, which is comparable to starter batteries. Safety and durability are the most important criteria. In addition, sealed valve-regulated lead–acid batteries are used because of their low maintenance requirements.

Solar thermal and photovoltaic (PV) applications are always associated with battery subsystems to balance wide fluctuations of input and output currents. To determine the optimal system dimensions for the specific storage application, the average electricity consumption and the diurnal consumption profile should be known. Other important parameters include those of the PV cells, which must be adapted to the seasonal variation of solar radiation. Use of grid-dependent PV cells reduces the intermittent nature of solar energy because the grid and small-scale electricity storage devices are employed as a backup system. Other solutions to cope with the seasonal differences combine grid, PV, and liquid natural gas (LNG) burners into a coordinated hybrid system for buildings. Table VI lists storage applications for PV supply technologies.

2.2.1.3 Batteries and the Environment The increasing use of secondary batteries, especially lead–acid or nickel–cadmium batteries, means that hundreds of tons of toxic heavy metals are discharged yearly into the environment. Potential environmental impacts from their improper disposal have been recognized as a problem worldwide. In

TABLE VI

System Power Range for PV Storage Applications[a]

Power range	Typical application	Examples
μW	Integrated transistors or chips with minimal energy consumption	Solar watches and calculators
mW	Equipment and installation with low energy demand and only periodic use	Portable receivers/transmitter, automatic devices such as ticket or vending machines, fire or security alarm systems
W	Installations for communication and measurement, small consumer households, or businesses	Devices on buoys or for TV, radio, and meteorological stations, electricity supply on boats or in vacation homes, electricity supply for heat pumps
kW	Stand-alone grids with electric equipment and installations	Remote estates, military

[a] *Source*. Kiehne, H. A., Berndt, D., Fischer, W., Franke, H., König, W., Köthe, K. H., Preuss, P., Sassmannshausen, G., Stahl, U.-C., Wehrle, E., Will, G., and Willmes, H. (2000).“*Batterien: Grundlagen und Theorie aktueller technischer Stand und Entwicklungstendenzen.*” Expert Verlag, Renningen.

Europe, the 1992 Government Action Plan for Waste and Recycling and the 1992 Waste Management Plan for Municipalities consolidated the framework of the Environmental Protection Act of 1994. In the United States, the 1996 Mercury-Containing and Rechargeable Battery Management Act (the battery act) promoted the collection and recycling or proper disposal of used nickel–cadmium and lead–acid batteries, clear labeling of batteries, and education of the public about recycling and disposal. Another goal is to phase out the use of mercury in batteries.

The use of nickel–cadmium batteries is proposed to be phased out of a wide range of household appliances or at least be restricted, for instance, to power tools requiring very rapid discharge. Another measure is to lower the threshold amounts of cadmium in batteries in a stepwise manner, which will ultimately require a change to alternative storage systems. Alternative secondary battery systems are lithium and nickel–metal hydride batteries.

The development of fuel cells for cars, trucks, and buses will reduce the environmental impact of mobility, even if natural gas supplies the fuel cells during transition stages. True "green mobility" may be achieved only if hydrogen supply and storage technology are developed using hydrogen generated from regenerative sources.

2.2.2 Ultra- or Supercapacitors

Capacitors are energy storage devices that use charge as a storage mechanism. A conventional capacitor with charge $+Q$ on one plate, $-Q$ on the other, and voltage V between them has a stored energy equal to $1/2\,QV$. Almost all capacitors use a dielectric material between the plates, which optimizes charge distributions. Dielectric capacitors can provide power densities many times more than 1 kW/kg and have very long cycle lifetimes, whereas batteries provide less than 0.2 kW/kg and have fewer cycles (generally 100–1000). However, dielectric capacitors have energy densities less than 1 Wh/kg, whereas batteries can provide more than 100 Wh/kg. The applicability of dielectric capacitors is therefore clearly limited to specific tasks requiring high power at high voltages over very short time periods (e.g., for lasers). Superconducting inductive systems have similar limitations.

Supercapacitors (scaps) or electrochemical capacitors (ECs), which have 500,000 times larger capacitance than conventional capacitors, can provide more than 1 kW/kg power output combined with more than 5 Wh/kg specific energy and a high cyclicity of thousands of recharge cycles. Scaps, also known as ultracapacitors or electrochemical double-layer capacitors, consist of carbon or other high-surface-area materials as a conductor and an electrolyte. Applications include acceleration power for electric and hybrid vehicles, electrical regenerative braking storage, power trains, starting power for fuel cells, pulse power for mobile and wireless telecommunications, and consumer and industrial electronic devices.

In contrast to batteries, scaps must be associated with a power supply system. They can be used as energy buffer banks to minimize the constraints of power supply. If coupled with batteries, they can reduce the peak power requirement, prolong battery lifetime, and reduce the energy requirement (or the size) of the battery. The batteries provide the energy, with scaps providing the instantaneous power needed. Depending on the configuration, scap systems can be used both as energy source and as buffer, or they can be applied as a load equalizer for elevators. Scaps work in PV-powered systems or stationary industrial power applications; as low-maintenance, solid-state alternatives to batteries for short-term bridging in UPS systems; or for peak-load buffering to increase efficiency and reduce the size and cost of stationary systems. As material costs decrease, low-cost scaps are expected to become the standard option of energy storage systems for consumer electronics, industrial, and transportation markets.

2.3 Electromagnetic Systems: Superconductivity

Superconductivity offers the ideal way of storing electric power directly. Theoretically, by using supercooled inductive coils, much higher storage capacities are achievable than in conventional capacitive or inductive systems.

Superconductors are being considered for SMES, in which electric energy is stored by circulating a current in a superconducting coil without resistive losses. Niobium–titanium alloys are used for storage at liquid helium temperatures (2–4 K). The use of superconducting materials with higher critical temperatures (e.g., 60–70 K) requires additional research and development. The efficiency of charging and discharging is very high because no energy conversion is involved; for this reason, SMES can respond rapidly, with a response that is limited by the time required for conversion between DC and AC power. Rapid response within seconds makes SMES attractive for load leveling and for frequency and voltage

control of the electricity grid while permitting a compact system design. Only SMES with relatively small storage capacities are commercially available. New SMES developments target storage capacities of approximately 100 kWh.

Large-scale applications depend on achieving high critical current densities (Jct) to be cost competitive with other technologies. High power and massive magnetic fields are involved, so careful consideration must be given to the consequences of an accidental loss of coolant; 10 MWh of stored energy released is equivalent to 1.18 tons of TNT.

SMES technology with 90% efficiency for storage of excess nighttime electrical energy is comparable to water-storage technology with efficiencies of 65–70%. Technological development, however, requires time and large monetary investments.

3. THERMAL STORAGE SYSTEMS

The energy content E of a thermal energy storage volume V is proportional to the temperature before (T_1) and after recharge (T_2). That is, $E = c_p(T_2 - T_1)V$, where c_p is the specific heat per unit volume—a storage media- or material-specific coefficient. Water has a high specific heat of 1 kcal/kg · °C compared to steel, which has a specific heat of 0.1 kcal/kg · °C. The transferred energy involved in temperature changes of materials is called sensible heat, whereas the energy involved in changing the phase of a material is called latent heat. Depending on restrictions of volume or pressure changes in gaseous or liquid storage media, the specific heat of constant volume C_v or of constant pressure C_p are important parameters in the design of efficient thermal energy storage systems.

Heat and cold storage systems are important for short-term and long-term (seasonal) storage. One of the benefits of short-term storage is to shift electric resistance heating to off-peak hours. Environmental benefits include the possibility of using renewable energy sources to increase the demand coverage. The benefit of long-term storage is that by balancing seasonal discrepancies in supply and demand, energy consumption can be significantly reduced.

The following systems exist for short-term storage:

- Water, which is the standard medium for heat storage
- Ice (phase change at 0°C, latent heat provides large energy density)
- Phase change materials (salt hydrates), which allow phase change at other temperatures besides 0°C are currently in the market introduction phase
- Sorption systems (e.g., H_2O/SiO_2 and silica gel), which are in the experimental stage, having higher energy densities are more suitable for long-term storage.

Other relevant parameters for thermal systems are energy losses as a percentage of the retrieved thermal energy, which depends on energy density, reflux temperatures, insulation quality, surface-to-volume ratio, and the duration of storage. The energy density (kWh/m^3) depends on the temperature of the media and its specific heat capacity. The cost of thermal systems depends on volume and energy stored (Table VII).

Water as thermal storage media has a low energy density and consequently needs larger volumes, with correspondingly large heat losses. The surface-to-volume ratio should be as small as possible, especially for long-term storage. The recovery efficiency of heat from thermal storage depends on the reflux temperature of the heat extraction system. Improvements are possible using heat pumps, although this is more costly.

Technological advances in phase change materials (PCMs) can increase the thermal mass per unit floor area of buildings and improve the efficiency of thermal systems. Adsorption systems have great potential as seasonal storage applications of solar thermal energy for single homes, for which less cooling is required. The heat coverage with solar thermal energy could technically reach 90–100%.

Long-term storage is often combined with solar thermal systems. Soil–heat exchangers integrated in pile foundation, soil, or groundwater systems (aquifers) are used. The energy used for circulating the storage media water through the system is determined by the permeability of the underground

TABLE VII

Overview of Short-Term Storage[a]

	Energy density (kWh/m^3)	Energy losses (estimate) (%)	Cost (<10 m^3) ($/m^3)	Cost (>100 m^3) ($/m^3)
Water	50–60	20	2000	700
Phase change material	50–120	12	2700	1300
Adsorption	200–250	5	6800	4500

[a] *Source*. Collinson (2001).

material and the system's depth. The corresponding net thermal energy retrieved, the size, and the temperature levels of the system are the most important characteristics. The costs are strongly determined by the required pumping capacity (m^3/h) and power capacity (kW) and less by the size of the system (Table VIII).

Underground soil or groundwater systems are very productive for cooling, when improved building construction, (automated) shading systems, highly efficient lighting systems, and electric appliances reduce cooling demand to a minimum. Combined with energy conservation strategies, cooling systems can meet the entire cooling load in most office buildings. In winter, the same system can be used to preheat the cold air drawn in for fresh air supply in office buildings, reducing heating demand by approximately 30%. Seasonal underground storage systems can even provide coverage of up to 70% space cooling in industrial buildings with cooling capacities of 40–70 W/m^2.

3.1 Water for Thermal Energy Storage

3.1.1 Thermal Storage Tanks

Centralized water thermal storage is by far the most common form of thermal energy storage. Usually, large hot-water storage tanks are buried underneath large infrastructure components such as athletic fields and parking garages. Conventionally welded steel tanks, reinforced concrete, or wire-wound concrete tank systems are used with capacities of 1 million gallons or more. Heat storage capacities range from 60 to 80 kWh/m^3.

Low heat-conducting tanks ($< 0.3\ W/m^2\ K$) have been developed in Germany using fiberglass composite materials. With volumes between 5 and 10 m^3, these innovative tanks are applicable for buffer and short-term storage in the range of hours to days. For storage in the range of weeks, volumes of 50–100 m^3, and for long-term or seasonal storage, volumes of 500–6000 m^3 can deliver thousands of ton-hours of hot water. The cost of large tanks (6000 m^3) is approximately \$100/m^3. Such tanks can also be used to store cold water.

Other thermal storage systems also used for cold-water storage are based on stratified storage underground tank systems combined with linear diffuser systems to reduce inflow turbulences. The different temperatures contained in a thermally stratified storage tank hold the density variation of warm and cold water. Thermally stratified storage tanks represent an effective technique that is widely used in energy conservation and load management applications. It is commonly applied in combination with solar energy or waste heat reuse systems. Thermal stratification improves the efficiency of storage tanks because heat at intermediate temperatures can be used to heat colder layers. System parameters include various inlet and outlet locations, velocities, temperatures, and heat loss. Heat conduction at tank walls and ambient heat loss through the cover strongly affect the stability of thermal stratification.

Long-term heat storage in combination with waste heat distribution, solar, or combined heat power (CHP) systems is also constructed using man-made water-permeable gravel pits insulated and covered with heat-damming materials, such as polypropylene foil, vacuum insulation foil, and glass granulates. The storage temperature is approximately 90°C. Heat storage capacity is 30–50 kWh/m^3.

Short-term or buffer heat storage systems are ubiquitous for generation of hot water in heaters or boilers. The size of decentralized heat storage systems depends on the water boiler output power needed to satisfy hot water and heating requirements. A minimum of 25 liters storage volume per kilowatt boiler output is needed; for more comfortable operation, 70 liters/kW is recommended. Decentralized thermal storage heater/boiler systems mostly use electrical night currents for electrical resistance heating. An important aspect of the short-term storage concept is maintaining thermal stratification. The performance of storage-type domestic electrical water heaters is thus greatly improved and energy conservation optimized. Designs are dependent on draw-off rates (usually 5–10 liters/min), with the placement of heating elements and residence time being important design parameters. Optimized ratios of tank size and draw-off rates together with better

TABLE VIII

Overview of Seasonal Storage[a]

	Pumping capacity (m^3/h)	Power capacity (kW)	Pumping energy (% of useful energy)	Cost (\$/m^3/h)
Soil heat exchangers	0.5–50	5–450	5–8	1800–4100
Groundwater system	10–500	100–4500	5–8	1600–2700

[a] *Source*. Collinson (2001).

thermal stratification inside the heater storage tank result in higher discharging efficiencies.

3.1.2 Large Underground Thermal Energy Storage Systems

Building, industrial, and agricultural sectors require much larger thermal storage dimensions. There are three forms of underground thermal energy storage systems (UTES):

- Thermal underground storage tubes (e.g., soil–heat exchanger), which require large storage volumes to improve storage efficiency, achieving 15–30 kWh/m^3
- Aquifer storage systems with reduced storage volume but site-specific requirements, achieving 30–40 kWh/m^3
- Man-made cavern storage systems with confined storage volumes, achieving 40–60 kWh/m^3.

Early adoption of energy storage in standard project designs is essential to improve energy efficiency. In nonsealed UTES systems, heat is normally stored between 15 and 40°C, whereas cold storage areas are between 5 and 25°C. Depending on the size of the area used, heat/cold storage capacities of up to 5 or 6 GWh per year are achievable. Newer concepts of UTES at approximately 70–90°C provide more economically efficient and environmentally benign energy systems with reliable long-term operation. Other types of UTES systems are aquifer thermal energy storage (ATES) and duct/borehole thermal energy storage, which can store waste heat from municipal facilities in summer and provide domestic hot water and space heating in winter.

Chemical aspects of thermal energy storage in aquifers must be investigated to solve clogging and environmental heat exchange problems. For example, at high temperature ATES consisting of vertical wells with horizontal drains, major problems can occur at the heat exchange interface where large amounts of calcite form. Developing and testing site-specific groundwater treatment methods involving chemical, microbiological, and environmental effects ensure required environmental standards. Adequate scaling of ATES improves reliability and avoids or reduces potential ecological impacts.

The implementation of heat/cold storage applications as a standard design option improves effective storage control and operating strategies. This results in increased energy efficiency and cost-effectiveness in building and industrial fields. A combined heat/cold ATES installed in Berlin in a new government building complex uses two separate aquifers at different levels, one at approximately 60 m for cold storage and the other at approximately 300 m for heat storage. The storage system is coupled with a heat pump and, in case of extra load in winter, with a CHP unit running on biofuels. At peak operation, this ATES system should provide 16-GWh heat and 3-GWh cooling capacity.

Man-made cavern storage systems are placed in leak-tight granite, gneiss, or hard sediment rock. Caverns can store heat at temperatures of approximately 90°C due to low heat-conducting properties. The cavern storage system of Lyckebo in Sweden has a storage volume of approximately 100,000 m^3 and a heat storage capacity of 5.5 GWh.

3.2 Latent Heat/Phase Change Systems

Although it is inexpensive, readily available, and possesses excellent heat transfer characteristics, water is limited as a viable storage media because of the large volumes needed to achieve adequate heat storage capacities. When space is limited, phase change systems are applied to make use of latent heat.

The oldest PCM in thermal storage is ice. Ice is used in glycol static ice systems with phase change at 0°C and an energy density of approximately 90 Wh/kg for cooling. Glycol static ice systems are costlier than cold-water systems but require less space. Heat storage at various temperatures can also be designed using other PCMs (Table IX). The overall temperature required to melt the PCM must be significantly less than the output that the heating system provides, making compounds with lower melting points more advantageous.

Organic PCMs are more expensive than inorganic salts but can be custom made to provide transition temperatures specific for a given application. Compared to inorganic salts, organic PCMs are nontoxic, noncorrosive, nonhygroscopic, more stable during repeated phase change cycles, and compatible with most building materials. PCMs have higher latent heat per unit weight, melt without leaving solid phase sediments, and, most important, show negligible supercooling tendencies. Although their potential flammability is a disadvantage, organic PCMs are used to absorb solar heat for air heating in buildings. Eutectic PCMs behave as salt hydrates but can be custom made to meet specific melting points. Costs are considerably higher than those of organic or inorganic PCMs.

PCM modules consist of a series of PCM-filled plastic pipes embedded in insulation material in order

TABLE IX

Transition Temperature and Latent Heat Energy of Common Groups of Phase Change Materials (PCMs)

Group	PCM type	Transition temperature (°C)	Latent heat (Wh/kg)	Thermal conductivity, liquid/solid (W/mk)
Inorganic salt hydrates	Calcium chloride	27–30	47–53	0.54[a]/1.09[b]
	Sodium sulfate (Glauber's salt)	32	70	—
	Zinc nitrate	36	41	0.46[c]/—

[l] 49.9°C.

to exchange heat with heating systems. In combination with thermal stratification tanks, flat PCM modules with different melting temperatures enhance efficiency because heat conduction at surfaces is eliminated and the stability of the stratification is improved. This method can be implemented with larger centralized thermal storage tanks.

3.3 Other Thermal Storage Systems

A different thermal storage system is based on the thermophysicochemical properties of assorted chemical compounds. For example, cooling is achieved in chemical heating/cooling pipe systems by the endothermic heat of combining solid– or liquid–liquid mixable materials. In solid–liquid pairs, urea–water and ammonium nitrate–water generate endothermic heat of 8.2 kW/kg when the materials are mixed. Similarly, isobutanol–acetonitrile and 1-butanol–acetonitrile produce 0.8 kW/kg. For regeneration, waste heat of 80°C can be used to redistill the mixtures. Evaluation of the most suitable mixing pairs in terms of cold/heat capacity must be implemented for each specific application.

Innovative latent heat storage systems have been developed for ventilation systems using molecular adsorption and desorption on chemical surfaces. With its extensive surface areas, zeolites are ideal materials that adsorb water vapor, effectively releasing a large amount of adsorption heat. This discharging process can heat inlet air from 25 to 100°C by streaming at 6000 m^3/h through 7 tons of zeolites and provides a heating power of 95 kW for 14 h per day. During low heat demand, the charging process takes in airstreams of 130°C in order to desorb water molecules from the zeolite surfaces, releasing a humidified airstream at 40°C. The storage capacity is approximately 150 kWh/m^3 of zeolite material.

4. CHEMICAL STORAGE SYSTEMS

The energy density achieved with chemical storage is approximately a factor 100 higher than that of any other storage technology discussed previously (Table II). This decisive advantage gives chemical storage systems unsurpassed competitiveness. Primary energy is predominantly stored chemically in large crude oil and natural gas storage tanks or as stockpiles or in silos of specific energy carriers, such as coal or biomass. Secondary or final chemical storage involves refined petroleum products kept in tanks of fuel stations, industries, vehicles, and households. Energy products from coal and biomass, such as briquettes, granulated coal, wood chips, or biomass pellets, are kept dry in sheds, cellars, or silos.

4.1 Coal

Coal is a combustible mineral formed over millions of years through the partial decomposition of plant material subject to increased pressure and temperature under the exclusion of air. Primary coal exists in different grades called anthracite, bituminous, and lignite, with decreasing heating values, respectively. Secondary coal is produced from primary coal into metallurgical coke, anthracite, bituminous, and lignite briquettes. World coal reserves are approximately 9.1×10^{11} tons, with annual consumption of 4.5×10^{9} tons.

In 1999, coal production was approximately 5 billion tons worldwide (Table X). Although production stagnated at this level, coal mining productivity has steadily increased during the past decade.

The key environmental drawback of coal mining is the continuous release of CO_2 due to the glow burn of coal floss. Glow burn is impossible to control because oxygen enters the vast underground coal reservoirs during mining activities, leading to self-ignition. Coal combustion releases particulates and the chemical compounds SO_2 and NO_x, which cause environmental acidification. Pollution abatement equipment enables modern plants to control these emissions. Together with other essential equipment for coal receiving, raw coal storage, coal preparation, coal transportation, and coal storage, this results in significantly higher capital investments.

Coal stocks are kept at electric utilities or at coke and power plants and other industrial facilities. At coal-handling facilities, crushers and granulators use coal delivered from different coal pits to produce coal fragments of approximately 50 mm. The raw coal for power plants or boilers is stockpiled or stored on site in coal silos. The coal is then crushed into powder in pulverizers to feed the plant's burners. Coal storage facilities consisting of coal bunkers, silos, or coal strait or stockpile slot systems allow coal from the different pits to be blended and provide short-term storage to accommodate peak shipping. Customized modeling solutions to deal with high fugitive dusting potentials, storm run-off collection, and settling ponds at ground storage facilities and railroads are necessary. Environmental quality control is maintained using air quality modeling and monitoring, including particulate source inventories, weather observation, and forecasting. In addition,

TABLE X

World Coal Production, 1999[a]

	Thousand short tons			
Region/country	Anthracite	Bituminous	Lignite	Metallurgical coke[b]
North America	4768	1,086,789	100,070	26,185
Central and South America	28	49,457	0	10,694
Western Europe	10,308	104,661	380,612	43,499

[a] *Source*. Energy Information Administration (http://eia.doe.gov).

the clean coal technology initiative has led to pollution control and power-generating processes using low sulfur subbituminous coal that reduces air emissions from coal-burning plants, including greenhouse gases. Newer technologies have the potential to utilize high-sulfur "dirty" coal and still achieve comparable air emissions. Enhancing power plant efficiency and capturing carbon gases further reduce CO_2 emissions.

4.2 Crude Oil

World oil reserves are estimated at 1.6×10^{14} liters (1×10^{12} barrels), with potentially comparable amounts of undiscovered oil resources. World consumption is 1.2×10^{10} liters per day. Current oil production is predicted to increase by at least 1 million barrels every year over the short term, with oil reserves remaining economically exploitable for the next 25 years. Prices are expected to increase until 2040 due to the use of costlier new exploitation technologies.

Having adequate storage capacities helps at least to balance short-term price fluctuations. In the long term, however, profitable returns on the hefty investments of oil firms may only be attainable if oil prices steadily rise and additional capital is made available at the right time. Efforts to develop a valid pricing system of as scarce a resource as crude oil seem unattainable due to many uncertainties, including unstable political scenarios. OPEC's current levels of oil production and other factors are major uncertainties impacting price stability. Storage alone provides no answer for these long-term uncertainties.

In the short term, simple market dynamics can utilize primary storage of crude oil to replenish low fuel stocks during mild winters when demand is low for heating oil, propane, and natural gas. In addition to the importance of primary storage for the functioning of the oil market, efficient secondary storage of petroleum products such as gasoline, diesel, jet fuel, other (mostly cracked) oil distillates used for heating, and other residual oil stocks (light and heavy oil) is crucial for corresponding energy services (Table XI).

Many countries regulate oil imports with the use of strategic petroleum reserves (SPRs), with compulsory storage ratios stipulated between importing companies and the government. Large consumer companies can join the contracted storage system under the obligation not to empty their stock below a given ratio. SPRs play a key role in stabilizing price fluctuations in the international energy markets.

Depending on the annual demand and capital cost of storage and the aging of oil, different amounts of stock are kept by the consumer companies. Aboveground and underground storage tanks are used for secondary storage of high- or low-sulfur distillates. The total fuel distillate ending stock in the United States was approximately 140,000 Mbbl in 2001, with approximately 40% high-sulfur and 60% low-sulfur distillates.

TABLE XI

Example of Crude Oil and Petroleum Storage: Product Stocks[a] from the United States in Mbbl (1×10^6 Barrels)[b]

Year/product	December 2001 (Mbbl)[c]
Crude oil[d]	312,000
Total motor gasoline	209,000
Reformulated	*44,900*
Oxygenated	*400*
Other finished	*116,200*
Blending components	*48,400*
Jet fuel	42,000
Distillate fuel oil[e]	144,500
$\leq$0.05% sulfur and under (low)	*82,300*
$>$0.05% sulfur (high)	*62,200*
Residual fuel oil	41,000
Unfinished oils	87,700
Other oils[f]	199,100
Total (excluding SPR)	1,036,100
Crude oil in SPR[g]	550,200
Total (including SPR)	1,586,300

[a] Product stocks include domestic and customs-cleared foreign stocks held at, or in transit to, refineries and bulk terminals and stocks in pipelines. Stocks held at natural gas processing plants are included in "other oils" and in totals. All stock levels are as of the end of the period.

[b] From the Weekly Petroleum Status Report, Energy Information Administration (http://eia.doe.gov).

[c] Data may not add up to total due to independent rounding.

[d] Crude oil stocks include domestic and customs-cleared foreign crude oil stocks held at refineries, in pipelines, in lease tanks, and in transit to refineries. These do not include those held in the Strategic Petroleum Reserve (SPR).

[e] Distillate fuel oil stocks located in the Northern Heating Oil Reserve are not included.

[f] Included are stocks of all other oils such as aviation gasoline, kerosene, natural gas liquids, and LRG's, other hydrocarbons and oxygenates, aviation gasoline blending components, naphtha and other oils for petrochemical feedstock use, special naphthas, lube oils, waxes, coke, asphalt, road oil, and miscellaneous oils.

[g] Crude oil stocks in the SPR include non-U.S. stocks held under foreign or commercial storage agreements.

4.2.1 Oil Tanks and the Environment

Oil storage tanks, some with capacities of more than 390,000 barrels (more than 16 million gallons), store crude oil, intermediate stocks (partially refined), finished products, and chemicals. To avert soil and water pollution, containment areas must be designed to hold their capacities in the event of a tank rupture. At refineries, containment systems also divert rainwater runoff to the refinery's effluent treating facilities to ensure that no traces of chemicals or hydrocarbons enter local waters. Processing crude oil can lead to methane venting, a potent greenhouse gas. To reduce methane emissions, liquid storage facilities are consolidated and centralized in the field. From an environmental perspective, all storage tanks should be impermeable to volatile organic compounds (VOCs) and should be equipped with pressure-vacuum valves combinable with a vapor recovery system. Emissions of gas built up in crude oil or produced in water storage tanks are controlled during handling by flare combusting of the VOCs or by tank battery vapor recovery systems. In order to meet air pollution standards, petroleum products are refined to sulfur concentrations as low as 5 parts per million (ppm). The gasoline additive methyl-tertiary-butyl ether must be eliminated gradually due to its persistent properties if leaked into water systems. Tens of billions of dollars are required for replacement and remediation of contaminated groundwater and soil, due to leaking petroleum hydrocarbon tanks in the United States during the early 1990s from secondary and final storage (mostly heating oil and gasoline tanks).

4.3 Natural Gas

World reserves of natural gas are estimated at $1.4 \times 10^{14}\,m^3$, with gross production of gas at $2.4 \times 10^{12}\,m^3$ per year. Natural gas hydrates from deposits in ocean floors contain vast potential, which currently cannot be exploited economically.

Seasonal fluctuation in the consumption of natural gas varies as much as 50% with changing weather conditions and heating and electricity demand. In the short term, more extensive variations can be observed. The volume of peak demand is unpredictable and the exact timing impossible without integrated storage systems. Because natural gas production does not correspond to these fluctuations, surplus gas is injected during low demand into numerous, mostly underground storage facilities for use during high-consumption periods. Underground storage systems are located in porous rocks of depleted fields or aquifers or in artificial underground caverns, such as abandoned mines or salt caverns. Well-functioning storage systems eliminate the need for expensive, additional pipeline transmission capacity that would be necessary to supply peak demand. In addition, they balance summer production levels with possible supply shortages in the winter.

A gas pipeline network connects supply and demand sides with corresponding storage sites. Storage facilities are located near consumption areas to reduce the occurrence of bottlenecks within gas transmission grids due to gaps between transportation capacities and withdrawals. Natural gas is stored in two basic ways: It is either compressed in tanks as LNG or stored in large underground storage facilities (Table XII). LNG is kept as a chilled and pressurized liquid in double-walled cryogenic vessels or tanks. For transportation by ships or trucks, LNG requires 600 times less storage space than its gaseous form, and its ignition potential is reduced. Natural gas kept in tanks as compressed natural gas is used as vehicle propellant in combustion engines. Volumetric capacity depends on the head and shell thickness of the storage vessel.

Increasing demand, changing demographics, and the deterioration of storage and pipeline systems pose significant technological challenges for the future. Natural gas usage is projected to increase at a rate of 2% per year for the next two decades due to increased substitution of petroleum, diesel, or oil. A significant shift in consumption patterns is expected as more natural gas is used for heating, cooking, and mobility along with the decentralized generation of electricity.

Although natural gas vehicles (NGVs) have penetrated niche commercial markets for buses, delivery vans, and trucks, their success is severely constrained by the cost, weight, and size of existing natural gas storage cylinders. To counter this, a state-of-the-art, safety-certified natural gas storage unit called the integrated storage system (ISS) was developed. The ISS utilizes lightweight, high-density

TABLE XII

Example of Natural Gas Storage[a]

Traditional storage	Salt caverns	Total
5927	145	6072

[a] *Source*. Primary storage in the United States for 2000 in volumes of billion cubic feet at 1 bar pressure and 15°C. Energy Information Administration, *Natural Gas Monthly* 2001 March (http://www.eia.doe.gov/oil_gas/natural_gas/nat_frame.html).

polyethylene in the construction of small-diameter cylinders (pressure cells), which are subsequently encapsulated within a high-strength fiberglass shell containing impact-absorbing foam. The total energy storage capacity of 45 liters of gasoline equivalent at a service pressure of 250 bar enables a NGV to travel more than 480 km before refueling. This is comparable to the distance traveled by vehicles powered by gasoline. ISS technology reduced the cost of NGV storage tanks by approximately 50%. Its weight savings is up to 70% compared to steel and aluminum cylinders, and ISS does not interfere with the car's crumple zone. For commercial viability, the cost of storage must be reduced.

4.4 Hydrogen

Hydrogen is mainly used as chemical feedstock in the petrochemical industry and in the food, electronics, and metallurgical processing industries. However, hydrogen is believed to have great potential as a major energy carrier for clean energy systems of the future.

Hydrogen can be used in transportation, construction, utilities, and industry as a chemical storage compound. It can be used to mitigate CO_2 emissions by upgrading carbon-rich fuels to less carbon-intensive fuels. Renewable energy resources may be used to extract hydrogen from water, which is then combusted by fuel cells, for example, reforming water and balancing the intermittent nature of renewables. Ideally, combusting hydrogen generates no atmospheric emissions other than water.

For vehicles, hydrogen would be ideal as a synthetic fuel because it is light and highly abundant. The hydrogen fuel could be stored in carbon composite tanks at pressures of up to 250 bar, providing fuel for more than 200 km. Provenzano *et al*. estimated that if a hydrogen combustion engine operates in lean burn mode, the vehicle produces no CO and only low NO_x emissions (10–100 ppm). Research is directed at developing hybrid zero-emission vehicles that use hydrogen for lean-burning, spark-ignited engines combined with flywheels, supercapacitors, or batteries as energy storage devices. Mobility based on hydrogen could become competitive with continued technological development and cost reductions. Regenerative energy storage for ultra-high-flying solar aircraft is another use for a hydrogen support system. The system was designed by NASA to store energy by converting the craft's excess solar power into hydrogen and oxygen during the day and then to use a fuel cell to "regenerate" electricity at night.

The hydrogen storage necessary to continuously power automobiles or fuel cells is a major safety problem. Hydrogen is stored as a compressed gas in vehicles or as a cryogenic liquid in physical storage systems for transport. The solid-state storage system is another, safer storage technology that could potentially store more hydrogen per unit volume. Solid-state systems bind hydrogen to a solid material such as carbon. Critical parameters for solid-state storage are hydrogen uptake capacities, controlled hydrogen release, and rapid hydrogen refilling. Potential advantages of solid-state storage are its applicability at higher temperatures and near ambient pressures. According to Schlapbach and Züttel, lightweight metal alloy hydrides are the most promising materials for hydrogen storage.

4.5 Biomass

Biomass fuels (biofuels) refer to chemical energy stored within plants by photosynthesis. Theoretically, 6.7% of the solar energy input on land could be converted to chemical energy by photosynthesis, although on average only 0.3% is stored as carbon compounds in land plants. Kheshgi *et al*. calculated net primary productivity to be 60 GtC per year on land and 50 GtC per year at sea. With different heating values, biomass varies in both its energy and its carbon content.

Primary biomass storage includes any organic matter available on a renewable basis. It comprises biomass stocks and an assorted range of waste and residue materials. The basis for secondary storage before distribution and final or end-use storage is a continuous biomass resource supply chain to produce solid and liquid biofuels or synthetic gases (syngas).

The chemical energy released as heat by combustion is mostly used for room heating or industrial processes. It can also be converted to electricity. Gaseous or liquid fuels such as methane, hydrogen, and alcohols or bio-oils can be produced from biomass instead of direct heat production. Liquid biofuels and biogas are applicable in IC engines or fuel cells as alternatives to petroleum-based fuels. The conversion of biomass to electricity is conceptually similar to the conversion of coal to electricity using either direct combustion or integrated gasification combined cycle technology.

The carbohydrates of biomass can be converted by fermentation to ethanol or by extraction and refining to plant oils. For example, corn can be converted to a fermentation feedstock, where microorganisms

including yeast and other bacteria produce ethanol, which can be refined and used for blended gasoline, an alternative transportation fuel. Another example is the reaction of plant oils (fatty acids) with methanol in the presence of a catalyst, producing biodiesel. Biodiesel is used as an alternative fuel especially in agriculture either in neat form or blended with petroleum diesel for use in diesel engines.

One major issue with regard to secondary or final storage of biofuel is the oxidative stability of the compounds. Stability test methods allow a customer to determine whether the fuel has remained stable in storage over extended periods of time. Biodiesel stored in standard diesel storage tanks interacts with the accumulated tank sediments and sludge from ordinary diesel and reduces the solvency problem of ordinary diesel. For solid fuel storage, security measures are vital for preventing (self)-ignition in the presence of heat and oxygen.

Biogas is the most promising biofuel. It is more directly accessible, has good storage stability, has better overall energetics, and can be applied more flexibly. It can also be produced by fermentation processes, pyrolysis, or gasification techniques from diverse biomass raw materials. Biogas from 1 kg of air-dried, gasified biomass stores approximately 8000 kJ of energy, which can deliver approximately 0.8 kWh of electric output. Biogas production from biomass pyrolysis takes place at high temperatures, under exclusion of oxygen in the presence of catalysts. Biogas storage is no different from the storage of natural gas. Since biogas contains hydrogen sulfide, tank materials must be H_2S resistant. The purity of biogas compared to natural gas is a controversial issue in debates on the economic feasibility of large biogas production plants, which would require hefty cost reductions and efficient conversion technologies.

The central problems in producing bioliquids are its economic cost and the negative energetics of production. Besides growing and harvesting the biomass stock, significant amounts of energy are consumed in the conversion of biomass to biofuels. Approximately 6% of the (lower) biomass heating value is used per unit production. Developments to improve the overall efficiency of biomass energy systems will be the key to making this a feasible alternative. Another distinct characteristic of biomass energy sources is the large terrain requirements for generating biomass stock. Terrestrial plants, however, are not the only option as renewable energy stock. Marine algae, including kelp, are potential renewable energy resources but are currently too expensive to utilize.

5. CONCLUSION

Although an efficiency loss is unavoidable for all storage systems, the capacity and services of energy systems, including load distribution and system reliability, must continually be optimized. Load-distribution strategies and energy end-use efficiency increase customer benefits, whereas energy storage and control devices allow consumers to time energy purchases and shift from high- to low-rate periods. Energy storage also increases system reliability and will be the key to balancing the intermittency of new renewable energy sources in the future.

Efficient electricity storage in larger quantities is only indirectly possible by using established storage techniques, such as pumped storage hydropower plants pumping water back to the reservoir at times of low electricity demand. For such large systems, the foremost limiting factor for future growth is the availability of suitable sites with low environmental impact. Similarly, the development of large-scale CAES will depend on the development of systems with man-made storage tanks.

During the past 20 years, smaller scale electricity storage technologies have advanced greatly. New energy storage systems involving flywheels are very promising, especially in combination with other storage technologies to support uninterruptible electricity supply systems, thus improving reliability and quality. Batteries remain significant for smaller appliances and applications in which grid power independence is necessary. Supercapacitors have been developed as an additional electricity storage technology to maintain grid stability and satisfy rapid power needs.

Thermal storage technologies are especially useful in combination with solar energy, CHP, and waste heat distribution to provide hot water and heat for housing. Although large thermal storage systems such as high-temperature UTES and ATES are more efficient, small-scale applications intelligently integrated into building technology have immense potential.

Chemical storage remains the definitive storage method, with its high energy density. The use of coal and oil, however, poses great problems for sustainable energy due to CO_2 emissions. The transition to natural gas, hydrogen, and biomass as prime chemical energy storage is envisaged for the future. Cost

reductions in the various chemical storage techniques will be crucial for applications in mobility, distributed electricity generation, and heat production.

Energy storage should be lean, safe, and reliable to contribute to the functioning of energy supply markets and energy systems. Some redundant capacity of energy storage is important for all sectors of the socioeconomy to cope with disruptions caused by various technical, economical, or political events.

Acknowledgments

I thank D. Spreng (CEPE) for his encouragement and advice with regard to this article. I am indebted to J. Appleby (Texas A&M University) for invaluable comments and corrections. I also thank M. Berg (Factor AG, Switzerland) for his valuable comments on the fossil fuel sections. Thanks also to D. Goldblatt for reading the manuscript. Finally, I thank Anne Semadeni-George for her extraordinary help in reducing the text to an acceptable length.

consumer surplus The monetary value individuals place on consumption in excess of the amount of money they have to pay to obtain it.
draw down The release of petroleum from strategic stocks.
***in situ* storage** Holding crude oil stocks in the ground by capping wells.
marginal excess tax burden The additional cost to the economy of another dollar of taxation.
market failure A situation in which the self-interested actions of market participants does not lead to an economically efficient allocation of resources.
mmb/d Millions of barrels per day.
oil price shocks Steep increases in the price of crude oil in the world market resulting form the sudden removal of supply from the market.
price elasticity of demand The percentage change in the quantity of a good demanded in a market resulting from a 1% change in its price.
price elasticity of supply The percentage change in the quantity of a good supplied to a market resulting from a 1% change in its price.
primary stocks Petroleum held by crude oil producers and refiners. Secondary stocks are those held by wholesalers and retailers; tertiary stocks are those held by consumers.
producer surplus Payments to producers of a good in excess of the minimum amount required to produce it.
risk aversion A preference for a certain payoff over a lottery with an expected outcome equal to the certain payoff.
salt domes Caverns in underground salt formations that can be created through the injection of fresh water and the removal of the salt in solution and used to store petroleum.
speculative stocks Petroleum accumulated in expectation of profitable sales at higher future prices.
strategic stocks Petroleum stocks held either to facilitate draw downs to reduce the economic impacts of supply disruptions or to deter purposeful reductions in supply for political ends.
supply disruption The sudden removal of substantial quantities of crude oil from the world market. Major disruptions occurred in conjunction with the Yom Kipper War (October 1973 to March 1974), the Iranian Revolution (November 1978 to April 1979), the Outbreak of the Iran-Iraq War (October 1980 to January 1981), and the Gulf Crisis (August 1990 to January 1991). The largest of these in magnitude was the Iranian Revolution, which removed 5.6 mmb/d for approximately 6 months.
surge capacity The incremental supply that can be added to the market over relatively short periods of up to 6 months.
working (operational) stocks Petroleum held to facilitate normal industry operations, including stocks in pipelines, tankers, and tank bottoms, stocks to smooth tanker deliveries, and stocks to accommodate seasonal demands.

Strategic petroleum reserves, also referred to as strategic petroleum stocks, are quantities of crude oil or petroleum products held either to facilitate draw downs to reduce the economic impacts of crude oil supply disruptions or to deter purposeful reductions in crude oil supply for political ends. They reduce the vulnerability of the world economy, especially the economies of petroleum importers, to the adverse consequences of sudden and steep price increases resulting from the removal of substantial quantities of crude oil supply from the world market. They make purposeful reductions in crude oil exports for political purposes less attractive by increasing the quantities that must be withheld to inflict any threatened level of harm on petroleum importers. In these ways, strategic petroleum reserves reduce the

risks to the world economy associated with reliance on geographically concentrated crude oil supplies.

1. IMPORTANCE OF STRATEGIC PETROLEUM RESERVES

A healthy world economy requires a steady flow of crude oil. In the short run, the relatively small absolute value of the price elasticity of demand for crude oil means that even modest reductions in supply can result in dramatic increases in price. Such price shocks result in direct losses to the national economies of net importing countries and produce adverse macroeconomic effects for most of the rest of the world. Indeed, economists attribute much of the poor economic performance of the world economy during the 1970s to the oil price shocks occurring in connection with the Yom Kipper War, which quadrupled world prices, and the Iranian Revolution, which doubled them. Continued dependence on petroleum as a major energy source will keep the world economy vulnerable to crude oil supply disruptions into the foreseeable future.

The risk of oil supply disruptions will remain high because of the concentration of crude oil production and reserves in the volatile Persian Gulf region. In 2002, the world consumed on average about 77 mmb/d of crude oil. Approximately 29% of this supply originated in the Persian Gulf. With more than half of the world's proved oil reserves, the Persian Gulf is likely to account for an even larger fraction of supply in the coming years. The disorder in Iraq and longer term concerns about the stability of the Saudi Arabian and Iranian regimes make it easy to imagine scenarios in which the world would lose some or all of the oil exported from the Persian Gulf. For example, a revolution in Saudi Arabia that damaged export facilities would deny the world oil market approximately 10 mmb/d and, without offsetting increments of supply, send the world price of oil to over $50/b. Less severe disruptions could originate in other parts of the world, such as the countries of the former Soviet Union. The primary purpose of strategic petroleum reserves is to provide a source for offsetting increments of supply in such situations.

2. HISTORICAL OVERVIEW

The holding of commodity stocks is one of the oldest functions of government—recall the biblical story of Joseph advising the Pharaoh to put away the surplus of the coming seven good years to be prepared for the seven lean years to follow. In the early twentieth century, oil came to top the list of critical resources as navies converted from coal to oil and economies became motorized. By the end of the century, civilian use came to overshadow military needs so that oil stocks came to be viewed as more important for economic than military security.

2.1 Naval Petroleum Reserve

The conversion of the U.S. Navy to oil-burning ships made access to petroleum an immediate national security concern. Even though the United States was then a net exporter of crude oil, beginning in 1912 the United States set aside oil-bearing lands in California, Wyoming, and Alaska as a naval petroleum reserve. The reserve was to ensure that crude oil would be available for use by the navy in the event of an extended military conflict.

The naval petroleum reserve can be thought of as *in situ* storage of strategic stocks. Rather than removing oil from the ground and placing it in storage, the oil is stored in place. Although *in situ* storage seems like a commonsense approach to creating strategic reserves, the historical experience with the naval petroleum reserve reveals several problems with storing strategic stocks in the ground.

First, unless the land area of the reserve is sufficiently large to preclude other land owners from tapping the same reservoir of oil, production must be undertaken to protect the reserve from commercial encroachment. This has been the case at one of the naval petroleum reserve sites since the 1920s, as well as intermittently at two of the other sites, including the infamous Teapot Dome. The problem was particularly severe in the U.S. context where the rule of capture gives ownership of oil and gas to anyone who brings it to the surface on their own land. Yet preserving the reserve would likely be a problem whenever the entire reservoir is not dedicated as strategic stocks.

Second, *in situ* reserves are often not located near transportation facilities with adequate capacity to handle surge production. In the case of the Alaskan Naval Petroleum Reserve, for example, a second Alaskan oil pipeline would have to be built and then left to stand idle if the oil from the reserve were to be available as additional supply to the market. Providing surge capacity places a high demand on transportation facilities.

Third, it is generally costly and difficult to keep shut-in wells in a state of readiness that allows them to achieve full levels of production rapidly. After the Six Day War in 1967, the secretary of the navy ordered one of the naval petroleum reserve sites to be prepared to produce at its maximum expected rate within 60 days. The readiness requirement was never met, and, when commercial production was begun in 1976, the maximum rates of production anticipated turned out not to be achievable.

In situ storage like that provided by the naval petroleum reserve has an even more fundamental disadvantage: the large amount of proved reserves that must be set aside to achieve substantial surge capacity. It is rarely possible to extract more than one-eighth of a reservoir within 1 year. Imagine that the United States wanted to have the capability for 3 mmb/d of surge capacity for 1 year. Reservoirs of approximately 8 billion barrels of proved reserves would have to be set aside, more than one-third of all U.S. proved reserves. Once the purpose of strategic oil stocks shifted from supporting military operations in extended conflicts to providing surge capacity for avoiding the economic losses from oil price shocks, *in situ* stocks were no longer appropriate as strategic stocks.

2.2 Stockpiling as a Response to Import Dependency

Several policies limited U.S. dependency on imported oil through the early 1960s. One was an oil import quota that attempted to limit imports directly. Initiated in 1957, it remained in effect until rising world prices and controlled domestic prices made it politically unworkable in 1973. The other was the pro-rationing of production in unitized oil fields by state regulatory agencies in Texas and Oklahoma. For example, the Texas Railroad Commission attempted to stabilize crude oil prices by raising and lowering the pro-rationing rate in response to changes in demand. By 1972, however, prorating reached 100%, removing the capacity of the state agencies to stabilize price.

The first proposals for holding strategic reserves came from economists who distinguished between import dependence and vulnerability. They argued that it was not import dependence per say that was worrisome, but rather that the imports were subject to disruption from world events. From this perspective, energy security could be achieved by reducing vulnerability even with substantial reliance on imports. These ideas began to take hold politically, but legislation to create a strategic petroleum reserve introduced in the Senate in April 1973 failed to pass.

2.3 International Energy Program

In October 1973 the Organization of Arab Petroleum Exporting Countries (OAPEC), a subset, including the most significant members, of the Organization of Petroleum Exporting Countries (OPEC), imposed an embargo on oil shipments to the United States and The Netherlands in retaliation for their support of Israel in the Yom Kipper War. At the same time, OPEC cut total production. Although the flexibility of the world oil market kept the United States and The Netherlands from suffering disproportionately from the embargo, the reductions in oil supply dramatically increased oil prices in the world market. In response, 16 of the then 24 members of the Organization for Economic Development and Co-operation (OECD) adopted the International Energy Program to protect its members from targeted embargoes and prepare for future oil supply disruptions. A formal oil sharing agreement was included to counter targeted embargoes, and requirements for national-level programs of demand restraint and the establishment of strategic petroleum reserves were included to reduce the impacts of supply disruptions.

The International Energy Program set a stock requirement for its members based on levels of imports. Specifically, each country is required to hold petroleum stocks, exclusive of military stocks and oil in transit at sea, equivalent to 90 days of net petroleum imports. (Members of the European Economic Community face a similar requirement based on consumption, with partial waivers for Britain and Denmark, its net oil exporters.) Countries may count as much as 90% of working stocks toward the requirement. In 1995, the members of the International Energy Program agreed to coordinate their draw downs of strategic stocks during oil supply disruptions, and to do so before initiating sharing arrangements.

The capability provided by the International Energy Program's stockpiling can be measured in terms of the maximum amount of petroleum that can be delivered to the world market at the onset of an oil supply disruption. Member country governments control public petroleum stocks that would enable them in an all-out coordinated draw down to release perhaps as much as 12 mmb/d of stocks during the first month of an oil supply disruption, followed by approximately 8 mmb/d for the next 2 months. In

subsequent months the volume of the draw down would decline steeply, reaching negligible levels by the eighth month. Some additional releases from commercial stocks could further augment the draw down, especially after prices peak.

3. RATIONALE FOR GOVERNMENT ROLE

Private firms routinely hold petroleum stocks. Transporters and refiners hold primary stocks to maintain the transportation system (tank bottoms and pipeline fill), to avoid production interruptions from delivery delays, and to smooth out seasonal demands. Wholesale and retail firms hold secondary stocks to ensure that they can meet customer demands. End users of petroleum products may hold tertiary stocks to reduce the consequences of delayed deliveries. In general, these are working, or operational, stocks in the sense that they provide the grease needed to keep the distribution system working smoothly. Beyond these routinely held stocks, firms may seek profits by buying speculative stocks at low prices in anticipation of future higher prices. Specifically, the holding of a barrel of speculative stocks will be profitable in an expected value sense if the percentage increase in the expected price less storage costs over the current price is greater than the rate of interest. For example, if the expected price 1 year form now were $35/b with physical storage costs to be paid at that time of $2/b, and the current price were $30/b, it would be profitable in an expected value sense to add to stocks if the interest rate facing the firm were 10% or lower. (The firm could earn $33 dollars by simply investing the $30 at the 10% interest rate instead of holding the stocks.) Does private speculation provide adequate strategic stocks from the perspective of society as a whole? In other words, are there market failures that provide a rationale for government stockpiling?

Policy analysts have identified a number of reasons why speculative stocks are likely to be too small to serve adequately as strategic stocks. First, private firms do not gain the full social benefits from draw downs. When firms draw down previously accumulated stocks to profit from higher prices, they produce an external benefit to society—lower prices for petroleum products than would have resulted in the absence of their draw down. This divergence between private and social benefits results in too little speculative stockpiling.

Second, private firms do not see the full social costs from accumulating stocks. When firms accumulate stocks, they do not take account of the social costs of the higher prices that result. Although this divergence could lead to too little speculative stockpiling, the likely timing of additions to stocks may actually add to the social costs of oil supply disruptions. Speculative stockpiling is most attractive to individual firms when they anticipate that prices will rise quickly. This is likely to be the case at the outset of supply disruptions as firms see events leading to supply reductions and attempt to add to stocks. This additional demand may make the price shock associated with the supply disruption steeper and more severe, adding to its social costs. In effect, the divergence between private and social costs is likely to lead to speculative stockpiling that increases rather than decreases social costs.

Third, the model of speculative stockpiling assumes that firms are risk neutral in the sense that they are indifferent between a certain payoff and a lottery with an expected value equal to the certain payoff. So, for example, a firm would be risk neutral if it were indifferent between a zero certain payoff and a lottery that gave a 10% chance of $9 payoff and a 90% chance of a $1 loss—although the expected payoff from the lottery is zero, 90% of the time the firm would lose money. It is quite likely that firms would exhibit some degree of risk aversion, which would lead them to choose lotteries only when their expected payoffs are substantially greater than zero. As speculative stocks are like lotteries, risk aversion would likely lead to less speculative stockpiling than would occur if the firms were risk neutral. From the social perspective, however, risk aversion calls for more stockpiling, with the small certain costs of accumulating stocks like a premium for insurance that reduces the large costs that result from oil price shocks.

Fourth, firms may anticipate that government interventions may prevent them from realizing profits from sales of stockpiled oil during price shocks. Throughout the 1970s, U.S. policies controlled the well-head prices of domestically produced crude oil and accumulated stocks. Although these price controls were fully removed in 1981, U.S. firms may anticipate the possibility of reimposition of such controls during a severe oil price shock in the future. This reduces the expected price of speculative stocks by reducing the probability of realizing extremely high prices. Of course, the prospect of the release of public stocks during price shocks also reduces the probability of realizing high prices and thus reduces

speculative stockpiling. At the same time, however, the existence of public stocks may make it less likely that the government will impose price controls and mandatory allocations, making speculative stockpiling more attractive.

Externalities, risk aversion, and fear of government expropriation make a strong case that speculative stockpiling alone will not provide sufficient strategic stocks from the social perspective. Thus, there is a strong rationale for public policy to increase the quantity of strategic petroleum reserves. Determining the appropriate policies for strategic stocks requires an assessment of their social costs and benefits.

4. ECONOMIC IMPACTS OF STOCK DRAW DOWNS

The economic benefits of strategic petroleum reserves accrue when they are drawn down during oil supply disruptions to reduce the magnitude of the resulting oil price shock. The economic impacts can be illustrated by considering hypothetical but plausible price and quantity changes in the world and the U.S. domestic crude oil markets (Fig. 1). The intersection of supply (S) and demand (D) in the world market, which yields an equilibrium price of $28/b and quantity of 76.8 mmb/d, represents a normal market period. At the world price of $28/b, the United States consumes 15.0 mmb/d and produces 5.8 mmb/d domestically. The difference between consumption and domestic production, 9.2 mmb/d, is imported. Now imagine that the 10 mmb/d produced by Saudi Arabia is removed from the market. The world supply curve shifts from S to S_d, inducing a price shock that raises price from $28/b to $64/b. In the U.S. market, the $64 price reduces the amount consumed and increases the amount domestically produced.

The net loss to the U.S. economy of the price increase is given by the area of the trapezoid inscribed by the points *cdfe*. It results from a consumer surplus loss equal to the area of trapezoid *bdfa* less producer surplus gains given by the area of trapezoid *bcea*. The total economic loss from the price shock can be divided into three components. First, consumers suffer a loss from consuming less—area *dfh*. Second, consumers transfer wealth to foreign oil producers equal to the area *cdhg*. Third, domestic producers spend real resources, equal to area *cge*, to increase production.

Now imagine that the United States, Germany, and Japan collectively draw down their national

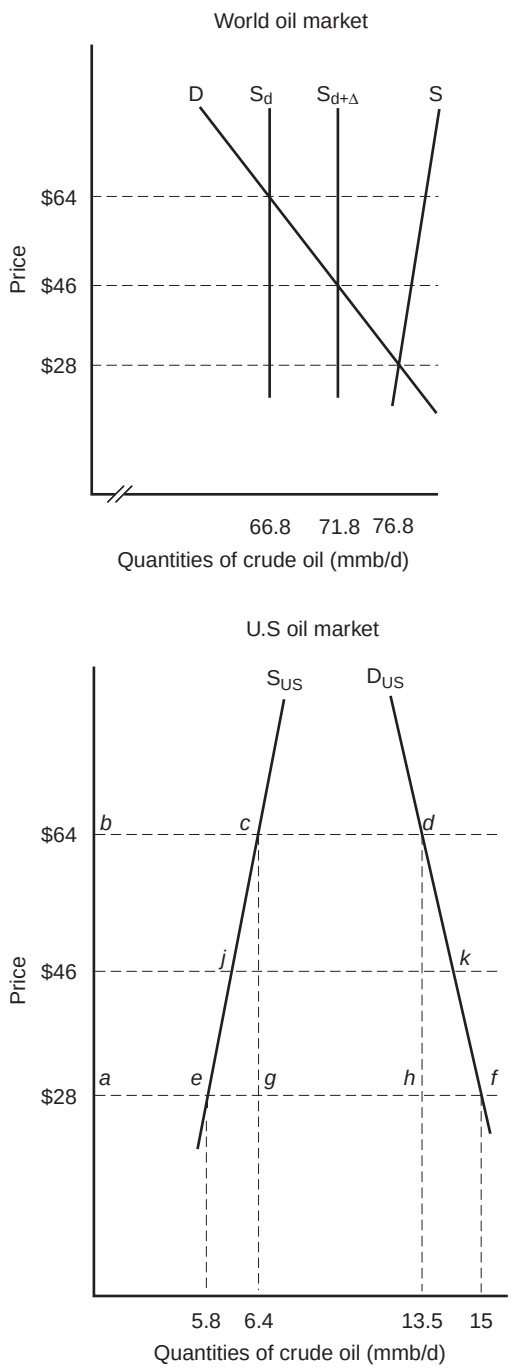

FIGURE 1 The economic impacts of strategic stock draw downs in the world and U.S. crude oil markets.

reserves at a rate of 5 mmb/d. This has the effect of shifting the world supply curve from S_d to $S_{d+\Delta}$. This additional supply in the world market drives price down to $46/b. The benefits of this draw down in the U.S. market can be seen as the difference between the surplus loss without the draw down (area *cdfe*) and the surplus loss with the draw down (area *jkfe*). The

direct net benefits of the draw down to U.S. consumers is therefore the area of *cdkj*, which equals approximately $140 million per day, or approximately $12.6 billion over 90 days.

The illustration makes clear that price is determined in the world market. Thus, draw downs are most appropriately thought of as affecting the world market. Draw downs by any country produce a benefit to petroleum consumes worldwide. Attempts to limit the benefits of draw downs domestically are doomed to failure, as relatively lower domestic prices would divert imports from the country to the higher priced world market, eventually equalizing price. The country drawing down does obtain a direct financial benefit through sales of the drawn down petroleum.

Three other points related to the illustration are relevant to the question of when strategic petroleum reserves should be used. First, efforts by private firms to add to speculative stocks as events lead them to anticipate the higher prices that will result from the supply disruption could be shown in the diagram as increases in demand. In terms of the figure, the speculative stockpiling would shift the demand curve, D, to the right, causing price to rise even higher than would be the case with only the loss of supply to the world market.

Second, the economic costs measured in the U.S. market by the net changes in consumer and producer surpluses do not include the macroeconomic costs that result from moving form low to high price equilibria. Interpretation of the surplus changes as economic effects assumes that prices of all other economic inputs and goods freely adjust to the higher price of petroleum. In most economies, however, there are price rigidities, such as labor contracts, that prevent prices from rapidly adjusting. Without free movement of prices, resources will not necessarily be used efficiently. For example, wage rigidities are likely to lead to higher rates of unemployment during oil price shocks. Uncertainty about the composition of post-disruption demand may depress investment. Overall, these additional costs are likely to grow more than proportionally with the size of the price shock, probably approximating the magnitude of the direct costs for a doubling of price.

Third, the illustration is a snapshot showing the initial impacts of the supply disruption. Over time, adjustment by producers, holders of speculative stocks, and consumers will reduce the price of petroleum even before the disrupted supply is returned to the world market. Oil producers will find it profitable to increase production from existing fields, say by using more expensive recovery methods or reopening previously closed stripper wells, which will tend to rotate the supply schedule, S, clockwise around its predisruption equilibrium. Once it appears that price has peaked, those holding speculative stocks will release them, adding to the available supply and removing any shift in demand caused by their accumulation efforts. Petroleum consumers will find ways of reducing petroleum consumption that will tend to rotate demand counterclockwise around the predisruption equilibrium. For example, during the first week of the disruption, consumers can turn down thermostats, make sure that their automobile tires are properly inflated, and take fewer trips; during the first month, they can obtain tune-ups for their automobiles, augment window insulation, and wrap water heaters in insulation; during the first 6 months, they can make more substantial changes in insulation, thermostats, appliances, and vehicles. Consequently, other things equal, the longer the disruption persists, the more market forces, both in terms of incremental supply and reduced demand, will tend to move the price of oil toward the predisruption equilibrium.

Each of these three points argue for large draw downs at the outset of supply disruptions. Immediate draw downs are likely to suppress speculative stockpiling, thus avoiding the additional price increase it causes. The disproportionate increase in macroeconomic costs with the size of the price shock argue strongly for using available strategic stocks to limit the initial magnitude of the price shock. The price mitigating market responses, as well as macroeconomic adjustments, that occur over time suggest that stocks will be relatively more valuable during major supply disruptions if used to support larger initial draw downs than to support smaller but longer draw downs.

5. COSTS OF STRATEGIC PETROLEUM RESERVES

Before strategic petroleum reserves can be drawn down, they must be accumulated and stored. In assessing costs, it is important to distinguish between budgetary costs and social costs. The former are the flows of funds from the national treasury to purchase resources for stockpiling; the latter are the economic value given up by use of the resources for stockpiling. Although budgetary cost is often politically relevant, social costs should be the basis for public policy.

Consider first government-controlled strategic stocks. Their budgetary costs include expenditures to construct (or purchase) storage facilities and maintain them, to connect storage facilities to oil distribution networks, and, most significantly in terms of magnitude, to purchase petroleum. An offsetting revenue is realized when the stocks are sold during drawn down. These budgetary costs may differ from social costs in a number of ways, however.

If petroleum purchases for strategic stocks drive up prices, then they will inflict economic losses on consumers. The economic costs of the price increase can be measured in the same way as price increases resulting from supply disruptions (Fig. 1). Generally, increments to strategic stocks are small relative to world consumption so that they generally will result in negligible, if any, price increases. The major exception occurs at the onset of supply disruptions. (Indeed, stopping ongoing purchases have the same effect as a draw down equal to the magnitude of the purchases.) If purchases are reduced or suspended when petroleum markets are experiencing upward price pressure, then the budgetary and social costs of oil purchases will closely correspond.

The taxes governments use to raise revenues create economic inefficiencies by distorting economic behavior. Economists refer to these inefficiencies as the marginal excess burden of taxation. In assessing the social costs of stockpiling, the marginal excess burden should be applied to revenue flows into and out of the national treasury. For example, if the marginal excess burden for the tax system of a country is 10%, a billion dollars of oil purchases would have a social cost of $1.1 billion and $20 billion dollars of revenue from a draw down would yield a social benefit of $22 billion.

A large discrepancy between budgetary and social costs results when the government bypasses market purchases to obtain oil. For example, the United States receives royalties of between 12.5 and 16.7% of oil obtained from leases on the federally owned outer continental shelf. Usually these royalties are collected as cash equivalents. Plans, however, call for receiving this oil in-kind and using it to fill the Strategic Petroleum Reserve. Although these royalties no longer pass through the budget, they have the same social costs as if they were purchased on the market.

A similarly large discrepancy between budgetary and social costs results when the government mandates that private firms hold strategic stocks. The budgetary costs for purchasing and storing oil will be zero, but the social costs include the purchase and storage costs borne by the firms.

Storage costs can vary greatly. Storage facilities vary greatly in their cost. Aboveground tanks typically cost between $15 and $18 per barrel to build and maintain. In contrast, storage in salt domes costs between $1.50 and $5.00 per barrel to build and maintain. Although abandoned salt mines may be available, salt dome capacity is generally created through solution mining, which involves injecting fresh water to dissolve salt that is removed in brine. Temperature differences in deep salt dome facilities provide natural circulation of stored petroleum. The abundance of salt domes on the Gulf Coast near major crude oil pipelines and tanker terminals provided the United States with opportunities for relatively low cost storage and transportation of strategic petroleum reserves.

Maintenance costs for crude oil stocks are generally low. They can be substantially higher for petroleum products, which tend to deteriorate in quality over time and therefore must be rotated out of stocks. The higher maintenance costs if petroleum product stocks has been one factor leading governments to hold mostly crude oil in government owned stocks. Another factor favoring crude oil over petroleum product stocks is the greater flexibility in product mixes afforded by crude oil stocks. For example, heating oil is likely be relatively more valuable during disruptions that occur during the Northern Hemisphere's heating season, while gasoline is likely to be relatively more valuable during its summer months. Refineries can alter the product mixes they obtain from crude oil, thus making more of the products that are relatively highly valued at the time.

6. TIME AND RISK

Strategic stocks share several characteristics with insurance. Just as the insurance premium must be paid in advance of the coverage obtained, petroleum must be accumulated prior to its use to counter the economic losses of an oil price shock. Just as events justifying claims against insurance coverage may never materialize, strategic stocks may never be drawn down. Analyses of the desirability of strategic petroleum reserves require attention to the timing of costs and benefits as well as to uncertainty about whether benefits will actually be realized.

Valuing costs and benefits that accrue at different times requires that they be put into a common metric. Economists do so by converting future costs

and benefits to their equivalent present values. The present value recognizes that consumers generally prefer to consume sooner rather than later. Although there is considerable controversy over the appropriate social discount rate that should be used to convert future costs and benefits to their present values, the general procedure is straightforward. In the case of assessing strategic stockpiling programs, current costs required to accumulate stocks receive higher weights than benefits that accrue in the future.

The more challenging analytical task in assessing stockpiling programs is how to deal with uncertainty. Will an oil supply disruption warranting use of strategic stocks ever occur? If so, when will it occur? How severe will it be? How long will it last? None of these questions can be answered with certainty.

Analysts typically replace these uncertainties with corresponding risks. For example, assume that there is some probability that a major disruption will occur each year. They can then assess the net benefits of a particular stockpiling program for different assumed values of this probability.

The earliest approaches posited a representative disruption scenario occurring, say, 10 years after the stockpiling program begins. The present value of the costs of accumulating and storing the stocks were estimated, as were the present value of benefits that would result from draw down of the stocks during the disruption scenario. The question could then be asked: How high a probability of the scenario occurring would be required to yield an expected value of net benefits of zero, so that the stockpiling program would just break even? For example, imagine that the present value of the costs of accumulating and storing the stocks were estimated to be $10 billion and the present value of the benefits were $100 billion, then the probability of the posited disruption would have to be at least 10% for the stockpiling program to break even. Decision makers could then be asked if their subjective assessment of the probability of the representative scenario were greater than this breakeven probability.

More sophisticated treatments of uncertainty require models that allow for differences in the timing, magnitude, and duration of oil accumulation, supply disruptions, and draw downs. Such models typically posit a transition matrix that specifies assumed probabilities of moving from one market state to another, say moving among normal, minor disruptions, and major disruptions. Dynamic programming or other solution techniques are then used to find the optimal stock acquisition or draw downs for any particular combination of current market state and stock size. In the United States, this approach generally supported expansion of the public reserves as well as large draw downs at the onset of major supply disruptions, even when there was a risk that the disruptions would persist beyond the point when stocks would be exhausted.

7. PROGRAMMATIC APPROACHES

OECD members have adopted a variety of approaches for meeting the International Energy Program requirement for holding 90 days of imports in stocks. All net importing members either require their domestic companies to hold strategic stocks or have standby authority to do so. Overall, company stocks account for approximately two-thirds of stocks held under the International Energy Program. In a number of countries, however, the stocks held in compliance with the International Energy program are largely working stocks that could not be fully deployed as strategic stock draw downs.

The most certain strategic stocks are those under direct government control in Japan, Germany, and the United States. Together, they could draw down 8.7 mmb/d during the first month of a major oil supply disruption. Such a rapid initiation of a coordinated draw down by these three countries at the outset of a supply disruption could substantially reduce its economic costs.

7.1 Japan National Oil Corporation

Even prior to the International Energy Program, Japan began requiring its firms to hold petroleum stocks. In 1978, it created the Japan National Oil Corporation. Currently, private firms have access to low-interest loans to cover the 25 days of imports they are required to hold above working stocks (45 days). The Japan National Oil Corporation has a goal of holding 90 days of imports. Currently, it has about 315 mmb in storage at 10 sites. Storage methods include conventional steel tanks, floating barges, and underground caverns.

The Ministry of Economy, Trade and Industry, subject to Cabinet decision, makes decisions about use of the stocks. Draw downs from company stocks are initiated by reducing the number of days of required stocks, as was the case in 1991 during the Gulf War; draw downs form the Japan National Oil Corporation would be directly ordered. Currently, the Japan National Oil Company could release 2.3 mmb/d during the first month of an all out draw

down, followed by rapid declines in succeeding months with negligible volumes by the sixth month.

7.2 Erdölbevorrantungsverband

The Oil Stockpiling Law of 1978 established the Erdölbevorrantungsverband (EBV) as an organization to hold petroleum stocks for Germany. All companies, except those in the chemical industry, that refine or import petroleum are compulsory members of the EBV. The EBV is funded solely through membership dues paid by companies in proportion to the quantities of gasoline, middle distillates, and fuel oils produced or imported. The dues are shown as itemized charges to retail customers. Thus, consumers rather than taxpayers finance the EBV. The EBV directors are appointed by an advisory board consisting of government and industry officials. Draw downs are initiated by the government under the Oil Stockpiling Law. Companies that have made higher dues payments receive higher priority in allocation.

In 1998, the government raised the stockholding requirement to 90 days of imports. Currently, the EBV stocks consist of 60% petroleum products and 40% crude oil, though the EBV has announced plans to reverse this proportion in order to increase flexibility in the products available during draw downs and reduce storage costs. Stocks are stored both regionally and in salt domes in Northern Germany. The EBV currently holds products equivalent to approximately 200 mmb of crude oil. During the first 3 months of a supply disruption, the EBV could support a draw down rate of approximately 2.3 mmb/d (0.9 mmb/d of crude oil and 1.4 mmb/d of products). A full draw down would exhaust reserves in 5 months.

7.3 The U.S. Strategic Petroleum Reserve

The Energy Policy and Conservation Act of 1975 called for the creation of a U.S. Strategic Petroleum Reserve of at least 150 mmb within 3 years and 500 mmb, then about 90 days of imports, within 7 years. Subsequent amendments increased the possible size to 1000 mmb. The Strategic Petroleum Reserve has capacity for holding 700 mmb of crude oil in salt dome caverns in Louisiana and Texas; it held 610 mmb crude oil in mid-2003. Since its permanent establishment in 2000, the Northeast Heating Oil Reserve has stored 2 mmb of heating oil in New Jersey, Connecticut, and Rhode Island.

The Strategic Petroleum Reserve provides substantial surge capacity. An all-out draw down of 4.1 mmb/d of crude oil could be sustained for approximately 3 months, with the rate declining in subsequent months as salt dome caverns are emptied. Routine draw downs occur on a regular basis to complete swaps with companies to adjust the grades of crude oil in storage. Draw downs have also been undertaken to raise revenue for deficit reduction. The president may order full-scale draw downs to counter severe energy supply interruptions that may cause major adverse impacts on national security or the national economy. Since 1990, the president has been authorized to initiate limited draw downs of up to 30 mmb in less severe circumstances.

The Strategic Petroleum Reserve was a draw down under presidential directive during the First Gulf War in cooperation with other International Energy Program countries. A week after the Iraqi invasion of Kuwait in August 1990, the secretary of energy announced a 5 mmb draw down to test distribution procedures and demonstrate resolve to use the reserve to counter an oil price shock. When the allied coalition air campaign began on January 16, 1991, the president put 30 mmb out to bid, 17 mmb of which were actually sold during the following 3 months.

The crude oil price fell almost $10/b immediately after the announcement of the draw down, but analysts disagree about whether the price decline resulted primarily from anticipation of the draw down or changing perceptions about the risks to Gulf oil supplies. Analysts also disagree about whether sooner use of the reserve would have prevented the run up in prices during the latter part of 1990's that slowed economic growth.

The history of the Strategic Petroleum Reserve often showed a divergence between congressional authorization to expand stocks and the willingness of Congress and the administration to appropriate funds to enable it. Quite frequently oil purchases for the reserve were suspended for budgetary reasons, and steps have not been taken to implement the full 1000 mmb capacity. The use of in-kind royalties from federal offshore oil leases and heightened national security concerns in the wake of 9/11, however, make it likely that, absent an oil supply disruption, the reserve will be filled to its capacity of 700 mmb over the next several years.

8. CONCLUSIONS

Strategic petroleum reserves reduce the vulnerability of the world economy to oil price shocks. Members

of the International Energy Program have accumulated substantial strategic stocks, even discounting those that are actually working stocks held by companies and unlikely to contribute to surge capacity. These stocks will become more valuable as the proportion of world supply originating in the Persian Gulf increases. International and national policies appear to be continuing to evolve in several ways that increase the chances that strategic petroleum reserves will be used effectively.

First, policy analysts and policymakers now generally realize that strategic stocks have their primary effect through the world oil market. The draw downs of national stocks have very little capability for differentially benefiting those drawing down. Domestic oil prices below world levels simply divert imports to the other countries, thereby equalizing prices. Rather than viewing strategic stocks as providing national benefits in terms of relatively lower domestic prices, they should be seen as contributing to lower world prices, which in turn reduces the negative impacts of supply disruptions on the world economy.

Second, this realization, along with increasing economic globalization, should encourage further efforts toward early and internationally coordinated use of strategic stocks. It should also make individual countries with large surge capacities, namely the United States, Germany, and Japan, less hesitant to initiate draw drowns even when agreement on coordination cannot be reached—any one country can realize large revenues from draw downs. Even if a country exhausts its strategic stocks, it will share in the benefits of later draw downs by other countries.

Third, although the language of the stockpiling agreement continues to emphasize total quantities of strategic stocks held, attention is increasingly being appropriately focused on maximum draw down rates during the first months of an oil supply disruption. This change in focus recognizes that a reduction in world supply has its most severe economic effects during the first 3 to 6 months before nondisrupted oil producers and consumers have time to change their mix of capital goods to in response to the higher prices.

Fourth, most national plans for draw downs take advantage of existing commercial networks. Allowing markets to move petroleum to its most valued economic uses helps ensure that this especially scarce resource during supply disruptions will reach its most valued uses and thereby limit economic losses to the greatest extent possible.

6. Conclusion

Glossary

consumer-subsidy equivalent Integrated metric of aggregate support provided to consumers by varied government policies; policies that act as taxes are incorporated by using the opposite sign.

cross-subsidies Policies that reduce costs to particular types of customers, products, or regions by increasing charges to other groups.

intermediation value Difference between the break-even cost of debt, insurance, or other programs to large governments and what these same services would cost if a smaller, higher risk private firm or individual had to buy them directly.

producer-subsidy equivalent Integrated metric of aggregate support provided to producers by varied government policies; policies that act as taxes are incorporated by using the opposite sign.

renewable portfolio standards Requirements mandating purchase of preset percentages of renewable electricity in particular service regions; the standards normally compete eligible supply sources against each other to minimize the per-unit subsidy.

subsidies Government-provided goods or services that would otherwise have to be purchased in the market or special exemptions from standard required payments or regulations; subsidies may be in cash but often involve shifting risks from private parties to taxpayers or the public.

Whether by intent or by accident, government interventions affect the relative prices of various energy technologies and with them the pattern of energy use and investment. Depending on their structure, interventions can act as either taxes or subsidies to particular technologies, producers, or consumers. The lines can blur; some "taxes" may be insufficient even to cover the cost of beneficial government services, leaving a residual subsidy to the "taxed" parties.

1. INTRODUCTION

Energy resources vary widely in terms of their capital intensity, reliance on centralized networks, environmental impacts, and energy security profiles. Although the policies of greatest import to a particular energy option may differ, their aggregate impact may be significant. Subsidies to conventional fuels can slow research into emerging technologies, thereby delaying their commercialization. Subsidies and exemptions to polluting fuels reduce the incentive to develop and deploy cleaner alternatives. Inadequate tracking and recovery of costs associated with protecting energy security reduces the drive toward diversification.

Justifications for energy subsidies include social welfare, protection and promotion of jobs or industries, rural development, and energy security. Existing policies often fail to achieve these aims in practice. Because subsidies can be worth millions of dollars and often require sophistication or connections to obtain, policies implemented to help poorer segments of society may end up enhancing the wealth of more powerful groups instead. Often, the objectives of subsidy programs can be achieved in a manner that is more narrowly targeted and efficient than the subsidy policies now in place. For example, decoupling subsidy payments from resource-depleting activities can greatly reduce the environmental damages associated with the transfers.

This article examines the general issue of subsidy definition and measurement and then presents central issues associated with subsidization at each stage of a

generic fuel cycle. Aggregate patterns of subsidization and the challenges of subsidy reform are addressed in the subsequent two sections.

2. SUBSIDY DEFINITION AND MEASUREMENT

Government interventions encompass a wide range of regulatory, fiscal, tax, indemnification, and legal actions. By modifying the rights and responsibilities of various parties involved with the energy sector, these actions decrease (subsidize) or increase (tax) either energy prices or production costs. As discussed in what follows, differing approaches to subsidy definition and measurement have historically led to disparate subsidy analyses that are difficult to compare or compile.

2.1 Common Disagreements in Subsidy Definition

Disagreements over the proper definition of subsidy are common. Conflicts often arise over the form and timing of the transfer, the definition of the "non-subsidized" baseline, and the boundaries of analysis.

2.1.1 Form and Timing of Transfer

Energy subsidies are often viewed primarily as cash payments from a government agency to private businesses or individuals. Payments to low-income households to enable them to purchase heating oil and grants to businesses to help them develop particular energy technologies are examples. In reality, subsidies can take many different forms, and a more accurate definition must include government-provided goods or services, including risk bearing, that would otherwise have to be purchased in the market. Much market activity involves controlling and sharing the risks and rewards of economic activities, and risk-oriented subsidies are quite important. Subsidies can also be in the form of special exemptions from standard required payments such as tax breaks. Although cash payments are easily measured within a single year, more complex subsidies such as loan guarantees are best evaluated over multiple years so that patterns in losses or investment distortion can be seen more clearly.

2.1.2 Defining the Baseline

Subsidies must often be measured against a baseline. What would taxes owed have been in the absence of this special tax break? How much would industry have had to pay in interest to build that new facility if the government had not guaranteed the loan? Many disagreements over subsidy definition originate in differing views on the appropriate baseline:

2.1.2.1 Indirect Versus Direct Transfers Some argue that interventions "count" as energy subsidies only if they directly target the energy sector. For example, the U.S. Energy Information Administration did not count subsidies to energy facilities provided by tax-exempt general-purpose municipal bonds in its tallies, arguing that the bonds did not constitute an energy subsidy if hospital and road construction could also use them. Similarly, fees to use the U.S. inland waterway system have historically been insufficient to reimburse system construction and maintenance costs. Although oil and coal industries are among the largest users of the system, the fee subsidies (which allow oil and coal a lower delivery cost than would otherwise be possible) are often discounted on the grounds that many commodities use the system. Because many subsidies tilt the energy-playing field toward a particular fuel even if there are also nonenergy beneficiaries, such policies should not be ignored. Rather, any policy that has the effect of subsidizing prices or production costs should be assessed. This may include policies targeted at single sectors, multiple sectors, specific geographic areas, or specific factors of production.

2.1.2.2 Externalities Although the levels vary by fuel, most energy production and consumption generate wide-ranging externalities such as pollution. Exemptions from appropriate environmental controls (e.g., less stringent air pollution control requirements for certain old power plants in the United States) penalize cleaner energy types and are properly viewed as subsidies. However, externalities do create an analytic challenge because they are difficult to monetize. Koplow and Dernbach documented that decisions about which externalities to include and how to value them can generate very large variation in subsidy estimates, on the order of hundreds of billions of dollars per year. Segregating externality-related subsidies from fiscal subsidies can help to improve data comparability and transparency.

2.1.2.3 Intermediation Value Subsidy recipients often incorrectly claim that risk-based subsidies such as loan guarantees have no value unless there are defaults. In addition to the direct cost of the government, all of these policies have an

intermediation value as well given that the government's cost of debt or indemnification is lower than what could be attained by the recipient on its own. For particularly high-risk endeavors, such as sales of large energy assets to politically unstable countries, the intermediation value can be very large. Because some energy resources have much greater access to these government programs than do others, distortions in relative energy prices can result. For example, transactional data on subsidized international lending assembled for the World Commission on Dams show that lending has heavily favored fossil fuels over renewables.

2.1.3 Boundaries of Analysis

Energy is a primary material, an input to refined energy products (e.g., gasoline, electricity), and an input to nonenergy materials (e.g., metals, consumer goods). To provide an accurate picture of energy subsidies, analytic boundaries with respect to three areas must be addressed: calculation of net values, level of government, and subsidies to complements.

2.1.3.1 Calculation of Net Values Because interventions can act as taxes or subsidies, interventions should be treated holistically so that end values represent net, rather than gross, subsidies to energy. Policies that affect multiple sectors need to be prorated so that only the portion applicable to energy is counted. Although proration is not always possible to do precisely (some policies have joint effects), reasonable allocations based on intensity of use, share of production, or similar metrics often provide reasonable proxies. Similarly, taxes or fees levied on fuels should be counted against the gross subsidy to generate the value net of offsets.

2.1.3.2 Level of Government Interventions occur at multiple levels of government, and all levels can affect energy costs to some degree. Analysis of these policies should be internally consistent; if tax offsets at the state level are deducted from energy subsidy values, state-level subsidies should be included as well.

2.1.3.3 Subsidies to Complements Energy subsidies have many second-order effects as they flow through other activities in the economy. Although detailed assessment is beyond the scope of this article, these policies can influence basic aspects of economic structure such as materials production, recycling, and energy demand. Subsidized electricity to primary aluminum is endemic and inhibits adoption of less energy-intensive materials. Similarly, subsidies for converting wastepaper, animal waste, and landfill gas into energy reduce the viability of recycling and composting alternatives. Widespread subsidies to driving spur increased road use and demand for gasoline.

2.2 Methods of Transferring Value

Table I provides an overview of intervention types. Depending on the policy specifics, many interventions generate either a net subsidy or a net tax. Cash transfers from government to private industry may originate from a handful of the intervention types, including direct spending, government ownership, and research and development (R&D) support. However, subsidies resulting from avoided expenditures by private firms are more common. These include government provision of market-related information; access to below-market credit, insurance, or government-provided goods and services; tax breaks; and exemptions from prudent regulation on health-, environment-, or safety-related aspects of an enterprise.

Market controls, including general regulations, provisions governing access to resources, restrictions on energy-related imports or exports, and purchase requirements can act as either a tax or a subsidy depending on one's market position. For example, past restrictions on oil exports from Alaska acted as a *de facto* tax on Alaskan producers because they could not sell output to the highest bidder. However, the very same policy provided oil subsidies to consumers on the West Coast of the United States. Although driven by government policy and having important effects on energy market structure, these policies often involve transfers between various producers and consumers rather than transfers from taxpayers. Cross-subsidies follow a similar pattern, with some users paying less than they should and others paying more than they should. They commonly occur when rate structures must be approved by governments or in markets protected from competition.

Special energy taxes, as their name suggests, tend to act as taxes rather than as subsidies. However, a tax should be classified as "special" only if it is above and beyond appropriate baseline recovery of revenue. The baseline taxation of energy should (1) compensate public sector owners for the sale of valuable energy resources, (2) recover public sector costs associated with the public provision of energy-related services, (3) equal the baseline tax on

TABLE I

Common Forms of Government Interventions in Energy Markets

Intervention type	Description
Access[a]	Policies governing the terms of access to domestic onshore and offshore resources (e.g., leasing)
Cross-subsidy[a,b]	Policies that reduce costs to particular types of customers or regions by increasing charges to other customers or regions
Direct spending[b]	Direct budgetary outlays for an energy-related purpose
Government ownership[b]	Government ownership of all or a significant part of an energy enterprise or a supporting service organization
Import/Export restriction[a]	Restrictions on the free market flow of energy products and services between countries
Information[b]	Provision of market-related information that would otherwise have to be purchased by private market participants
Lending[b]	Below-market provision of loans or loan guarantees for energy-related activities
Price controls[a]	Direct regulation of wholesale or retail energy prices
Purchase requirements[a]	Required purchase of particular energy commodities, such as domestic coal, regardless of whether other choices are more economically attractive
Research and development[b]	Partial or full government funding for energy-related research and development
Regulation[a]	Government regulatory efforts that substantially alter the rights and resposibilities of various parties in energy markets or that exempt certain parties from those changes
Risk[b]	Government-provided insurance or indemnification at below-market prices
Tax[a,b]	Special tax levies or exemptions for energy-related activities

[a] Can act either as a subsidy or a tax depending on program specifics and one's position in the marketplace.

[b] Interventions included within the realm of fiscal subsidies.

other commodities, and (4) charge an appropriate levy for negative externalities associated with production and use of the resource. Many assessments of energy taxation fail to incorporate appropriate measures for baseline levels, improperly classifying as an "energy tax" or an "environmental tax" policies that in fact recover only a portion of public costs and leave residual subsidies.

Government ownership of energy-related enterprises, including power generation and transmission, oil production and refining, coal mines, and road and pipeline networks, is common around the world. Many of these activities generate large subsidies to consumers as well as depleting fiscal resources. Subsidies are multilayered. The enterprise is often fairly high risk, attains access to low-cost tax-exempt government debt, pays no taxes on net income, and is not expected to earn a return on capital. Operating losses may ensue above and beyond these cost structure subsidies due to poor controls or politicization of the rate structure. These enterprises can be complex and difficult to analyze but often contribute to significant energy market distortions.

2.3 Methods of Measuring Subsidy Magnitude

Efforts to assess subsidy magnitude have generally focused either on measuring the value transferred to market participants from particular programs (program-specific approach) or on measuring the variance between the observed and the "free market" price for an energy commodity (price gap approach). One set of methods that captures both pricing distortions (net market transfers) and transfers that do not affect end market prices (net budgetary transfers) is the producer subsidy equivalent (PSE) and consumer subsidy equivalent (CSE) metrics commonly employed in the agricultural sector. Use of these in the energy sector has so far been limited to annual assessments of PSEs for coal in a handful of countries.

These approaches differ in the amount of data required to calculate them and in the degree to which they successfully measure budget transfers plus market transfers. Program-specific transfer assessments capture the value of government programs benefiting (or taxing) a particular sector, whether these benefits end up with consumers (as lower

TABLE II

Overview of Subsidy Measurement Approaches

Approach/description	Strengths	Limitations
Program specific: Quantities value of specific government programs to particular industries: aggregates programs into overall level of support	Captures transfers whether or not they affect end market prices Can capture intermediation value (which is higher than the direct cost of government lending and insurance	Does not address questions of ultimate incidence or pricing distortions Sensitive to decisions on what programs to include Requires program-level data
Price gap: Evaluates positive or negative "gaps" between the domestic price of energy and the delivered price of comparable products from abroad	Can be estimated with relatively little data; very useful for multicountry studies Good indicator of pricing and trade distortions	Sensitive to assumptions regarding "free market" and transport prices Understates full value of supports because ignores transfers that do not affect end market prices
PSE/CSE: Systematic method to aggregate transfers plus market supports to particular industries	Integrates transfers with market supports into holistic measurement of support Separates effects on producer and consumer markets	Data intensive Little empirical PSE/CSE data for fossil fuel markets

Source: Koplow, D., and Dernbach, J. (2001). Federal fossil fuel subsidies and greenhouse gas emissions: A case study of increasing transparency for fiscal policy, *Annu. Rev. Energy Environ.* **26,** 361–389.

prices), producers (through higher revenues), or resource owners (through higher rents). Unless integrated into a macroeconomic model, this information tells little about the ultimate incidence of the subsidy programs and their effect on market prices. By definition, the price gap metric highlights observed price distortions, although it misses the often substantial fiscal supports that do not affect consumer energy prices but do affect the structure of supply. The combination of PSE and CSE data provides insights into both. Table II briefly summarizes the main approaches that have been used in both domestic and international subsidy assessments as well as their respective strengths and limitations.

3. SUBSIDIES THROUGH THE FUEL CYCLE

Because no two fuel cycles are exactly the same, examining subsidies through the context of a generic fuel cycle is instructive in providing an overall framework from which to understand how common subsidization policies work. Subsidies are grouped into preproduction (e.g., R&D, resource location), production (e.g., extraction, conversion/generation, distribution, accident risks), consumption, postproduction (e.g., decommissioning, reclamation), and externalities (e.g., energy security, environmental, health and safety).

3.1 Preproduction

Preproduction activities include research into new technologies, improving existing technologies, and market assessments to identify the location and quality of energy resources.

3.1.1 Research and Development

R&D subsidies to energy are common worldwide, generally through government-funded research or tax breaks. Proponents of R&D subsidies argue that because a portion of the financial returns from successful innovations cannot be captured by the innovator, the private sector will spend less than is appropriate given the aggregate returns to society. Empirical data assembled by Margolis and Kammen supported this claim, suggesting average social returns on R&D of 50% versus private returns of only 20 to 30%.

However, the general concept masks several potential concerns regarding energy R&D. First, ideas near commercialization have much lower spillover than does basic research, making subsidies harder to justify. Second, politics is often an important factor in R&D choices, especially regarding how the research plans are structured and the support for follow-on funding for existing projects.

Allocation bias is also a concern. Historical data on energy R&D (Table III) demonstrate that R&D spending has heavily favored nuclear and fossil energy across many countries. Although efficiency,

TABLE III

Federal Research and Development Support by Energy Type

Region	Nuclear fission	Fossil fusion	Fossil energy	Renewables, efficiency, conservation	Other[a]
United States (percentages)					
1950–1993[b]	49.2	13.1	21.5	16.2	0

[d] International Energy Agency. (2003). *Research and Development Database*.

renewables, and conservation have captured a higher share of public funds during recent years, the overall support remains skewed to a degree that may well have influenced the relative competitiveness of energy technologies. Extensive public support for energy R&D may also reduce the incentive for firms to invest themselves. U.S. company spending on R&D for the petroleum refining and extraction sector was roughly one-third the multi-industry average during the 1956–1998 period based on survey data from the U.S. National Science Foundation. For the electric, gas, and sanitary services sector, the value was one-twentieth, albeit during the more limited 1995–1998 period.

3.1.2 Resource Location

Governments frequently conduct surveys to identify the location and composition of energy resources. Although these have addressed wind or geothermal resources on occasion, they most often involve oil and gas. Plant siting is another area where public funds are used, primarily to assess risks from natural disasters such as earthquakes for large hydroelectric or nuclear installations. Survey information can be important to evaluate energy security risks and to support mineral leasing auctions, especially when bidders do not operate competitively. However, costs should be offset from lease sale revenues when evaluating the public return on these sales. Similarly, the costs of siting studies should be recovered from the beneficiary industries.

3.2 Production

Energy production includes all stages from the point of resource location through distribution to the final consumers. Specific items examined here include resource extraction, resource conversion (including electricity), the various distribution links to bring the energy resource to the point of final use, and accident risks.

3.2.1 Extraction of Energy Resources

General procedures for leasing access to energy minerals on public lands and more general subsidies for promoting energy extraction both are important areas to evaluate. Extraction-related subsidies are most common for oil and gas production, although they also support nuclear fission (due to uranium mining), geothermal, and coal.

3.2.1.1 Accessing Publicly Owned Energy Resources Terms of access for energy minerals on public lands can be a source of enormous subsidies. In

countries where leases or concessions are granted through graft rather than competitive bidding, wealth transfers worth billions of dollars can occur. Although there are not good statistics on the losses, the problem appears to be large. Oxfam America finds that states most dependent on oil tend to have very low Human Development Index (HDI) rankings. The HDI, developed by the UN Development Program, ranks states according to a combined measure of income, health, and education. Transparency International finds strong linkages between large mining and petroleum sectors as well as elevated levels of bribery and corruption. Low-cost access to energy minerals also tends to remove the incentive for careful management because profits can be had even with inefficient operation. Lease operation can also generate subsidies such as when self-reported royalties are calculated improperly. The Project on Government Oversight has documented state and federal court awards in excess of $10 billion in response to litigation in the United States over oil and gas royalty underpayments.

3.2.1.2 Promoting Extraction Activities Policies to reduce the cost of extraction are widespread and often take the form of tax or loan subsidies or royalty concessions. They are found at both the national and state levels. Particular market niches may be targeted, from geographical (e.g., deep sea recovery of oil, timbering in a particular forest), to technological (e.g., tax breaks for more advanced oil drilling or coal gasification), to life cycle related (e.g., lower royalties on idle wells that are restarted). In some cases, baseline tax policy may be applied by firms in creative ways to generate large subsidies. U.S.-based multinationals receive a tax credit for foreign taxes paid to avoid double taxation of foreign income. Yet in many oil-producing regions with low or no corporate income taxes, foreign governments have reclassified royalty payments into corporate taxes, generating a tax write-off estimated by Koplow and Martin at between $0.5 billion and $1.1 billion annually.

However, many subsidies to extraction are not restricted to particular market niches. Percentage depletion allowances in the United States allow most firms mining oil, gas, uranium, or coal to deduct more costs from their taxable income than they have actually incurred. Accelerated write-offs of extraction-related investments are also common. For example, many multiyear costs in the U.S. oil and gas industry may be deducted immediately (expensed) rather than over the useful lives of the investments. All of these special provisions tend to reduce the effective tax rate on benefiting energy industries. Data collected by the Energy Information Administration (EIA) suggest that the major U.S. energy firms paid federal taxes that were one-quarter to one-half the prevailing nominal rates between 1977 and 1995.

3.2.2 Conversion

Raw energy materials normally go through some conversion prior to consumption. Crude oil is refined into a wide range of specialized products such as gasoline and heating oil. Coal may be pulverized or cleaned prior to use. A combination of heat and machinery converts raw fuels (including wind and solar) into electricity. Common government supports to the conversion stage include capital subsidies, production tax credits or purchase requirements, and exemptions from appropriate protections for environmental quality, worker health, and accident risks. Because this third category affects multiple phases of the fuel cycle, it is addressed in a separate section.

3.2.2.1 Capital Subsidies Subsidies to capital formation, usually through accelerated depreciation or investment tax credits, are common. Although applicable to multiple economic sectors, they are often of great benefit to energy producers. This is due both to their relative capital intensity and to provisions in the tax code that grant special accelerated depreciation schedules for energy-related assets. For example, in the United States, three sectors of relevance to energy—electric light and power, gas facilities, and mining, shafts, and wells—have allowable depreciation schedules that are 28, 45, and 44% faster, respectively, than the actual economic depreciation of their assets according to data compiled by the U.S. Treasury. Capital subsidies are of greatest benefit to large-scale generation assets with long construction times (nuclear, hydro, and coal) and are of greatest detriment to energy resources that conserve capital (most prominently energy conservation).

3.2.2.2 Tax Credits/Purchase Mandates A second class of subsidies to the conversion stage are tax credits or purchase mandates for certain types of energy. These subsidies occur at both the federal and the state/provincial levels and most often support emerging power sources such as solar, wind, and biomass-based electricity. Whereas many of the subsidies to conventional power sources are expensive regardless of whether the energy investments ultimately succeed, the tax credits and purchase mandates tend to be more efficient. For example,

federal tax credits for wind energy in the United States cost taxpayers nothing unless a private investor is successful in getting a wind plant operating. If the plant goes offline, so too do the credits. Renewable portfolio standards (RPSs), a common form of purchase mandates adopted by many U.S. states, are even more efficient. In addition to providing no subsidy unless the power is delivered, RPSs often compete eligible power sources against each other, driving down the unit subsidy as technologies improve.

Despite their benefits, these approaches have run into some political problems. Specifically, as the subsidies have grown, so too has lobbying pressure to expand the range of eligible sources. Federal tax credits now include poultry waste, a great benefit to the handful of very large chicken processors. At the state level, unsustainable biomass sources are sometimes included, as are waste-to-energy and landfill gas systems. Thus, although energy diversification goals are still being met, the supply is not necessarily renewable or particularly clean.

3.2.3 Transportation and Distribution

Fuel cycles may involve multiple transportation steps, including movement of raw fuels to point of refining, refined fuels to the point of consumption, and movement of wastes to disposal sites. Relevant modes of transport include road, rail, water, pipelines, and transmission lines.

Although specific energy resources vary widely in their transport intensity and in the modes of transportation and distribution on which they rely (Table IV), there are some common themes. Government construction, maintenance, and operation of transportation infrastructure frequently give rise to subsidies when user fees do not cover costs. These subsidies are often understated because municipalities might not properly cost the resources being

TABLE IV

Impact of Transport Subsidies on the Energy Sector

Transport mode	Issues	Energy sector impacts
Water: Inland	Waterway maintenance often provided by governments; user fees may not recover costs	Reduces delivered price of bulk oil and coal
Water: Coastal and international	Coastal ports, harbors, and shipping oversight subsidized by federal and other government entities; user fees might not recover costs	Reduces delivered price of bulk oil and coal
	Fuel consumed during shipment in international waters generally tax free	
Road	Most roadways are municipally owned and operated; user fees (primarily from fuel taxes) often insufficient to cover costs	Primarily benefits refined petroleum products
	Large trucks often pay proportionately less in taxes than the damage they cause roadways	Waste products from coal combustion or waste-to-energy plants may sometimes move by truck as well
Rail	Many rail lines do not recover their full costs	Largest beneficiary is coal, with some benefits to oil
Pipeline	Rights of way, safety and security, and environmental cleanup contribute to reduced costs of pipeline ownership and operation	Primarily benefits oil and natural gas
	Depending on circumstances, government ownership may generate large subsidies to users and use government monopoly to levy high taxes on users	
Electrical Transmission Grid	Rights of way, tax breaks for municipal ownership or capital investment, and government research and development can generate subsidies to eletrical distribution	Benefits all sources of centralized electricity in proportion to their share as a prime mover in generating stations; coal, nuclear, natural gas, hydroelectricity, and oil are the main beneficiaries
	Inaccurate pricing of distance can generate cross-subsidies to rural users

consumed. For example, tax exemptions on transportation bonds used to finance roads are routinely ignored, as are the free grants of rights-of-ways for rail, road, pipeline, and transmission links. So too is the opportunity cost of land covered by roadways and parking facilities. Although this space occupies 1.7, 2.1, and 3.5% of the total land area in the United States, Germany, and Japan, respectively, Todd Litman of the Victoria Transport Policy Institute noted that no property tax is paid on the vast majority of this space. This understates the direct costs of the infrastructure and the rights to use it.

Cross-subsidies between user groups may further distort relative prices. Large trucks pay less in highway fees than the damage they cause, generating an incremental subsidy to deliveries of refined fuels such as gasoline. Deep-berth ships such as large oil tankers may be the primary drivers of channel- or port-deepening projects, yet they often contribute to costs based only on volume of shipments. In the electricity sector, transmission tariffs may represent broad averages of the cost of service rather than rising as the distance traveled and density of users decline. By delivering subsidized electricity to remote users, transmission cross-subsidies mask the cost of line maintenance and new construction. This can destroy niche markets in which off-grid technologies (often renewable) would otherwise have been able to compete. Cross-subsidies between peak pricing and low demand periods are also common in electricity markets because real-time metering is not widely used at the retail level. This can dampen retail investments in demand-side management.

Power sources such as wind and solar require no shipment of input fuels or waste. Improved energy efficiency and some off-grid technologies require no transmission grid either. As a result, subsidies to energy transport can increase the barriers to renewable energy and efficiency. A major U.S. study conducted by Cone and colleagues in 1978 found that an estimated $15.2 billion in federal money subsidized transport of U.S. oil stocks between 1950 and 1977. The policies generating these subsidies have continued during the ensuing quarter-century or so.

3.2.4 Accident Risks

A handful of energy activities have the potential to cause catastrophic harm, including large oil spills, dam failures, and nuclear accidents. Many governments cap, shift, or ignore the potential liabilities from these activities. Functioning insurance markets and litigation would normally help to drive up prices for the more dangerous energy sources or particularly negligent operators. Government policies that mask these signals impede substitution to safer alternatives.

3.2.4.1 Large Oil Spills Within the United States, the Oil Pollution Act of 1990 stipulates use of commercial insurance for a first tier of insurance. A public trust fund financed by levies on oil sales provides supplemental coverage, although payments out of the fund are capped at $1 billion per incident. Based on empirical assessments of spill cleanup costs by Anderson and Talley, at least five spills over the past three decades or so would have exceeded the $1 billion cap, although most spills will be adequately covered. Internationally, the 1992 Civil Liability Convention governs liability for oil spills, also using a two-tier system. Insurance held by the vessel owner provides the first tier. Levies on cargo owners feeds the second tier, with receipts held in the International Oil Pollution Compensation Fund. The maximum compensation available from both tiers is roughly $174 million, a level shown to be insufficient by spills occurring in both 1997 and 1999. Although the caps are likely to be raised by 50%, Alfred Popp, chairman of the group working on the latest rounds of reforms, noted that concerns about liability shortfalls persist. The subsidy value of these caps is not known.

3.2.4.2 Dam Failures Many activities that would pose a very large potential risk if accident scenarios materialized rely on a system of strict liability. Strict liability focuses only on magnitude of the potential damages rather than on the intent, negligence, or degree of care of the operator. Although the failure of a large dam near a populated area can cause catastrophic loss of life, assurance for such potential liabilities is poorly characterized. Although loss of life from a dam failure will likely trigger widespread litigation, the rules of that litigation are predominantly set at the state level. Analysis by Denis Binder for the Association of State Dam Safety Officials indicates that a slight majority of states reject strict liability in dam failures. Furthermore, the piecemeal approach to coverage within the United States makes it difficult to evaluate whether existing coverages are adequate. Poor characterization of the risks extends to the international arena as well. To the extent that liability insurance is not in place or is too low, subsidies to hydroelectricity would result.

3.2.4.3 Nuclear Accidents Nuclear accidents can expose large populations to dangerous levels of radioactivity, triggering enormous liabilities for the

firm responsible. Caps on nuclear liability are common throughout the world. The United States, under the Price–Anderson Act, has a two-tier system of indemnification: a first tier of commercial insurance ($300 million per reactor) plus a second pooled tier (maximum of $83.9 million per reactor) funded by retroactive assessments on all reactors in case any reactor has an accident. Japanese nuclear operators must provide financial security of $520 million; damages above that amount will be paid by the government. In China, the limit is roughly $36 million. In Ukraine, it is roughly $70 million.

International efforts to standardize liability under the Convention on Supplementary Compensation for Nuclear Damage would establish minimum liability coverage worldwide, although for many countries this would also constitute the maximum. Under the convention, operators would directly face a first tier of liability. A country fund would provide secondary coverage. Because country payments rely on a sovereign guaranty rather than a prefunded instrument such as a trust fund, they may be at some risk.

Aggregate coverage under the U.S. system is estimated at roughly $9.2 billion per accident, although most of this is paid out over nearly 9 years by utilities, so the present value of the coverage is substantially lower. Liability levels established under the convention would provide less than $900 million per accident. Loss statistics from the Insurance Services Office and from the Disaster Insurance Information Office provide some context. Since 1950, there have been approximately 20 hurricanes with adjusted damages in excess of the convention cap, and both Hurricane Andrew and the Northridge earthquake had damages that exceeded the Price–Anderson cap even before adjusting retroactive premiums to present values.

Subsidies arise when government caps fall below expected damages from an incident and caps under both Price–Anderson and the convention are likely to do so. Damages above that level are, in effect, shifted to the state or to the affected population. Heyes estimated that the subsidy to reactors under Price–Anderson ranges between 2 and 3 cents per kilowatt-hour, a value that would roughly double the operating costs of nuclear plants. In addition, there are incremental subsidies associated with indemnification for nuclear contractors and government-owned facilities. Because other countries have lower liability caps and weaker inspection regimes, they likely have higher liability subsidies as well.

3.3. CONSUMPTION

Government support for energy consumption falls into three main categories: poverty alleviation, economy-wide below-market pricing, and targeted subsidies for certain classes of consumers.

3.3.1 Poverty Alleviation

Subsidies to heat and power for poorer citizens are common, frequently in the form of a lump-sum grant or reduced cost access to municipal resources. Often consumption oriented, these subsidies may miss opportunities to implement conservation measures among the target populations. Targeting can be a problem as well, with funds not reaching the groups most in need. According to the International Energy Agency (IEA), the poorest citizens often rely on noncommercial fuels such as dung (biomass comprises as much as 80% of the energy market in rural countries with a high reliance on subsistence agriculture) or live outside the reach of the subsidized electrical grid.

3.3.2 General Subsidies

Nations with large domestic energy industries sometimes institute policies that keep local prices well below world levels. These subsidies may protect antiquated energy-consuming industries that otherwise would be unable to compete, or they may serve as "rewards" to the electorate for supporting a particular official. For example, price gap data for Venezuela and Iran compiled by the Organization for Economic Cooperation and Development (OECD) and IEA show that these large oil producers heavily subsidize both industrial and residential use of petroleum. Subsidies are also common in many service areas close to large municipal hydroelectric generating stations. For example, rates to customers of the Power Marketing Administration dams in the United States were long heavily subsidized. Although the quantities of power or oil flowing through these regions make these subsidies seem costless, they are not. Domestic sales at subsidized rates forgo energy export revenues, increase local pollution, and contribute to a production base that is increasingly noncompetitive with that deployed elsewhere in the world.

3.3.3 Targeted Exemptions

Most OECD countries exempt coal and heavy fuel oils used in industry, as well as aviation fuels used on international flights, from the baseline levies on energy. Excise tax rates on coal used in the industrial

or power sector are often lower than those on much cleaner natural gas. The OECD noted that these exemptions "effectively mean that a large proportion of total carbon emissions in OECD countries is untaxed," generating weaker incentives to adopt even low-cost abatement options.

3.4 Postproduction Activities

Energy production and conversion require large facilities, often located in remote or pristine environments. Postoperational cleanup can be complex. Decommissioning addresses removal of physical infrastructure, whereas remediation and reclamation address problems with land and water. For markets to make accurate decisions about the relative cost of energy resources, the cost of these postproduction activities must be included in energy prices during the operating life of the facility in much the same way that the cost of an employee pension would be. Indeed, failure to accrue funds for postclosure costs during operations would make public subsidy likely given that revenues often drop to zero on plant closure.

3.4.1 Decommissioning

Decommissioning subsidies arise when infrastructure removal costs are ignored or underestimated or when accrued funds are mismanaged. Costs can be significant at large-scale energy installations such as hydroelectric dams and oil refineries. Where installations are remote (e.g., offshore oil rigs), radioactive (e.g., nuclear plants), or widely dispersed (e.g., gathering pipelines), costs per unit of capacity can be particularly high. Requirements for long-term environmental or safety monitoring (e.g., nuclear plants and some mines) can drive costs up further.

Pipelines and hydroelectric dams provide examples of costs being ignored entirely. Koplow and Martin made inquiries to many U.S. officials regarding pipeline closure. They found that although there are regulations governing proper abandonment, advance funding of closures was not required. The risks of insolvency appeared to be fairly high, especially for the smaller companies that often own older gathering pipelines. Regarding dams, the U.S. Federal Energy Regulatory Commission indicated in a 1994 policy statement that it will "not generically impose decommissioning funding requirements on licensees" but rather will stipulate them on a case-by-case basis at the time of relicensing. According to Andrew Fahlund of American Rivers, this policy has been implemented such that if a "dam owner is too poor, it is too burdensome to require them to maintain a fund, and if they are rich, they will have plenty of money available for such an eventuality."

Underestimating decommissioning requirements is of great concern with nuclear plants. IEA data indicate that the anticipated cost per unit of power capacity can vary by a factor of 10 across plants. IEA multicountry data suggest median decommissioning values of between 21 and 37% of the overnight capital cost (i.e., before financing) to build the plant. If funds are not properly accumulated during the plant's operating life, taxpayer burdens will be large. Inadequate provision for closure is also apparent in the oil and gas sector. Koplow and Martin found shortfalls in funding to plug and abandon oil wells in the United States approaching $600 million per year, of which approximately 75% represented insufficient bonding at wells still in operation.

Public bailouts can also be required if accrued funds for postclosure activities are lost through negligence, bankruptcy, or theft. If funds are retained within the firm, bankruptcy is a significant risk, especially given the 40- to 60-year time frame between fund collection and use. Increased segregation of each energy asset into its own company (now becoming the norm in the U.S. nuclear industry) greatly increases this risk. Loss through negligence is less likely where regulations preclude speculative investing. Nuclear decommissioning trusts within the United States are held outside the firm and are subject to conservative investment requirements to reduce the likelihood of loss.

3.4.2 Reclamation and Remediation

Small subsidies to site reclamation and remediation may arise through government-sponsored research into remediation technologies or through regulatory oversight of extraction activities that are not recovered via user fees. Much larger subsidies are associated with remediation of government-owned energy-related installations or where reclamation bonding has been insufficient to pay for the damage caused by private operators. James Boyd at Resources for the Future pointed to widespread inadequacy of reclamation bonding levels. For example, in the U.S. states of Indiana, Kentucky, and Tennessee, reclamation of coal mine sites is below 20%. Reclamation bond levels have generally been inadequate. Estimated liability for high priority (public health and safety concerns) coal mine remediation in the United States is $6.6 billion, according to the U.S. Office of Surface Mining Reclamation and Enforcement. Many mining regions

around the world have unreliable, incomplete, or nonexistent data on abandoned mines and their associated costs. These shortfalls may be made up by general tax revenues. However, more often, resource damage is not mitigated and continuing environmental releases are not controlled. Spending to address environmental concerns at nuclear energy-related infrastructure owned by the U.S. government has run approximately $500 million per year, much of which is paid by general taxpayers.

3.5 Energy Externalities

External costs of energy production and consumption can include pollution, land degradation, health impairments, congestion, and energy security. This article differentiates between two types of subsidies. The first involves existing government spending to address recognized problems associated with particular energy resources. Included here would be public funding to protect energy supplies and assets; public absorption of energy worker health care costs; and/or public subsidies to pollution control or abatement. Because this spending involves actual outlays, it is counted as a fiscal subsidy. A second class of policies involves loopholes in regulatory controls that allow additional damages to human health or the environment to continue without compensation. This second group is often difficult to quantify and is segregated as an externality.

3.5.1 Energy Security

Energy plays a central role in industrialized economies, and supply disruptions can trigger widespread economic dislocations. Geopolitical problems, accidents, and terrorism all are potential triggers. Lovins and Lovins identified a handful of factors that drive security concerns. These include long distribution channels, geographically concentrated delivery or production systems, interconnected systems that can spread failures, specialized labor and control systems to operate capital-intensive facilities that are very difficult to replace, and dangerous materials that can elevate the severity of any breach.

Energy security strategies include protection of energy-related assets and supply routes, stockpiling of vulnerable resources, and supply diversification. Where costs of these responses are borne by the general public rather than by the appropriate energy producers and/or consumers, the market incentive to build a more resilient, decentralized, and diversified supply system is reduced. Security subsidies tend to benefit oil the most, with particularly high transfers to imported oil from unstable regions such as the Persian Gulf. Additional beneficiaries are centralized electricity and natural gas. Off-grid power and conservation are the sources most disadvantaged. Subsidies to protecting energy installations and stockpiling are explored in detail in the following subsections.

3.5.1.1 Protection of Assets and Supply Links The larger the energy installation, the greater the target and the bigger the dislocation that an attack or accident would cause.

Defending energy-related assets is an increasing concern of governments around the world. Pipeline defense is listed as its own objective within Georgia's defense and security strategy. The United States has become involved with training the Colombian military to defend oil pipelines in that country, pushing for funding of $98 million to support the effort. Within the United States, core assets include the Trans-Alaska Pipeline System (TAPS), through which nearly 25% of total U.S. crude production flows, and nuclear plants. In response to inquiries from Koplow and Martin, Alaskan and federal officials said that no public funds were spent ensuring TAPS security. Nonetheless, the military has historically conducted training and planning exercises around the pipeline. In the nuclear sector, increased public subsidies have come through rising deployment of state-level security or National Guard troops around plants during periods of high terrorist alerts. However, surveys of nuclear plant workers by the Project on Government Oversight reveal employee concerns that training and spending levels are still insufficient. Although these anecdotes indicate that public expenditures in the area of protecting energy-related assets are likely large, data to quantify the subsidies are generally unavailable.

The costs of defending oil shipments through the Persian Gulf is an exception. As one of three central missions for the U.S. military in the region, there have been multiple efforts to value the subsidy to oil. Koplow and Martin reviewed eight historical studies of these costs and found general agreement that this presence is of great benefit to oil supply security. Disagreements centered on cost attribution. Some assessments attributed an extremely small portion of the military cost to oil, arguing that the same basic force structure would be needed for the other missions. Koplow and Martin pointed out that equivalent arguments could be made for each mission area given that the common costs of the vessels and personnel are what are most expensive.

They argued instead for treating the military presence through the lens of joint costs and allocating a reasonable portion (in this case, one-third) to the oil sector. This approach yields a subsidy to the oil sector in the range of $11.1 billion to $27.4 billion per year (roughly $1.65–$3.65/barrel originating from the region), depending on which of the detailed costing studies are used. Although funded by U.S. taxpayers, the benefits accrue to oil consumers in Europe and Japan as well. Recovering this cost via an excise fee on shipments would help to encourage increased supply diversification.

3.5.1.2 Stockpiling Petroleum has been the main focus of stockpiling efforts given its importance to world transport and military readiness. Under the terms of the IEA, oil-importing member states are required to hold stocks equal to 90 days of the previous year's net oil imports as a buffer against short-term supply disruptions. Subsidies arise if the costs of stockpiling are borne by taxpayers rather than by oil consumers. Relevant expenses include constructing and operating the stockpiles, interest costs on oil inventories and infrastructure, and any payments to third parties for nongovernmental stockpiling (two-thirds of IEA-mandated stocks are held commercially).

Buffer stocks for oil within the United States are held within the publicly owned Strategic Petroleum Reserve (SPR). The SPR has incomplete cost accounting, most prominently ignoring the interest costs associated with more than $16 billion it has spent to purchase its oil inventory since the reserve's inception. Private firms must finance all working capital, including inventory, in their operations, and cost savings from reducing inventory levels can be large. Public oil stockpiles are no different; capital tied up in the enterprise much be borrowed, at interest, through Treasury bond markets. Analysis by Koplow and Martin for 1995 estimated annual subsidies to the SPR at between $1.7 billion and $6.l billion, depending on whether unpaid interest on oil inventories is compounded. Because carrying costs are sensitive to the cost of capital, declining interest rates during recent years mean that current SPR subsidies will be lower than they were during the mid-1990s. Although the details of stockpile financing in other countries are not easy to discern (the IEA collects data only on physical flows, not on financial flows), some countries do recover at least a portion of their stockpiling costs from consumers. These include Japan, France, Germany, Korea, and Taiwan.

Subsidies to stockpiles slow transition to less vulnerable, more diversified supplies. Formal tracking of stockpile finance by the IEA, as well as the formalization of accounting rules for calculating costs, would leverage market forces for improved supply security.

3.5.2 Environmental, Health, and Safety Externalities

Externalities involve damages associated with energy production or use that are imposed on surrounding populations or ecosystems without compensation. These may include environmental damage, materials damage, human health effects, and nuisance factors such as bad smells and loud noises. Worker health is sometimes not counted as an externality under the argument that workers are compensated for the added risks of their jobs through higher wages. Such a conclusion requires that workers have some degree of choice in whether or not to accept jobs and that employers can be taken to task retroactively for gross negligence. This is not the case in many countries around the world. As a result, it is reasonable to consider as subsidies high levels of occupational illness, especially when the costs of maintaining those workers falls on the general taxpayers.

Governments are routinely involved with efforts to make certain energy-related activities safer for workers. This is most prominent regarding coal and nuclear fuel cycles, where dedicated government agencies exist to inspect and educate mines and production sites. If these costs are not paid entirely by the producers or consumers of the affected energy type, subsidies ensue. Public responsibility for workers' health care and/or pension costs also constitute subsidies. This has been quite common in the area of coal. For example, government payments to U.S. coal miners afflicted with black lung have exceeded $30 billion. Black lung levels are now rising (or are being better documented) in other countries such as Russia, Ukraine, and China. Coal mine fatalities continue at extremely high levels in many of these countries as well.

Although difficult to quantify and normalize, external costs arise in many different ways through the fuel cycle. Table V provides an overview of these costs, in large part relying on data developed by ExternE. A project of the European Commission, ExternE has more than 50 research teams trying to quantify the externalities for key fuel cycles.

External costs are highest for coal and oil, although newer conversion technologies can reduce the toll per unit of power significantly. The environmental costs of nuclear power also appear low, even

TABLE V

Overview of Externalities by Energy Resource

Fuel	Years of life lost/TWh[a]	Environmental damage costs (Euro-cents/kWh)[a]	Quantifiable external costs (Euro-cents/kWh)[b]
Coal, 1995	1065	13	2.6
Coal, >2000	113	4	3.4 (lignite)

though they are quite sensitive to assumptions regarding accidents at plants. The data also indicate that renewable energy sources would become far more competitive if the market were forced to account for external costs.

4. PATTERNS OF SUBSIDIZATION

Developing an aggregate picture of energy subsidization is extremely difficult due to the scope of policies affecting the sector and to tremendous fragmentation of the data across thousands of government ministries worldwide. There has been no global multifuel estimate of energy subsidy magnitude, although two efforts come close. Myers and Kent developed a global estimate for fossil ($119 billion/year) and nuclear energy ($12 billion/year), with an additional $200 billion per year in externalities. Van Beers and de Moor estimated global subsidies to all fuels ($250 billion/year, with more than 60% supporting fossil) but did not include externalities. Both estimates were built by aggregating data from preexisting smaller assessments rather than from a comprehensive policy survey. Different definitional and valuation approaches, as well as gaps in regions covered, make aggregation difficult. Although the resultant values indicate that energy subsidies are quite large, they are unlikely to provide much precision as to the true subsidy magnitude.

Common themes are nonetheless visible across many of the smaller studies. For example, Koplow and Dernbach found that the fossil share of total subsidies exceeded 55% in four of six major U.S. multifuel energy subsidy studies conducted since 1978. In the remaining two, methodological inconsistencies largely explain the deviation. Within the fossil category, coal and/or oil normally received a larger share than did cleaner natural gas. Estimates for nuclear varied more widely. Where liability caps for accidents and capital subsidies were included, nuclear subsidies comprised 25% or more of the totals. Where they were incorrectly excluded, reported nuclear subsidies were much lower. Renewables and efficiency garnered 5% or less in most of the studies. Only when many large subsidies to other fuels were excluded did the aggregate subsidy estimates fall low enough to bring the renewables/efficiency share above 15%.

This pattern across fuels is broadly consistent with trends discussed earlier in this article. Historical spending on R&D has heavily favored fossil fuel and nuclear power, as has the use of export credit agencies. Subsidies to capital formation have supported primarily these same fuels, whereas those to energy security have favored oil and nuclear energy.

Failure to internalize pollution or health externalities generates subsidies primarily to coal and oil. Yet for many large industrial consumers, these fuels are exempt from taxation throughout the OECD. Government support for renewables, efficiency, and conservation is extremely modest. There have been recent gains in the share of public R&D supporting these areas, and some newer energy resources are eligible for tax credits or are included within purchase mandates. However, the overall pattern is one in which established energy types, often with poor environmental profiles, continue to receive most of the public support provided to the energy sector.

5. SUBSIDY REFORM

Modeling efforts, summarized by Koplow and Dernbach, suggest that subsidy reform is likely to generate environmental gains. Within the United States, modeling suggests that reforms could achieve a substantial (18% of the nonsequestration reductions) portion of the Kyoto 2010 carbon reduction targets. Modeling of international reforms projects some global reductions in greenhouse gas emissions by 2010 (0.2–8.0%), although results are sensitive to assumptions regarding subsidy values and fuel substitution options. Given the hundreds of billions of dollars involved with current subsidies, reforms also seem likely to reduce fiscal expenditures in many countries throughout the world.

Energy subsidies and subsidy reform have attracted the attention of many international governmental and nongovernmental organizations, as well as country-level ministries, over the past 15 years or so. Despite this attention, successful reforms have been few. This outcome reflects the role of political economy in subsidy creation, continuation, and reform. Who gets public resources is often an intensely political decision. Powerful groups in society are best positioned to institute policies that generate transfers to themselves. Furthermore, the theory of rent seeking indicates that groups that have received subsidies in the past will invest at least a portion of those gains to ensure that the subsidies keep coming.

Fossil, nuclear, and hydro energy sources all have been around for a long time, involve large companies and/or large government ministries, and have sufficient scale to dedicate staff to political lobbying. In addition, because the cost of many subsidies rises as the installed base eligible for them grows, the large installed base of fossil, nuclear, and hydro also contributes to these resources capturing the lion's share of subsidies.

Given the strong political opposition to subsidy reform, a transitional process to precede policy change with much increased transparency makes sense. Initial steps to qualitatively identify and describe subsidies seems simple but can greatly change the political dynamics of subsidization by making recipients more visible to their competitors and the taxpayers. Quantifying the value of these transfers is the next step and helps policymakers to prioritize which subsidies are most important to address first. Consistent approaches should be used so that estimates done for different countries, or those done by different researchers, can be compared more easily. Separating externalities from fiscal subsidies is one element of standardization, as is applying consistent rules on offsets.

Modeling the impacts of these transfers on human, environmental, and fiscal health should come next, followed by modeling the effects of potential subsidy reforms. Summarizing a series of global workshops on energy subsidies, the UN Environment Program suggested that reforms should be implemented gradually and with strong transitional policies. A gradual approach might not make sense in all cases given that political forces may be able to stop some reforms entirely. However, transitional approaches that decouple payments from practices that harm human health or the environment should be pursued. Eligibility for existing subsidies can also be made contingent on acceptable environmental practices. Finally, new or replacement subsidies should be structured to leverage competitive markets (as do the RPSs) rather than providing support whether or not there is a successful outcome.

6. CONCLUSION

Subsidies remain a large presence in energy markets throughout the world. The scope, complexity, and politics of these policies help to explain why there is no global subsidy data set. However, all indications are that these subsidies cost hundreds of billions of dollars per year, impede market penetration of cleaner and more efficient methods of providing energy services, and increase damages to human health and the environment. Efforts to overcome the inherent political resistance to subsidy reform are needed, if only to greatly improve the ability to identify, describe, and quantify subsidies to particular fuels throughout the world.

Glossary

developed land As defined by the U.S. Department of Agriculture, developed land is any land no longer a part of the rural land base of the United States. This includes large tracts of urban and built-up land, tracts of built-up land of less than 10 acres, and land outside of built-up areas that is part of a transportation system (i.e., roads, rail, and associated rights-of-way).

metropolitan statistical areas As defined by the U.S. Office of Management and Budget and used by the U.S. Census, this is the delineation of urban areas that includes the central city and any surrounding counties that are socially and economically connected to an urban center.

smart growth Alternative forms of development that use land efficiently, mix land uses (such as housing, business, and shopping), and encourage walking and public transit in addition to driving while protecting surrounding open space.

sprawl Low-density, automobile-dependent development with a strict separation of land uses.

vehicle miles traveled Surface transportation miles traveled annually by passenger and freight vehicles in the United States.

Shifting from the 19th to the 20th century, new forms of transportation reshaped U.S. urban areas. Streetcars and subway lines transformed cities such as Boston, New York, and Chicago, allowing for dense concentrations of businesses and hotels. These areas were surrounded by neighborhoods often bound by ethnicity and class.

Idealists planned expansions of the city as a whole through movements such as the City Beautiful movement and the Garden Cities movement as well as through model new suburbs such as Radburn, New Jersey, Mariemont, Ohio, and Greenbelt, Maryland. These designs were precursors for those built throughout the country to fulfill the American Dream of owning a single-family detached home and an automobile. The dream became reality for millions of Americans in the years after World War II, and construction accelerated due to incentives such as the home mortgage deduction and infrastructure investments.

Most notable in terms of its impacts on our energy consumption have been investments in highways needed to serve the form of transportation that would eclipse transit—the automobile. Additionally, the large structures connected by ribbons of asphalt in suburbia have consumed increasingly more energy. This article discusses suburbia's ascendance in the United States, the transportation and construction impacts of this trend, as well as some alternatives to sprawl being debated including "smart growth." Smart growth entails new policies and incentives to create a greater variety in the supply of modes of transportation coupled with more and better travel demand management to conserve energy and improve environmental quality.

1. SUBURBAN SPRAWL

Much of current land development takes a form called suburban sprawl. Sprawl can be roughly defined as low-density development with a strict separation of land uses connected mostly (or only) by roads and highways. Although some sprawl occurred in the form of streetcar suburbs in the first couple of decades of the 20th century, sprawl accelerated after World War II as returning G.I.s, their families, and

Pittsburgh	676,806	12	604,332	16	520,117	24

[a] Data from Teaford (1993).

other citizens left cities for the suburbs in increasing numbers. This led to declines in the populations of central cities during the latter half of the 20th century (Table I).

A study by Janet Rothenberg Pack for the Brookings Institution examined population trends in 277 metropolitan statistical areas and found that flight from existing urban areas occurred throughout the United States from 1960 to 1990. The findings are summarized in Table II. In addition to the city-to-suburb migration evidenced by Table II, it is also clear that there have been interregional population distribution changes. Southern and western regions experienced the most population growth during these three decades. The population of suburban areas of these regions more than doubled from 1960 to 1990 (Table II).

Evidence shows that these population trends are continuing and that land development is occurring at twice the rate of population growth. Some of the best U.S. land-use data collection is done by the U.S. Department of Agriculture under the auspices of the Natural Resources Inventory (NRI). The NRI defines developed land as land that is no longer a part of the rural land base of the United States. This includes large tracts of urban and built-up land, tracts of built-up land of less than 10 acres, and land outside of built–up areas that is part of a transportation system (i.e., roads, rail, and associated rights-of-way). This land specifically consists of cropland, pasture land, range land, forest land, land enrolled in the federal Conservation Reserve Program, and other rural land. According to the NRI, U.S. land development has accelerated from 1.4 million acres per year in the 1980s (1982–1992) to 2.1 million per year in the 1990s (1992–1997).

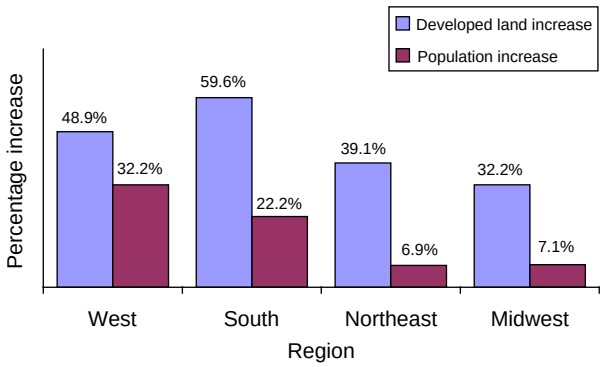

FIGURE 1 Population vs urbanized land growth by region, 1982–1997, as summarized in "Who Sprawl's Most? How Growth Patterns Differ across the U.S.," prepared in July 2001 by W. Fulton *et al.* for the Brookings Institution Center for Urban and Metropolitan Policy.

There are important regional differences in the relationship between these two factors in the sprawl equation. In the past couple of decades, the west has been growing but not sprawling as much as it has in the past (due in part to limits of developable land, whether due to topography or federal ownership), the northeast and the midwest have been sprawling but not growing much, and the south continues to grow and sprawl rapidly (Fig. 1).

2. TRANSPORTATION IN SUBURBIA

According to the U.S. Department of Transportation (DOT), as of 1995, every U.S. driver spent an average of 443 h every year behind the steering wheel, or 43 h more than in 1990. Although commuting to and from work only accounts for one-fifth of the miles that Americans drive daily, it is also notable that peak commuting hours have been increasing. In 1982, the average daily congested period was 2 or 3 h, but by 1999 this had doubled to 5 or 6 h.

There are economic impacts as well. Americans now spend more on transportation than food, clothing, or health care. As of 1998, according to the U.S. Department of Labor, 17.9¢ from every household dollar is spent on transportation, 98% of which is spent on buying, operating, and maintaining cars. This household expenditure is second only to housing (19¢). Transportation is also sapping the strength of the American economy. The Texas Transportation Institute found that congestion cost 75 metropolitan areas $67.5 billion due to lost income and increased truck operating costs as well as excess fuel consumption (5.7 billion gallons) in 2000.

During the latter half of the 20th century, U.S. planners, engineers, and decision makers relied mostly on the expansion of road system capacity to alleviate traffic congestion. As quoted in "Divided Highways," a history of the U.S. interstate highway system, in June 1969 Transportation Secretary John Volpe commented on this problematic modus operandi:

> *The federal government spends as much money on highway construction in 6 weeks as it has put into urban transit in the last 6 years. … Unless we intend to pave the entire surface of the country—and no one wants that—we have to stop this trend. We already have 1 mile of highway for every square mile of land area in the USA.*

According to the DOT, 30 years later the United States had 2 miles of highway for every square mile of territory. This country has made massive investments in building a 4-million-mile highway and road network since World War II. According to a 1997 National Research Council report, U.S. highways, streets, and associated rights-of-way totaled approximately 20 million acres, or 1% of U.S. land area. Based on this figure, the Harvard School of Design estimated roads impact one-fifth of the U.S. land base in the forms of fringe noise, air, and water pollution effects from vehicle traffic.

The environmental impacts of our growing road system are significant. Habitat loss and fragmentation reduce wildlife population diversity and abundance, contributing to species imperilment. In fact, the National Wildlife Federation reported that sprawl is the main cause of species imperilment in California. Wetlands loss can also be traced to our expanding transportation system: in the Environmental Protection Agency's (EPA) "National Water Quality Inventory: 1996 Report to Congress," 6 states reported significant wetlands loss due to highway construction and 10 reported significant loss due to residential development. This report also found that 38% of assessed U.S. estuary miles are impaired and that 46% of this impairment is due to polluted urban runoff. This is not surprising. Runoff from impervious surfaces such as roads is considerable: Runoff from a 1-acre parking lot is 16 times that of an undeveloped meadow.

Americans have made good use of increases in pavement. U.S. vehicle miles traveled (VMT) increased steadily throughout the second half of the 20th century. According to the DOT, from 1970 to 1990 VMT doubled from 1 to 2 trillion per year, and as of 1998 Americans traveled 2.6 trillion miles annually.

Driving increasingly more miles has meant turning away from other modes of transportation, such as mass transit. Using data originally from the DOT and the American Public Transportation Association and subsequently provided by the Surface Transportation Policy Project, Fig. 2 highlights this relationship for most of the 20th century. Transit boardings hit their peak in 1946 at approximately 23.5 million, whereas annual VMT decreased during World War II (1943–1945) and then continued its climb. This brief reversal of centurywide trends can be attributed to wartime policies such as the rationing of gasoline. In the 1920s, the larger trend lines had already taken shape. At century's end, however, VMT was barely growing, whereas transit stabilized and grew steadily from 1996 to 2001. The latest data available from 2002 show a decline in transit use of 1.3% and an increase in VMT of 1.7%. One overall trend is clear: Americans are driving increasingly more every year (Fig. 2).

2.1 Transportation Impacts on Energy and Air Quality

All of this driving has a major impact on U.S. petroleum consumption. According to the DOT, the transportation sector consumes more than 65% of the petroleum used in the United States and highway vehicles account for approximately 84% of this consumption. Basically, Americans are consuming increasingly more oil just to get around, despite improvements in efficiency. Stagnating fuel economy of the U.S vehicle fleet due to the popularity of sport utility vehicles and light trucks doubtless contributes to this trend. According to the EPA, U.S. fuel economy peaked in 1987–1988 and is currently 6% lower than in 1988. Using U.S. Department of Energy (DOE) data, Fig. 3 shows that oil consumption by the U.S. transportation sector closely follows VMT growth—steadily upward toward the 9 million barrels per day mark.

Unfortunately, combustion of all this oil also pumps many unhealthy pollutants into the air. In addition to carbon monoxide (CO), cars and trucks are also the source of volatile organic compounds (VOCs) and oxides of nitrogen (NO_x). When VOCs and NO_x mix while exposed to the hot sun, a chemical reaction takes place producing ozone. In recent years, ground-level ozone has been particularly problematic for large, sprawling U.S. cities such as Atlanta and Houston. Ozone is an irritant to the lungs and eyes, causing coughing and chest pains. It aggravates asthma and can have especially harmful effects on children, who breathe more air per pound of body weight than adults.

Transportation is responsible for many of these emissions, as Benfield *et al.* found in their 1999 book, "Once There Were Greenfields":

> *In particular, cars and other highway vehicles continue to emit some 60 million tons of carbon monoxide per year, about 62% of our national inventory of that pollutant; cars and other highway vehicles continue to emit some 7 million tons per year, almost 26%, of our volatile organic compounds … and they emit around 8 million tons per year, about 32%, of our nitrogen oxides.*

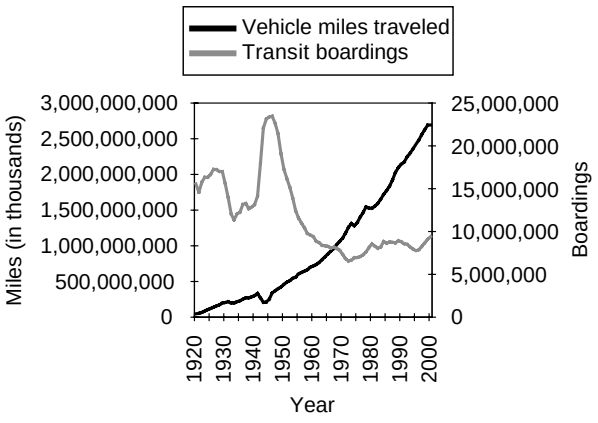

FIGURE 2 Change in transit boardings and vehicle miles traveled between 1920 and 2000. Data originally from the U.S. Department of Transportation and the American Public Transit Association as provided by the Surface Transportation Policy Project.

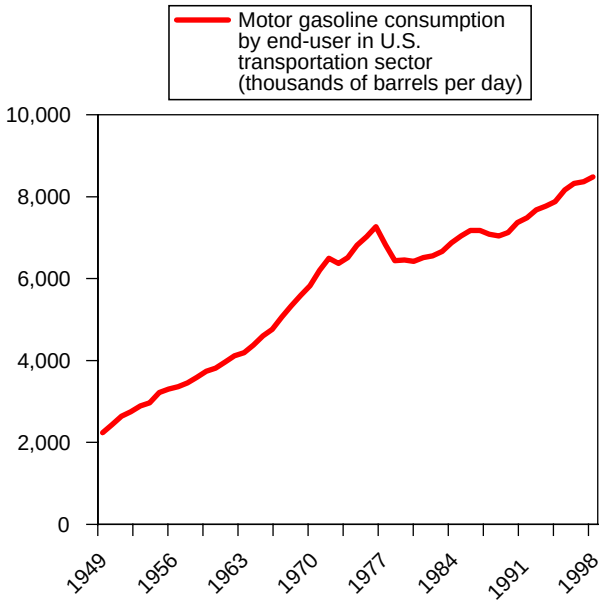

FIGURE 3 Increase in oil consumption by U.S. transportation sector, 1949–2001. Data from the U.S. Department of Energy.

The transportation sector is also a growing part of the total anthropogenic greenhouse gas emissions, especially carbon dioxide. According to the EPA, transportation sources accounted for approximately 31% of U.S. carbon emissions (460.4 million metric tons of carbon) in 1997. This sector is growing rapidly: Total emissions increased 10% between 1990 and 1997. According to the DOE, more than half of this increase can be traced to cars and trucks: As of 1999, 60% of transportation-related emissions were due to the combustion of gasoline.

3. STRUCTURES IN SUBURBIA

Although the impact of a transportation sector that underwent near-complete transformation in the 20th century has been examined most closely by experts and scholars, the low-density patterns of development have also meant an increase in the average size of houses, schools, and commercial buildings. This too has energy impacts.

3.1 Residential Buildings

According to the DOE, housing is the second largest source of carbon emissions in the United States. In 1999, residential buildings accounted for 19% of total U.S. CO_2 emissions at 290.3 million tons of carbon equivalent. According to the DOE, electricity accounted for most (63%) household carbon emissions as of 1997. Not surprisingly, the large-lot, detached-housing-only residential units that make up an increasing part of the U.S. landscape consume a great deal of electricity (as well as other types of energy) compared to more modestly sized housing types. In fact, according to the DOE, as of 1997 single-family detached housing made up by far the largest percentage of residential sector energy consumption at 73.4%.

Table III summarizes consumption levels for different U.S. housing types in 1997.

A good measurement for the increase in housing size in the United States is the number of rooms in a unit. The DOE's 1997 Residential Energy Consumption Survey showed that the size of units has grown steadily larger, resulting in greater energy use due to increased requirements for heating, air-conditioning, as well as lighting. Figure 4 shows this trend from 1978 to 1997.

Another yardstick for comparing the environmental impacts of different housing types is the ecological footprint of a given residence. Ecological footprint analysis is a tool designed by William Rees of the University of British Columbia and Mathis Wackernagel of the nonprofit Redefining Progress in the 1990s. This framework basically measures the depletion of "natural capital" by calculating how much world-average bioproductive land is needed to sustain a given population. The tool is versatile and has been used by households, schools, cities, and even nations.

This method of analyzing the impact of human activity sometimes uses the loss of "sinks" (soil,

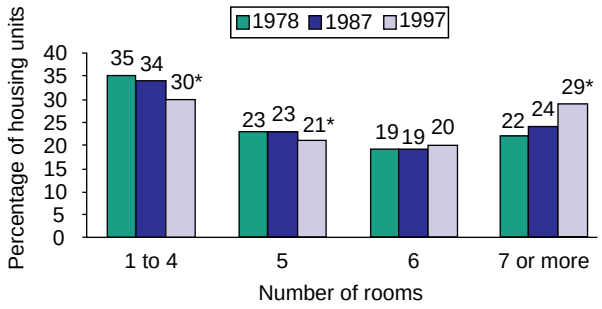

FIGURE 4 Increases in the number of rooms per household, 1978–1997. *The difference between the 1978 and 1997 estimates is statistically significant at the 95% confidence level. Data from the Energy Information Administration, Residential Energy Consumption Survey, 1978, 1987, and 1997.

TABLE III

Energy Consumption by Household Type in the United States, 1997[a]

	Type of housing unit				
	All households	Single-family, detached	Single-family, attached	Multifamily, 2–4 units	Multifamily, 5 + units
Electricity consumption per household (kWh)	10,219	11,778	8071	6505	5990

[a] Data from the Energy Information Administration.

vegetation, and water resources that absorb CO_2, removing it from the atmosphere) to account for fossil fuel consumption. It also includes the bioproductive-land-equivalent impacts of food, the built environment, and forest. Overall, it is a useful sketch tool for comparing impacts, and an analysis of housing footprints yields interesting results. Specifically, Table IV provides the results of a 1995 study of different Canadian housing types using this tool.

Suburban sprawl includes a large number of single-family detached houses. For every detached house built instead of a townhouse, ecological footprint per capita increases 17%. Also, for every detached house built instead of an apartment, a person's ecological footprint increases 40%.

As the awareness of the significant impacts of residential development on the environment has grown, a cottage "green building" industry has also grown. Several U.S. jurisdictions and groups have codes, departments, or certification programs for green building. Austin (Texas), Boulder (Colorado), San Francisco, Seattle, Dade County (Florida), Oregon, Pennsylvania, New Jersey, New York, Minnesota, Maryland, Colorado, and Texas all feature green building efforts of some kind. Among private sector groups, the National Association of Homebuilders, the American Institute of Architects, the American Lung Association, and the Energy Efficient Building Association have programs. The U.S. Green Building Council is also working with nongovernmental organizations such as the Natural Resources Defense Council (NRDC) to develop standards for residential development as part of its Leadership in Energy and Environmental Design (LEED) certification process.

This increased interest in green building is driven in part by increasing demand. For example, 89% of U.S. consumers surveyed in a 2000 *Professional Builder* magazine poll said they "were willing to pay more for green building features if they improved quality, durability, and the health of the home." More than half would pay an additional $2500–5000 and 9.5% would pay an additional $10,000 for a green home.

Considerable energy savings are possible through efficient design. In a 1998 study of the savings possible via cost-effective energy efficiency investments (in lighting, appliances, etc.) in Illinois, the American Council for an Energy Efficient Economy (ACEEE) found that 32 and 27.5% savings in electricity were achievable for existing and new single-family units, respectively. A similar 1997 ACEEE study found 37.5% (existing) and 26.5% (new) in possible savings in Pennsylvania and New York and a 51.5% (existing) and 30.0% (new) possible savings in New Jersey, all for single-family units. Therefore, possible electricity savings through energy efficiency improvements for the type of housing typically found in sprawling developments in these four states ranges from 26.5 to 51.5%.

However, few green building programs integrate criteria about neighborhood density and location efficiency, which are key components of smart growth. Changes are afoot, though. For example, Austin, Texas, has a Smart Growth Initiative complete with a matrix for calculating just how "smart" particular development proposals are, and LEED is developing new design standards that integrate "smart growth" criteria. Given the popularity of the approximately 100 New Urbanist developments built thus far, the addition of location efficiency as a criterion for determining how "green" a building is should ensure that such buildings continue to fetch a premium in the marketplace.

3.2 Educational Buildings

Buildings in the U.S. educational system comprise approximately 13% of total commercial building floorspace. According to the DOE, they are the largest at 25,100 square feet on average per building, compared to the average for all commercial buildings

TABLE IV

Footprints of Various Household Types in Acres[a]

	Category				
	Standard lot detached house	Small lot detached house	Townhouse	Walk-up apartment	High-rise apartment
Housing	1.95	1.95	1.61	1.16	1.16

[a] *Source*: Walker and Rees (1997). For more information, see http://www.ecologicalfootprint.org.

of 12,800 square feet. Newer schools use more energy per square foot than older schools, according to the Energy Information Administration. The National Trust for Historic Preservation finds that newer schools are larger and more apt to be located in sprawl locations than older ones. In 2000, the Department of Education studied the functional age of schools, or the number of years since a building had been constructed or renovated, and found that newer schools were larger:

> *On average, small schools had older functional ages than medium or large schools. Additionally, large schools were more likely than small schools to have a functional age of less than 5 years, and the small schools were more likely than large schools to have a functional age between 15 and 34 years.*

This is not surprising given requirements imposed on school construction by states and localities. For example, many states adhere to the guidelines created by the Council of Educational Facility Planners International (CEFPI) when planning new school construction:

- At least 10 acres of land plus 1 acre for every 1000 students for elementary schools
- At least 20 acres of land plus 1 acre for every 100 students for middle schools
- At least 30 acres of land plus 1 acre for every 100 students for high schools

Not surprisingly, buildings on this land are also larger than they have been in the past. In 1995, CEFPI released what it terms the "starting point" for planning the size of school buildings. Size of schools is partly determined by climatic conditions. For this reason, CEFPI lists different averages for currently existing school buildings in different regions. One region encompasses nearly the entire United States (48 states). For this region, the recommended starting point average gross square footages per student are 111.5 for elementary schools, 154.4 for middle schools, and 160.7 for high schools.

3.3 Commercial Buildings

According to the DOE, in 1999 commercial buildings consumed 16% of U.S. primary energy, and 75% of this consumption was in the form of electricity. As of 1995, the greatest energy consumers were buildings that provided or hosted food sales or services, health care-related services, lodging, public assembly, public order and safety services (i.e., police stations), and office spaces. According to the Alliance to Save Energy, carbon dioxide emissions from the commercial buildings sector have increased 30% since 1980, faster than any other sector.

The DOE sums up the scale of our stock of commercial buildings as follows:

> *In 1995, there were 4.6 (with a ±0.4 margin of error) million commercial buildings in the United States comprising 58.8 (±3.9) billion square feet of floorspace. That amount of commercial floorspace exceeds the total area of the state of Delaware and amounts to more than 200 square feet for every resident in the United States.*

In spite of the tremendous amount of land development in recent decades, this stock is surprisingly comprised mostly of older buildings. The median building age is 30.5 years, and more than half of the buildings were built before 1970. According to the DOE, site energy intensity has not decreased significantly since the beginning of the 20th century. A lack of progress in the 1990s is confirmed by a November 2000 assessment of energy consumption by the EPA, which states, "Total energy consumption in commercial buildings remained roughly constant from 1989 to 1995, as did energy use per square foot."

Highlighting the potential to conserve energy, the EPA cites studies showing that "by investing in simple profitable building upgrades, many U.S. homes and businesses could reduce their annual energy use by nearly 30%." Through both private and public sector programs, such savings have been achieved in some cases. The EPA's Energy Star program, for example, claims to have partnered with 15% of the "commercial, public, and industrial building market" and rewarded 90 energy-saving buildings with the Energy Star label. These buildings prevent 45 million metric tons of carbon equivalent worth of emissions. Also, the Rocky Mountain Institute has performed many studies that show potential energy savings for commercial buildings: In one analysis, they found potential savings of 75% for a vacant 13-story, 200,200-square foot office building outside Chicago.

4. LAND USE, TRANSPORTATION, AND ENERGY CONSUMPTION IN OTHER COUNTRIES

Urban settlement patterns in other countries have remained fairly compact. Combined with adequate transportation infrastructure, this leads to lower dependence on the automobile in countries such as those in Europe. In fact, European land-use and

transportation policies and practices are often evoked when trying to define policy alternatives for achieving more effective growth management in the United States.

For example, Pietro Nivola of the Brookings Institution finds that U.S. cities interested in improving their condition could adopt some policies used frequently in Europe, such as reducing public funding for highway construction, reducing urban crime, and providing fiscal relief for city businesses and residents through revenue-sharing arrangements such as those used by Germany and Canada. Timothy Beatley of the University of Virginia has researched best practices in European countries, including Copenhagen's 1947 land-use "finger plan" that concentrates development into a hand shape, with the city center as the palm and transit-line-centered digits extending outward with protected green spaces between the lines. Due in part to the choices offered by these innovative land-use and transportation policies, 31% of Copenhagen commuters ride transit to work and 34% bike to work. This compares poorly to U.S. cities, where transit and bike home-to-work trips make up merely 5% and 2% of the total, respectively.

European cities are faring better in terms of fuel use. In 1999, Europe was second only to the United States (at 25%), with 15% of total global carbon emissions from fossil fuels. However, according the DOE, European emissions per capita were less than half those of the United States (2.4 vs 5.6 tons).

A study of 48 global cities by Peter Newman and Jeffrey Kenworthy shows just how energy-intensive U.S. transportation patterns have become. The averages for gasoline used for private transportation are summarized in Fig. 5.

They found generally that gasoline-oriented cities are "heavy energy users while those with any significant level of electricity use [to run a rail system] in their transportation system are low energy users overall." Even after correcting for economic factors, such as U.S. income, gasoline prices, and fuel efficiencies, they found that gasoline use was still significantly higher (47–63%) in the United States than in other world cities, on average. In fact, the authors noted that "a purely economic approach to transportation matters will be inadequate, and that matters of infrastructure and urban form have direct influence on transportation patterns." One advantage to investing in more transportation options in order to reduce trips and trip lengths is a phenomenon termed transit leverage. Newman and Kenworthy cite Neff, who found that transit does not simply replace car travel on a one-to-one ratio. In fact, Neff found that 8.6–12.0 km (5.3–7.4 miles) of car travel is replaced by 1 km (0.62 miles) of transit according to data from the United States.

Interestingly, Newman and Kenworthy also found that there is little connection between transportation and economic growth. Whereas in U.S. cities gross regional products per capita were only 0.85 those of Europe, car use was 2.41 times higher in the United States.

Nonetheless, the suburban sprawl model is being adopted by Second and Third World countries as a means to prosper. Private car use in Europe and China is increasing. As Molly O'Meara Sheehan of the Worldwatch Institute wrote,

> *In the Czech Republic, car use surged and public transit use fell as the number of suburban hypermarkets ballooned from 1 to 53 between 1997 and 2000. Today, the proliferation of such developments around Prague has boosted the number of hypermarkets in the Czech Republic above that in The Netherlands.*

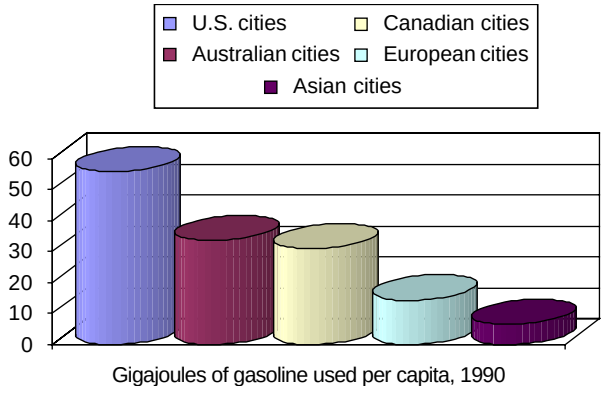

FIGURE 5 Gasoline use per capita in the United States, Canada, Europe, Australia, and Asia.

5. TRANSPORTATION ALTERNATIVES FOR U.S. SUBURBS

As discussed previously, since the mid-20th century popularization of the automobile, the usual response to demand for faster commutes and trips has been to provide a more ample supply of new highway and road capacity. However, in recent years various studies have described a phenomenon that puts in doubt the effectiveness of this tactic for reducing congestion. The phenomenon is not surprising: Greater availability of pavement spurs more and longer trips by road users. What is sobering is the extent of the phenomenon.

The influence of new road and lane construction on travel behavior is referred to as induced travel, which has been studied in all 50 states and 70 regions. The idea is simple: New road capacity acts as a magnet for drivers, inducing them to take more and longer trips than they would have otherwise. According to the growing academic literature as summarized in 2000 in a presentation by Lewison Lee Lem of the EPA, the impact can be substantial: An average increase of 10–30% of total VMT can be traced to induced travel. Short-term induced increases range from 2 to 5% for every 10% increase in road capacity. Long-term increases may result in increasing travel 5–10% for every 10% increase in capacity.

Some of this additional traffic is also a product of new land development and new users who occupy new subdivisions and shop in new malls. Transportation investments often have an impact on land development. A study performed for the Brookings Institution by Marlon Boarnett confirmed the relationship between transportation policy and land use, concluding that highways can induce changes in regional development patterns. In fact, this study found that highway investments shift economic development away from existing communities to newly built areas. Just as empty roads and traffic lanes act as magnets for new driving, highway interchanges draw new development.

Smart-growth policies and practices offer one possible way to deal with out-of-control VMT and pavement growth. These policies are being embraced by localities and states throughout the country. It is time for such a shift. Many surveys in the past few years have shown that Americans are tired of suburban sprawl and its symptoms—loss of open space, traffic congestion, and blight in older communities. For example, in a 1999 poll by the Pew Center for Civic Journalism, sprawl and its effects tied with crime as the issue of most importance at the community level.

What is smart growth? Roughly, smart growth is development that involves a mix of land uses (e.g., commercial and residential), which occurs in or adjacent to existing communities and which provides a variety of transportation choices for residents and workers. Orienting and designing new development to make it convenient for residents and workers to take transit is especially important, and there is even a name for this kind of development—transit-oriented development.

Many advocates propose taking advantage of significant infill development and redevelopment opportunities created by population declines in central cities and older suburbs and postwar leapfrog development patterns. Retrofitting U.S. suburbs so that we take advantage of vacant and abandoned lots means more compactness and convenient access to shops and potential workplaces. After decades of sprawl, there are plenty of opportunities for such retrofits. One example that is receiving much attention is "greyfields." These are the older regional malls that litter many older suburbs. Unfortunately, "litter" is an all-too-apt term since many of them are vacant, having been left behind by companies seeking to build ever-larger stores and malls. According to a study by PricewaterhouseCoopers and the Congress for New Urbanism, 140 of approximately 2000 regional malls are greyfields, and 200–250 are on their way to that status. These sites are perfect for redevelopment given their large size—35 acres on average—plus the fact that their location in older suburbs often means proximity to transit.

Redevelopment activities such as this will mean more jobs and more residents per acre, which many studies have found correlate well with decreases in VMT. A 1992 study by Cambridge Systematics found 20–25% fewer car trips per household in more compact, transit-oriented suburbs than in sprawling, auto-dependent suburbs. In a 1994 NRDC-sponsored study of several San Francisco communities, John Holtzclaw found that a doubling of residential density is accompanied by a 20–40% reduction in VMT. Also, Reid Ewing concluded in a 1997 study that when controlling for effects of variables such as income, a doubling of urban densities results in a 25–30% reduction in VMT.

It is important to clarify that when researchers say "doubling," they are usually talking about modest regional or neighborhood averages for density or compactness. Some Americans might think that the only alternative to sprawl is New York City-level density. However, this is not the case. There are a number of alternatives to suburban sprawl, including some models within suburbia. For example, Ed Risse of Synergy Planning estimated in 2001 that if the Washington, DC region were to adopt the suburb of Reston's density of 9 or 10 people per acre, the region would be able to accommodate 25 years of demand for urban development on vacant and underutilized land within a 20-mile radius of Washington's center. Reston is only compact relative to other segments of suburbia: It remains a quiet, leafy community due in part to the 1300 acres of green spaces it has permanently set aside.

Some studies of the impacts of changes in the built environment on travel demand have yielded various results. In a 2001 synthesis of the literature, Reid Ewing and Robert Cervero concluded that travel

TABLE V

Summary of Environmental Protection Agency Findings Predicting Daily Vehicle Miles Traveled (VMT) and CO_2 Reductions in Infill/Redevelopment Building Scenarios

Location	Daily VMT (%).	CO_2 reduction (%)
San Diego, CA	48 (per capita)	45
Montgomery County, MD	58 (per capita)	46
West Palm Beach, FL	61 (per capita)	50
Atlanta, GA	14.5–52	Not calculated

demand is pretty inelastic in the face of individual changes in the built environment, but that there are large cumulative effects, a combination of smart-growth characteristics, such as increases in density, mixing land uses, design changes, and wider regional accessibility of different land uses.

New, sophisticated modeling techniques have demonstrated the effectiveness of such strategies. Several EPA studies utilize four-step travel demand models to show that major reductions in VMT are achievable. These models use information about travel patterns to calculate how many trips will be generated, where trips will be distributed, and how the trips will be split between different transportation modes (i.e., walking, biking, train, and bus) and also to assign the traffic among different routes and times of day. In two studies, the EPA worked with local jurisdictions to choose likely sites for infill/redevelopment and greenfield development and used transportation models to forecast differences in miles traveled. Table V summarizes the findings.

Examining development patterns in the San Francisco, Los Angeles, and Chicago areas, NRDC researchers found strong correlations between density and urban form and VMT. In areas with smart-growth characteristics, such as small lot sizes, transit services, and walkable neighborhoods, residents find it less necessary to drive. This powerful relationship is expressed in Fig. 6.

Also, in EPA-commissioned studies of travel behavior in the Sacramento and Nashville regions, NRDC and Criterion Consultants found that VMT per capita in neighborhoods was lower in urban and older suburban neighborhoods. In Nashville, VMT per capita was 30% lower among suburbanites in an older, more compact suburb as opposed to a newer, more sprawling suburb. In Sacramento, the rate of fuel consumption was as much as 50% lower in an urban community compared to two suburban neighborhoods.

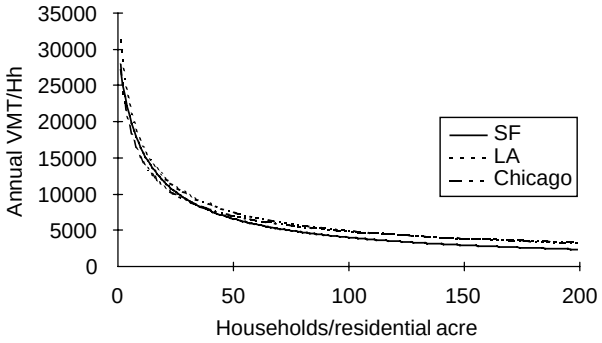

FIGURE 6 Relationship between VMT per household and residential density in the San Francisco (SF), Los Angeles (LA), and Chicago metropolitan areas.

It should be noted that there is great potential for synergy among several nascent market transformations, including smart growth. The combination of green building techniques, cleaner vehicle technologies such as hybrid engines and fuel cells, and changes in development of new suburbs and retrofits of existing communities should yield significant benefits in terms of energy conservation, climate change, and environmental quality.

5.1 The Return of Rail?

When we selected cars and trucks as our vehicles of choice, we shunned another kind of infrastructure—rail, especially intracity rail. Urban streets and even highways took the place of trolley systems that spread like webs through our cities. We had built approximately 45,000 miles of trolley lines by 1915. According to the American Public Transportation Association, we currently have a paltry 3100 miles of light and heavy rail serving our cities. As discussed previously, ridership on public transportation peaked at 23.4 billion trips in 1946 and declined steadily throughout the decades, bottoming out in 1972 at 6.5 billion.

However, there have been considerable increases in recent years and for 5 years in a row in the late 1990s the rate of transit boarding growth actually exceeded the growth rate of driving. The trend during the past 10 years is shown in Fig. 7.

In response to increasing demand, new rail starts have increased in recent years, including some starts in unexpected southern and western cities. As columnist Neal Peirce noted, applications for federal funding for new bus and rail projects leaped from 20 in 1997 to 191 in 1998. The federal program for new transit starts remains popular and hence oversubscribed. Also, the American Public Transportation Association reported that as of 2000, there

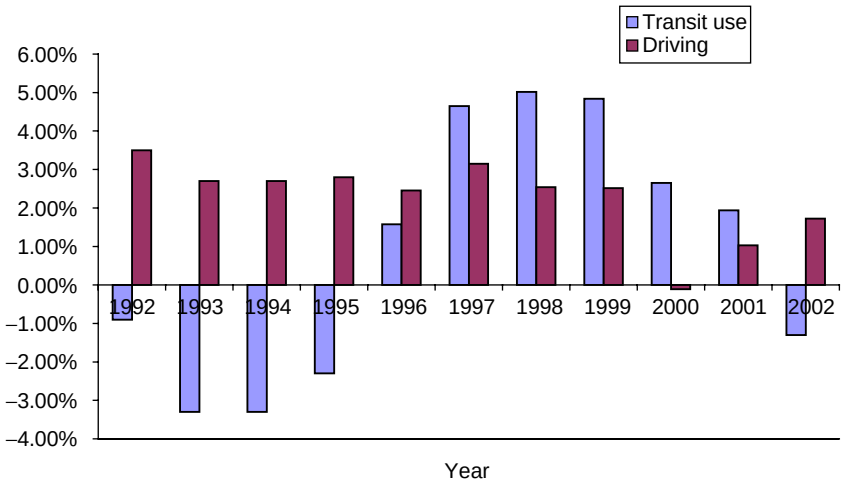

FIGURE 7 Percentage change in the growth of transit use and vehicle miles driven in the United States, 1992–2002. Data originally from the U.S. Department of Transportation and the American Public Transit Association as provided by the Surface Transportation Policy Project.

were approximately 1500 miles of new light rail and heavy rail lines in the proposal, planning, design, or construction phase.

This boom in new rail construction is a nationwide phenomenon. The following are examples from Railway Age's 2001 "Passenger Rail Planner's Guide":

- Charlotte, North Carolina, has completed a major investment study for an 11.5-mile light rail line that will share 2 miles of track with the town's trolley.
- Atlanta's Metropolitan Area Rapid Transit Authority (MARTA) is planning to extend its rail system with a 4.2-mile line, and work has begun on a 47-acre transit-oriented development on MARTA-owned land that will include BellSouth as a tenant.
- The Southwest Ohio Regional Transit Authority and the Transit Authority of Northern Kentucky are studying an 18-mile light rail segment that would connect Covington, Kentucky, and central Cincinnati.
- A 17.4-mile light rail extension in St. Louis was slated to open this year, and an additional 8.8-mile segment is planned.
- The Dallas Area Rapid Transit Authority is constructing two new lines for its successful system, which will more than double the system's current 20 miles.
- The Denver Regional Transportation District recently opened an 8.7-mile extension to its system and is planning another 19-mile line.
- Salt Lake City recently built a 15-mile light rail line that is wildly popular; several extensions are planned or under way.

Many jurisdictions devoting resources to building new transit are outside of America's Rust Belt and in the Sun Belt—the American south and west. Increasing rail investments can help to catalyze transit-oriented smart growth since concentrating development around rail nodes helps ensure their fiscal viability. In fact, the Federal Transit Administration includes land-use criteria when awarding Full Funding Grant Agreements for new transit service. New transit investments throughout the country provide evidence that smart-growth strategies are widely applicable—both for revitalizing northeastern and midwestern cities and older suburbs that have felt sprawl's impacts most keenly and for the rapidly growing southern and western United States.

In summary, the possible comeback of rail transportation in the United States is good news indeed for those concerned about 20th-century changes in development patterns that have transformed suburbanization, transportation, and energy consumption in the United States.

Glossary

astronomical unit (**AU**) The mean distance of the earth from the sun, which is 1.495979 10^8 km.
chromosphere Layer immediately above the photosphere where many strong Fraunhofer lines are in emission at the limb of the disk.
corona The extended upper atmosphere of the sun, normally seen only at the time of a total solar eclipse or from satellites with an occulting device to cover the much brighter white light solar disk; its outer bounds reach beyond the earth as the tenuous heliosphere.
corona hole Region on the solar disk where surface magnetic fields open out to allow particle streaming and subsequent magnetic storms on the earth.
faculae Bright markings on the solar disk especially evident toward the limb; faculae give rise to positive blips in the irradiance time record.
granulation The fine mottling pattern on the white light photosphere of the solar disk.
insolation Energy input to the earth's surface that depends on the geographic latitude, atmospheric absorption, and the like.
irradiance The amount of electromagnetic power that flows across a surface (W/m^2).
limb darkening The dimming of the solar disk toward its edge; it is an indicator of a photospheric temperature gradient that diminishes with height.
photosphere The solar disk in white light; most Fraunhofer lines are formed in the upper photosphere.
radiance The power radiated from a unit area on a planar source into a unit solid angle ($W/steradian/m^2$).
sunspots Dark markings on the solar disk, usually consisting of an umbra and the surrounding less dark penumbra.
transition layer A dynamic, high-temperature layer between the chromosphere and the corona; characterized by emission from ionized lines such as Si IV, C IV, and N V, it clearly displays the structure of magnetic field lines.
ultraviolet (**UV**) Radiation shorter than visible wavelengths between 0.4 and 0.2 μm; extreme ultraviolet (EUV) is < 0.2 μm.

The sun is the primary source of energy on the earth. Most of this energy (99%) is in the form of electromagnetic radiation. Nuclear fusion in the sun's core is the origin of this energy. Space-borne radiometers have allowed the sun's radiation to be measured over the past quarter-century or so, and the result is constant to approximately 0.1%. This article considers these measurement techniques and their limitations. Ultraviolet emissions and particle flows, although relatively minute, are strongly modulated by the sun's 11-year magnetic cycle and produce noticeable effects on the earth's upper atmosphere. The long-term record of the sun's output and its magnetic cycle is indirectly revealed by historic sunspot records and from the geo-sited nuclides of ^{14}C and ^{10}Be. Other solar-type stars suggest other activity cycles that the sun might have exhibited in the past or might develop in the future.

1. SOLAR INTERIOR AND NUCLEAR FUSION

The chemical composition of the sun is 71% hydrogen, 27% helium, and 2% other elements. According to the Big Bang theory of the origin of the universe, only hydrogen and a few light elements were created. The presence of heavier elements, such as Fe, Ca, and Mg, indicates a stellar evolution that

 © 2004 Elsevier Inc. All rights reserved.

includes material processing in the distant past through a supernova explosion.

Physical conditions in the solar interior are such that perfect gas laws apply. Therefore, one can calculate that at the sun's center the density is $\rho = 150\,\text{g/cm}$ and the temperature is $15 \times 10^6\,\text{K}$. At this density and temperature, the proton–proton (p-p) reaction takes place:

$$^1\text{H} + ^1\text{H} \rightarrow ^2\text{D} + \text{e}(+) + \nu \text{ releasing } 1.44\,\text{MeV of energy } (\nu = \text{neutrino}) \quad (1)$$

$$^2\text{D} + ^1\text{H} \rightarrow ^3\text{He} + \gamma\ (5.49\text{MeV}) \quad (\gamma = \text{gamma ray radiation}) \quad (2)$$

$$^3\text{He} + ^3\text{He} \rightarrow ^4\text{He} + (2)^1\text{H}\ (12.86\text{MeV}) \quad (3)$$

Thus, H is burned to produce He, and this is the source of the sun's luminosity ($L = 3.845 \times 10^{26}$ W). The age of the sun, which is approximately the age of the earth, is estimated to be 4.5×10^9 years. In the core, 50% of H has now burned.

Fusion energy generation is confined to the inner third of the solar radius, or $0.3\,\text{R}_\odot$. Energy flows outward by radiation to $0.75\,\text{R}_\odot$, where a convective zone of transport sets in via "giant cells." At the surface, the final convection elements are the white light granulation. Bright granules of observed mean dimension 1.4 seconds of arc (range 0.25–3.50, arcsec) are buoyed to the surface and radiate into space, and the resulting cooled gas (−300 K) descends as dark intergranule lanes (Fig. 1).

It takes approximately 10 years for core radiation (gamma rays or radiation whose wavelength is $< 0.01\,\text{nm}$) to diffuse to the surface and degrade to a cooled gas (effective temperature 5777 K or visible radiation). Currently, core conditions can be sensed from the neutrino flux (in minutes), which verifies the forgoing model of the solar interior. Seismic waves, which pass through the sun in hours, are detected at the surface as small Doppler shifts of the Fraunhofer lines and likewise substantiate the solar model.

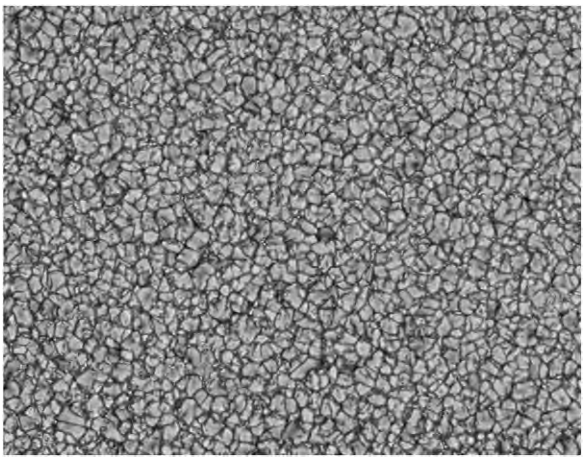

FIGURE 1 White light of solar granulation in a quiet (nonmagnetic) region. (Dutch Open Telescope, La Palma, Canary Islands, October 19, 2001)

2. MAGNETISM AND THE ACTIVITY CYCLE

The sun is a largely passive body. In fact, the sun possesses magnetic fields whose surface manifestation waxes and wanes at approximately 11-year intervals. This introduces the dynamic aspects of the sun. Unlike the earth, with its buried magnetic dipole, the sun's magnetism is observationally a surface phenomenon. Subsurface magnetism must exist, but we know little about it directly. The sun does not rotate as a solid body but rather exhibits differential rotation, with a surface angular rate at the equator greater than that at higher latitudes. Theory proposes that this differential rotation acts as a dynamo to intensify any diffuse magnetism in the sun's convective zone. Once magnetism is concentrated by this dynamo, the associated gas is less dense than nonmagnetic surroundings and is buoyed to the surface, eventually emerging as dark sunspots. Sunspots are dark because convection is inhibited inside them. (It should be noted that subsurface gas is nearly completely ionized, a plasma that is a perfect electrical conductor, and that magnetic fields are "frozen in" and virtually indestructible. A fraction of the sun's magnetism may actually be a relic from when the sun condensed out of the solar nebula.)

Sunspots typically appear in bipolar pairs having field strengths in their dark umbrae of 2000 to 3500 Gauss. It takes only a few days for a large sunspot group to form. Because sunspots are dark, the sun's total radiation diminishes proportional to their area up to 0.1%. Afterward, surface motions "nibble" away at sunspots and carry off the fields by a random walk fashion to create faculae. Faculae have fields of 500 to 1000 Gauss and are relatively bright. Thus, dark sunspots transform to bright faculae that outlive the spots themselves. In this way, over time, sunspots enhance solar luminosity by approximately 0.1%.

Figure 2 is a "magnetogram" of the sun near cycle maximum. On this picture, light areas represent positive (north) fields, and dark areas represent

negative (south) fields. The fragmented fields are cospatial with faculae. Most of the solidly light or dark areas are composed of unresolved faculae. Spots are not distinguishable here but lie within the shaded areas. Compare this figure with Fig. 3, which is the same type of picture at solar minimum. The fragmented fields in Fig. 3 are likewise faculae.

In 1843, Schwabe discovered that the number of spots on the solar disk is cyclic, with an average period of approximately 11 years. The sunspot cycle is synonymous with the magnetic or activity cycle. Besides sunspot number, other "solar indexes" include the number of sunspot groups, 10-cm radio flux, and the strength of certain spectrum lines. Fraunhofer lines, such as NaDl (596 nm) and CN (388 nm), report on the upper photosphere, CaK (393 nm) reports on the chromosphere, He (1083 nm) reports on the chromosphere and corona, and Lyman-α (121 nm) and other highly ionized lines, on the transition layer.

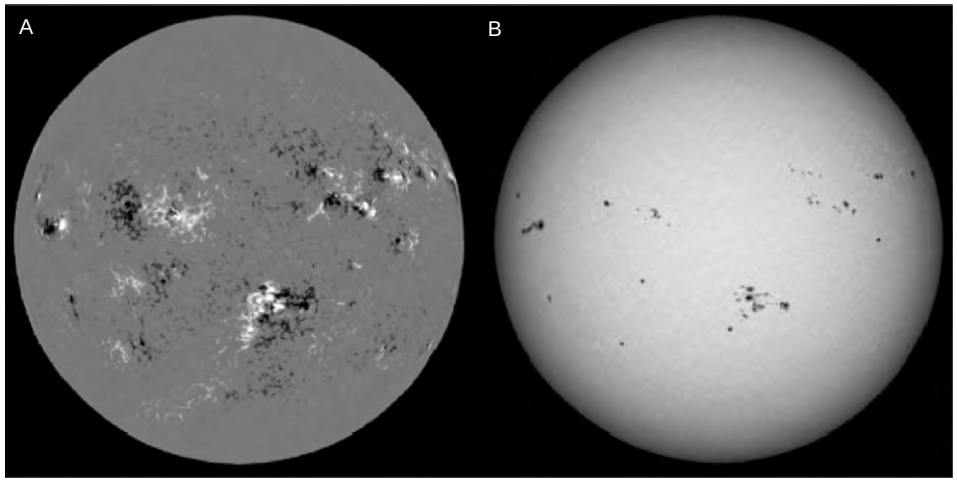

FIGURE 2 (A) A full-disk magnetogram taken near solar maximum on July 20, 2000. This is a computer-drawn picture showing polarization in the Fe (868.8-nm) line. When certain lines are formed in the presence of a magnetic field, Zeeman effect splitting occurs, with the amount being proportional to field strength, and the split components are polarized depending on magnetic polarity. A magnetograph measures these parameters. In the picture, white is north magnetic polarity, and black is south magnetic polarity. The east limb of the sun is on the left. The sun rotates east to west. The northern and southern activity belts are separated by the equator, which spans the middle. (B) A white light image for the same date.

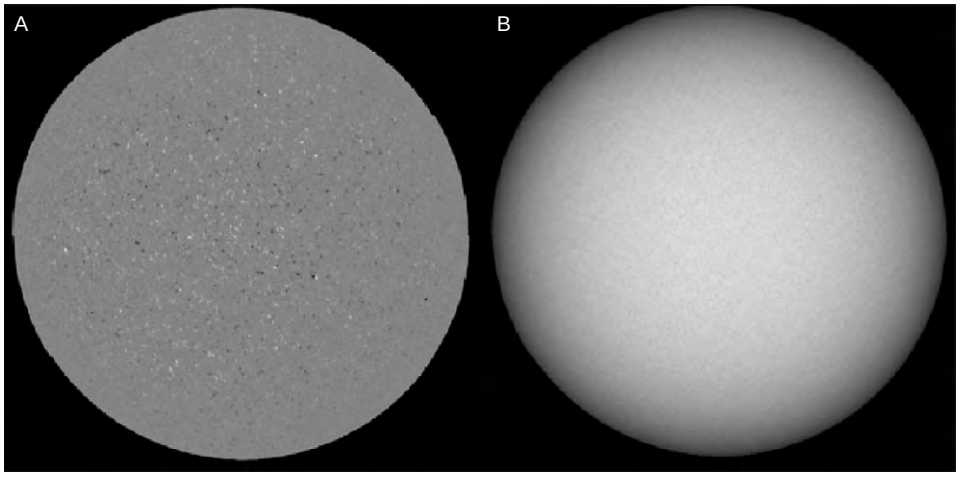

FIGURE 3 (A) A full-disk magnetogram at solar minimum on October 12, 1996. There are no sunspots or active regions at this time. Compared with Fig. 2, the sensitivity is increased to better show the weak magnetic features. These are either old facular remnants or short-lived ephemeral regions. Notice a weak grouping of white (north polarity) regions near the north heliographic pole (top) and of black (south polarity) regions at the south (bottom). These correspond to what is called polar faculae, a phenomenon dependent on the phase of cycle. (B) A white light solar image.

If spectroscopic observations are made in unimaged sunlight, in effect one is observing the sun as a star. Full-disk indexes include spectrum line strengths, or magnetic fields summed over the disk, or simply a number depending on the total count of spots on the disk. Full-disk solar indexes are found to track the activity cycle very well and can serve as surrogates for total solar irradiance (TSI). Particularly if one averages in time, solar indexes give nearly identical-looking signals. Figure 4 compares TSI, sunspot number, chromospheric He (1083 nm), chromospheric CaK, and the magnetic field obtained by averaging, without regard to polarity, the magnetic field over the whole disk. (If one pays attention to polarity, the + north-seeking fields largely cancel out the − south-polarity fields and the field average approaches zero.) Most of the differences seen in Fig. 4 arise from incompleteness of the various index time series owing to observing conditions (weather) or other factors. This means that long-term records, such as sunspot number, allow one to extrapolate recent TSI measurements, which began only in 1978, back to earlier epochs.

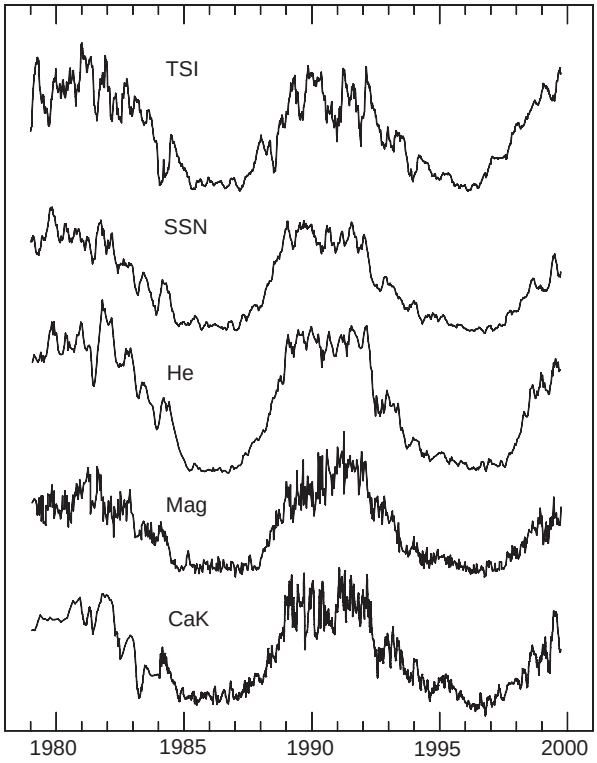

FIGURE 4 Full-disk surrogates for solar activity. TSI, total solar irradiance composite record according to Frohlich and Lean; SSN, international sunspot number; He, helium (1083-nm) line depth; Mag, magnetic field measured with the Vacuum Telescope on Kitt Peak; CaK, calcium K line central intensity measured at Kitt Peak and at Sacramento Peak. A running mean has been applied according to the completeness of the data.

Historic records of sunspot number, since the discovery of sunspots by Galileo, have shown intervals where there are markedly few sunspots. Named after their chroniclers, these epochs are called the Maunder (1645–1715) and the Dalton minima (1790–1820) (Fig. 5). Besides the 11-year Schwabe cycle, there is a weaker 90-year so-called Gleisberg cycle. Other cycles emerge from indirect indexes of radioisotopes, such as ^{10}Be and ^{14}C, in terrestrial reservoirs.

3. TOTAL SOLAR IRRADIANCE

Table I summarizes the energy output of the sun. By far, electromagnetic radiation (light) dominates. This is called TSI, which excludes a minute contribution at radio wavelengths and, due to variable transmission of the earth's atmosphere, must be measured with spacecraft radiometers. Presumably, the neutrino flux does not count because it is not absorbed on earth. The energy distribution by wavelength is given in Table II.

The modern radiometer is a precision device represented by the Active Cavity Radiometer Irradiance Monitor (ACRIM). ACRIM has been placed on-board a succession of satellites around the earth. It consists of a black body cavity into which sunlight is admitted through an exactly known aperture. When a cover is opened, the temperature rise over a time interval is compared with the comparable temperature rise due to electrical heating in an identical but closed comparison cavity. Once corrected for departure of the satellite from 1 AU, precise measurement of this electrical quantity of heat yields the TSI (in W/m^2). Both cavities are connected to heat sinks that periodically dump their accumulated heat.

Errors in TSI are determined by preflight calibration uncertainty and some deterioration of the black cavity due to outgassing and ultraviolet (UV) radiation damage in space. Two systems are always flown, with one being exposed only occasionally. Despite all precautions, it has proved to be difficult to cross-calibrate radiometers with sufficient accuracy. It has been proposed that radiometers be placed on the International Space Station. This would allow periodic recalibrations from the ground. The results from several radiometer experiments are summarized in Fig. 6, where the following is concluded:

- TSI is 1367 W/m^2 $\pm$ 0.1%.
- Accuracy (absolute calibration) is approximately 0.1%.
- Precision (scatter or noise) is 0.01%.

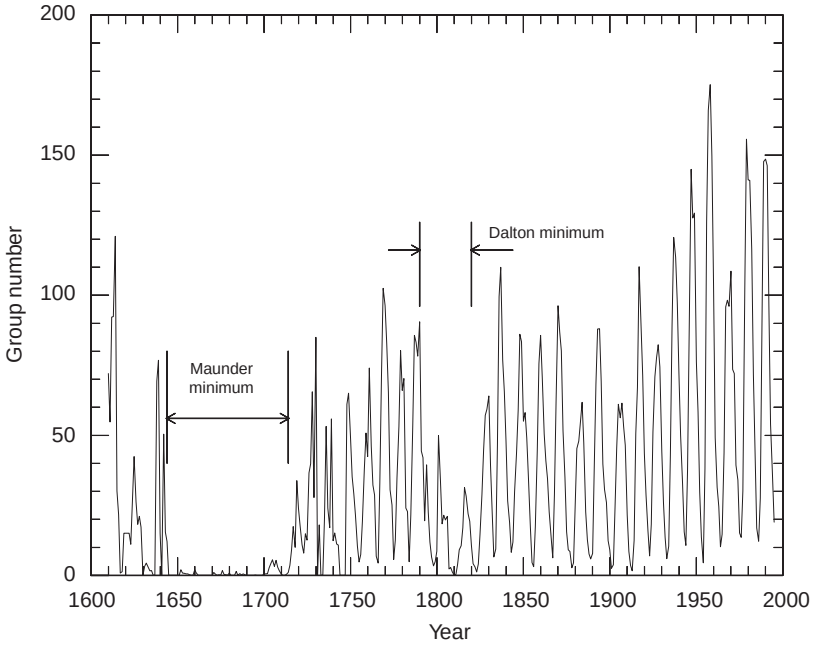

FIGURE 5 Group sunspot numbers clearly displaying the Maunder and Dalton minima.

TABLE I

Total Energy (W/m^2 at 1 AU)

Source	Energy	Activity cycle variation (percentage)
Radiation		
Irradiance	1367.10	0.08
Particle and fields		
Neutrinos	50	50 (?)
Solarwind	10^{-3}	None (?)
Magnetic field	10^{-5}	None (?)

TABLE II

Distribution of Energy (W/m^2 at 1 AU)

Wavelength	Energy	Activity cycle variation (percentage)
4 μm to ∞	0.7	—
300 nm to 4μm	1350	0.08
120 to 300 nm	16	10–50
Lyman-α	3×10^{-3}	100
30 to 120 nm	2×10^{-3}	150
10 to 30 nm	10^{-5}	—

Most of the TSI variance displayed in Fig. 6, within any given experiment, arises not from errors but rather from true solar variability imposed by dark sunspots (-0.1%) and bright faculae ($+0.1\%$). These features are seen on the solar disk in Fig. 7. Both sunspots and faculae are magnetic features; thus, the magnetic activity cycle is revealed. Careful photometry of the solar disk by astronomers at California State University, Northridge, has demonstrated that 90% of the TSI variance can be accounted for by sunspots and faculae. New results from the high-resolution Swedish Telescope indicate that perhaps tiny, not previously seen, faculae may make up part of the remaining 10%.

When experts model the radiometer experiments and attempt to connect the various experiments, two different time series emerge. One, by Claus Frohlich and Judith Lean, is seen in the upper part of Fig. 8. This record displays no trends beyond the activity cycle. The second and lower plot, by Richard C. Willson and Alex Mordvinnov, displays increased irradiance ($+0.04\%$) at the 1995–1996 minimum. Curiously, the latter finds possible supporting evidence from the behavior of Fraunhofer line strengths, as observed with the 1-m Fourier Transform Spectrometer (FTS) at Kitt Peak in Arizona (Fig. 9). Besides the FTS data, David Gray has studied the behavior of the weak temperature-sensitive C (538-nm) line, which is formed at practically the same level as the white light continuum giving rise to the TSI signal. Gray found an increase in

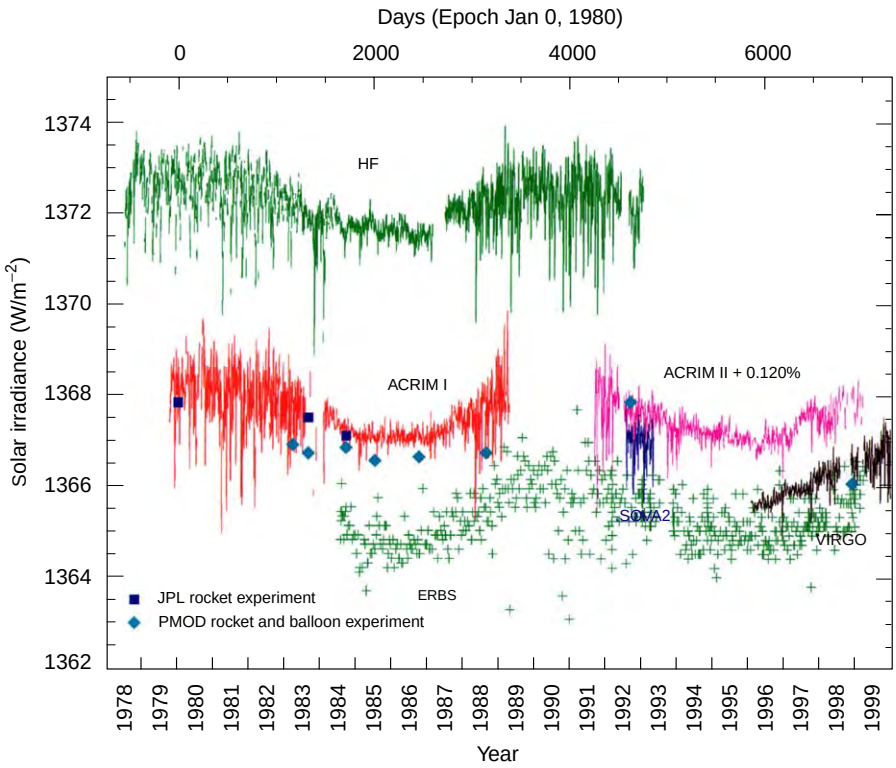

FIGURE 6 Raw total solar irradiance data, uncorrected except for adjustment to 1 AU. HF, Hickey–Frieden experiment on Nimbus 7; ACRIM, Active Cavity Radiation Irradiance Monitor on Solar Max Mission (SMM) and later on Earth Radiation Budget Satellite (ERBS); SOVA2, a solar variability experiment that has flown on several short-term flights; VIRGO, Variability of Solar Irradiance and Gravity Oscillations experiment on the SOHO spacecraft. Results from several rocket and balloon flights are included. The latter offer the advantage of postflight calibrations.

photospheric temperature of 0.014 K/year. These various, and in some ways discordant, results remain open to further study at this time.

A new set of radiometers was launched on the Solar Radiation and Climate Experiment (SORCE) early in 2003. The aim of this experiment is complete coverage of the solar output from X rays to 2.7 μm in the infrared. This data had not been released at the time of this writing. A proposed instrumental advance could be "cryogenic radiometers," but such devices have not yet been tested in space.

One might expect the quiet sun atmosphere to be heated by faculae or perhaps cooled by sunspots. Full-disk magnetograms (i.e., pictures that map the sun's magnetism) look very different at activity maximum from how they look at activity minimum (Figs. 2 and 3). At maximum, much of the solar surface seems to be covered by magnetic fields, but such pictures are misleading for two reasons: insufficient resolution and the fact that the fields expand above the photosphere, where the measurements are made, so as to appear more contiguous than they really are. Recent high-resolution pictures show that fields at the photospheric surface are in fact sparse compared with nonmagnetic surface area. Figure 10, taken in an active region near the disk center and at much higher resolution than either the facular picture in Fig. 6 or the magnetograms, illustrates this. It is not quite a picture in white light; rather, it was taken in the "G-band" (i.e., a narrow blue filter centered at 430.4 nm), which favors the middle photosphere level. This allows one to see faculae at the disk center. The small bright wiggles are really faculae that are cospatial with the magnetic fields on magnetograms. Notice that these faculae largely avoid the granules. Time-series "movies" show that the granules push around the faculae but are otherwise unaffected by them. In other words, magnetic fields thread through the solar surface without any apparent interaction with the gas there. Temperature measurements (using temperature-sensitive spectrum lines) show that the quiet sun gas is in fact the same temperature at solar minimum as at solar maximum. This means the apparent TSI rise at solar maximum represents magnetic features only and not temperature change of the global sun. (The previously cited results of Willson

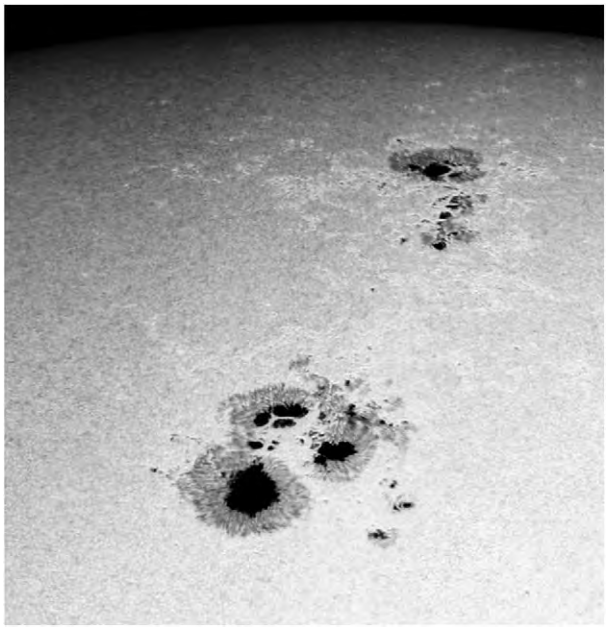

FIGURE 7 Photograph showing apparent sources of TSI variation that are evident near the solar limb. Dark sunspot umbrae, with surrounding fibral penumbrae, suppress radiation. Bright faculae, which are longer lived than sunspots, cause a net rise of TSI. Limb darkening, or the decrease in white light disk intensity as one approaches the limb, is not known to vary with time.

and Mordvinnov, and of Gray, of a temperature rise minute to minute runs counter to this statement, and the matter requires further clarification.)

Theory supports these observational results. One might expect to see a bright ring around a sunspot to balance the energy trapped at the spot umbra. Henk Spruit modeled this condition and found that the energy diffuses into the convective envelope with a time constant of 1 month to 1 year. There is no localized increase in temperature. (Reported bright rings around spots turn out to be indications of abnormal granulation that is pushed around by facular fields.)

If the sun's temperature is constant, maximum to minimum, where does the 0.1% excess energy at solar maximum come from? Eugene Parker, eminent theorist of the "solar wind" and "solar dynamo," concluded that at this time we do not understand the exact physics of a variable-output sun.

Although the sun's radiative output in the UV is very small (Table II), emission lines such as Lyman-α display a large cycle variability and affect the earth's thermosphere. During solar maximum, there can be a threefold increase in the atmospheric density at an altitude of 600 km. This induces noticeable drag to low earth orbit satellites such as the Hubble Space Telescope, so they must be reboosted from time to time.

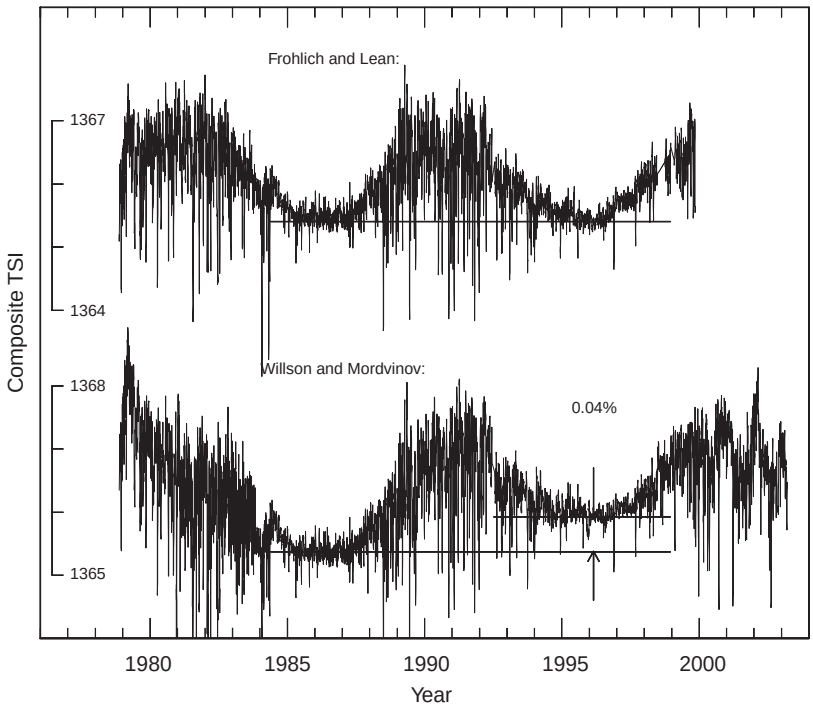

FIGURE 8 Same data as in Fig. 6 modeled in an attempt to provide a composite record capable of showing longer time trends. The Frohlich and Lean result at top shows the activity cycle with no trends. The Willson and Mordvinov construction at bottom displays a 0.04% rise between solar minima in 1985–1987 and 1995–1997.

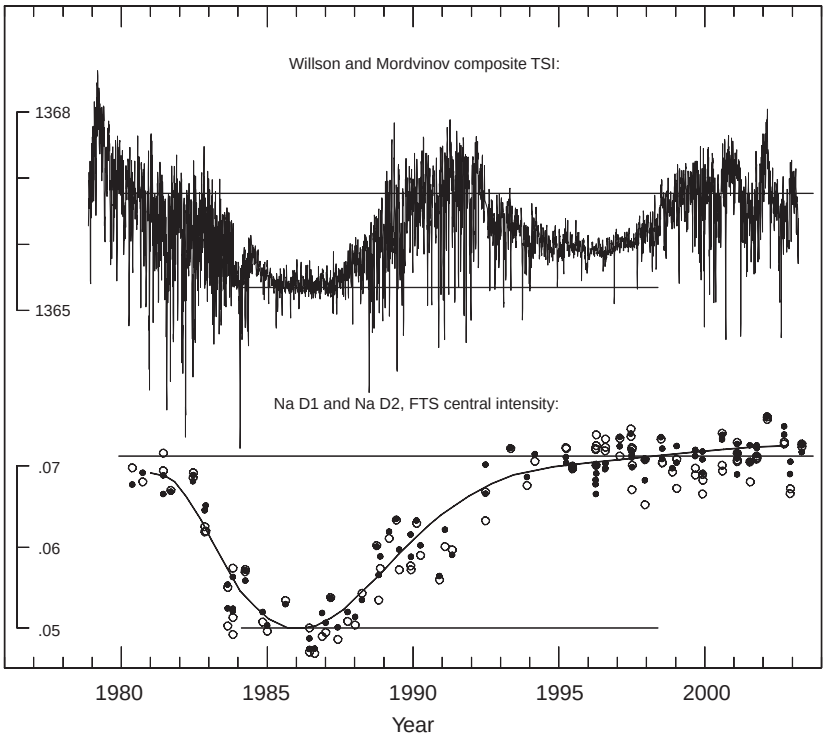

FIGURE 9 Comparison of the Willson and Mordvinov TSI solar minimum rise with the behavior of the Fraunhofer lines formed in the high photosphere. These lines failed to show the 1995–1996 minimum seen clearly in chromospheric lines. Plotted here is the central intensity of the strong sodium D lines. Other strong high photosphere lines, such as Fe and Mg, behave about the same. This indicates a temperature rise in the high photosphere at the 1996 minimum as compared with the 1986 minimum.

4. SOLAR WIND AND PARTICLE FLUX

Charged particles continually spiral outward from the sun to interact with the earth's magnetosphere. This solar wind, which is part of the extended solar atmosphere or heliosphere, traces out an Archimedes spiral path defined by the interplanetary magnetic field. Table III lists the bulk properties of the solar wind. One might expect that the chemical composition of the wind would mimic that of the photosphere, but it does not. Elements whose first ionization potential are below 10 eV are sometimes enhanced by a factor of roughly four. Some sort of selection mechanism takes place, probably in the chromosphere.

Pictures of the upper solar atmosphere, the transition region, indicate that the majority of surface fields are closed bipolar loops. However, surface evolution of magnetism may result in sizable areas where the field lines open out. These areas are called "corona holes" and are the sites of prolonged steady particle flows. When positioned favorably on the disk, coronal holes are identified with geomagnetic storms. Most easily seen in X rays and extreme ultraviolet (EUV) pictures, such as in Fig. 11, corona holes can also be mapped from the ground using the intensity of the He (1083-nm) line.

Besides the solar wind, coronal mass ejections (CMEs) and short-lived chromospheric flares can disturb the earth environment. Figure 12 shows a large CME in progress. The frequency of CMEs varies with the solar cycle, being weekly at solar minimum and increasing to once or twice daily at solar maximum. The fact that CME activity persists at solar minimum (when the TSI is constant) is evidence that there is more to the sun's output than is revealed purely by disk radiometry.

Solar flares are a result of unstable magnetic conditions, usually associated with sunspots. Observationally, a solar flare is seen in the H-α line as a brightness increase that lasts from a few minutes up to an hour. Gamma rays, hard X rays, extreme UV radiation, and microwave radio emission are released, mostly during the "flash phase" that lasts only a few minutes. This electromagnetic radiation reaches the earth at the speed of light in 8

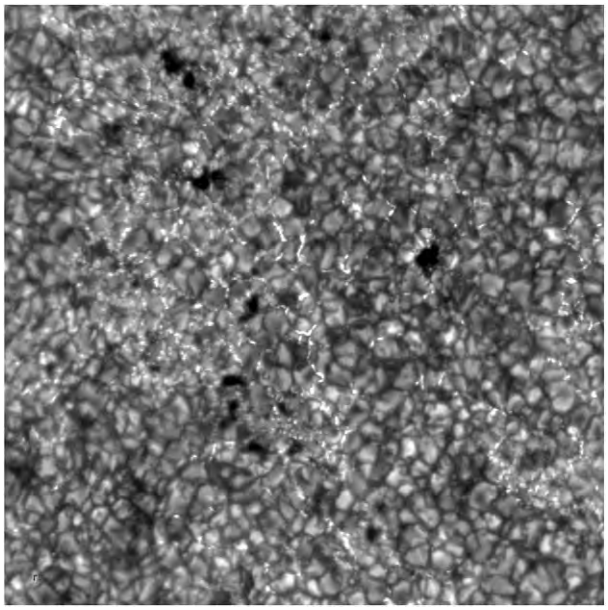

FIGURE 10 High-resolution photograph in an active region near disk center. The mottles are solar granulation similar to that in Fig. 1. Note that some granules are bright and others are not so bright. A granule is surrounded by a dark area (intergranule lane). The tiny dark features are pores, which are small sunspots without penumbrae. The bright squiggles are called filigree and represent the site of nonsunspot fields or faculae. Notice that the filigree favor intergranule lanes. Even though this is part of an active region, the relative area occupied by magnetic fields is small, and the fields thread through the granules with little or no interaction (Swedish Telescope, La Palma, Canary Islands, September 20, 1993).

TABLE III

Bulk Properties of the Solar Wind

	Low speed	High speed	Average
Particle number density N (cm^{-3})	12	4	9
Particle velocity V (km/s)	327	702	468
Particle energy (W/m^2) 2.15×10^{-3}			1.68×10^{-3} 2.05×10^{-3}
Composition (N_α/ Np)	0.038	0.048	0.047
Magnetic field B (y)	—	—	6.2 ± 2.9
Magnetic energy density $B^2/8\pi$ (W/m^2)	—	—	1.7×10^{-13}
Magnetic energy flux $V(B^2/8\pi)$ (W/m^2)	5.6×10^{-6}	12×10^{-6}	8×10^{-6}

min. Particles in the form of protons and alpha particles are also released in abundance, but like solar wind, they are confined to the Archimedes spiral of the interplanetary field and may take a day

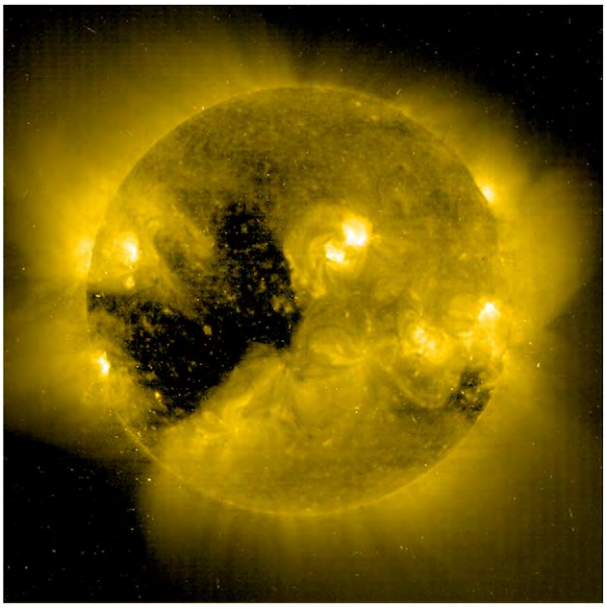

FIGURE 11 A coronal hole clearly displayed in EUV picture from the SOHO satellite on June 24, 2003. The narrow-band filter employed here is centered on Fe XV 284 A. When this hole rotates to the western side of the sun a week later, particles from the hole will spiral out to the earth and cause geomagnetic storms.

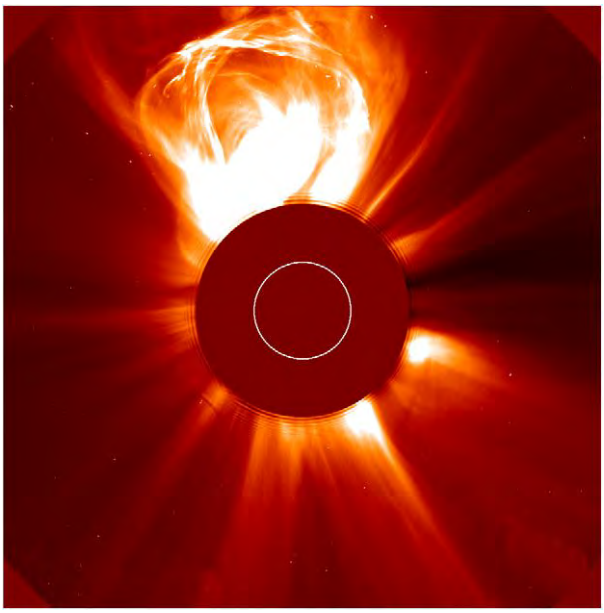

FIGURE 12 Coronal mass ejection (CME) observed on February 17, 2000, in white light by the Large Angle Spectrographic Coronagraph (LASCO) experiment on the SOHO satellite. This eruption is in the plane of the sky and not toward the earth. The solar disk is occulted with the position and size of the actual disk marked. In addition to the CME bubble, one can see the coronal streamers that are typical of solar maximum. The field of view is 6 $R_\odot$.

or more to reach the earth. Because of their spiral path, a flare site 50° west of the meridian on the solar disk is more propitious for producing a terrestrial interaction.

5. ORBITAL MODULATION

Table IV lists geometric factors related to the energy input to the earth. Apart from the 100% modulation of the night/day diurnal cycle, the first item is solar rotation. The sun rotates with a period of 27 days in a sidereal reference frame or 25 days synodic as seen from the earth. Active regions are not distributed uniformly around the sun, and as they transit the visible disk, because of solar rotation, they modulate the TSI ($\pm 0.1\%$), $\pm 1\%$ in the near UV, and $\geq 25\%$ at Lyman-α.

The second item, and a fundamental consideration, is the variable earth–sun distance owing to the earth's elliptical orbit. This induces a 365-day modulation of $\pm 1.7\%$ in apparent TSI. Maximum energy occurs around January 4 (perihelion), whereas minimum energy occurs around July 7 (aphelion). The time of perihelion precesses with a 26,000-year period.

The third effect is more subtle and is caused by the inclination of the sun's equator to the ecliptic, or plane, of the earth's orbit. The inclination is zero on January 5 and June 6. It is a maximum of $+7.2°$ on September 8 and $-7.2°$ on March 7. Its importance depends on the way in which active regions are distributed in latitude over the solar disk.

The fourth item is the Milankovich effect. In 1920, Milankovich, a Yugoslav astronomer, calculated that, owing to planetary perturbations; eccentricity of the earth's orbit varies with a period of approximately 100,000 years, obliquity oscillates with a period of 41,000 years, and the spin axis precesses with a period of 23,000 years. These factors, which are hard to quantify exactly, obviously influence solar insolation and may play a role in producing ice ages.

The fifth item, recently resurrected by astronomer Willie Soon, has to do with the wobble of the sun around the center of mass (barycenter) of the planetary system. In 1965, P. D. Jose pointed out that this motion ranges from 0.01 to $2.19\,R_\odot$, with a period of 178.7 years. Correlations with sunspot numbers (always suspect) have been pointed out, but a physical basis for such a motion affecting sunspots is lacking.

TABLE IV

Geometric Effects

Effect	Period	Modulation amplitude
Solar rotation	27 days	λ-dependent exponential decrease with λ in UV
		1% at λ 300 nm
		25% at λ 120 nm
Earth–sun distance	365 days	$\pm$ 1.7% (maximum on January 2)
		Precesses through the year, with 26,000 year period
Inclination of sun's equator to ecliptic	365 days	$B_0 = 0°$ January 5 and June 6
		$B_0 = -7.2°$ March 7
		$B_0 = +7.2°$ September 8
Milankovich effect	40,400 years	1.2% low latitudes
		2.5% high latitudes
Archimedes spiral	—	Optimum solar long: 50° west of central meridian
		Delay 1 to 4 days
Barycenter motion	178.7 years	?

6. LONG-TERM VARIATIONS IN SOLAR OUTPUT

This section first looks at what stellar evolution theory tells us about the past and future of the sun on cosmic time scales. Then, it examines the sunspot number record for evidence of solar variability in our own lifetimes and somewhat earlier. It extends the record back many millennia, using radioisotopes as tracers of activity cycles. Finally, it inquires about what other solar-type stars say about cycles in general and how this relates to the sun.

When the sun collapsed out of the solar nebulae, gravity was balanced by pressure, and possibly by magnetic fields, until the sun evolved into a stable "main sequence" star some 5×10^9 years ago. Initially, hydrogen burning was confined to the sun's extreme core, and its luminosity was then 70% of its current value. If the sun suddenly assumed this reduced output, the earth would freeze over. There is little or no geological evidence that this has happened in the past, and this early dim sun is considered a puzzle. Presumably the explanation has to do with the composition of the earth's primeval atmosphere, which was completely different from what it is today.

Currently, hydrogen burning in the p-p reaction is confined to within $0.3\,R_\odot$. As hydrogen is further depleted after another 5×10^9 years, hydrogen burning will be confined to a shell of increasing radius and

the sun will expand greatly by a factor of 30, becoming a luminous red giant. Life will no longer be possible on earth. In fact, recent modeling suggests that the earth will become uninhabitable in only 500 million years. After the hydrogen is gone, the sun will contract, burn helium, and eventually end up a white dwarf the size of the earth. That is the big picture.

Of more interest today is solar variability at the current time and in the immediate past. In 1976, Jack Eddy compared the historic sunspot number record with auroral sightings, and with terrestrial reservoirs of ^{14}C time series, to identify the Maunder minimum. Of course, this was pre-ACRIM, but his finding of a correlation between solar and terrestrial events established the validity of the exercise.

Sunspot number archives are by no means of uniform quality over time. Since the international geophysical year (1956–1957), the competition has been keen to observe and report on sunspot numbers. But before that, the efforts were mixed, and during the century following Galileo's telescopic discovery of sunspots, we have little idea how intensively the sun was observed. French astronomers, particularly scientists such as Elizabeth Ribes at Meudon, have searched obscure sources for missing sunspot data. Recently, Doug Hoyt and Ken Schatten found that by plotting sunspot group numbers rather than simply numbers of sunspots, the early record became more complete and possibly more reliable (Fig. 5). However, there is little doubt as to the reality of the Maunder minimum.

The historic sunspot record extends back roughly 400 years, whereas radioisotope tracers can, in principle, yield information on solar activity to 100,000 BP (before present). Following a recent review article by Jürg Beer, this article now examines the past millennia of solar activity using radioisotopes found in tree rings and glacial ice as tracers.

Galactic cosmic rays flow through the solar system continually. So far as is known, this flux of cosmic rays is constant. Galactic cosmic rays are made up of protons (87%), helium nuclei (12%), and heavier elements (1%). Depending on energy, these particles interact with nitrogen and oxygen in the atmosphere to produce ^{14}C and ^{10}Be. Disturbances of the earth's geomagnetic field, and the magnetic field of the heliosphere, scatter cosmic rays and reduce their terrestrial flux. In particular, coronal mass ejections, which are associated with sunspot activity, modulate the flux of the low-energy component of cosmic rays.

Naturally occurring isotopes are ^{12}C and ^{9}Be, whereas the cosmic ray products are the radioisotopes ^{14}C and ^{10}Be. ^{14}C has a lifetime of 5730 years and a cosmic ray production rate in the atmosphere of 2 atoms/cm^2/s. ^{10}Be has a lifetime of 1.5×10^6 years but a production rate of only 2% that of ^{14}C.

After creation, ^{14}C undergoes a rather complex mixing process, being circulated between the atmosphere and oceans before finally being absorbed by the biosphere (e.g., in trees). For this reason, its ability to show the 11-year Schwabe cycle is attenuated by a factor of 100 and tree rings do not show the 11-year cycle. The isotope ratio $^{14}C/^{12}C$ displays up to 10% variation over the past 10,000 years, with little latitude dependence. Long-term trends are thought to be due mostly to slow changes in the geomagnetic field, with a weak but clear solar modulation superimposed to mark the Maunder minimum.

^{10}Be has a much more direct path from its source of origin in the stratosphere until, for example, deposition in snow on a Greenland glacier. Its time resolution is roughly 1 year, so that the Schwabe cycle is nicely revealed. In common with ^{14}C, it is modulated mainly by the geomagnetic field. It shows a decided preference for polar latitudes, whereas ^{14}C is latitude independent. These differences between ^{14}C and ^{10}Be can be used to cancel the dominant signal from geomagnetism and geochemical effects. Anthropogenic change from carbon-burning fuels is a new and disturbing signal during the 19th century.

A spectral analysis by Paul Damon and colleagues of the ^{14}C tree ring records revealed the 88-year Gleissberg cycle. Similar study of ^{10}Be ice core records showed the 11-year Schwabe cycle and a 205-year cycle that is named after De Vries. Both ^{14}C and ^{10}Be records show periods of low activity that are designated Maunder, Spoerer, and Wolf minima. Although dating is a potential problem, ^{10}Be ice cores can trace the Schwabe cycle back 100,000 years.

Finally, this article turns to solar-type stars as a guide to activity cycles and what to expect. The sun is classified as a G2V (i.e., a main sequence dwarf), based mainly on the relative strengths of its spectrum lines. (Astronomers classify stars as O, B, A, F, G, K, or M, based on low dispersion spectra. The series represents a run of temperature, with O being hot stars with He II absorption and M being cool stars with strong molecular TiO bands. Each class is further subdivided by numbered category (1, 2, …9). In addition, there are luminosity classes ranging from I (supergiants) to V (main sequence dwarfs). An experienced observer can immediately classify a star simply by inspection of its spectrum. The photometric color of stars is a rough guide to spectral type and is a handy method when large numbers of stars must be examined. Of course, spectrum study requires spectra.)

During the 1960s, Olin Wilson began a program of intensive observations of the calcium H and K lines in stars judged to be similar to the sun. This was undertaken at Mount Wilson Observatory in Southern California, and many well-known astronomers, notably Sallie Baliunas and Robert Noyes, joined in the effort. The idea was an exciting one. Are there stars out there just like our sun? Of course, there are vast numbers of stars to be considered. The first criterion was blue–visual magnitude (B-V) or color (for the sun, B-V = 0.65), then spectral class as described previously. Finally, there is the question of age gleamed from the spectrum. It is known that activity cycles decline with age. Some idea about activity, and hence age, is inferred from the strength of the calcium H and K lines.

One of the first results of this search was a curious dearth of stars like the sun—solar twins. Even to this day, and after studying hundreds of candidates, no exact twin has been found. At the time of this writing, the closest solar-like star is 18 Scopii, whose spectrum is roughly the same but whose cycle activity has a greater amplitude.

On the positive side, many cycles are found that are comparable to that of the sun. Other stars, which otherwise qualify as to age and spectrum, exhibit little or no cyclic amplitude. It is conjectured that these stars may be in a state comparable to the Maunder minimum. Looking back on the millennia records from ^{14}C, one will notice that the sun has been inactive every few hundred years or roughly one-third of the time. This condition could account for stars without cycles, and it supports the hypothesis that the sun may again become inactive. On the other hand, depending on circumstances at the birth of a star, there may be cases where the nebular condensation had very low angular momentum initially. This would create stars without appreciable activity cycles, that is, stars in a perpetual state of Maunder minimum.

The question of age is a complication circumvented by a scheme devised by Mark Giampapa and Richard Radick. With help from fellow astronomers, they have been observing solar-type stars in the open-cluster M67. The advantage is that all of the stars would be expected to have the same age, thereby eliminating that variable. What has been found so far is that solar-type cycles do dominate but that there seems to be a separate class of extra-strong cycles. This project has been ongoing.

The ^{10}Be archives strongly suggest, from signals of solar-type stars and from solar activity such as CMEs (which continue to bombard the earth even at solar minimum), that there is a lot going on with the sun of which we are currently unaware. Plenty of work exists for future generations of solar physicists.

Glossary

Action Impact Matrix (AIM) A sustainomics tool that helps to identify and analyze economic–environmental–social interactions and to formulate effective sustainable development policies; individual cells in the matrix help to explicitly identify key linkages, focus attention on methods of analyzing important impacts, and suggest action priorities and remedies.

durability An integrative approach focusing primarily on sustaining the quality of life, typically by meeting prudent environmental, social, and economic sustainability requirements; durable development paths permit growth but are not necessarily economically optimal.

economic sustainability Maximizing the flow of income that could be generated while at least maintaining the stock of assets (or capital) that yields these beneficial outputs; economic efficiency continues to ensure both efficient resource allocation in production and efficient consumption choices that maximize utility.

environmental sustainability Preserving the overall viability and normal functioning of natural systems, including improving system health and dynamic ability to adapt to change across a range of spatial and temporal scales; for ecological systems, sustainability is defined by a comprehensive, multiscale, dynamic hierarchical measure of resilience, vigor, and organization.

equity An ethical and people-oriented concept focusing on the basic fairness of both the processes and outcomes of decision making, including the distribution of economic, social, and environmental assets and entitlements.

optimality An approach used in economic analysis to generally maximize (or minimize) a single objective such as welfare (or costs), subject to the requirement that the stock of productive assets (or welfare itself) is non-decreasing in the long term.

social sustainability Preserving the overall viability and normal functioning of social systems.

sustainable development A process for improving the range of opportunities that will enable individual humans and communities to achieve their aspirations and full potential over a sustained period of time while maintaining the resilience of economic, social, and environmental systems.

sustainable energy development The harnessing of energy resources for human use in a manner that supports lasting development.

sustainomics A transdisciplinary, integrative, comprehensive, balanced, heuristic, and practical meta-framework for making development more sustainable.

Following the 1992 Earth Summit in Rio de Janeiro, Brazil, including the adoption of the United Nations' Agenda 21, and the 2002 World Summit on Sustainable Development in Johannesburg, South Africa, sustainable development has become well accepted worldwide. World decision makers are looking at this approach to solve many critical problems, including traditional development issues (e.g., energy use, economic stagnation, poverty, hunger, illness) as well as newer challenges (e.g., environmental degradation, globalization).

1. BASIC FRAMEWORK

Sustainable energy development involves the harnessing of energy resources for human use in a manner

 © 2004 Elsevier Inc. All rights reserved.

that supports lasting development. This article begins with a review of sustainable development itself before describing its application to energy. The World Commission on Environment and Development originally defined it as "development which meets the needs of the present without compromising the ability of future generations to meet their own needs." Among many subsequent definitions, the sustainable development triangle in Fig. 1A shows one widely accepted concept proposed by Munasinghe at the 1992 Earth Summit in Rio de Janeiro, Brazil. It encompasses three major perspectives: economic, social, and environmental. Each viewpoint corresponds to a domain (and system) that has its own distinct driving forces and objectives. The economy is geared toward improving human welfare, primarily through increases in consumption of goods and services. The environmental domain focuses on protecting the integrity and resilience of ecological systems. The social domain emphasizes enriching human relationships, achieving individual and group aspirations, and strengthening values and institutions.

Meanwhile, energy has emerged as a key resource that interacts critically with the economic, social, and environmental dimensions of sustainable development. First, it has long been perceived as a major driving force underlying economic progress, and in turn, economic growth itself further stimulates energy demand. Second, energy production and use are strongly interlinked with the environment. Third, energy is a basic human need that significantly affects social well-being. Recently, growing energy demand has also become associated with global climate change, posing an unprecedented challenge to humanity. The wide-ranging potential impacts of energy production and consumption on sustainable development, and vice versa, are reviewed in this article.

Given the lack of a specific approach or practical framework that attempts to define, analyze, and implement sustainable development, Munasinghe proposed the term "sustainomics" to describe "a transdisciplinary, integrative, comprehensive, balanced, heuristic, and practical meta-framework for making development more sustainable." Figure 1B indicates how the sustainomics framework (or the emerging "science of sustainable development"), as well as the associated transdisciplinary knowledge base, would support a comprehensive and balanced assessment of trade-offs and synergies that might exist among the economic, social, and environmental dimensions of sustainable development. Balance is also needed in the relative emphasis placed on traditional development (which is more appealing to the South) versus sustainability (which is emphasized by the North). The optimality and durability approaches (described later) play a key role in integrating economic, social, and environmental issues. Many disciplines contribute to the sustainomics framework given that sustainable development itself involves every aspect of human activity, including complex interactions among socioeconomic, ecological, and physical systems.

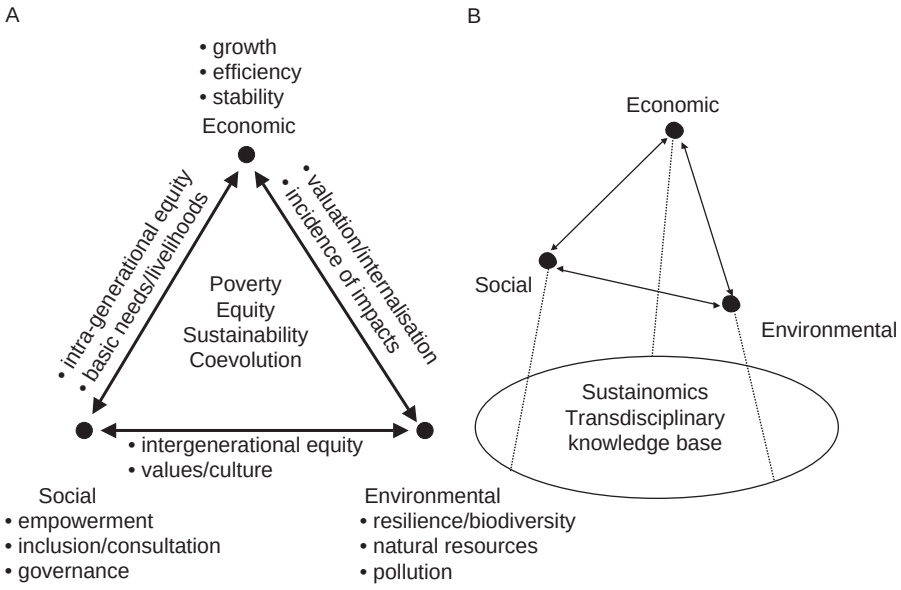

FIGURE 1 (A) Elements of sustainable development. (B) Sustainable development triangle supported by the sustainomics framework. Adapted from Munasinghe (1992).

Historically, the development of the industrialized world has focused on material production. Not surprisingly, most industrialized and developing nations pursued the economic goal of increasing output and growth during the 20th century. Thus, traditional development was strongly associated with economic growth as well as with important social dimensions (poverty and equity are discussed later). By the early 1960s, the lack of "trickle down" benefits to the growing numbers of poor in developing countries resulted in greater efforts to improve income distribution directly. The development paradigm shifted toward equitable growth, where social (distributional) objectives, especially poverty alleviation, were recognized to be as important as economic efficiency. Protection of the environment has now become the third major pillar of sustainable development. By the early 1980s, a large body of evidence had accumulated that environmental degradation was a major barrier to development, and new proactive safeguards were introduced (e.g., the environmental assessments).

In the sustainomics framework, sustainable development is described as a process for improving the range of opportunities that will enable individual humans and communities to achieve their aspirations and full potential over a sustained period of time while maintaining the resilience of economic, social, and environmental systems. Thus, sustainable development requires both increases in adaptive capacity and opportunities for improving economic, social, and ecological systems. Improving adaptive capacity increases resilience and sustainability. Expanding the set of opportunities for improvement gives rise to development. Heuristic behavior of individual organisms and systems facilitates learning, the testing of new processes, adaptation, and improvement.

The precise definition and implementation of sustainable development remains an ideal, elusive, and perhaps unreachable goal. Sustainomics proposes a less ambitious, but more focused and feasible, strategy that merely seeks to "make development more sustainable." Such an incremental (or gradient-based) method is more practical because many unsustainable activities are easier to recognize and eliminate. This approach seeks continuing improvements in the current quality of life at a lower intensity of resource use, thereby leaving behind for future generations an undiminished stock of productive assets (e.g., manufactured, natural, and social capital) that will enhance opportunities for improving their quality of life.

2. ELEMENTS OF SUSTAINABLE DEVELOPMENT

2.1 Economic Aspects

Economic progress is often evaluated in terms of welfare (or utility), measured as willingness to pay for goods and services consumed. Thus, many economic policies typically seek to enhance income and induce more efficient production and consumption of (mainly marketed) goods and services. The stability of prices and employment are among other important objectives.

Economic efficiency is measured against the ideal of Pareto optimality, which encourages actions that will improve the welfare of at least one individual without worsening the situation of anyone else. The idealized, perfectly competitive economy is an important (Pareto optimal) benchmark, where (efficient) market prices play a key role in both allocating productive resources to maximize output and ensuring optimal consumption choices that maximize consumer utility. If significant economic distortions are present, appropriate shadow prices need to be used. The well-known cost–benefit criterion accepts all projects whose net benefits are positive (i.e., aggregate benefits exceed costs). It is based on the weaker "quasi"-Pareto condition, which assumes that such net benefits could be redistributed from potential gainers to losers, leaving no one worse off than before. In more general terms, interpersonal comparisons of welfare are fraught with difficulty, both within and across nations and over time (e.g., the value of human life).

Based on the pioneering work of Lindahl and Hicks, the modern concept underlying economic sustainability seeks to maximize the flow of income that could be generated while at least maintaining the stock of assets (or capital) that yields these beneficial outputs. Economic efficiency continues to ensure both efficient resource allocation in production and efficient consumption choices that maximize utility. Problems arise in identifying the kinds of capital to be maintained (e.g., manufactured, natural, human, and social capital) and their substitutability. Often, it is difficult to value these assets and the services they provide, particularly for ecological and social resources. Even key economic assets may be overlooked, especially in informal or subsistence economies where non-market-based transactions are important. Meanwhile, the equation of welfare with monetary income and consumption has been challenged for many years. More recently, Maslow and

others have identified hierarchies of needs that provide psychic satisfaction beyond mere goods and services.

The issues of uncertainty, irreversibility, and catastrophic collapse pose additional difficulties in determining dynamically efficient development paths. Many commonly used microeconomic approaches rely on marginal analysis (e.g., comparing incremental costs and benefits of economic activities). Such methods assume smoothly changing variables and, therefore, are rather inappropriate for analyzing large changes, discontinuous phenomena, and sudden transitions among multiple equilibria. Recent work has begun to explore the behavior of large, nonlinear, dynamic, and chaotic systems and concepts such as system vulnerability and resilience.

2.2 Environmental Aspects

Development in the environmental sense is a recent concern relating to the need to manage scarce natural resources in a prudent manner because human welfare ultimately depends on ecological services. Ignoring safe ecological limits could undermine long-run prospects for development. The growing literature on the theme of environment and sustainable development includes books by Faucheux and colleagues, describing models of sustainable development, and Munasinghe and colleagues, explicitly addressing the links between growth and environment

The environmental interpretation of sustainability focuses on overall viability and normal functioning of natural systems. For ecological systems, sustainability is defined by a comprehensive, multiscale, dynamic hierarchical measure of resilience, vigor, and organization. In 1973, Holling defined resilience as the ability of an ecosystem to persist despite external shocks, that is, the amount of disruption that will cause the ecosystem to switch from one system state to another. An ecosystem state is defined by its internal structure and set of mutually reinforcing processes. Vigor is associated with the primary productivity or growth of an ecosystem. Organization depends on both complexity and structure of the system. For example, a multicellular organism such as a human is more highly organized than a single-celled amoeba. Higher states of organization imply lower levels of entropy. Thus, the second law of thermodynamics requires that sustainability of complex organisms and systems depends on the use of low-entropy energy derived from their environment that is returned as (less useful) high-entropy energy. The ultimate source of this energy is solar radiation.

In this context, natural resource degradation, pollution, and loss of biodiversity are detrimental because they increase vulnerability, undermine system health, and reduce resilience. The notions of a safe threshold and carrying capacity are important, often to avoid catastrophic ecosystem collapse. It is useful to also think of sustainability in terms of the normal functioning and longevity of a nested hierarchy of ecological and socioeconomic systems ordered according to scale; for example, a human community would consist of many individuals who are themselves composed of a large number of discrete cells. Gunderson and Holling used the term "panarchy" to denote such a hierarchy of systems and their adaptive cycles across scales. A system at a given level is able to operate in its stable (sustainable) mode because it is protected by slower and more conservative changes in the supersystem above it while being simultaneously invigorated and energized by faster changes taking place in subsystems below it.

Sustainable development is not necessarily synonymous with maintaining the ecological status quo. A coupled ecological–socioeconomic system could evolve while maintaining levels of biodiversity that guarantee resilience of ecosystems on which future human consumption and production depend.

2.3 Social Aspects

Social development usually refers to improvements in both individual well-being and the overall welfare of society resulting from increases in social capital, typically the accumulation of capacity enabling individuals and communities to work together. The institutional component of social capital involves formal laws as well as traditional or informal understandings that govern behavior, whereas the organizational component is embodied in individuals and communities operating within these institutional arrangements. The quantity and quality of social interactions underlying human existence (including levels of mutual trust and shared social norms) help to determine the stock of social capital. Thus, social capital grows with greater use and erodes through disuse, unlike economic and environmental capital, which are depreciated or depleted by use. Furthermore, some forms of social capital may be harmful (e.g., cooperation within criminal gangs).

There is also an important element of equity and poverty alleviation. Thus, the social dimension of development includes protective strategies that reduce vulnerability, improve equity, and ensure that basic needs are met. Future social development will

require sociopolitical institutions that can adapt to meet the challenges of globalization. The latter often destroys traditional coping mechanisms that have evolved in the past (especially to protect disadvantaged groups).

Social sustainability parallels environmental sustainability because human settlements, such as cities and villages, are also habitats. Reducing vulnerability and maintaining the health (e.g., resilience, vigor, organization) of sociocultural systems and their ability to withstand shocks are also important. Enhancing human capital (through education) and strengthening social values, institutions, and governance are key aspects. Many harmful changes occur slowly, and their long-term effects are often overlooked in socioeconomic analysis. Preserving cultural capital and diversity worldwide, strengthening social cohesion, and reducing destructive conflicts are integral elements of this approach. An important aspect involves empowerment and broader participation through subsidiarity, that is, decentralization of decision making to the lowest (or most local) level at which it is still effective. In summary, for both ecological and socioeconomic systems, the emphasis is on improving system health and its dynamic ability to adapt to change across a range of spatial and temporal scales rather than on conserving some "ideal" static state.

2.4 Poverty and Equity

Poverty and equity are two important issues that have social, economic, and environmental dimensions (Fig. 1A). More than 2.8 billion people (nearly half of the global population) live on less than U.S. $2 per day, and 1.2 billion barely survive on less than U.S. $1 per day. The top 20 percentile of the world's population consumes approximately 83% of total output, whereas the bottom 20 percentile consumes only 1.4%. Income disparities are worsening; the per capita ratio between the richest and the poorest 20 percentile groups was 30 to 1 in 1960 and increased to more than 80 to 1 by 1995.

Equity is an ethical and usually people-oriented concept with primarily social, and some economic and environmental, dimensions. It focuses on the basic fairness of both the processes and outcomes of decision making. The equity of any action may be assessed in terms of a number of generic approaches, including parity, proportionality, priority, utilitarianism, and Rawlsian distributive justice. Societies normally seek to achieve equity by balancing and combining several of these criteria.

Poverty alleviation, improved income distribution, and intragenerational (or spatial) equity are key aspects of economic policies seeking to increase overall human welfare. Broadly speaking, economic efficiency provides guidance on producing and consuming goods and services more efficiently but is unable to provide a means of choosing (from a social perspective) among alternative patterns of consumption that are efficient. Equity principles provide better tools for making judgments about such choices.

Social equity is also linked to sustainability because grossly unfair distributions of income and social benefits are unlikely to be lasting in the long run. Equity will be strengthened by enhancing pluralism and grassroots participation in decision making and by empowering disadvantaged groups. In the long term, intergenerational equity is vital, where the economic discount rate plays a key role with respect to both equity and efficiency aspects. The sustainomics framework outlines methods of reconciling potential conflicts between equity and economic efficiency.

Equity in the environmental sense has received recent attention due to disproportionately greater environmental damages suffered by poor groups. Thus, poverty alleviation efforts are being broadened (beyond raising monetary incomes) to address the degraded environmental and social conditions facing the poor.

In summary, both equity and poverty have not only economic but also social and environmental dimensions; therefore, they need to be assessed using a comprehensive set of indicators (rather than income distribution alone). From an economic policy perspective, emphasis needs to be placed on expanding employment and gainful opportunities for poor people through growth, improving access to markets, and increasing both assets and education. Social policies would focus on empowerment and inclusion by making institutions more responsive to the poor and removing barriers that exclude disadvantaged groups. Environmentally related measures to help poor people might seek to reduce their vulnerability to disasters, crop failures, loss of employment, sickness, economic shocks, and so on. Thus, an important objective of poverty alleviation is to provide poor people with assets (e.g., social, natural, economic) that will reduce their vulnerability. Such assets increase the capacity for both short-run coping and longer run adaptation to external shocks. The forgoing ideas blend with the sustainable livelihoods approach, which focuses on access to portfolios of

assets, capacity to withstand shocks, gainful employment, and social processes.

An even broader nonanthropocentric approach to equity involves the concept of fairness in the treatment of nonhuman forms of life or even inanimate nature. One view asserts that humans have the responsibility of prudent "stewardship" over nature, and this goes beyond mere rights of usage.

2.5 Consistent Integration of Economic, Social, and Environmental Considerations

This subsection compares the concepts of ecological, social, and economic sustainability. Maintaining the set of opportunities, as opposed to preserving value of the asset base, is important. The preservation of biodiversity maintains options and allows the system to retain resilience by protecting it from external shocks, in the same manner that preservation of the capital stock protects economic assets for future consumption. Differences emerge because under the Hicks–Lindahl income measure, a society that consumes its fixed capital without replacement is not sustainable, whereas using an ecological approach, loss of resilience implies a reduction in the self-organization of the system but not necessarily a loss in productivity. In the case of social systems, resilience depends on the capacity of human societies to adapt and continue functioning in the face of stress and shocks. Thus, linkages between sociocultural and ecological sustainability emerge through the organizational similarities between human societies and ecological systems and the parallels between biodiversity and cultural diversity. In the longer term, the concept of coevolution of social, economic, and ecological systems within a larger, more complex adaptive system provides useful insights regarding harmonious integration of the various elements of sustainable development (Fig. 1A).

It is important to integrate and reconcile the economic, social, and environmental aspects within a holistic and balanced sustainable development framework. Economic analysis has a special role in contemporary national policymaking because some of the most important decisions fall within the economic domain. Although mainstream economics that is used for practical policymaking has often ignored many crucial aspects of the environmental and social dimensions of sustainable development, there is a small but growing body of literature that seeks to address such shortcomings.

Two broad approaches, based on the concepts of optimality and durability, are relevant for integrating the economic, social, and environmental dimensions of sustainable development. Although there are overlaps between the two approaches, the main thrust is somewhat different in each case. Uncertainty often plays a key role in determining which approach would be preferred. For example, relatively steady and well-ordered conditions may encourage optimizing behavior by planners attempting to control and even fine-tune outcomes, whereas subsistence farmers facing chaotic and unpredictable circumstances might opt for more durable responses that simply enhance survival prospects.

2.6 Optimality

The optimality-based approach has been widely used in economic analysis to generally maximize welfare (or utility), subject to the requirement that the stock of productive assets (or welfare itself) is nondecreasing in the long term. This assumption is common to most sustainable economic growth models. The essence of the approach is illustrated by the simple example of maximization of the flow of aggregate welfare (W), cumulatively discounted over infinite time (t), as represented by the following expression:

$$\max \int_0^\infty W(C,Z).e^{-rt}\mathrm{d}t.$$

Here, W is a function of C (consumption) and Z (set of other relevant variables), whereas r is the discount rate. Further side constraints may be imposed to satisfy sustainability needs (e.g., nondecreasing stocks of productive assets). One typical application of optimization involves electric generation expansion planning, where analysts seek to minimize the present discounted costs of generation to meet the desired demand forecast over several decades at a given level of reliability.

Some ecological models also optimize variables related to system vigor such as energy use, nutrient flow, and biomass production. In economic models, utility is often measured in terms of net benefits of economic activities, that is, the benefits of development activities minus corresponding costs. More sophisticated economic optimization approaches include environmental and social variables (by attempting to value environmental externalities, system resilience, etc.). However, given the difficulties of quantifying and valuing many such "noneconomic" assets, the costs and benefits associated with market-based activities tend to dominate in most economic optimization models.

Basically, the optimal growth path maximizes economic output, whereas the sustainability requirement is met by ensuring nondecreasing stocks of assets. Some analysts support a "strong sustainability" constraint, which requires separate preservation of each category of critical asset (e.g., manufactured, natural, sociocultural, and human capital), assuming that they are complements rather than substitutes. Other researchers have argued in favor of "weak sustainability," which seeks to maintain the aggregate monetary value of the total stock of assets, assuming that various asset types are substitutes and may be valued.

Side constraints are often necessary because the optimization approach (including economic efficiency and valuation) might not be easily applied to ecological objectives, such as protecting biodiversity and improving resilience, or to social goals, such as promoting equity and empowerment. Such environmental and social variables cannot be easily incorporated within a single valued objective function based on cost–benefit analysis. Thus, techniques such as multicriteria analysis (MCA) may be required to facilitate trade-offs among noncommensurable variables. Moreover, the lagged price system might not anticipate irreversible environmental and social harm and nonlinear system responses that could lead to catastrophic collapse. Therefore, noneconomic indicators of environmental and social status would be helpful. The constraints on critical environmental and social indicators are proxies representing safe thresholds that help to maintain the viability of those systems. Risk and uncertainty will also necessitate the use of decision analysis tools.

2.7 Durability

The second broad integrative approach focuses primarily on sustaining the quality of life, for example, by satisfying environmental, social, and economic sustainability requirements. Such a framework favors "durable" development paths that permit growth but are not necessarily economically optimal. There is more willingness to trade off some economic optimality for the sake of greater safety (i.e., risk aversion) to stay within critical environmental, social, and technical limits. The durability approach would facilitate the design of energy systems that are more resilient and less vulnerable to disruptive shocks.

Economic system durability might require consumption levels to be maintained, that is, per capita consumption that never falls below some minimum level or is nondeclining. The environmental and social sustainability requirements may be expressed in terms of indicators of "state" that monitor the durability or normal functioning of complex ecological, social, and technoeconomic systems. For example, consider an electric power system where durability may be represented by various indexes of system reliability (e.g., loss of load probability [LOLP], frequency and duration of outages [F&D]) and system stability (especially transmission and distribution systems) in relation to external shocks (e.g., storms) that might cause the breakdown of critical system components (e.g., generators, lines).

There is the likelihood of further interaction here due to linkages among the sustainability of social, ecological, and technoeconomic systems; for example, social disruption and conflict could exacerbate damage to both ecological and technoeconomic systems and vice versa. In fact, long-standing social norms in many traditional societies have helped to protect the environment.

Durability encourages a holistic systemic viewpoint, and this is important in sustainomics analysis. The self-organizing and internal structure of complex systems often makes "the whole more durable (and valuable) than the sum of the parts." A narrow definition of efficiency based on marginal analysis of individual components may be misleading. For example, it is more difficult to value the integrated functional diversity in a forest ecosystem than to value the individual species of trees and animals. Therefore, the former is more likely to fall victim to market failure (as an externality). Furthermore, even where correct environmental shadow prices prevail, some analysts point out that cost minimization could lead to homogenization and consequent reductions in system diversity. Systems analysis also helps to identify the benefits of cooperative structures and behavior that a more partial analysis might neglect.

The possibility of many durable paths favors simulation-based methods, including consideration of alternative futures (rather than one optimal result). This approach parallels research on integrating human actors into ecological models, including multiple-agent modeling to account for heterogeneous behavior, bounded rationality leading to different perceptions and biases, and social interactions involving imitation, reciprocity, and comparison.

In the durability approach, maintaining asset stocks enhances system sustainability because various forms of capital are a bulwark that decreases vulnerability to external shocks and reduces irreversible harm rather than merely producing more

economic outputs. System vulnerability, resilience, vigor, organization, and ability to adapt will depend dynamically on the capital endowment as well as on the magnitude and rate of change of a shock; for example, in the case of an electric power system, vulnerability and risk of failure depend on the traditional reserve margin (supply minus demand) as well as on the probability of breakdown of key system components or stochastic surges in demand.

2.8 Indicators

Because asset stocks are important to both the optimal and durable approaches, the practical implementation of sustainomics principles will require the identification of relevant economic, social, and environmental indicators at various levels of aggregation ranging from the global/macro to the local/micro. Indicators must be comprehensive in scope, must be multidimensional in nature (where appropriate), and must account for spatial differences.

Measuring economic, environmental, human, and social capital also raises various problems. Manufactured capital may be estimated using conventional neoclassical economic analysis. Market prices are useful when economic distortions are relatively low, whereas shadow prices could be applied in cases where market prices are unreliable. Natural capital needs to be quantified first in terms of key physical attributes. Typically, damage to natural capital may be assessed by the level of air pollution (e.g., concentrations of suspended particulates, sulfur dioxide, greenhouse gases [GHGs]), water pollution (e.g., biochemical oxygen demand [BOD], chemical oxygen demand [COD]), and land degradation (e.g., soil erosion, deforestation). Then this physical damage could be valued using environmental and resource economics techniques. Human resource stocks are often measured by educational levels, productivity, and earning potential. Social capital is more difficult to assess. Putnam described it as "horizontal associations" among people or social networks and associated behavioral norms and values that affect the productivity of communities. Social capital may be viewed more broadly in terms of social structures that facilitate the activities of agents in society, including both horizontal and vertical associations (e.g., firms). An even wider definition is implied by the institutional approach that includes not only the mainly informal relationships implied by the earlier two views but also more formal frameworks provided by governments, political systems, and legal provisions. Recent work has sought to distinguish between social capital and political capital, that is, the networks of power and influence that link individuals and communities to the higher levels of decision making.

2.9 Complementarity and Convergence of Optimal and Durable Approaches

The two approaches are often complementary in national economic management. For example, economy-wide policies involving both fiscal and monetary measures (e.g., taxes, subsidies, interest, foreign exchange rates) might be optimized using quantitative macroeconomic models. Nevertheless, decision makers inevitably modify these economically "optimal" policies before implementing them to take into account other durable sociopolitical considerations (e.g., poverty alleviation, regional factors) that facilitate governance and stability. The determination of an appropriate target trajectory for future global GHG emissions provides another useful illustration of the interplay between durability and optimality.

In practice, the two approaches point to convergent solutions. First, wastes ought to be generated at rates within the assimilative capacity of the environment. Second, scarce renewable resources should be used at rates compatible with the natural rate of regeneration. Third, nonrenewable resource use rates should depend on the substitutability between these resources and technological progress. Both wastes and natural resource inputs might be minimized by moving from linear throughput to closed loop (or recycling) mode. Finally, inter- and intragenerational equity (especially poverty alleviation), pluralistic and consultative decision making, and enhanced social values and institutions are important additional aspects.

GHG mitigation provides an interesting example of how such an integrative framework could help to incorporate climate change policies within a national sustainable development strategy. The total GHG emissions rate (G) may be decomposed as follows:

$$G = (Q/P) \times (Y/Q) \times (G/Y) \times P,$$

where (Q/P) is quality of life per capita, (Y/Q) is material consumption required per unit of quality of life, (G/Y) is GHG emissions per unit of consumption, and P is population. A high quality of life is consistent with low total GHG emissions, provided that each of the three terms on the right-hand side could be minimized. Reducing (Y/Q) implies "social decoupling" (or "dematerialization"), whereby satisfaction becomes less dependent on material

consumption through changes in tastes, behaviors, and social values. Similarly, (*G*/*Y*) may be reduced by "technological decoupling" (or "decarbonization") that reduces the intensity of GHG emissions in consumption and production. Finally, population growth could be reduced, especially where emissions per capita are already high. The linkages between social and technological decoupling need to be explored. For example, changes in public perceptions and tastes could affect the directions of energy technology and influence the effectiveness of mitigation and adaptation policies.

Climate change researchers are currently exploring the application of large and complex integrated assessment models (IAMs). IAMs include coupled submodels representing various ecological, geophysical, and socioeconomic systems where there is scope to apply the optimality and durability approaches consistently.

2.10 Tools for Sustainable Development Analysis and Assessment

Some important tools for sustainable development analysis and assessment include the Action Impact Matrix (AIM) for prioritizing the economic, environmental, and social interactions of various macroeconomic and sectoral development policies; advanced cost–benefit analysis, including economic valuation of environmental and social impacts; and MCA, especially in cases where some impacts cannot be easily quantified in monetary terms.

Sustainable development assessment (SDA) is another important tool to ensure balanced analysis of both development and sustainability concerns in policies and projects. The economic component of SDA is based on conventional economic and financial analysis (including cost–benefit analysis). The other two key components are environmental assessment and social assessment. SDA also includes poverty assessment. Thus, SDA seeks to integrate and harmonize economic, environmental, and social analyses.

3. SUSTAINABLE ENERGY DEVELOPMENT

3.1 Linkages between Energy Use and Sustainable Development

3.1.1 Energy–Economy Linkages

The economy–energy interaction has been well analyzed in terms of energy as a driving force for economic progress, especially since the industrial revolution and the extensive use of fossil fuels. Modern economies could not function without commercial energy. Figure 2 shows that future consumption of nearly all forms of energy will

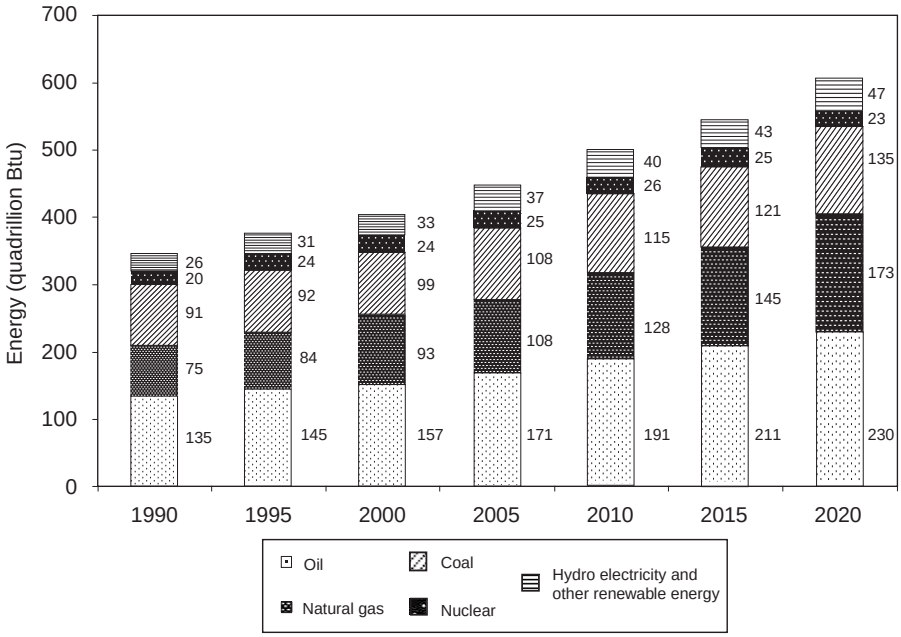

FIGURE 2 World consumption of energy by source, 1990–2020.

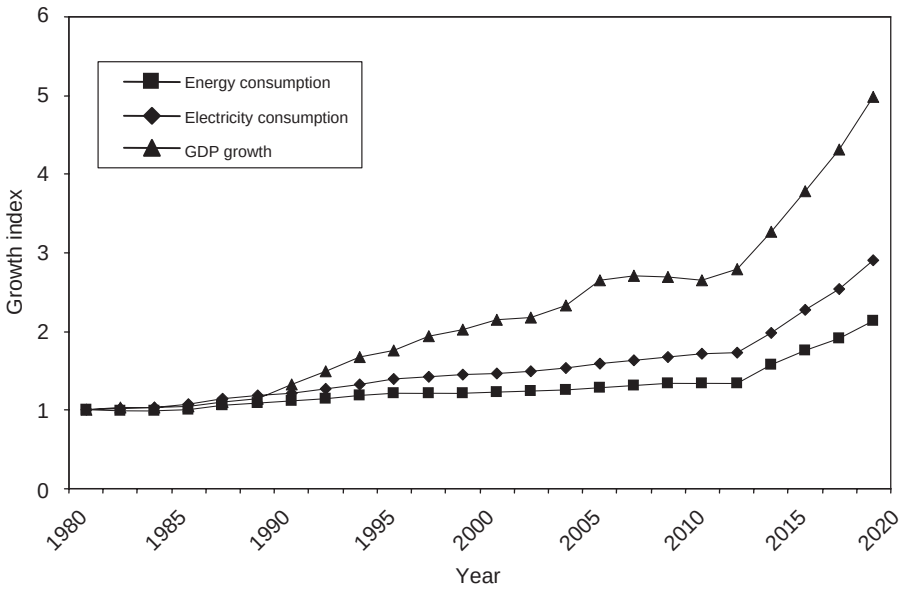

FIGURE 3 Growth of world energy and electricity consumption and gross domestic product (GDP), 1980–2020. 1980 actuals: energy, 285 quadrillion Btu; electricity, 7420 TWh; GDP, $10.8 trillion.

continue to rise, with fossil fuels such as oil, natural gas, and coal playing the dominant role.

The intimate relationship between total energy use and economic output is further clarified in Fig. 3. One hopeful trend is that technological progress and efficiency improvements have reduced the energy intensity of economic production (i.e., lower requirements of physical energy per unit of economic output). Electricity will continue to play an increasingly important role as a safe, clean, and convenient form of energy.

3.1.2 Energy–Environment–Society Linkages

The environmental and social implications of energy use have not been as well analyzed as have energy–economy linkages. Although electricity has relatively few environmental and health consequences at the point of end use, key environmental and social issues arise from power generation. However, the extent and nature of impacts differ among energy sources. Oil- and coal-fired plants not only have national impacts but also have regional and global environmental and health effects. Complete life cycle analyses involving the mining, refining, processing, transport, conversion, and transformation of various fuels such as oil, coal, and nuclear materials all give rise to significant impacts. Even new and renewable energy sources such as wind power, geothermal energy, biomass, and ocean energy, which are perceived to be "clean," have some negative social and environmental impacts.

3.1.3 Transnational Issues

Acid deposition is perhaps the most serious of the transnational issues faced today. Acid deposition is a result of oxides of sulfur and nitrogen that originate from fossil fuel combustion, falling to the ground as particulates and acid rain. Coal- and oil-fired power stations emit significant amounts of sulfur dioxide and nitrogen oxides into the atmosphere. The transport of sulfur dioxide occurs over distances of more than 1000 km, causing the deposition of emission products across national boundaries. Acid depositions caused by sulfur and nitrogen oxides result in damage to trees and crops and sometimes extend to acidification of streams and lakes, resulting in destruction of aquatic ecosystems. They also lead to the corrosion, erosion, and discoloration of buildings, monuments, and bridges. Indirect health effects are caused by the mobilization of heavy metals in acidified water and soil.

Other important transnational issues include environmental and health impacts of radiation due to severe nuclear accidents, oceanic and coastal pollution due to oil spills, downstream siltation of river water in one nation due to deforestation of water sheds and soil erosion in a neighboring country, and changes in hydrological flow and water conditions caused by dams.

3.1.4 Global Issues

The Intergovernmental Panel on Climate Change (IPCC) has identified energy use as the major

contributor to anthropogenic GHG emissions, mainly CO_2 and other gases such as N_2O, CH_4, and chlorofluorocarbons (CFCs) that will lead to climate change and undermine sustainable development prospects. First, global warming poses a significant potential threat to the future economic well-being of large numbers of humans. Second, climate change could also undermine social welfare and equity in an unprecedented manner. Third, from an environmental viewpoint, increasing anthropogenic emissions and accumulations of GHGs will significantly perturb a major global subsystem—the atmosphere. Climate change will also threaten the stability of a range of critical interlinked physical, ecological, and social systems and subsystems.

3.2 Framework for Sustainable Energy Development at the National Level

Sustainable development is the broad rationale underlying most national-level planning and policymaking. Power and energy planning must also be part of, and closely integrated with, overall sustainable development strategies to meet many specific, interrelated, and frequently conflicting national objectives. Some specific goals for sustainable energy development might include ensuring economic efficiency in energy supply and use to maximize growth, including energy efficiency-related objectives such as energy conservation; raising sufficient revenues from energy sales to finance sector development; addressing socioeconomic concerns such as meeting basic energy needs of the poor and developing special regions (particularly rural or remote areas) and priority sectors of the economy; preserving the environment; diversifying supply, reducing dependence on foreign sources, saving scarce foreign exchange, and meeting national security requirements; ensuring price stability; and so on.

3.2.1 Integrated Approach

Successful planning and implementation of national energy programs must explicitly link the energy sector to sustainable development of other parts of the economy. An integrated approach will help decision makers to formulate policies and will provide market signals and information to economic agents that encourage more efficient and sustainable energy production and use. Figure 4 depicts such an approach to decision making, within a hierarchical conceptual framework for sustainable energy development, to be implemented through a set of energy supply and demand management policies. The middle column shows the core—an integrated, multilevel analytical framework. The top level of sustainable energy development recognizes transnational linkages. Thus, individual countries are embedded in an international matrix, and global economic, social, and environmental conditions will impose exogenous inputs or constraints on national decision makers.

The second hierarchical level in Fig. 4 focuses on the multisectoral national economy of which the energy sector is a part. Thus, energy planning requires analysis of links between the energy sector and other sectors, including energy needs of user sectors (e.g., industry, transport, agriculture), input requirements of the energy sector, and impacts of energy supply and pricing policies.

The next level of sustainable energy development disaggregates the energy sector into subsectors such as electricity and petroleum products. This permits detailed analysis, with special emphasis on interactions among various energy subsectors, substitution possibilities, and resolution of policy conflicts.

The lowest hierarchical level pertains to energy analysis within each energy subsector, where line institutions (both public and private) carry out detailed energy resource evaluation, planning, and implementation of projects (including sustainability assessments).

In practice, the various levels of sustainable energy development merge and overlap considerably, requiring careful study of (inter)sectoral linkages. Energy–social–environmental interactions (represented by the vertical bar in Fig. 4) cut across all levels and provide important paths for incorporating environmental and social considerations into national energy policies.

Sustainable energy development facilitates policymaking and does not imply rigid centralized planning. The process results in the development of a flexible and constantly updated sustainable energy strategy designed to meet national goals. This strategy (of which the investment program and pricing policy are important elements) may be implemented through energy supply and demand management policies and programs that make effective use of decentralized market forces and incentives.

In particular, SED implies improvements in overall economic efficiency through better energy management. Figure 4 shows various policy instruments available to decision makers for implementing sound energy management. While formulating policy, one

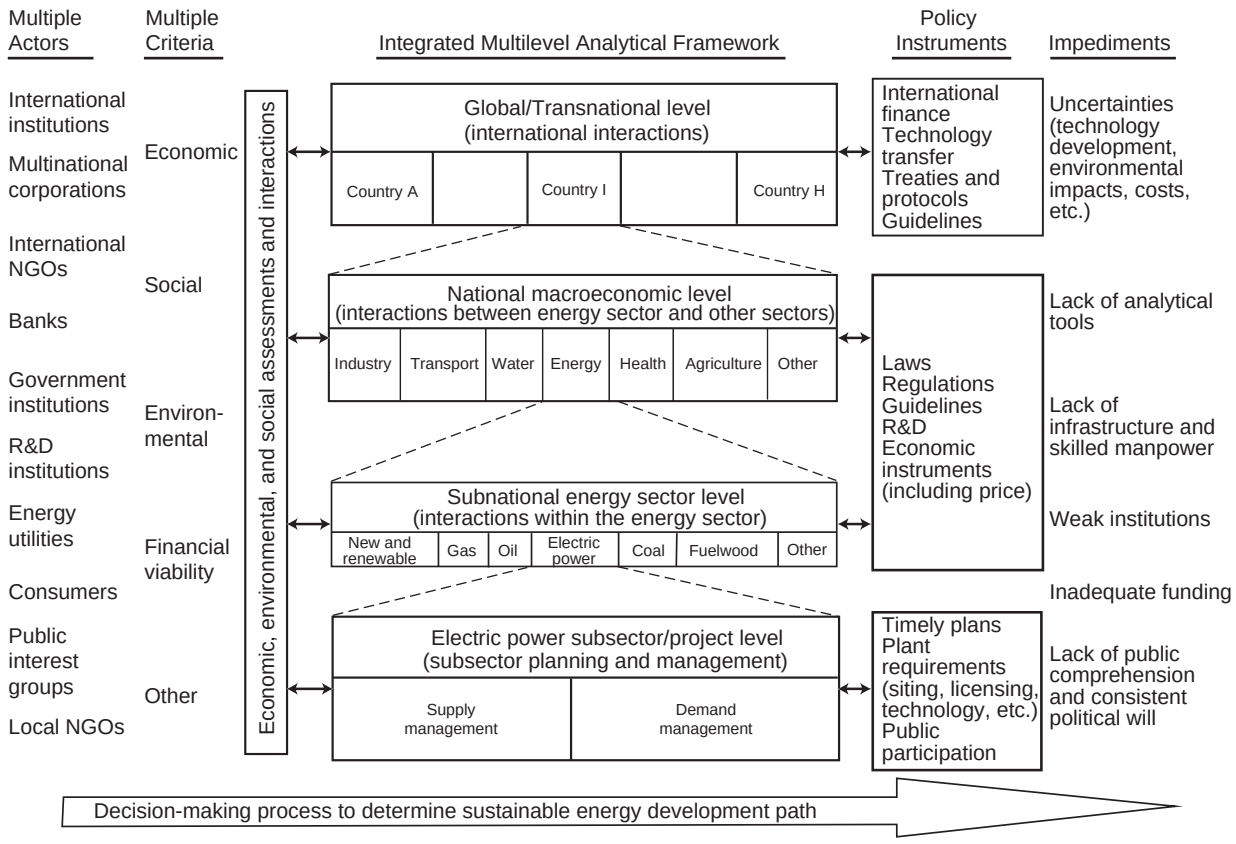

FIGURE 4 Framework for sustainable energy development. NGOs, nongovernmental organizations; R&D, research and development.

must consider the interests of multiple actors, ranging from international institutions to local energy users. The figure also indicates the most important impediments that limit the effectiveness of policies.

Investments offer a good opportunity to pursue sustainable energy development. In 10 years or so, new plants will account for more than half of the industrial output of developing countries, and in 20 years or so, new plants will account for practically all of it. Therefore, it will be possible to have a major impact by putting in place policies, legislation, mechanisms, systems, and incentives that facilitate sustainable energy development.

3.2.2 Identifying Sustainable Energy Options: "Win–Win" Options versus Trade-Offs

To identify sustainable energy options, policymakers need to consider the economic, social, and environmental aspects of sustainable development. Options that lead to improvements in all three indexes are referred to as "win–win" options. Once win–win options are realized, policymakers are able to make trade-offs among other available options.

Incorporating environmental and social externalities into energy decision making is particularly important where concerns (e.g., pollution from nuclear or fossil-fueled plants, inundation at hydro plants) have hampered project implementation. Environmental and social concerns need to be addressed early, that is, at the sectoral and regional planning stages rather than at the final stage of project SDA. Unfortunately, when one deals with energy sector issues at this aggregate planning level, the application of many project-level valuation techniques becomes extremely difficult. First, the impacts are difficult to value (e.g., health effects of pollutants from coal-fired generating stations, biodiversity loss from large-scale hydro storage, impacts of GHG emissions). Doubts raised about the valuation techniques themselves divert attention away from critical policy trade-offs. Second, many techniques appropriate at the micro level are less effective at the sector level. Thus, contingent valuation is more valid where respondents can be asked specific

questions about local impacts of a particular project to which they can relate, and it is difficult to apply at the sector level where one deals with large numbers of technology, site, and mitigation options.

In countries where inappropriate policies have encouraged wasteful and unproductive uses of some forms of energy, better energy management could lead to improvements in economic efficiency (higher value of net output produced), energy efficiency (higher value of net output per unit of energy used), energy conservation (reduced absolute amount of energy used), and environmental and social protection (reduced energy-related environmental and social costs). However, it might not be possible to satisfy all of these goals simultaneously. For example, in some developing countries where existing levels of per capita income and energy consumption are very low, affordable energy might have a high priority to meet basic energy needs.

The economic efficiency criterion, which maximizes the value of net output from all scarce resources in the economy (including energy), normally subsumes purely energy-oriented objectives such as energy efficiency and conservation. Furthermore, costs arising from energy-related adverse environmental impacts may be included in the energy economics analytical framework to determine how many other benefits society should be willing to forgo so as to avoid environmental damage.

Energy use and production in developing countries can be improved in several ways to make them more sustainable. First, energy efficiency may be increased by supply- and demand-side improvements. Second, environmentally and socially more benign technologies can be introduced, including fuel switching and renewable energy sources. Finally, price, institutional, and regulatory reforms could contribute to sustainable energy development.

3.2.3 Sustainable Energy Development Options Matrix

Table I shows typical impacts of selected energy options on the three elements of sustainable development. Although efficient supply-side options have clear economic gains in terms of savings in capital investments and environmental benefits from reductions in GHG emissions that result from decreased energy supply, they do not have obvious social benefits. Efficient end use options, as shown in the case of an efficient fuelwood stove, have benefits relating to all three elements. Although advanced technologies, such as clean coal combustion technologies, help to reduce air pollutants (e.g., CO_2, NO_x) that cause respiratory diseases and reduce productivity, many developing countries cannot afford such high-cost technologies. Likewise, renewable energy sources also provide environmental and social benefits by reducing a country's dependence on traditional fossil fuels. However, in terms of power-generating costs, renewables are often more expensive than fossil fuels.

TABLE I

Selected Sustainable Energy Development Options Matrix

	Impact		
Option	Economic	Environmental	Social
Supply efficiency	+	+	
End use efficiency	+	+	+
Advanced technologies	−	+	+
Renewables	−	+	+
Pricing policy	+	+	+/−
Privatization/decentralization	+	+/−	+/−

4. APPLYING THE SUSTAINABLE ENERGY DEVELOPMENT FRAMEWORK

This section presents practical case studies that illustrate the application of the ideas presented earlier.

4.1 Global Transnational Scale: Interplay of Optimality and Durability in Determining Global GHG Emission Target Levels

Optimization- and durability-based approaches can facilitate the determination of target GHG emission levels. Under an economic optimizing framework, the ideal solution would be, first, to estimate the long-run marginal abatement costs (MACs) and the marginal avoided damages (MADs) associated with various GHG emission profiles (see Fig. 5C where the error bars on the curves indicate measurement uncertainties). The optimal emission levels would be determined at the point where future benefits (in terms of climate change damage avoided by reducing one unit of GHG emissions) are just equal to the corresponding costs (of mitigation measures required to reduce that unit of GHG emissions), that is,

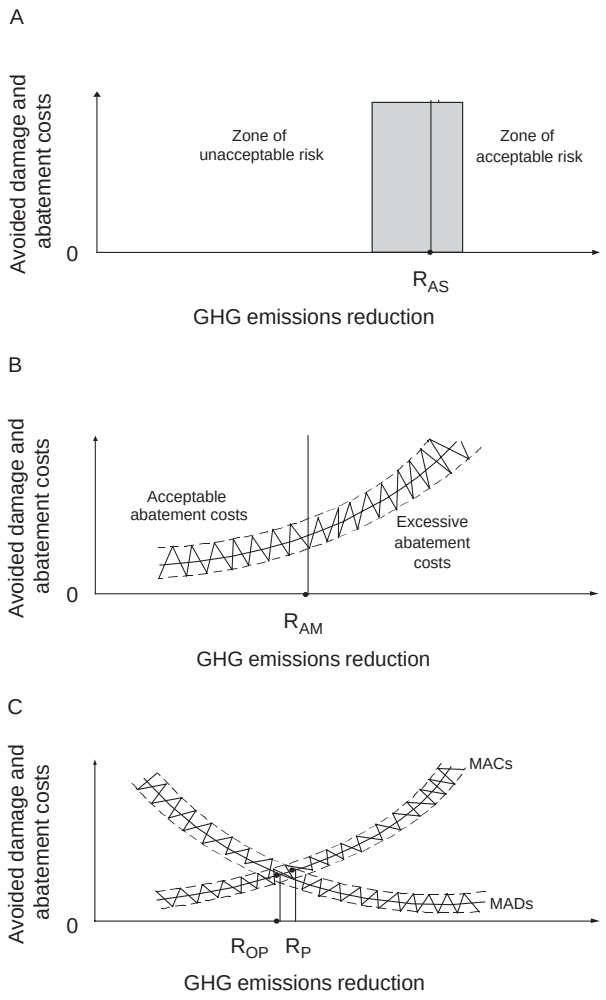

FIGURE 5 Determining abatement targets: (A) absolute standard; (B) affordable safe minimum standard; (C) cost–benefit optimum. Adapted from Intergovernmental Panel on Climate Change (1996, Fig. 5.10).

MACs = MADs at point R_{OP}. Durable strategies become more relevant when we recognize that MACs and/or MADs might be poorly quantified and uncertain. Figure 5B assumes that MACs are better defined than MADs. First, MACs are determined using technoeconomic least cost analysis, an optimizing approach. Next, the target emissions are set on the basis of the affordable safe minimum standard (at R_{AM}), which is the upper limit on costs that will still avoid unacceptable socioeconomic disruption. This is closer to the durability approach.

Finally, Fig. 5A indicates an even more uncertain world where neither MACs nor MADs are defined. Here, the emission target is established on the basis of an absolute standard (R_{AS}) or safe limit that would avoid an unacceptably high risk of damage to ecological (and/or social) systems. This last approach would be more in line with the durability concept.

4.2 National Economy-wide Scale: Using the AIM for Macro Policy Analysis

National policymakers routinely make key macro-level decisions that could have (often inadvertent) environmental and social impacts that are far more significant than the effects of local economic activities. At this macroeconomic level, recent work has focused on incorporating environmental considerations such as depletion of natural resources and pollution damage into the system of national accounts via useful new indicators and measures such as the system of environmentally adjusted environmental accounts (SEEAs), green gross national product (GNP), and genuine savings. In this context, the AIM approach is a sustainomics tool that helps to identify and analyze economic–environmental–social interactions and formulate effective sustainable development policies.

Table II shows a simplified AIM, although an actual one would be larger and more detailed. The AIM helps to promote an integrated view, meshing development decisions with priority economic, environmental, and social impacts. The left-most column lists examples of key development interventions (both policies and projects), whereas the top row indicates some typical sustainable development impacts/issues. Thus, the elements or cells in the matrix help to accomplish the following:

- Explicitly identify key linkages
- Focus attention on methods of analyzing important impacts
- Suggest action priorities and remedies

At the same time, the organization of the overall matrix facilitates the tracing of impacts as well as the coherent articulation of the links among a range of development actions, both policies and projects.

4.2.1 Screening and Problem Identification

One of the early objectives of the AIM–based process is to help in screening and problem identification by preparing a preliminary matrix that identifies broad relationships and provides a qualitative idea of the magnitudes of impacts. Thus, the preliminary AIM helps to prioritize the most important links between policies and their sustainability impacts.

One typical primary energy policy shown in the third row of Table II involves increasing energy

TABLE II

A Simplified Preliminary Action Impact Matrix

		Impacts on key sustainable development issues			
Activity or policy	Main objective	Land degradation and biodiversity loss	Air pollution GHG emissions	Resettlement and social effects	Other
Macroeconomic and sectoral policies	Macroeconomic and sectoral improvements	Positive impacts due to removal of distortions Negative impacts mainly due to remaining constraints			
Exchange rate	Improve trade balance and economic growth	(−H) (deforest open-access areas)			
Energy pricing	Improve energy use economic and efficiency		(+M) (energy efficiency)		
Others					
Complementary measures	Socioeconomic and environmental gains	Enhance positive impacts and mitigate negative impacts (above) of broader macroeconomic and sectoral policies			
Market based			(+M) (pollution tax)		
Non-market based		(+H) (property rights)	(+M) (public sector accountability)		
Investment projects	Improve effectiveness of investments	Investment decisions made more consistent with broader policy and institutional framework			
Project 1 (hydro dam)		(−H) (inundate forests)	(+M) (displace fossil fuel use)	(−M) (displace people)	
Project 2 (Reafforest and relocate)		(+H) (replant forests)		(+M) (relocate people)	
Project N					

Note. Several typical policies and projects, as well as key economic, environmental and social issues, are shown. Some illustrative impact assessments are also indicated, where + and − signify beneficial and harmful impacts, and where H and M indicate high and moderate intensity, respectively.

prices closer to marginal costs to improve energy efficiency while decreasing air pollution and GHG emissions. A complementary environmental policy measure indicated in the fourth column consists of adding pollution taxes to marginal energy costs, a measure that will further reduce air pollution and GHG emissions. Increasing public sector accountability constitutes another complementary policy that will reinforce favorable responses to these price incentives by reducing the ability of inefficient firms to pass on cost increases to consumers or to transfer their losses to the government.

Near the bottom of Table II, a major hydroelectric project is shown as having two adverse impacts (inundation of forested areas and village dwellings) as well as one positive impact (replacement of thermal power generation, thereby reducing air pollution and GHG emissions). A reafforestation project coupled with resettlement schemes helps to address the negative impacts.

Therefore, this matrix–based approach encourages the systematic articulation and coordination of policies and projects to make development more sustainable.

4.2.2 Analysis and Remediation

This process may be developed further to assist in analysis and remediation. For example, more detailed analyses and modeling may be carried out for those matrix elements in the preliminary AIM that had already been identified as representing high-priority linkages between economy-wide policies and economic, environmental, and social impacts. This, in turn, would lead to a more refined and updated

AIM that would help to quantify impacts and formulate additional policy measures to enhance positive linkages and mitigate negative ones. The types of more detailed analyses that could help to determine the final matrix would depend on planning goals and available data and resources. They may range from fairly simple methods to rather sophisticated economic, ecological, and social models, included in the sustainomics toolkit.

4.3 Subnational Scale: Energy Sector Planning

The incorporation of environmental and social externalities into decision making is particularly important in the electric power sector. Meier and Munasinghe, in their Sri Lanka study, demonstrated how externalities could be incorporated into power system planning in a systematic manner. Sri Lanka currently depends largely on hydro power for electricity generation, but over the next decade or so the main choices seem to be large coal- or oil-fired stations or hydro plants whose economic returns and environmental impacts are increasingly unfavorable. In addition, a wide range of other options (e.g., wind power, increasing use of demand-side management, system efficiency improvements) complicates decision making, even in the absence of environmental concerns.

The methodology involves the following steps: (1) definition of generation options and their analysis using sophisticated least cost system planning models; (2) selection and definition of attributes that reflect planning objectives; (3) explicit economic valuation of those impacts for which valuation techniques can be applied with confidence, with the resultant values then being added to the system costs (the main economic attribute); (4) quantification of those attributes for which explicit economic valuation is inappropriate but for which suitable quantitative impact scales can be defined; (5) translation of attribute value levels into value functions (known as "scaling"); (6) display of trade-offs to facilitate decision making; and (7) definition of options for further study, also involving discarding eliminating inferior options.

4.3.1 Main Results

The main set of sectoral policy options examined included (1) variations in the currently available mix of hydro and thermal (coal and oil) plants, (2) demand-side management (e.g., compact fluorescent lighting), (3) renewable energy options (e.g., wind generation), (4) improvements in system efficiency (using more ambitious targets for transmission and distribution losses than the base case assumption of 12% by 1997), (5) clean coal technology (e.g., pressurized fluidized bed combustion [PFBC] in a combined cycle mode), and (6) pollution control technology options (e.g., various fuel switching and pollution control options such as importing low-sulfur oil for diesels and fitting coal power plants with flue gas desulfurization [FGD] systems).

A limited number of criteria or attributes should be selected with care to reflect issues of national as well as local project level significance. CO_2 emissions were used as a proxy for the potential impact on global warming. Health impacts were measured through population-weighted increments in both fine particulates and NO_x. To capture the potential biodiversity impacts, a probabilistic index was derived. Employment creation was used as an illustrative social impact.

Figure 6A illustrates a typical trade-off curve for biodiversity. The "best" solutions lie closest to the origin. The so-called trade-off curve is defined by the set of "noninferior" solutions, representing options that are superior regardless of the weights assigned to the various objectives. For example, on this curve, the option defined as "no hydro" is better than the "wind" option in terms of both economic cost and biodiversity loss.

Although most options in Fig. 6A have index values that fall between 50 and 100, the no-hydro option has a zero value because thermal projects that constitute this option lie at sites of low biodiversity value (either close to load centers or on the coast). Meanwhile, wind plants would require large land areas, and their biodiversity indexes are higher. However, vegetation on the south coast (where wind power plants would be located) has relatively low biodiversity value; therefore, the overall biodiversity impact of this option is small. In summary, the best options (on the trade-off curve) include the no-hydro and run-of-river hydro options that require essentially zero inundation. The extreme outlier at the top right-hand corner is the Kukule hydro dam; it has a biodiversity loss index ($B = 530$) that is much larger than those for other options ($B\text{s} = 50$–70).

The trade-off curve between health impacts and average incremental cost is different (Fig. 6B). The "iresid" point on this trade-off curve (low-sulfur imported fuel oil at diesel plants) is better than the use of flue gas desulfurization systems ("FGD" point) in terms of both economic cost and environment.

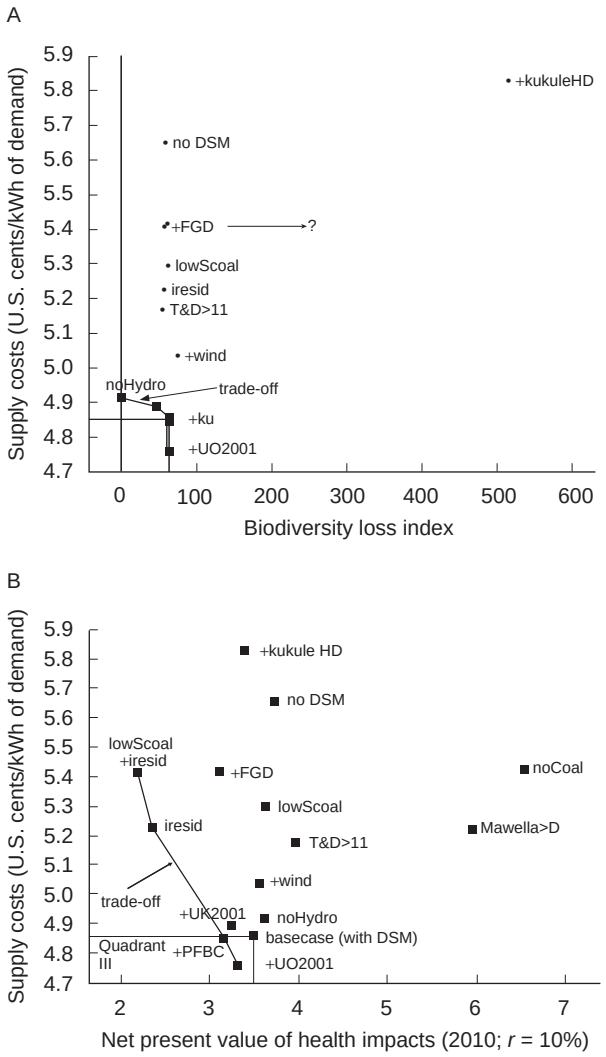

FIGURE 6 Trade-off curves between economic costs and (A) biodiversity impacts and (B) health impacts. Reproduced from Meier and Munasinghe (1994).

4.3.2 Conclusions

There are several useful conclusions. First, the results indicate that those impacts for which valuation techniques are relatively straightforward and well established (e.g., the opportunity costs of lost production from inundated land, benefits of establishing fisheries in reservoirs) are small compared with overall system costs, and so including them in the benefit–cost analysis does not materially change results. Second, even in cases where explicit valuation is difficult (e.g., mortality and morbidity effects of air pollution), implicit valuation based on analysis of trade-off curves can provide important guidance to decision makers. Third, certain options were clearly inferior or superior to other options when one examines all impacts simultaneously. For example, the high dam version of the Kukule hydro project can be safely excluded from further consideration here due to poor performance on all attribute scales. Fourth, it is possible to derive attribute scales that provide useful proxies for impacts that are difficult to value. For example, the population-weighted, incremental, ambient air pollution level was the proxy for health impacts, yielding several important conclusions independent of any economic values assigned to health effects.

Finally, with respect to the practical planning, the study identified several priority recommendations, including the need to reconsider (1) demand-side management options, especially fluorescent lighting; (2) whether the current transmission and distribution loss reduction target of 12% ought to be further reduced; (3) possibilities of PFBC technology for coal power; (4) replacement of some coal-fired power plants (on the south coast) by diesel units; and (5) cooling system options for coal plants.

4.4 Local Project Scale: Multicriteria Analysis of Small Hydroelectric Power Projects

Well-accepted environmental and social assessment procedures at the project/local level may be readily adapted to assess environmental and social effects of micro-level activities. When monetary valuation of environmental and social effects is not feasible, MCA may be used. This subsection summarizes how Morimoto and colleagues have used MCA to compare hydroelectric power schemes. The three main sustainable development issues considered are the economic costs of power generation, the ecological costs of biodiversity loss, and the social costs of resettlement.

The principal objective is to generate additional kilowatt-hours of electricity to meet growing power demand in Sri Lanka. Assuming that the benefits from each additional kilowatt-hour are the same, the analysis seeks to minimize economic, social, and environmental costs of generating one unit of electricity from various hydropower sites. Following the MCA approach, environmental and social impacts are measured in different (nonmonetary) units instead of attempting to economically value and incorporate them within the monetary-valued cost–benefit analysis framework.

4.4.1 Environmental, Social, and Economic Indicators

Sri Lanka has many varieties of endemic or endangered fauna and flora. Often, large hydro projects destroy wildlife at dam sites and in

downstream areas. Hence, a biodiversity loss index was estimated for each hydroelectric site as the main ecological indicator.

Although dam sites are usually in less densely populated rural areas, resettlement is still a serious problem. In general, people are relocated from the wet zone to the dry zone where soils are less rich; therefore, the same level of agricultural productivity cannot be maintained. In the wet zone, multiple crops, including paddy, tobacco, coconuts, mangoes, onions, and chillies, can be grown. However, these crops cannot be cultivated as successfully in the dry zone due to limited water and poor soil quality. Living standards often become worse, and several problems (e.g., malnutrition) can occur. Moreover, other social issues might arise, including erosion of community cohesion and psychological distress due to changed living conditions. Hence, minimizing the number of people resettled due to dam construction is an important social objective.

The project costs are available for each site, from which the critical economic indicator (average cost per kilowatt-hour/year) may be estimated. The annual energy generation potential at various sites ranges from approximately 11 to 210 kWh (Fig. 7). All three variables (biodiversity index, number of people resettled, and generation costs) are weighted by the inverse of the amount of electrical energy generated. This scaling removes the influence of project size and makes them more comparable.

4.4.2 Basic Results

A simple statistical analysis shows that pairwise, there is a little correlation among the quantity of electricity generated, average generation cost, number of people resettled, and biodiversity index.

Figure 7 shows that on a per kilowatt-hour/year basis, the project named AGRA003 has the highest biodiversity index, HEEN009 has the highest

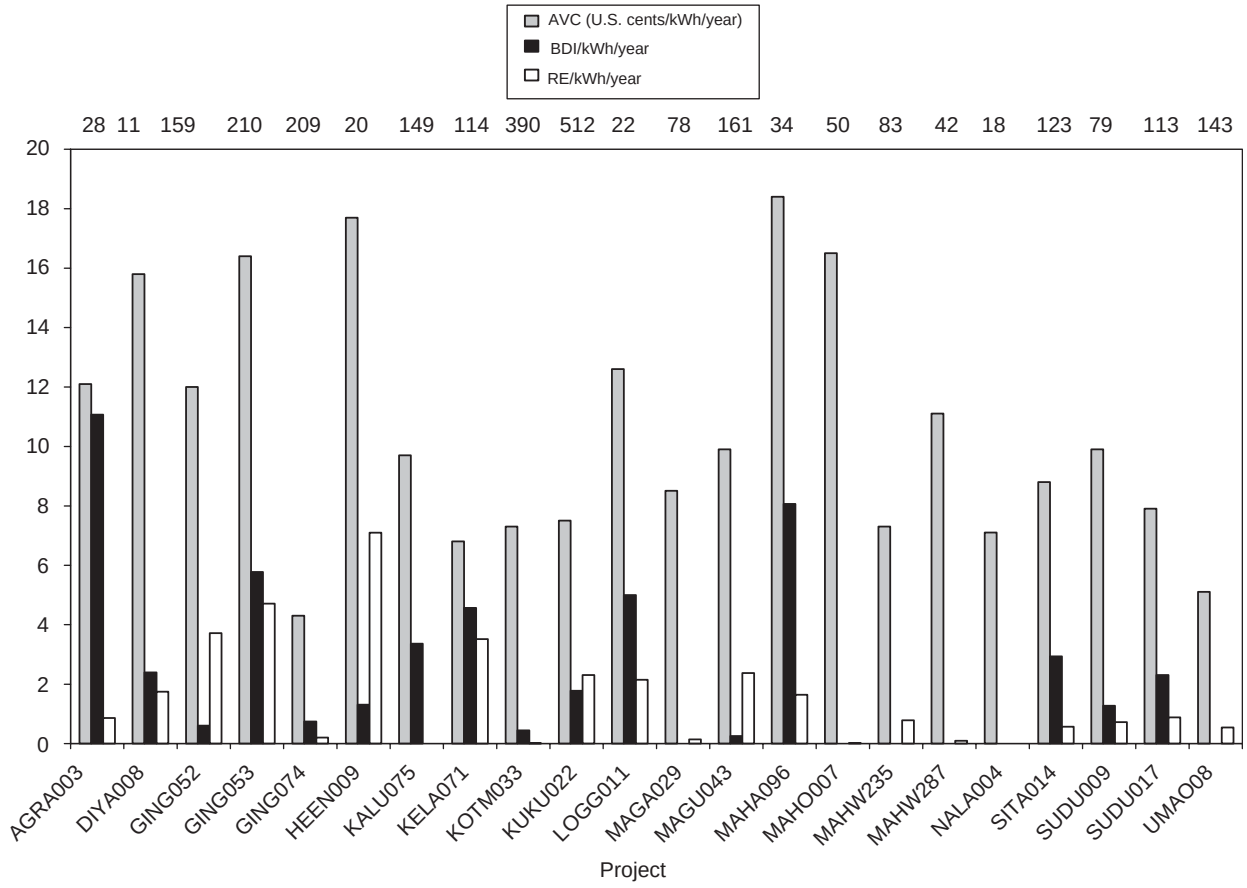

FIGURE 7 Average generation costs (AVC), biodiversity index (BDI), and number of resettled people (RE) by hydroelectric project. All indexes are per kilowatt-hour/year. Numbers of people resettled and the biodiversity index are scaled for convenience (by the multipliers 10^{-5} and 10^{-9}, respectively). The values across the top of the graph indicate the annual energy generation in gigawatt-hours. Adapted from Morimotor, Munasinghe, and Meier (2000).

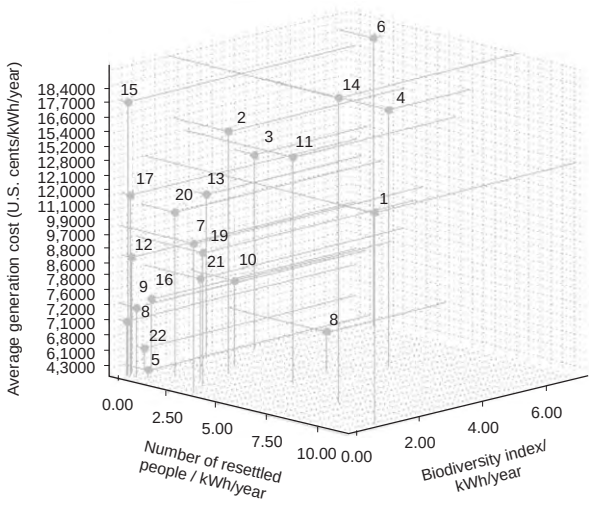

FIGURE 8 Three-dimensional MCA of sustainable development indicators for various hydropower options. Reproduced from Morimoto, Munasinghe, and Meier (2000).

number of resettled people, and MAHA096 has the highest average generation cost. Further important comparisons may be made. For example, KALU075 is a relatively large project whose costs are low, whereas MAHA096 is a smaller scheme with much higher costs with respect to all three indexes. Another observation is that a project such as KELA071 fully dominates GING053 given that the former is superior in terms of all three indicators. Similar comparisons may be made among other projects.

Figure 8 provides a three-dimensional analysis of sustainable development indicators for these hydropower sites where the respective axes represent economic, ecological, and social objectives. The closer to the origin any given coordinate point lies, the better the corresponding project is in terms of achieving these three objectives. This type of analysis gives policymakers some idea about which project is more favorable from a sustainable energy development perspective.

Suppose that all three objectives are arbitrarily given equal weight. Then, each project may be ranked according to its absolute distance from the origin. For example, rank 1 is given to the one closest to the origin, rank 2 is the second closest, and so on (Fig. 8). On this overall basis, from a sustainable energy development perspective, the most favorable project is GING074 (rank 1), whereas the least favorable is MAHA096 (rank 22).

4.4.3 Conclusions

The strength of this type of analysis is in helping policymakers to compare project alternatives more easily and effectively. The simple graphical presentations are readily comprehensible and clearly identify sustainable development characteristics of each scheme. The multidimensional analysis supplements more conventional cost–benefit analysis (based on economic analysis alone). Because each project has different features, assessing them by looking at only one aspect (e.g., generation costs, effects on biodiversity, impacts on resettlement) could be misleading.

There are some weaknesses in the MCA approach used here. First, for simplicity, each major objective is represented by only one variable, assuming that all of the other attributes are minor. In reality, there may be several additional variables that could describe the economic, social, and environmental aspects of sustainable development. Further analysis that includes other attributes might provide new insights. A second extension of this study is to include other renewable sources of energy in the analysis. Finally, more sophisticated three-dimensional graphic techniques may yield better and clearer representations.

widget A hypothetical product used in classroom examples.

System dynamics is a computer-based method for studying dynamic behavior. The method is normally applied when the dynamic behavior is viewed as a problem. The problematical behavior might take the form of highly volatile oscillations in prices, for example. System dynamics can help the analyst understand how the elements of the system interact to create the oscillations. The analyst would construct a mathematical model to represent the elements and their interactions. The model is then simulated on the computer to determine if simulated oscillations are similar to the oscillations observed in the industry. The analyst would then use the model to experiment with changes in the system that could lead to improved behavior. System dynamics has been applied to a wide variety of energy systems. The applications have dealt with challenges faced by utility managers, state regulators, and national policy makers. This article presents a description of system dynamics followed by summaries of three applications to energy systems.

1. SYSTEM DYNAMICS

The system dynamics approach was pioneered by Jay W. Forrester and colleagues at the Sloan School of Management at the Massachusetts Institute of Technology during the 1960s. In 1977, Coyle classified system dynamics as "that branch of control theory which deals with socioeconomic systems and that branch of management science which deals with problems of controllability." The method was well described by Forrester in 1961. In 2000, Sterman published the most comprehensive text.

The basic building blocks of system dynamics models are stocks and flows. Stocks represent where accumulation or storage takes place in the system. Flows represent the actions that directly influence the stocks. Figure 1 shows an example of a single stock to represent the volume of water stored in a reservoir. This stock is increased by the upstream flow and lowered by the flow of water released at the dam.

Figure 2 shows a combination of six stocks and six flows. The stocks represent the storage of petroleum products in the world oil industry. The flows show the movement of products from the oil fields of Kuwait to the fuel tanks in our personal vehicles.

Stocks and flows provide the foundation for system dynamics models. The next step is to add the variables needed to explain each flow. Figure 3 illustrates with a model of a sales company. A single stock is used to represent the number of salespersons, whereas flows are used to keep track of new hires

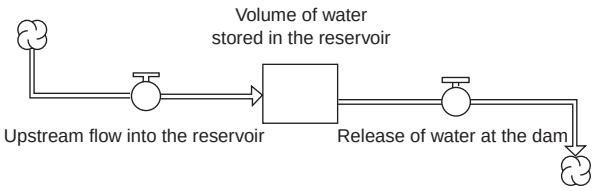

FIGURE 1 Example of a stock and flows. Adapted from A. Ford, "Modeling the Environment: An Introduction to System Dynamics Modeling of Environmental Systems." Copyright 1999 by Island Press. Reprinted by permission of Island Press.

and departures. The remaining variables are used to explain the flows. In this example, an exit rate is used to explain the departures, whereas a hiring fraction helps explain the new hires. New hires depend on the budgeted size of the sales force, which depends on the sales department budget and the average salesperson's salary. The sales department budget depends on the annual revenues and the fraction devoted to sales. Annual revenues depend on widgets sold and the widget price. Widget sales depends on the size of the sales force and the effectiveness of each salesperson.

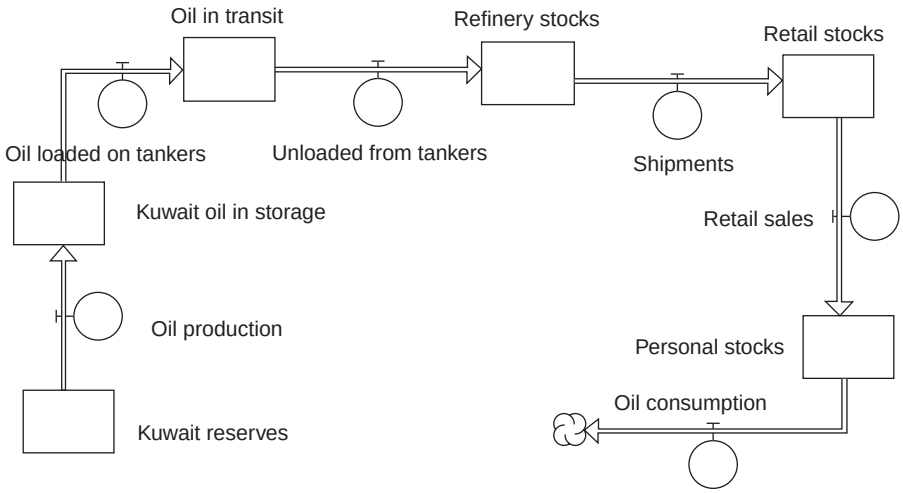

FIGURE 2 Example of stocks and flows in the petroleum industry. Adapted from Ford (1999). Reprinted by permission of Island Press.

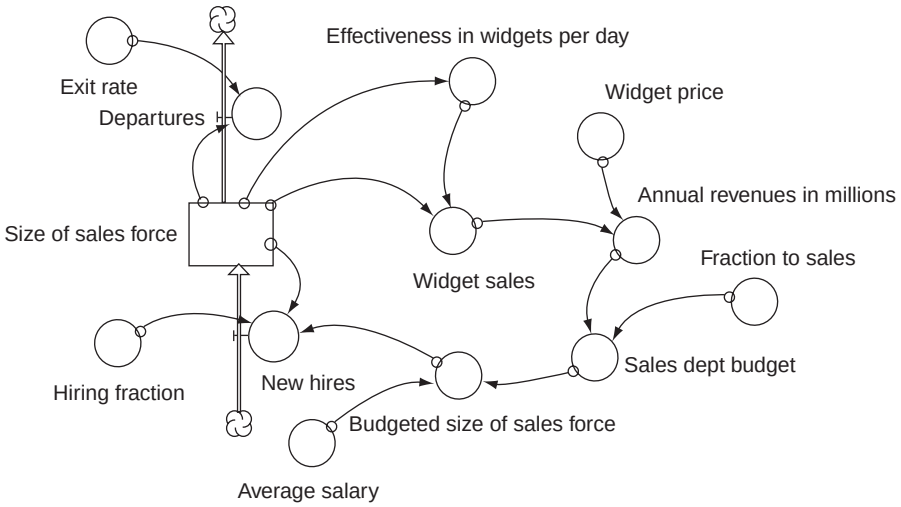

FIGURE 3 A system dynamics model of a hypothetical sales company. Adapted from Ford (1999). Reprinted by permission of Island Press.

In this classroom example, effectiveness is assumed to decline when there is a larger sales force.

2. SOFTWARE

The images in Figs. 1–3 were created with Stella software by High Performance Systems. Stella is one of several icon-based programs to aid the construction and simulation of system dynamics models. Stella diagrams are shown in many of the figures in this article, but equally useful models may be constructed with any of the stock-and-flow programs, such as Vensim or Powersim. The programs use somewhat different symbols, as shown by the Vensim diagram of the sales model in Fig. 4. Although the symbols may differ, the programs are fundamentally the same. They are all designed to facilitate the construction of stock-and-flow models and to show dynamic behavior through numerical simulation.

3. INFORMATION FEEDBACK

The sales company will grow rapidly if the personnel are highly effective at selling widgets. The rapid growth is made possible by positive feedback, a closed chain of cause and effect that acts to magnify change in a system. In this example, an increase in the sales force can lead to higher sales, higher revenues, increased budgets for the sales department, more new hires, and an even larger sales force in the future. Understanding positive feedback is crucial if we are to understand the potential for systems to grow in a rapid manner.

However, as the company grows larger, each person is assumed to be less effective at selling widgets. This assumption introduces negative feedback, a closed chain of cause and effect that acts to reduce the change in a system. In this example, an increase in the sales force can lead to lower effectiveness, lower sales, less revenues, lower budgets for the sales department, fewer new hires, and a smaller sales force in the future. Understanding negative feedback is crucial if we are to understand the limits and stability of systems.

Figure 5 shows the combination of positive and negative feedback loops at work in the sales company. This diagram uses words for each of the variables and arrows for the causal connections. The arrows are arranged to allow the eye to easily follow the closed chains of cause and effect. A plus sign in the middle of the loop denotes the positive feedback that allows the company to grow. The minus signs in the middle of the loops denote the three negative loops in the sales model.

System dynamics is based on the premise that understanding dynamic behavior requires one to understand the interplay between the feedback loops in a system. A closely related tenet is that our mental skills are not sufficient to interpret the feedback structure of systems. It appears that we are good at

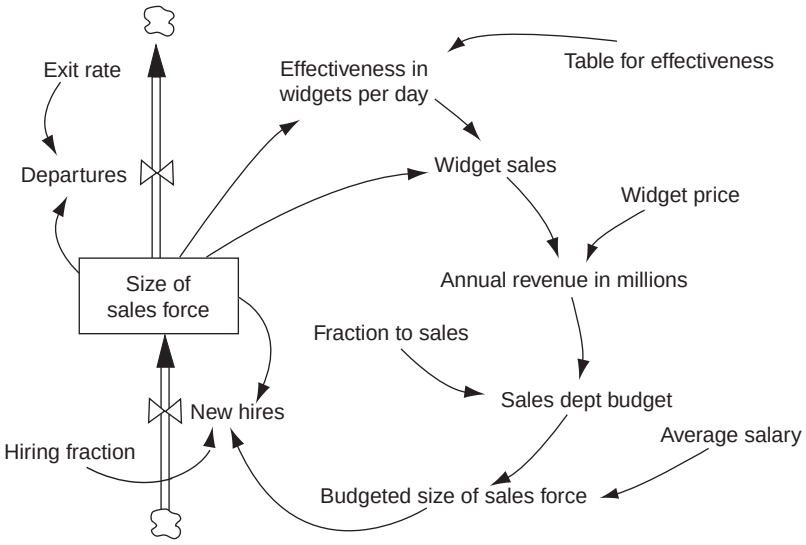

FIGURE 4 Vensim diagram of the sales company model. Adapted from Ford (1999). Reprinted by permission of Island Press.

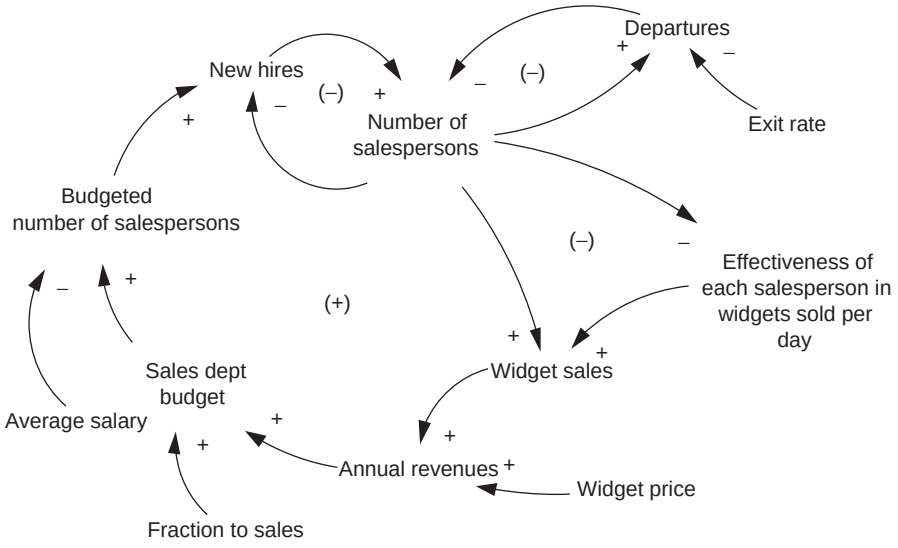

FIGURE 5 Feedback loops in the model of the sales company. Adapted from Ford (1999). Reprinted by permission of Island Press.

making lists of the many factors that might be important in a system, but we are limited in our ability to simulate the interaction between the key factors. Also, it appears that our mental skills are not sufficient to anticipate how the interactions in a system lead to growth, decay, oscillations, or other patterns of dynamic behavior.

System dynamics models are constructed with the goal of improving our understanding of dynamic behavior and anticipating the impact of policies that could lead to improved behavior. This goal has been reached in a wide range of energy models, including those that deal with privatization of electricity in the United Kingdom and deregulation of electricity in the United States. Other applications deal with variability of electricity supply in Columbia and conservation policy in the northwest region of the United States. In the following sections, three applications are described to convey a sense of the usefulness of the approach.

4. MODELS FOR NATIONAL ENERGY POLICY

One of the earliest applications to energy systems was Roger Naill's 1973 model of the exploration and production of natural gas in the United States. The model assigned one stock to represent the proven reserves of natural gas and a second stock for the unproven reserves. The model simulated the natural gas discoveries and production from 1900 to 2020 with different assumptions about the size of the resource base and different policies on price regulation. The model was used to illustrate how the resource could be depleted in a surprisingly short interval when demand is growing in an exponential fashion.

The natural gas model was expanded to represent all of the fossil fuels—oil, coal, and natural gas. The expanded model simulated end-use demands for fossil fuels as well as the intermediate demands in the electricity sector. The new model, known as FOSSIL1, was much larger than the previous model, so space does not allow for a description of the many stocks and flows. The model focused on the difficult transition from conventional fossil fuels (e.g., oil) to ultimate sources (e.g., renewables). The most important application of FOSSIL1 was a simulation analysis of the policies advocated in the first National Energy Plan issued by President Carter in April 1977. The simulations indicated that the plan would "fall short of solving the nation's energy dilemma," but it would delay world oil shortages by approximately 10 years.

Naill and colleagues were asked to expand the model for policy support at the Office of Analytical Services of the U.S. Department of Energy. The expanded model was called FOSSIL2. The new model retained the focus on the difficult transition from conventional to ultimate sources of energy, but it was greatly expanded to represent the many fuels, technologies, regulations, and policies of interest to the Department of Energy. A typical simulation covered the interval from 1900 to 2100. In 1992, Naill described the model's development and applications during both the Carter and the Reagan

administrations. He explained that system dynamics proved to be well suited for the analysis of the national energy system because of the ease of simulating stocks and flows and the importance of representing information feedback acting primarily through energy prices.

5. INCENTIVES FOR ELECTRIC VEHICLES

Another application focused on electric cars and their impact on an electric utility in California in the 1990s. Utility companies were considering incentives to promote the sale and use of electric vehicles. This is an intriguing idea but not a new one. It was first proposed by Thomas Edison, who encouraged the power companies of his day to build garages for electric vehicle owners. In the 1990s, California utilities proposed giving their customers financial incentives to reduce the purchase price of an electric vehicle. Increased sales of electric vehicles would lead to higher electricity consumption during nighttime hours when the demand could be satisfied by idle generating capacity. Utilities argued that incentives could lead to cleaner air and possibly lower electric rates. The reduction in electric rates might arise if the utility earned more in revenues from electricity sales than it would spend on fuel for the extra electricity generation. A system dynamics model was constructed to represent the vehicle purchase decisions of drivers and the accumulation of electric vehicles in the utility company's service territory. The model also simulated the operation of the company's power generators and the cash flows associated with financing the incentive program. The simulations suggested that it would be extremely difficult for the utility company to finance the incentives without having to raise its retail rates. The study concluded with the suggestion that feebates might be a more suitable method of promoting the sale of electric vehicles.

A feebate program would be run by a state or air shed regulator. The "fee" in feebates represents a fee imposed on the purchase price of a dirty vehicle. The "bate" represents a rebate to the person who purchases a clean vehicle. The idea is to finance the rebates for the clean vehicles with the fees imposed on the dirty vehicles. Proponents argue that feebates could be designed to reward cleaner vehicles, regardless of their technology or fuel. If one were thoughtful about the relative size of the fee and rebate, feebates might be designed with the cash inflow from fees balancing the cash outflow for rebates.

System dynamics was used to study the dynamic challenges faced by a program manager who would be charged with promoting the sale of cleaner vehicles while keeping the cash flows in the program fund in approximate balance. The feebate model was adapted from the model of the California utility company and designed for ease of use by students as well as industry experts. The model is sufficiently compact that the key stocks and flows may be shown here.

Figure 6 shows vehicle sales and retirements along with annual travel and annual emissions. A stock of cars is used to represent the cars in use in a hypothetical air shed. The model distinguishes between cars fueled by gasoline, methanol, electricity, and compressed natural gas, with market shares estimated with a discrete choice model based on stated preferences in a survey of Californians. The Stella diagram in Fig. 6 shows three-dimensional icons to represent variables with six different values, one for each of the six types of vehicles in the model.

Figure 7 shows the portion of the model simulating the cash accumulating in the state fund. The main cash flow into the fund is the collection of fees imposed on people who purchase dirty vehicles. The main cash outflow is rebates paid to people who elect to purchase cleaner vehicles. As in Fig. 6, three-dimensional icons are used to represent variables with six different values, one for each type of vehicle.

The feebate model has been designed as a flight simulator, a highly interactive version of a system dynamics model to promote learning through interactive experimentation. Flight simulators have proven useful in a variety of business systems, including health care, airlines, insurance, real estate, and project management. The feebate flight simulation has proven useful primarily in the classroom, where it helps students experiment with their ideas of how to control a feebate program. Figure 8 shows the flight simulator part way through a simulation in which the student has set no fees and no rebates. This "do-nothing" simulation will provide a reference case for comparison with subsequent simulations with an active feebate programs.

The students' challenge is to introduce fees and rebates to reduce emissions while keeping the balance in the state fund within reasonable limits. This is a controllability challenge, one well suited for that "branch of management science which deals with problems of controllability."

6. POWER PLANT CONSTRUCTION IN THE WEST

The third application deals with power plant construction in the deregulated electricity markets and is described in a special issue of the *Journal of Industry and Trade* devoted to the California electricity crisis. Many believe that competitive electricity markets are prone to the same cycles of boom and bust that appear in commodity markets and in a specialized industry such as real estate. The system dynamics study demonstrated how boom and bust might appear in the western electricity system. The model simulates wholesale electricity market prices in the western United States, as explained in Fig. 9.

Figure 10 shows the simulated construction in a business-as-usual scenario. The model represents the construction of gas-fired combined cycle (CC) power plants by merchant investors. The curves in Fig. 10 are simulation results; the small rectangles are information buttons positioned to represent actual investments in CCs. The construction curve in Fig. 10 shows that the number of CCs under construction peaks near the end of 2001. From this point forward, construction completions are greater than construction starts, and the total megawatts of CCs under construction declines. This simulation suggests that we were at the crest of a building boom in 2001. As the construction is completed during 2002 and 2003, installed CC capacity will increase to approximately 27,000 MW by the start of 2004. Figure 10 shows a second wave of construction beginning in 2006 and peaking near the end of 2007.

This simulation scenario, created in November 2001, suggests that we were in the midst of a building boom, with the actual construction well

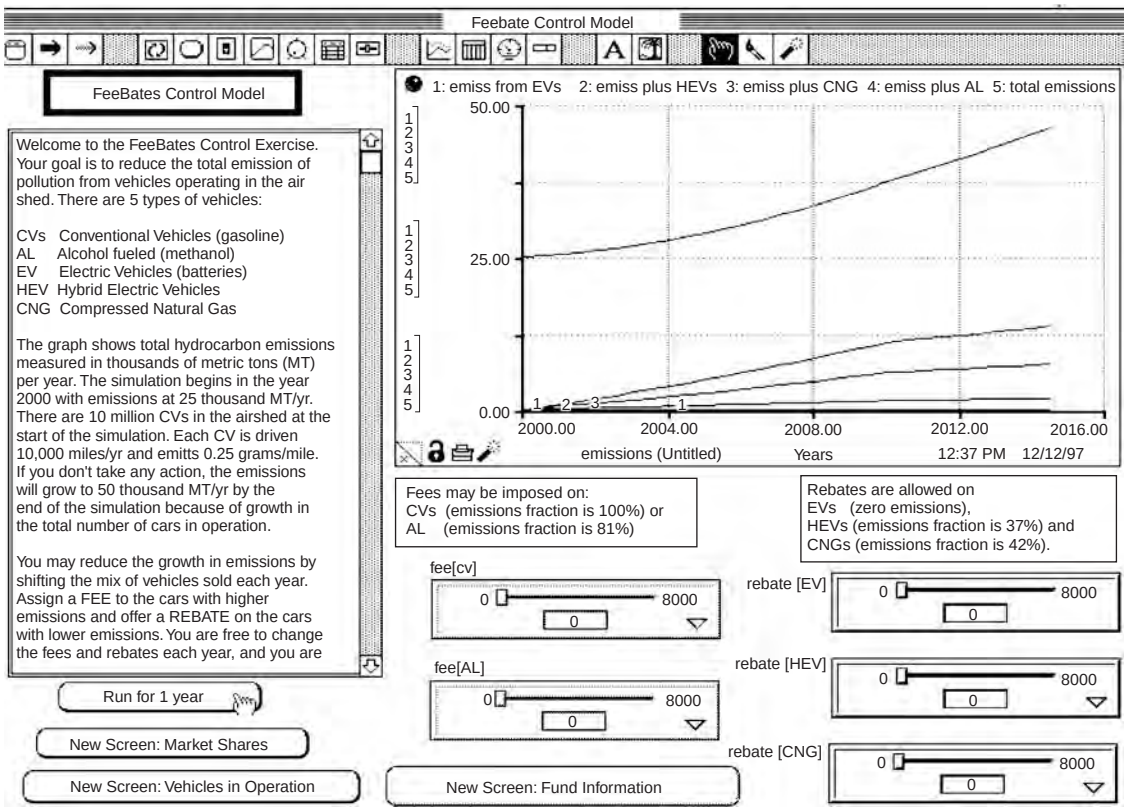

FIGURE 8 Results from a "do-nothing" simulation with the feebate model. Adapted from Ford (1999). Reprinted by permission of Island Press.

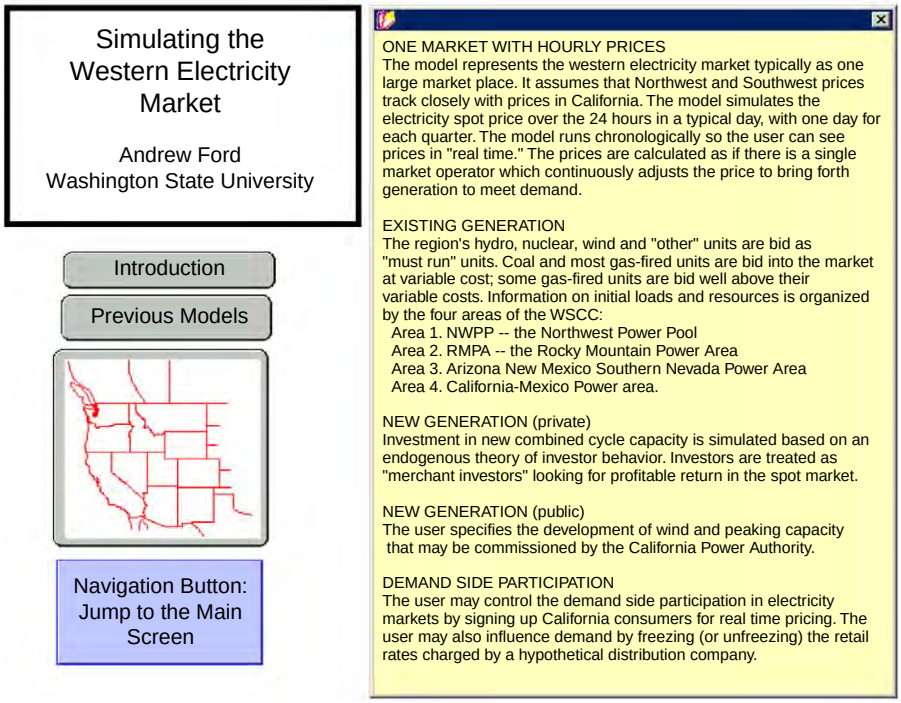

FIGURE 9 Opening screen of the western market model.

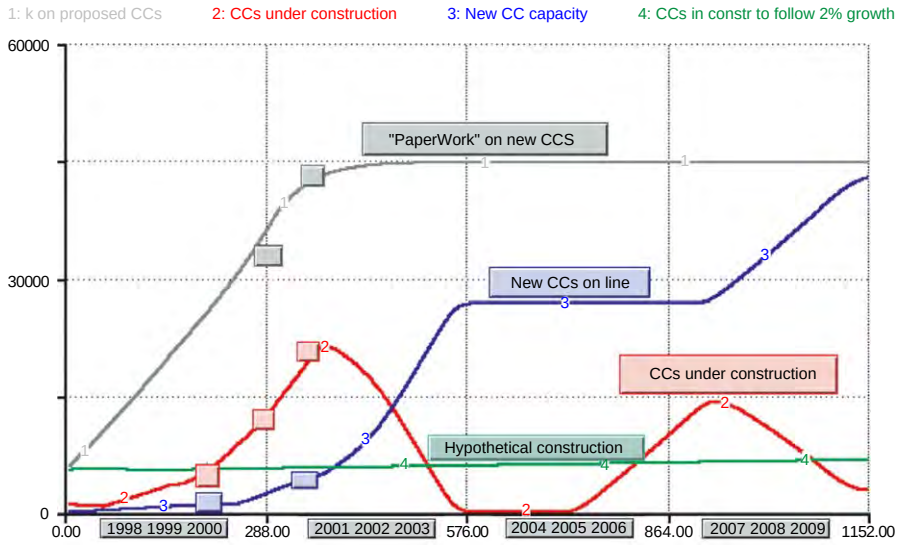

FIGURE 10 Simulated construction in the business-as-usual scenario.

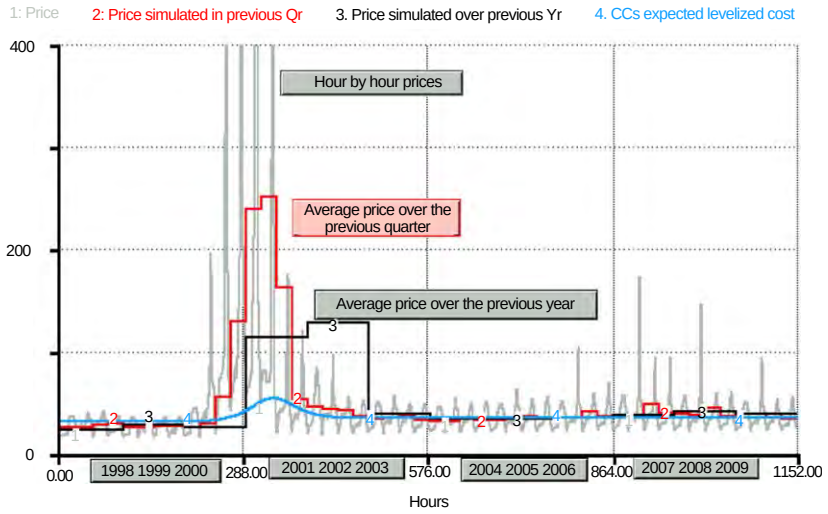

FIGURE 11 Wholesale market prices in the business-as-usual scenario.

above the hypothetical construction. This overbuilding situation continues until midway through 2003. For the next 3 years, however, the scenario envisions construction below the levels needed to keep pace with demand. During this interval, investors are reluctant to start construction, even though they hold a huge number of approved permits. Investors hold off on construction starts until 2006–2007.

Figure 11 shows market prices in the business-as-usual scenario, with the vertical scale running from \$0 to 400/MWh. The simulation indicates that hourly variations for typical days in 2002 and 2003 would be much smaller than the variations in 2001. Figure 11 shows that quarterly prices continue to decline during the interval from 2002 to 2004. The construction boom allows for much lower prices for the interval from 2002 to 2005. The figure shows that price spikes could reappear as soon as 2006 and 2007. The spikes are much less severe than the spikes in 2000 and 2001. The improved behavior arises because the scenario is based on average gas and hydro conditions. For example, gas prices do not skyrocket in 2006 like they did in 2000. Also, hydro generation does not decline in 2006 and 2007, like it did in 2000 and 2001. These assumptions mask the underlying deterioration of the

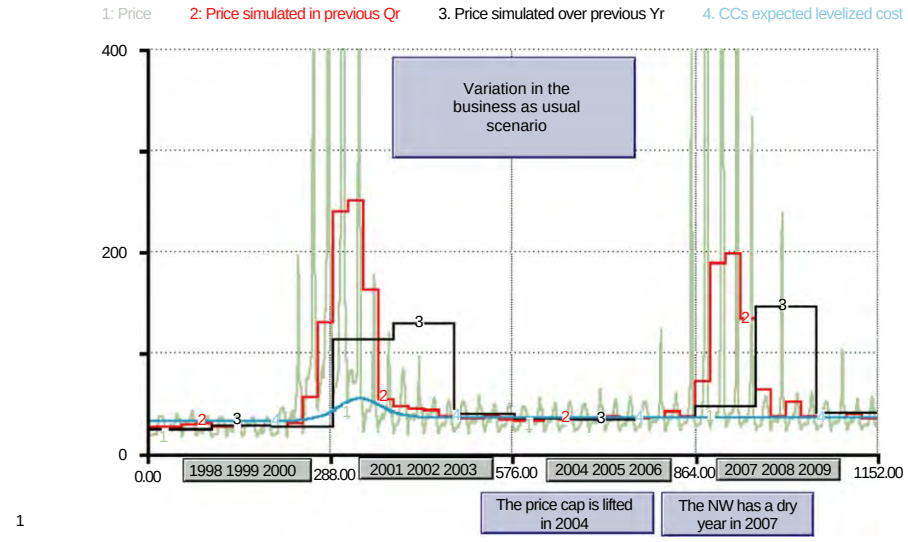

FIGURE 12 Market prices in a variation of the business-as-usual scenario.

supply–demand balance that occurs during the lull in construction.

Figure 12 shows a variation in the opening scenario to unmask the difficult conditions that could emerge within the next decade. The new simulation assumes that the northwest experiences a dry year in 2007 and that the price cap is lifted at the start of 2004. (We might envision the cap would be eliminated because those who oppose price caps would win adherents to their view during the previous 2 years—years of low prices and declining construction.) Figure 12 shows hourly prices spiking off the chart in 2007. Quarterly prices would climb to approximately $200/MWh, and the average annual price for 2007 would increase to $146/MWh, a value that exceeds the annual prices seen in either 2000 or 2001. Reserve margins (not shown here) would decline to levels lower than the simulated reserves in 2000 and 2001.

These simulations were used to promote discussion of fundamental changes in wholesale electricity markets. Without fundamental changes, the next construction boom would occur too late to prevent a decline in reserve margins and the reappearance of price spikes. If we continue with the current market structure, we run the risk of exposing the western electricity markets to another round of reliability alerts and price spikes. Alternative scenarios were generated to show the benefits of capacity payments to encourage private investment and state funding to finance public investment. On the demand side, simulation scenarios showed the benefits of implementing real-time pricing in California.

7. SUMMARY

System dynamics has been applied to a variety of energy systems at the local, state, and national level. Previous applications indicate that the method is valued for the clarity of stocks and flows and the ease of simulating the feedback loops that give rise to dynamic behavior.

Glossary

charterer An individual or entity, such as an oil company, that contracts the services of a ship under different chartering arrangements.
charterparty The chartering agreement or contract between a ship owner and the charterer.
deadweight (DWT) A rough measure of the cargo-carrying capacity of an oil tanker.
Panamax The largest size ship that can safely transit the Panama Canal given the limitations of the Panama Canal locks.
spot charter A ship contracted for a specific voyage by a charterer.
Suezmax A fully loaded tanker that can transit the Suez Canal.
supertankers Large and ultra large tankers.
time charter The leasing of a ship for a given period of time by a charterer.

Tanker transportation serves as a vital link in facilitating the movement of oil and petroleum products from their limited sources of origin to their innumerable destinations the world over. This particular segment of the ocean shipping industry constitutes the largest component of seaborne cargo movements today, with tanker cargoes accounting for approximately one-third of all cargoes shipped by sea. Although oil is also transported through pipelines as well as by tanker trucks and tanker rail cars, these movements are relatively minor and often confined to national or (in some limited cases) intraregional trades. Accordingly, this is a crucial transportation segment for the global community of oil consumers as well as for the oil suppliers and traders and also the owners of these ships. Aside from its vast commercial implications, tanker transportation is also becoming an epicenter of global attention for reasons ranging from environmental sensitivity to geopolitical apprehension, as evidenced through the actions and reactions resulting from a November 2002 catastrophe involving a laden tanker off the Brittany coast of Spain as well as the involvement of Venezuelan oil tankers in that South American nation's ongoing economic paralysis at the time of this writing. Although not widely recognized outside the industry, tanker transportation has always had inextricable links with oil trading and its geopolitics from its very formative years.

1. BRIEF HISTORY OF OIL TRADING AND TANKER TRANSPORTATION

1.1 The Early Years

Oil trading began during the late 19th century, with the United States being the leading source and the U.S.-based Standard Oil being the most dominant player, exporting refined oil to Europe using its fleet of purpose-built small ships. The Nobel brothers, sons of Alfred Nobel (the inventor of dynamite), built up a competing European fleet during the mid-1880s to trade oil from Russia that flourished until the Bolshevik revolution. Crude oil trading was not considered a feasible option during those years due to the relatively low value of the commodity. During the post-World War I era, short-haul crude oil trade originated, with most movements being to the United States from the nearby Latin American sources of Mexico and Venezuela. As the crude oil trade increased gradually, so did the need for new refining

capacity in major consumption markets. The Middle East and its vast oil resources came under Allied control during World War II and helped to meet the wartime logistical needs of the Allied forces. Another major development during those war years was the rapid construction of a large number of T-2 tankers by U.S. shipyards to supply fuel to the Allied fleet. On completion of the war, the surplus T-2 tankers were sold off at low prices, laying the foundation for the shipping fortunes of many entrepreneurial tanker owners during subsequent years.

During the postwar era, the Middle East emerged as the focal point of the oil industry, which by this time had supplanted coal as the most dominant source of primary energy for a world economy recuperating from the ravages of two closely fought world wars. Thus, although the Gluckauf, a prototype of the modern oil tanker, was launched in 1886, the highly specialized tanker transportation sector of the current vintage did not originate until the 1940s and 1950s. The increased demand for crude oil came not only from the United States and Western Europe but also from a rapidly recovering Japan, a nation devoid of indigenous oil resources. The distances between such major consumption and production centers of crude and refined oils contributed toward increased demand for the transportation of those commodities, crude oil in particular. Accordingly, the demand for oil tankers rose, hence the meteoric growth of that specialized market in a very short span of time. As viewed by maritime economists, tanker transportation is a derived demand industry, for fluctuations in the oil volumes traded usually lead to very perceptible impacts on the trading conditions within the tanker market.

Until 1952, tankers were operated primarily by the big oil companies, with independent ship owners playing a fringe role. It was typical to find marine transportation divisions within the corporate hierarchies of the vertically integrated multinational oil majors. Traditional ship owners entered the market for a brief span in 1953, to be followed later by government-owned shipping companies. By the early 1960s, the oil majors' investment in direct ownership of oil tankers had dropped to approximately one-third of the global fleet. However, the oil majors still maintained direct control of 90% of their transportation requirements, supplementing their owned fleets with ships on long-term time charter from independent ship owners. It was important for the oil companies to maintain such control because the ocean transportation component was a factor input in the landed price of their commodity. If this were to vary depending on daily market swings, it would have an impact on the price of crude oil from various suppliers despite its being a homogenous commodity. Accordingly, the oil majors procured barely one-tenth of their transportation requirements of those years from the open market through spot charter agreements. Although they had the wherewithal to provide all of their tanker needs in-house, such an attempt would only help their competitors, especially the smaller oil companies (as postulated by Zannetos), so this was not attempted.

1.2 The Golden Years

The 1960s was a period of spectacular growth in the oil industry in general, and the tanker market in particular, due to its derived nature. The rapidly growing U.S., Western European, and Japanese economies consumed large quantities of crude and refined oils, and the United States, an oil exporter during earlier years, became dependent on foreign oil by the mid-1960s. Correspondingly, oil tankers began to increase in both number and size. The ship size limitation of 65,000 deadweight (DWT) imposed by the dimensions of the Suez Canal was no longer relevant, with the bigger vessel sizes benefiting from their economies of size and contributing toward lower unit cost of oil transportation. The construction of *Universe Apollo* of 100,000 DWT in 1959 was a major landmark, as was the construction of the first ultra large crude carrier (ULCC), *Universe Iran*, 10 years later in 1969. A study by Tusiani documented that although the first 200,000-DWT tanker was not delivered until 1966, by 1973 there were a total of 366 such very large or ULCCs in trade, with another 525 being under construction or on order at the time—ample testimony to the sanguinity of the period. Thus, with the increase in demand for crude and refined oils apparently showing no end in sight, new tankers of increasing sizes, financed by overly optimistic shipping financiers, were being ordered at unprecedented levels, characterizing the 1960s and early 1970s as golden years of the tanker transportation sector.

From the oil majors' perspective, their domination of the retail market was challenged by the evolution of the oil spot market in Rotterdam, Netherlands, during the late 1960s that allowed the entry of nontraditional retailers in the market. The role of politics in oil trading and tanker transportation had also become clearly obvious by this time, starting with a brief closure of the Suez Canal in the wake of its nationalization by Egypt in 1956, leading to an

immediate increase in freight rates for a brief span of time. A more lasting closure of the Suez Canal that began in 1967, as war broke out between Egypt and Israel, remained in effect until 1975. This increased the sailing time to destinations in Europe and North America, thereby increasing the demand for tankers and further consolidating the good fortune of some tanker owners. The Organization of Petroleum Exporting Countries (OPEC) cartel, formed in 1960, remained relatively benign during the decade and did not flex its political muscle until 1973. Thus, as discussed next, an era of turbulence and uncertainty quickly permeated the oil trade and tanker transportation market, in stark contrast to the opulent 1960s and early 1970s.

1.3 The Uncertain Years

The Yom Kippur War of 1973 put a dramatic end to the phenomenal growth that oil and tanker markets experienced during the previous two decades. This, along with the Arab embargo of oil shipments to the United States and The Netherlands and the increasing dependence of the United States on oil imports, led to the first oil price shock during which the OPEC nations raised the price of a barrel of oil fivefold on an average to $10/barrel. Furthermore, the Arab nations expropriated American and European oil investments in their countries. However, all of these were merely temporary setbacks, and the global demand for oil increased again once the embargoes were lifted. The Middle East consolidated its position as the world's largest exporter of oil by the late 1970s, supplying close to three of every five barrels of oil exported in the world. However, the increasing oil prices made oil exploration economically feasible in politically safer locations such as Alaska and the North Sea. The apparent reemergence of stability in oil market was once again disturbed by political events in Iran, hence the second oil supply shock in 1979–1980 that quadrupled oil prices. The subsequent introduction of oil conservation initiatives in major consuming nations, as well as the sudden growth of non-OPEC sources of oil, made significant inroads in the market share of the Middle East crude oil in particular. The collective effects of these developments were so remarkable that the level of global oil consumption reached in 1979 was not surpassed until 1990 and was only 13% higher even 21 years later in 2000.

The events of this period were particularly troubling for tanker owners who were left with surplus shipping capacity (built under speculative contracts signed during the waning golden years discussed in the previous section) and huge mortgage payments. Thus, the golden era of the tanker transportation sector came to an abrupt end and was replaced by a period of gloom and doom that only worsened during the 1980s as the sector began to bear the full brunt of the conservation measures enacted after the second oil supply shock. As the oil prices began to stabilize, the cohesion of the OPEC cartel itself came under threat, with member nations undercutting each other and crude oil prices dropping to as low as $10/barrel. The price eventually stabilized at approximately $15 to $18 per barrel by the late 1980s, and trade volumes resumed their increasing trend. Once again, the demand for oil tankers began to rise, as did the profitability of tanker owners, until that trend was altered by a new set of problems triggered by the grounding of the Exxon *Valdez* (discussed later). The next section discusses current trends in oil movements, an understanding of which is essential to comprehend the dynamics of the contemporary tanker transportation market.

2. CURRENT OIL MOVEMENTS AND TANKER DEMAND TRENDS

International Energy Agency statistics show that total primary energy supply through crude oil increased from 2880 million tons of energy in 1973 to 3700 million tons of energy in 2000. Table I shows the major producers of crude oil and petroleum products in 2001, and Table II shows the major exporters and importers for the year 2000. A recent study by Glen and Martin estimated that 59% of world oil produced in 2000 was traded by sea, a significant increase from the prior levels of 48% in 1990 and 56% in 1995. However, estimating demand for tanker transportation based purely on the volumes traded would be inaccurate unless the distances involved were also included. As an example, the disruption in oil movements caused by the Iraqi invasion of Kuwait induced nations such as the United States to partially substitute their dependence on Middle East oil with oil from closer, politically safer locations such as the North Sea, West Africa, Venezuela, Mexico, and Colombia. In such cases, even if the volumes imported were to stay the same, the demand in ton-miles would drop. A study by Kumar reported that a shift of 10 million barrels per day in sourcing the U.S. crude oil imports from the

Middle East to the North Sea would reduce tanker demand in ton-miles, making 32 very large crude carriers (VLCCs) redundant. Likewise, a shift in the sourcing of crude oil in Western Europe from the Middle East to closer sources, such as Russian and North Sea oil, would have a similar detrimental effect on tanker demand. In situations like this, unless tanker demand in other optimum long-distance routes pick up, the very large tankers will migrate into suboptimal routes that are usually served more

efficiently by smaller vessels, and this will lower the freight rate for all players in the market.

It is worth noting that the ton-mile demand for oil tankers reached its highest value in 1977, whereas the crude oil volume traded continued its upward trend until 1979. The ton-mile peak reached for crude oil movements remains unsurpassed even today. Currently, although the United States alone is responsible for one-quarter of the world crude oil consumption, much of its imports come from closer locations that include Canada, Mexico, Venezuela, West Africa, and Colombia. The Former Soviet Union is now a prominent supplier of oil to Europe. Although roughly one-half of all current world crude oil exports originate from the Middle East, and its major export markets are currently in the Asia Pacific region to countries such as Japan and South Korea. Because the Middle East–Asia Pacific trade is a relatively long distance trade optimal for the large tankers and also because the overall crude oil volumes transported by sea are on a rising trend, the redundancies made by the crude oil sourcing shifts in Western Europe and the United States have not had a sustained direct impact on the market for very large tankers. As indicated in Table III, the estimated productivity of tanker fleet in terms of cargo loaded per deadweight ton, as well as the ton-mile demand, is on a steady upward trend after its precipitous drop during the 1980s and early 1990s. However, as noted by Glen and Martin, the average tanker haul recorded in 2000 was 4917 miles, while the average in 1977 was 6651 miles. The 26% drop in ton-mile demand is too severe a shock for a forlorn tanker owner reminiscing about the golden years. The major export areas in oil trade for the year 2000, in descending order, were the Arabian Gulf, West Africa, Venezuela, Mexico, North Africa, the Black Sea, Sidi Kerir, Indonesia/East Malaysia, China, the East Mediterranean, the Baltic Sea, and the Red Sea. The major import areas for 2000, also in descending order, were Western Europe, the United States, Japan, South Korea, Canada's east coast, Taiwan, and Hong Kong.

TABLE III

Estimated Productivity of Oil Tankers for Selected Years

Year	Oil cargo carried (in million tons) by Tankers > 50,000 DWT	Tons per DWT of tankers	Demand in billion ton-miles	Ton-miles per DWT
1970	1182	8.58	6039	43.82

3. TANKER NOMENCLATURE AND FLEET STATISTICS

Oil tankers can be classified into two broad categories: crude oil tankers and product tankers. Crude oil tankers are typically large dedicated ships that carry solely crude oil. As an example, the *Jahre Viking*, a crude oil tanker built in 1977, is the largest floating object ever built and would require 16,500 road tanker trucks to empty its full load of cargo. Although it is theoretically possible for a crude carrier to carry petroleum products, the time and monetary costs associated with tank cleaning for such a switch would be prohibitively high so that it is rarely done these days in tanker operations. The crude carriers are classified based on their carrying capacity and suitability for a particular trade, as depicted in Fig. 1. However, there is considerable variation in the deadweight figures for a particular class. For example, a deepening of the Suez Canal would propel an upward adjustment of the capacity of a Suezmax tanker. The VLCCs and ULCCs are usually used on the long-distance hauls, whereas the medium-sized vessels, Suezmax and Aframax, are used in the medium-distance ranges (e.g., from West Africa to the United States). The Panamax vessels are the largest tanker sizes that can transit the Panama Canal.

The product carriers, which are smaller vessels than the crude carriers, transport both the clean and dirty products of the petroleum refining process. However, because of the level of tank cleaning required, they usually do not switch from carrying clean products to carrying dirty products. Contrary to the crude carriers, product carriers are built to facilitate the carriage of multiple products simultaneously. They are kept well segregated throughout the loading, loaded passage, and unloading operations using a complex and sophisticated network of pipelines and valves on-board the ships. Furthermore, whereas the crude oil movements are typically one-way trades that consist of a loaded transit between one of the few export locations in the world and a major refining center followed by a ballast voyage back to the load port, product carrier

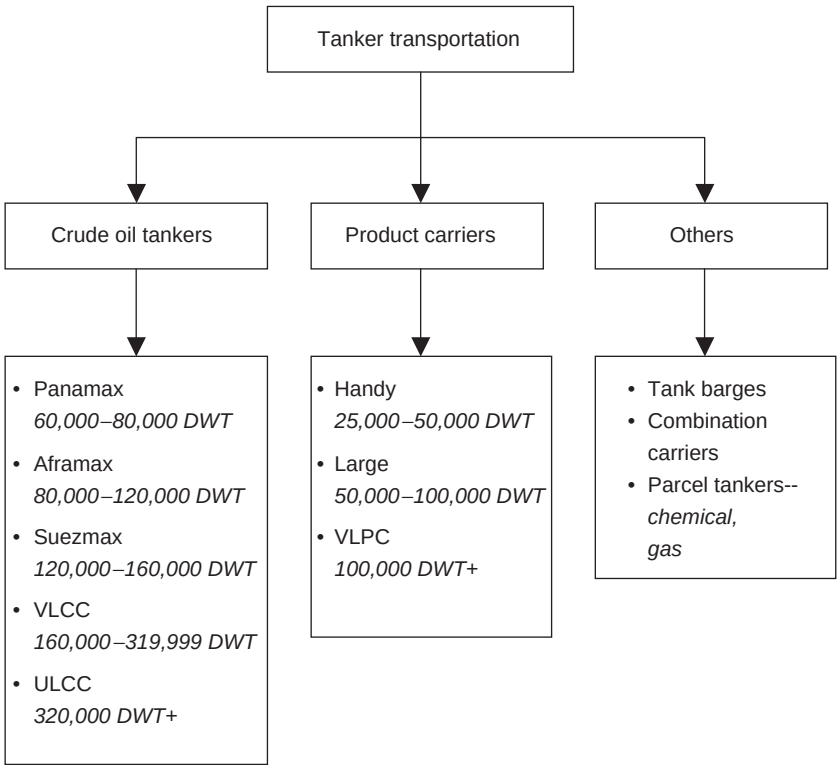

FIGURE 1 Tanker classification. VLCC, very large crude carrier; ULCC, ultra large crude carrier; VLPC, very large product carrier.

movements are more dynamic and provide better vessel use. It is not unusual to find a product carrier bringing certain products to a particular site followed by loading a different group of distillates from a refinery in that discharge port or its vicinity for discharging elsewhere.

Figure 1 also includes a third category that consists of tank barges and other ships linked to the transportation of oil and its by-products. Tank barges usually operate in coastal trade. Combination carriers, specially constructed ships that can switch from trading bulk crude oil to trading dry bulk commodities, are relatively small players in today's tanker market. The parcel tanker sector consists of highly specialized chemical tankers, liquefied petroleum gas (LPG) carriers, and liquefied natural gas (LNG) carriers. These vessels also operate outside the tanker market and are not typically included in a discussion on tanker transportation. Figure 2 provides a summary of the tanker fleet developments during the past decade or so. It shows the total tanker (gross) and net tanker fleet for each of the years, with the difference being the idle capacity. The total active fleet for each year is obtained when the combined carrier tonnage is added to the net operating fleet for each chosen year. As shown, the global tanker fleet is on a rising trend once again and the idle capacity is on the decline, showing a tightening market in general.

4. THE ECONOMICS OF TANKER MARKETS

Zannetos's extensive analysis of the tanker market found it to be rather concentrated, with 1.5% of the owners owning 35% of the fleet and the remaining 65% dispersed among the rest of the owners, none of which had a capacity share that exceeded 7% of the global fleet. Paradoxically, despite the seemingly concentrated nature of tanker ownership, Zannetos found that the market for oil tankers behaved as if it were perfectly competitive. Although a study by Kumar in 1995 based on the tanker market conditions of the post-Exxon *Valdez* years highlighted the elevation of entry barriers in tanker markets and the potential for oligopolistic behavior by incumbents, it is fair to surmise that the market has remained highly competitive throughout its life span. This section

	1989	1992	1995	1998	2001	2002
Tanker fleet	233.9	255.4	265	268.7	284.1	283.5

Active fleet	233.3	255.7	263.3	266.2	290.7	291.2

FIGURE 2 Tanker fleet statistics. Data from R. S. Platou (2002).

provides a discussion of the ownership trends, market dynamics, cost categories, and tanker freight rates.

4.1 Tanker Ownership and Market Mechanics

Although the market has maintained its competitive features, the ownership structure in the market has undergone radical changes. The oil majors, in particular, have shifted away from a policy of direct control of bulk of their tanker transportation needs to one of greater dependence on the spot market for chartering ships on an "as needed" basis. The study by Glen and Martin provided three reasons for the ongoing structural change in the composition of ownership of oil tankers: the evolution and growth of the spot market for oil and oil products, a change in the logistics strategy of oil companies, and the increasing environmental awareness of the public at large that has led to the imposition of new environmental regulations that directly affect tanker operations. Their study also found that the tanker fleet owned by the top 10 independent owners was 162% larger than the fleet size owned by the top 10 major oil companies. However, if one were to eliminate the fleet owned by government-owned oil companies from the preceding statistics, the tonnage owned by the remaining oil majors would be close to 10% of the fleet owned by the top 10 independents. Using capacity shares as a proxy for market competitiveness, the tanker market maintains a highly competitive stance. It also meets the basic behavioral assumptions of the perfect competition model within limits.

The demand for oil tankers can be satisfied either through their direct ownership or through the well-established tanker charter market that exists in commercial centers such as London and New York. The charter market brings together cargo brokers and ship brokers acting as agents of the cargo owners and ship owners, respectively. With the help of their specialized knowledge, tankers are fixed either on long-term charters or, increasingly, on spot or voyage charters. Whereas a time charter agreement allows the exclusive use of a ship and its crew for an extended period of time (e.g., 1 year), the spot or voyage charter agreement covers one specific voyage. It is also possible to acquire tankers on bareboat charter, an arrangement under which bare ships are handed over to the chartering interest, typically for long periods of time (e.g., 5 years). The charter agreement in all cases is generally referred to as a charterparty. There are a number of standardized time and voyage charterparty clauses in existence today that are widely understood by all parties involved and constitute the boilerplate clauses of all charterparties.

4.2 Tanker Costs and Operations Management

There are three categories of costs involved in tanker operations and management: capital cost, running cost, and voyage cost. Capital cost is the cost of acquiring the tanker and represents a fixed cost. Running cost is a semivariable cost and includes crew salaries and subsistence cost, maintenance and

dry-docking costs, stores and lubricant costs, and administrative expenses. Voyage cost varies with individual voyages depending on the distance and the route involved. Examples of this category include fuel cost, tug and pilot charges, port and harbor dues, and cost of transiting a canal(s). The preceding costs are borne by either the charterer or the ship owner under different charter agreements. With a voyage charter, the ship owner bears all three costs and any surplus from the charterhire would be the owner's profit. With time charter agreements, the ship owner bears capital cost as well as running cost, whereas with bareboat charters, the ship owner bears only the capital cost, with all other costs being borne by the charterer.

Unlike capital costs and voyage costs, running costs can be trimmed through various strategies. Accordingly, ship owners might pursue entrepreneurial options such as flagging their vessels in countries outside their own where there is a more benevolent attitude toward shipping through liberal regulatory and taxation policies. These convenient open flags of registry also offer liberal crewing options, particularly attractive to ship owners from nations such as the United States where labor costs are approximately five times more expensive than the going international market rates. As shown in Fig. 3, the tanker tonnage of developed market economy nations has been halved during the past 30 years, whereas the tonnage of the open registry fleet has doubled and that of the developing countries has quadrupled. As Kumar and Hoffman discussed in their recent study, such trends have led to the globalization of the shipping industry in general. Indeed, the tanker market exhibits very high levels of globalization, with the nations of Panama and Liberia being the largest registries of such vessels, although the beneficial ownership of those vessels still remains in traditional ship-owning nations such as Greece, the United States, and Japan. Unfortunately, such practices may also be used by unscrupulous ship owners to overcome the mandated minimum standards of safe ship operation, resulting in tarnishing the image of such liberalism in shipping.

Another strategy to bring down the operating cost of tankers, used independently or in combination with the flagging out strategy, is through outsourcing the technical management of ships to a third party that specializes in ship management. This has become particularly useful during the contemporary era because it helps the ship owners focus more on the strategic aspects of ownership while delegating the mundane technical aspects to a specialist who has the expertise as well as the economies associated with managing the operations of a larger fleet of ships. Furthermore, with the entry of unconventional ship owners such as pension funds and banks, there is no option but to use such dedicated ship managers who possess the technical know-how and expertise. The market for ship managers is also highly competitive with relatively no entry barriers, and there is considerable swapping of ships from one manager to the other as warranted by circumstances.

	1970	1980	1990	1998	1999	2000
Developed market economy countries	63.9	52.5	37.3	29.8	30.5	30
Open registry	26.4	36.2	41.6	51.2	50.2	50.8
Developing countries	4.7	7.7	16.3	15.9	16.2	16.1

FIGURE 3 Tanker ownership by country groups. Data from UN Conference on Trade and Development (2001).

4.3 Freight Rates

It is to be noted that transportation cost is a very small component in the retail price of oil. As an example, the study by Glen and Martin noted that in the United Kingdom, the transportation cost component amounts to less than 1.3% of the landed cost of petrol. The relatively minor incidence of the freight component in the landed cost makes it highly inelastic in nature, as predicted by economic theory and also as documented by various studies. However, as was made painfully clear especially after the second oil price shock, the demand for tanker transportation is directly related to economic activity in general so is elastic. Thus, it would be typical to find a global recession during which manufacturing activity is considerably reduced, negatively affecting the demand for oil tankers and with the resulting excess supply of shipping capacity suppressing the freight rates. The industry is very cyclical in nature, with no reliable forecasting mechanism to predict its vacillations. A period of high freight rates, whether caused by external stimuli (e.g., war, political boycott) or random events (e.g., an unusually strong winter in the northern latitudes), usually leads to high exuberance in the market. It is immediately reflected through increased new orders for ships, rising prices of second-hand ships, and reduced scrapping of older tonnage. The ship owners often find the circumstances to be changing precipitously in the other direction, more often for reasons beyond their control, although their own actions during the years of opulence may have indirectly contributed to the volatility and made the transition even more painful.

There are different ways of expressing tanker freight rates. The term used to quote freight rates in the spot market is in WorldScale (WS), where WS100 is a nominal index number. The WorldScale Association publishes an annual listing of WS100 rates (in dollars/metric ton) for all potential trade routes for a standard 75,000-DWT tanker operating under assumed conditions and earning a notional daily hire of $12,000. The principle behind the WS system is that regardless of the voyage undertaken, identical tankers will earn the same gross revenue per day. The WS nominal rate serves as a starting point for spot charter negotiations, and because the total earnings are proportional to the quantity of cargo carried, a vessel with a lower carrying capacity would typically bargain for a higher WS rating than would a larger vessel, assuming that both were trading on an identical trade. Any spot market fixture in which freight rates are expressed in dollars per ton can be converted into WS figures that facilitate easier comparison of market conditions. By converting the WS figures into time charter equivalent (TCE), a comparison can be made to the current rates in the time charter market. Likewise, a fixture in the time charter market can be converted into a WorldScale equivalent (WSE) for comparison with rates in the spot market. From a ship owner's perspective, it would be preferable to have the ship on long-term time charter when the spot rates are headed down, whereas spot fixtures would be more attractive in a rising market. However, tanker chartering still remains more of an art than a science given the inability to foresee the market changes with any level of comfort.

Ship owners have the option of laying up their ships when the market conditions are poor. Although this eliminates their voyage costs and reduces the running costs, there will be no respite from making capital cost payments. As the market recovers, idle capacity reenters the trade. However, as noted by R. S. Platou, a leading ship broker, so long as the capacity use remains below 80%, freight rates remain relatively stable. Glen and Martin referred to this as the elastic segment of the short-run supply curve of tankers. The slope of the curve increases beyond the 80% range and becomes fully vertical (completely inelastic) when all existing ships are used. Under such circumstances, any increase in the derived demand would cause dramatic fluctuations in the freight rate and, hence, the profitability of tanker owners. In the long run, the introduction of newer and more efficient ships would bring down the marginal cost of transporting the oil, culminating in the low incidence of ocean freight in the landed cost of oil discussed earlier. Furthermore, recent studies by Kavussanos and by Glen and Martin showed that different sizes of tankers operate in distinct markets with varying levels of risk and returns, although all of the submarkets remain interdependent in the long run. One commonality that affects all segments of the market, and that is becoming increasingly significant, is the regulatory environment in which all tankers operate.

5. THE REGULATORY ENVIRONMENT

The operations on-board an oil tanker are radically different from those on other types of ships, primarily due to the physical properties of the cargo. The entire cargo operations are highly automated and proceed with no one on-board the ship or shore seeing the cargo physically. Even minor misunderstanding of an order or a miscalculation can cause a

major spill in pristine locations. By the same token, a tanker crewed by properly trained seafarers under good management could very well be the safest ship afloat. Although most tanker voyages today are completed safely and go unreported, even a minor tanker pollution accident often gets widespread attention from the media, and the image of a polluted beach laden with dead flora and fauna is a sad and telling picture. Given the increasing environmental awareness of society at large, a tightening of the regulatory environment of oil tankers was only to be expected. Furthermore, investigations of many maritime casualties have shown repeatedly that most accidents were attributable to the human factor.

The International Maritime Organization (IMO), a multilateral governmental entity established under the auspices of the United Nations to promote safer shipping and cleaner seas, has been a key player in this field. The 1973/1978 MARPOL Convention imposed on tanker transportation greatly ameliorated the operational pollution of the seas, previously the predominant cause of oily efflux from tankers. The International Safety Management (ISM) Code Amendment to the Safety of Life at Sea Convention and the Amendments to the Standardization of Training, Certification, and Watchkeeping (STCW) Convention are two recent multilateral regulatory developments of particular significance. The ISM Code for the Safe Operation of Ships and Pollution Prevention applies a very tough set of standards to all aspects of shipboard operations and management. Furthermore, the shore office and the management of the firm also come under scrutiny, thereby expanding the scope of the regulatory reach to areas that were traditionally excluded. The Amendments to the STCW Convention have attempted to raise the threshold of seafarer education and training in general by mandating the minimum acceptable levels. The establishment of such a floor in maritime education was long overdue given the wide disparity in the knowledge, skills, and abilities of seafarers and the propensity of unscrupulous ship owners toward staffing their vessels with the cheapest crews available.

The most drastic regulatory impact on tanker transportation came from a unilateral regulation enacted by the United States in response to the grounding of the Exxon *Valdez* off Alaskan waters. The U.S. Oil Pollution Act (OPA) of 1990 is a comprehensive plan to prevent and clean up oil spills, impose greater liability on those responsible for spills, and compensate those who suffer resulting economic damage. Its provisions include liability, compensation, prevention, and removal aspects of a pollution incident. It mandated the need for double-hull tankers and established a phase-out period for the existing single-hull tankers. Above all, the law also eliminated the limitation of liability of ship owners involved in pollution incidents, and many tanker owners immediately responded by staying away from the U.S. market (at least temporarily). The IMO enacted new tanker design rules in the wake of the U.S. initiative, giving ship owners the option of building ships with double hulls or an equivalent level of protection. However, given the U.S. mandate, the industry has gravitated toward the double hull as the requisite standard bearer.

Given the diversity in ship ownership and operation, the existence of multilateral and/or unilateral regulations alone does not necessarily make the industry any safer. Investigation of past casualties has often shown some flag states to be negligent in enforcing the statutes. As a result, many nations have enacted a procedure whereby ships that visit their ports are inspected by local authorities for compliance with international standards. Such port state control inspections are now very common in most trading areas and result in rogue ships being arrested and their names being publicized through the media Despite all of the new regulations, tanker accidents still do happen, as was illustrated in the case of the ship *Erika*, a 1970s Japanese-built, Maltese-flagged, Italian-owned tanker. The ship, laden with 30,000 tons of viscous fuel oil on a voyage from Dunkirk to Leghorn (under charter to TotalFinaElf, the French oil major), encountered stormy seas and sank off the coast of France in December 1999, spilling 12,000 tons of its cargo and causing severe environmental and economic damage. The IMO, under pressure from the European Union, amended the MARPOL Convention in April 2001 to speed up the phasing out of single-hull tankers and also empowered member states to ban the entry of such tankers that are more than 25 years old. One direct consequence of the changing regulatory ambience has been the trend toward divestment of tankers by oil majors such as Exxon–Mobil. Currently, the oil majors' tanker fleet is the smallest that they have ever had during the modern tanker era.

6. RECENT DEVELOPMENTS AND OUTLOOK FOR THE FUTURE

Developments during the first 3 years of the new millennium serve as an excellent synopsis of the

unpredictability of the tanker transportation sector. Commercially, 2000 was an exceptional bull market year, with a tightening supply of ships and increasing demand. However, there was a precipitous downward dip in 2001, as depicted in Fig. 4, due to a global recession that led to lower demand for oil along with the rising security concerns resulting from the World Trade Center attacks. The relatively weak winter season in North America and the reemergence of Russia as a major player in the oil export sector did not help the tanker market either. However, the market dynamics changed dramatically in mid-October 2002, once again driven by geopolitical developments. As the possibility of a U.S. attack on Iraq became evident in October 2002, charterers began stockpiling inventory prior to the outbreak of hostilities and increasing the demand for modern larger tankers that eventually filtered down to the smaller classes of ships. Furthermore, the ongoing political crisis in Venezuela had halted oil exports from that nation. This affected the tanker market directly due to the involvement of striking government-owned Venezuelan tankers as well as to the urgency to find alternate oil supplies for the United States, a nation that depended on Venezuela for 13% of its oil imports before the political crisis began. Because the new supplies would have to come from more distant sources, this would also add to the demand in ton-miles of oil movements in 2003. The OPEC cartel, faced with the high oil prices affecting their potential market share, has been moving to increase production and attempt lowering the crude oil price to the $25 to $28 range, which is optimal for their own sustained competitiveness. The increased loading from OPEC nations will also need larger tanker tonnage and, hence, will increase their demand. The trade journals reported a tripling of the daily charterhire for modern VLCCs to $74,000 per day in early January 2003 from the 2002 average level of $23,300 per day.

The spectacular progress made in the safety of the sea and in the reduction of environmental pollution from tanker operations was documented in a recent study on oil in the sea by the U.S. National Research Council. According to that study, 62% of the petroleum hydrocarbon inputs into North American marine waters during the 1990s came from natural seeps, 32% came from the consumption of oil, and only 3.5% came from the transportation of petroleum (none of which was caused by routine operations such as tank cleaning). The corresponding worldwide figures were 46, 37, and 11.5%. The Kumar and Hoffman study also documented the decreasing loss of ships and lives at sea. However, there was yet another tanker laden with heavy fuel oil that broke and sank off the coast of Spain in November 2002, a stark reminder of the *Erika*

	1997	1998	1999	2000	2001
VLCC, modern	36.6	33.3	19.6	53.4	34.7

FIGURE 4 Average single voyage freight rates. Data from R. S. Platou (2002).

tragedy. The *Prestige*, the ship in question, was a 26-year-old, Japanese-built, Bahamas-flagged single-hull tanker operated by a Greek firm, certified by a U.S.-based classification society, and on charter to a Switzerland-based Russian trading company carrying heavy fuel oil from Latvia to Singapore. This has reenergized the opposition to single-hull tankers in the European Union as well as in the United States. The European Union has been pushing for a ban on all single-hull tankers by 2010 as well as on any tanker more than 23 years old, 5 years ahead of the current mandate. It also has banned such tankers carrying the heavy fuel oil-type cargo from calling at European ports. This will affect the market significantly given that 53% of the world tanker fleet is of single-hull design and 80% of those ships are at least 15 years old.

Although the preceding analysis appears to imply that owners of good modern tankers stand to gain from the ongoing market volatility, there are notable troubling developments as well. Piracy attacks against merchant ships are on the ascent once again and currently cost the global economy $25 billion per year, according to the International Maritime Bureau. The consequences of a piracy attack on a laden oil tanker in a sensitive region could be truly catastrophic, and the economic damages could be phenomenal. Furthermore, the attack on a French tanker off the coast of Yemen in October 2002 is a sad reminder that tanker transportation could easily become a defenseless and innocent victim of terrorism. The recent Al Qaeda warning to slash the economic lifeline of the world's industrialized societies sounds ominously true given the inherent vulnerability of tanker transportation.

1. **Principles and Issues in the Taxation of Energy**
2. **Taxation of Upstream Energy Production**
3. **Taxation Of Downstream Energy**

Glossary

downstream The stage of use or consumption of energy products.
elasticity The percentage change of a response, such as the quantity demanded, caused by a 1% change in some driving force, such as the price of the good.
excise A fixed amount of tax for each unit sold of the good.
externality A negative externality is created when the actions of one producer or consumer produce an effect that has negative consequences for other producers or households not involved in the decision to take that action.
Ramsey taxes The set of taxes on goods and services designed to raise a given sum of money for the government while minimizing the welfare loss to consumers from the higher prices caused by the taxes.
rent The economic rent of a natural resource is the difference between the price it can be sold for and the full cost of production including the minimum required return on investment.
subsidy The sale of a good below the cost of production financed out of the government budget.
upstream The stage of production of oil, gas, or coal.

Taxes on energy range from those raised on electricity sales, which are generally similar to the general range of taxes on other goods and services, through to taxes on automotive fuels, which in most countries are considerably higher than taxes on other goods and contribute large amounts to government budgets, and finally to taxation on the production of oil (which occurs on a sizable scale in more than 50 countries), which can account for a very large fraction of total government revenue and of the country's national income. A number of factors determine the relative taxation on different energy products; these include factors related to income distribution and equity, to the need to attract investment into the energy sectors, and to the correction of various negative externalities, where the use of a fuel by an individual firm or household leads to adverse impacts on other firms and households. The magnitude of tax receipts from upstream energy production leads to a number of special issues. First, there is the design of the tax structure so as to yield the maximum benefit to the country not only at the present moment but also over the future through its incentives for further investment into the natural resource. Second, the tax receipts need to be transparent to avoid misappropriation, and third, their use and expenditure need to be well planned so as to avoid macroeconomic distortions following ill-founded policies and to preserve equity at the individual and regional levels. The nature of the energy sector is such that the oil sector, both upstream and downstream, has the most distinct tax issues; gas upstream followed by coal is the next most specific, and the taxation of electricity is treated virtually everywhere the same as any other good and raises few distinct issues. The relative importance of these factors is reflected in the amount of space devoted to them in this article.

1. PRINCIPLES AND ISSUES IN THE TAXATION OF ENERGY

The taxation of energy, which involves the transfer of money to the central or local government, related to the production or consumption of energy by a firm or household, is a major source of revenue for most governments in both industrial and developing countries. Taxes are levied both on the upstream (production of primary energy sources, such as crude oil or natural gas) and on the downstream, where the

 © 2004 Elsevier Inc. All rights reserved.

primary source has been transformed or transported to a point where it is consumed (electricity, gasoline). Downstream energy taxes, which are often high compared to the costs of production or the price of a unit of consumption net of tax, can have impacts throughout an economy through raising the price at which energy is sold, as well as providing a source of revenue to finance government spending. Since all consumers, apart from the poorest families in developing countries, and virtually all firms use commercial sources of energy (biomass collected and burnt by households and small farmers being an example of noncommercial and therefore nontaxed energy), this taxation, through both its universality and its magnitude, substantially affects most households directly through the price paid for energy and indirectly through the impact of the cost of energy on the price of other goods purchased.

The structure of upstream taxation on the extraction of oil, gas, and coal is extremely important for attracting investment into these sectors and hence for ensuring that the government can benefit from revenues into the future. Since natural resources often command substantial elements of rent, whereby the sale price is greater than the full cost of extraction, there is a natural tendency for governments to attempt to capture a large share of such rents, but this must be balanced against future receipts, since too high a tax rate will discourage investment and reduce the future tax base.

Taxes, in addition to providing valuable revenue for governments, alter the behavior of firms and consumers as they react to higher costs and prices. This can be used as a policy instrument for reducing certain "external effects" of the consumption of certain forms of energy, whereby damage is caused, to those not using these sources, by the emissions from their combustion.

1.1 Theoretical Issues in the Taxation of Energy

The primary purpose of all forms of taxation, whether on energy or on nonenergy items, is to raise money for the government to finance its expenditures. Taxes finance the majority of government expenditure (the rest being financed by borrowing, which will have to be repaid from future taxation) so that the general level of taxation is determined by the requirements for government spending. However, the same total revenue can be raised by many different combinations of taxes, so that the tax rates on individual items and groups of items can be adjusted to reflect other criteria. First, the balance between direct taxation of incomes and the indirect taxation of goods and services will reflect the ease of collection, with low-income developing countries relying more on indirect taxes, which are easier to collect. Second, the relative tax rates on different goods will reflect the impacts on household welfare. Principles of tax design have been developed, following the seminal work of Ramsey, which suggest that goods with higher price elasticities of demand (sensitivity to a given percentage changes in prices) should attract the lowest tax rates and those with lower price elasticities should attract higher tax rates. This principle can be elaborated to take account of the degree to which consumers will substitute between particular goods as the tax rate of one is raised relative to that on the other. A further consideration for tax design is that, under certain assumptions, it is not optimal to tax goods when they are used as an input to another good (such as the case of fuel oil used for generating electricity) because it is less damaging to welfare to tax the final good itself. The generalized Ramsey rule can then, in principle, be used to calculate a set of tax rates that raises a given sum of money at the least loss of economic welfare to households in the economy. The set of "optimal taxes" that satisfy these principles is in practice difficult to calculate precisely because of the very large informational requirements that it has and also because it rests on a number of assumptions that do not hold exactly in most countries.

Two further adjustments to the principles of determining the relative tax rates on different goods are of considerable practical importance. Because many governments are concerned with equity and income distribution, there is a common suggestion that tax rates on those goods that form a relatively higher share of the budget for low-income households should be lower and tax rates on those goods that are relatively more important for high-income groups should tend to be set relatively high. A final consideration comes from the fact that the consumption and use of various forms of energy, as well as conferring benefits on those that use them, create damage and impose costs (both indirect and direct) on those who do not use them. This consideration has led some governments to raise taxes further on such fuels in order to discourage their use and reduce the negative effects on nonusers (the "polluter pays" principle). This element is referred to as a Pigovian tax. An extension of this principle is that it is socially more beneficial to correct an externality by taxing

the offending good, rather than by subsidizing a substitute good that creates a smaller external effect.

1.2 Issues in Designing Tax Systems

Governments, in moving from general considerations for the raising of revenue to practical issues, face a number of difficulties. Often, the costs of collection of certain taxes would be so high, in relation to the revenue raised, that relying on such a tax would not be cost-effective. For example, the taxation of incomes in many countries is extremely difficult because of the lack of any apparatus to assess incomes. In particular, in developing countries with a large self-employed sector, even identifying who the income earners are would be very costly and then obtaining any independent check on the levels of incomes would be equally difficult. Hence, although higher income groups may be taxed directly, the government will typically look at indirect taxation on goods (including energy) and services as a more effective way of collecting the revenue required. Conversely, in countries with well-developed means of identifying income earners and their sources of incomes, direct taxes play a much more important role for the government's total budget.

The production of energy, as with other goods and services, is also subject to those taxes that are borne by companies. The major forms of such taxes are corporate taxes, which are a tax on profits, and dividends taxes, which are a tax on incomes received from profits. If these are applied at the same rate, irrespective of the sector involved, then the main effect is to raise revenue for the government, rather than to shift the relative supply or demand of one sector versus another. Again, such taxes are most important in countries where accounting systems are better developed.

Indirect taxation on goods and services has several forms. Tax rates can be set as a percentage of the final sales price or of value added; the amounts per unit sold collected from such taxes will rise or fall as prices rise and fall. Alternatively, taxes can be set as fixed amounts per unit (excise duty) that do not change with prices. The use of a system of value-added taxes (VAT) requires accounts to be drawn up by all firms in the production chain, which again is difficult to monitor in less advanced countries. Hence, VAT systems are found mainly in more advanced economies, whereas sales taxes, which require the identification only of final sellers, are relatively more common in less developed countries.

Downstream taxation of oil products, whether or not the country is an oil producer, tend to attract the general sales tax rate (or VAT) levied on all other goods, plus an additional excise duty, which usually varies among them. The use of this additional tax component on oil products can be justified by several arguments: there are easily identifiable points of sale; they have relatively low price elasticities; in some countries they are of larger importance for higher income groups than lower income groups; and there are associated negative externalities from their combustion. The use of an excise duty (a fixed sum per unit sold) also gives some stability to this important source of revenue, which otherwise could experience major variations because of the volatility of the sales tax per unit received caused by large fluctuations in the world oil price.

Governments raise revenue from the taxation of upstream energy, especially oil, through a number of instruments, not all of which are called taxes, but which function in largely the same way as taxes in terms of revenue raising. These include royalty payments, normal company taxes, bonus payments, profit oil, and government participation sales. The particular forms involved in the oil fiscal system, because they have different impacts on returns to the companies and to the government in varying circumstances (primarily the costs of production, the output of oil, and the price of oil), will determine the willingness of the private sector to invest in the sector and hence the government's ultimate access to revenue from this source. If the total tax rate is set very low, there will be plenty of investment but little tax revenue, whereas if the tax is set very high, there will be little investment and again little tax revenue. Good tax design attempts to ensure a fairly steady tax revenue stream, which will be high and robust against a variety of circumstances. Upstream taxes are unlike most other forms of taxation in that some elements applying to a particular project are part of a bargain struck before the investment takes place and are not usually changed during the life of that investment. They can, however, vary from project to project depending on the particular factors involved at the time of the negotiation. Upstream tax elements of general application have tended to be changed frequently as profitability has changed over time.

1.3 Taxes and the Government Budget

Energy taxes are an important source of revenue in virtually every country and, for countries that are oil and gas producers, they can be the dominant source

of government revenue. Data covering a large number of countries are not available, but information shown in Table I is indicative. For those of the lower income countries that were not oil producers and that had no upstream tax revenue, the taxes on petroleum products accounted for as much as one-quarter of all government revenue, whereas for the higher income countries, even if they were oil producers, downstream oil product tax revenue accounted for approximately 5% of total tax revenue. The United States was exceptional in its share being under 2%. This reliance on petroleum products for taxation also explains why non-oil-producing governments can be strongly affected by variations in the international price of crude oil and oil products. Since the elasticity of demand for such products is typically low—a price fall of 10% might lead to a rise in consumption of not more than 5%—a fall in oil prices would lead to a fall in government revenue if the tax rate were proportional to prices. Hence, governments usually impose a large fixed excise-duty element to ensure a more steady revenue stream. The disadvantage of excise duties is that they do not increase with a general increase in the price level (inflation) so that governments must adjust the rate periodically to ensure that tax revenue stays constant in terms of its purchasing power.

TABLE I

Tax Revenue from Domestic Consumption of Petroleum Products

Taxes on energy products are not usually hypothecated—they are not earmarked for specific uses—but rather go into the general budget, together with all other tax revenues, for allocation to the various items of government expenditure. In some countries, taxes on transportation fuels are linked directly to government expenditures on road maintenance and construction, as a way of ensuring that those who use roads most pay directly for some of the costs of their use of the road system. This arrangement is based on a crude approximation between tax paid and the wear caused, because higher fuel consumption will be associated with heavier vehicles as well as with greater distance traveled.

Upstream sources of energy are subject to distinct forms of taxation. For countries that produce oil or gas, the importance of tax revenues from these activities can be overwhelming. For coal, where rents are altogether much smaller in most cases, the tax receipts from royalties are important but not dominant in the economy. Most of the world's large coal producers are also large economies so that the relative size of the coal sector is less dominant than is the oil sector in a number of the small economies where oil is produced.

Although details of individual upstream oil taxes (and other fiscal charges) paid are often confidential, and governments in many developing countries are reluctant to publish figures on their total oil revenues, some estimates are available. Table II shows the huge dependence of certain countries on upstream oil taxes for the government budget and also their dominant role in the macroeconomy. The availability of such large sums of money, which will last only for the life of the oil fields, poses very special problems for the government. The size of these revenues, their sensitivity to variations in the world oil price, and their temporary nature have led governments in a number of oil-producing countries to establish special "oil funds" into which part of the revenue is paid. Such funds, which may be purely a bookkeeping exercise in the general budget and not a separate fund in a true sense, have been used for budget stabilization and for savings ("future generations fund"). A stabilization fund accumulates money from oil tax receipts when the oil price is higher than some projected average value and releases funds into the budget when the oil price is lower than some value. This has the

TABLE II

Tax Revenues from Upstream Oil and Gas for Selected Countries

Country	As % of government revenue	As % of national income
Algeria	65	30
Angola	70–90	>60
Cameroon	20	<5

Norway	15	10
Venezuela	55	28

Note. Values are estimates from various sources including McPherson (2002) for the period around 2000.

effect of allowing the government expenditure to be stabilized even when oil tax revenues vary. Oil savings funds are designed to accumulate funds and invest them separately in a responsible fashion, so as to provide an income for the country at a later date when the oil starts to run out or when the country can spend the money more effectively. The amount of oil tax revenue going to the budget will depend on whether the rules for accumulation into such funds are mandatory or optional. Similarly, the rules for withdrawal are specified in different ways in different countries, although the government can always change the rules to meet pressing needs. Another way in which upstream revenues are earmarked is seen in countries where there is a formula for returning part of the revenue to the regional or local government in the area where the extraction is taking place. This is done in order to give local communities, who feel a particular ownership of the resource and are directly impacted by its extraction in their neighborhood, some direct financial benefits from the revenues collected by allowing them to have control over how it is spent in their region.

Where there is a formal federal system (e.g., Canada or Nigeria), the tax revenues can be channeled through the regional governments, which may involve significant dialogue and negotiations. Where there is no regional government, the actual channeling and use of funds according to local wishes create a need for an extra mechanism for dialogue between the central government and local communities.

1.4 Energy Taxes and Environmental Concerns

The combustion of fossil fuels and of biomass creates a number of external effects, which societies are becoming more aware of and more anxious to mitigate. The selection of different tax rates for fossil fuels is one of the most important policy instruments to achieve such an effect. The three classes of activity that have received the most attention with regard to the treatment of externalities are the use of gasoline and diesel as automotive fuels, the use of coal and fuel oil to generate electricity, and the use of biomass for cooking and heating.

Fuels used in small low-stack sources, which are primarily vehicles but also include small diesel generators, have both local and global environmental impacts. The emissions of fine-particulate matter, sulfur dioxide, and oxides of nitrogen (which are also ozone precursors) have adverse impacts on health, especially in mega-cities, where the volume and density of traffic are very high. In particular, the incidence and severity of respiratory diseases are associated with particulate emissions. Policies to improve fuels' qualities are being widely implemented in countries with serious urban air pollution, with the United States and the European Union taking the lead in pursuing the best available technology. For example, cities such as Delhi, Los Angeles, and Mexico City have suffered from deteriorating air quality and as a result have taken aggressive action to monitor and reduce air pollution. However, particularly in the European Union, the use of increased taxes on fuels, as well as raising extra revenue for governments, has been seen as a way to reduce or slow the growth in their consumption and hence to improve the levels of urban air pollution. In addition, any such reduction in fuel use will also reduce the emission of carbon dioxide, which is a greenhouse gas and is associated with global warming, which can have effects on societies far in time and place from when and where the original combustion took place. Since raising taxes on automotive fuels also reduces consumer welfare, there must be a balance between these two effects, so that tax rates reflect the relative values a society places on these factors.

Additional and important externalities of vehicle use come from the impacts on congestion, on the incidence of accidents, and on the damage to roads from their use. Greater vehicle use imposes costs on other users in terms of time taken to drive to a particular location (especially at peak times) and on

the number of accidents caused, some of which are fatal. Because the decision to drive, use another form of transport, or stay at home depends on the costs to the individual traveler, but not on the costs imposed on others, fuels taxes have been seen as a corrective to these problems also. In all these cases, there may be policies that impact more directly on the relevant factor (e.g., a tax on emissions rather than fuel used, a tax on axle weight, or a charge for driving at peak times) but the simplicity of imposing a tax on the fuel itself, which then links to all these concerns, has thus far meant that policymakers have only just begun to make use of such more finely tuned corrective schemes.

Estimates for the optimal gasoline taxes in the United States and the United Kingdom that take most of these factors into account have been made. This tax, together with other taxes, is required to raise a fixed sum of money for the government while maximizing the welfare of society as a whole. Although the calculations are based on a number of assumptions about individual parameters, such as the economic cost of a fatal accident, Table III gives some important results that are fairly robust to variations in the assumptions. These calculations indicate that the optimal U.S. excise tax rate (exclusive of federal and local sales taxes) is approximately twice the actual rate, whereas in the United Kingdom it is approximately half the actual rate. The sizes of the various components indicate that the extra amount of tax required to make the optimal adjustment for global pollution effects is small, whereas that for local pollution is substantial (approximately 15% of the optimal excise tax would be for this component). The amounts related to the direct externalities caused by congestion differ substantially between the two countries, reflecting their individual characteristics, but are large in both. The component designed to reduce the use of fuel, and hence reduce the incidence of accidents, also accounts for a large fraction of the tax. The pure Ramsey component, which relates to raising finance for the government (over and above that already raised through the component designed to discourage pollution) in such a way as to minimize the welfare losses to consumers, is approximately 25% of the total tax rate. A particularly important effect in calculating the optimal tax is shown to be the incorporation of the impacts of increased fuel taxes on the fuel efficiency of vehicle miles driven. Evidence suggests that fuel efficiency per mile does increase substantially as fuel taxes are increased, so that taxes need not be as high to combat pollution as they would be if there were no response in fuel efficiency. These calculations also suggest that gasoline taxes are much higher than the general level of taxation of goods, so that the relatively small extra component required to reduce consumption in line with damage from global warming can be easily accommodated.

TABLE III

Illustrative Calculations for Optimal Gasoline Taxes in the United States and United Kingdom (in Cents per Gallon at U.S. 2000 Prices)

Tax component	United States	United Kingdom
Pollution, fuel-related (global)	5	5
Pollution, distance-related (local)	16	17
Congestion	30	68
Accidents	24	20
Ramsey component	26	23
Optimal tax	101	134

Diesel fuel, when it is used solely as an input to a further economic activity (as for the transportation of materials and as a fuel in power stations), would not need be taxed if these final products were taxed and if there were no externality associated with the fuel combustion. However, diesel does create substantial emissions that create local damage (especially from vehicles) so that considerations similar to those for determining the level of gasoline taxation apply to the taxation of automotive diesel. One particular issue that concerns policymakers in many countries is the relative tax rates for gasoline and for diesel. Gasoline taxes are usually higher, which leads, over the longer run, to a substitution away from gasoline-fueled vehicles toward diesel-fueled vehicles. Since the congestion- and accident-related effects of the two are similar, attention is then focused on their relative pollution effects and in particular on whether the local damage from diesel might not be greater than that from gasoline. More important may be the fact that diesel is also used as an intermediate good, as for commercial and industrial vehicle transport, which leads to a focus on taxing the final good rather than the intermediate good and hence to setting lower tax rates on diesel than on gasoline.

Environmental concerns also impact attitudes regarding the taxation of coal, fuel oil, and natural gas. Coal and fuel oil are consumed largely as inputs to electricity and, according to pure Ramsey-type principles, need not be taxed in that use if electricity

were taxed and there were to be no external effects from their combustion. However, both fuels create strong negative externalities in terms of their emissions, unless very substantial and expensive techniques are used for removing the pollutants. Again, taxes on these fuels can be used to encourage the switching to another less polluting fuel. Since natural gas is very much less polluting than these other fuels, the relative tax rate on its use can be adjusted downward to encourage its use in situations where it would not otherwise be used.

In some countries, such as South Africa and China, household consumption of coal is still substantial and has large negative external effects, but the desire to support the local industry has thus far kept the governments from discouraging the use of coal through higher taxation.

A final reason for lowering the taxes on those fuels (and electricity) used for cooking is that, in countries where biomass is available, poorer households often use biomass as the main fuel of choice. This creates very considerable indoor air pollution, which has large adverse health effects for women and children from inhalation, and, although this is not an externality that requires correction through a "making the polluter pay" approach, it can be seen as a demerit good where users do not fully understand the consequences of their own actions. In the general case of demerit goods, taxation is often used to discourage households from using those goods whose consumption is in fact bad for their own welfare, as in the case of tobacco. However, biomass has two distinct characteristics: first, it can be an absolute necessity for the poorest households, and second, it is often not a marketed good. In rural and periurban areas, households often collect the biomass themselves (rather than purchase it directly) since it is free in monetary terms (although it may takes much time and effort on the part of women to collect the fuel). This can lead to gradual deforestation (as in Haiti or parts of Indonesia), which in turn has adverse ecological effects. A strategy of taxing the offending good (biomass) and not reducing taxes on the substitute goods (e.g., kerosene) is not available because biomass is either not marketed at all or else is sold through very informal systems. Hence, policies to encourage a switch from the use of biomass to commercial fuels such as kerosene, through lower tax rates or even subsidies, have been justified as a way to reduce this environmental damage and to improve the health of these households. The effectiveness of such a scheme is limited in cases where households are so poor that they are unwilling to purchase any commercial fuel (at prices sustainable for the government) rather than to use nonmarketed biomass.

1.5 Taxation and Income Distribution

Any system of taxing goods and services is likely to have differential impacts on households of different income levels. In industrialized countries, the majority of households own cars, so that a tax on automotive fuels is likely to be regressive because expenditure on them will take a larger share of the household budget for lower income households. However, in developing countries, lower income households neither own cars and directly consume transportation fuels nor are connected to the electricity grid. Thus, raising taxes on these products in developing countries is likely to result in an improvement in income distribution, because the better off may pay more in both absolute and relative terms. Indeed, with such a case, equity can be seen as an extra factor to be taken into account following the analysis described in the previous section. In developing countries, this might justify tax rates on gasoline being further raised. However, the position of the taxation of other petroleum products is more sensitive to the importance of the distribution of income. For example, diesel-fueled transportation (buses and trucks) is important for poorer urban households and nonautomotive fuels (liquified petroleum gas and kerosene) are important for lighting and cooking for a wide range of the lower to middle income groups in many developing countries. Nonautomotive fuels are not associated with creating congestion and economic loss or with high levels of local pollution, so that tax rates on these fuels would be expected to be lower than that for gasoline. In addition, their greater importance in the budgets of lower income (if not the poorest) households in developing countries has led governments concerned with income distributional consequences to lower tax rates on these items, in line with a generalized Ramsey approach, which indicates that there should be lower taxes on those goods consumed relatively largely by the poor and higher taxes (so as to obtain the same overall revenue) on those goods consumed more intensively by better off households. Indeed, in many developing countries, these products are often subsidized by the state (effectively negative taxation, where the state returns some money collected from other taxes to the consumers of these goods).

Attempts to introduce substantially different tax rates on the various petroleum products, where the

costs of production are fairly similar, can lead to sufficiently large retail price differences such that fuel adulteration starts to occur. Consumers or retailers may dilute diesel fuel with kerosene, which loses the government revenue, or, more seriously, dilute gasoline with kerosene, which increases engine deposits and emissions. Similarly, the situation where fuel destined for export is not subject to taxation, yet fuel for domestic consumption incurs heavy taxation, leads to fuel designed for export to be diverted illegally to the domestic market. Large differences in tax rates between neighboring countries can lead to smuggling and illegal sales, which avoid the payment of such taxes.

1.6 Political Economy of Energy Taxation

Decisions on how to tax upstream or downstream energy supplies are taken by governments and reflect the importance of the various factors outlined above. Different groups in society attach different degrees of importance to these factors and accordingly would wish to see taxes reflect this. For downstream production (electricity, petroleum products) where the price, net of tax, would be close to the total costs of production in competitive markets, the imposition of taxes then transfers money from one group (the users) to whichever groups benefit from tax expenditures. In addition, the reduction in consumption and local pollution resulting from the higher prices may benefit a different group within the country and, through any impacts on global warming, may benefit people outside the country.

Governments that have historically subsidized or set disproportionately low taxes on energy products, as a way of supporting poorer members of society (as in many developing countries), have often later realized that the cost of such a program is huge and have wished to reduce the financial burden to the budget of the subsidies by raising prices to cover costs. Table IV indicates that for eight of the largest energy-using countries outside the industrialized world: (1) the average subsidy on energy is approximately 20% of the price of energy and (2) removing these subsidies by this amount and allowing consumer expenditure to be redistributed to other goods would increase the countries' gross domestic product by approximately 0.75%, reduce energy consumption by 13%, and reduce carbon dioxide emissions by approximately 16%. Nevertheless, the visibility of energy prices and their importance to groups in society that are politically well organized and articulate (such as motorists' organizations) has meant that governments have found it difficult to reduce subsidies or increase taxes by substantial amounts. In several developing countries, programs to increase fuel prices by reducing subsidies or increasing taxes, without elaborate public relations campaigns, have resulted in widespread demonstrations, with the result that the proposed increases have had to be substantially cut back or even canceled.

The political economy of upstream oil taxation is distinct, because of the fact that the strategy of the Organization of Petroleum Exporting Countries (OPEC) is to act as a cartel and to adjust the production of oil so as to ensure that the world price

TABLE IV

The Results of Removing Energy Subsidies

Country	Subsidy as % of price	Gain as % of GDP[a]	% Reduction in energy consumption	% Reduction in CO_2 emissions
China	10.9	0.37	9.4	13.4
Russia	32.5	1.54	18.0	17.1

[a] GDP, gross domestic product.

of crude remains well above the full cost of production, and because of the fact that the costs of supply vary so much between countries. These have resulted in a situation in many countries where there is such a large element of economic rent (the difference between the full cost of production and the selling price) that there is a natural tendency for many parties to attempt to capture it. The state, which in most cases is the owner of the unexploited oil and gas, either can develop the oil itself (as in the case of Mexico) and capture the rent directly or can sell the rights to produce the oil and capture some of the rent through this transaction and, by taxing these companies, transfer further rent through the tax system. Further bargaining within the state, as between central, regional, and local governments, over who actually receives the taxation can take place, and in countries with poor governance and lack of transparency, the rents may be captured by parties other than the government itself, through various corrupt practices.

2. TAXATION OF UPSTREAM ENERGY PRODUCTION

2.1 The Structure of Upstream Energy Taxation

The structure of taxation on the extraction of oil, gas, and coal, and the factors influencing the choice of the tax instruments, which enter contracts between the owners of the resource (the government) and the producers of the resource, can be analyzed with respect to not only the impact on the returns to the two parties but also the impacts on the risks carried by each party. In the exploration and production of oil, gas, and coal, there are some very important risks to be borne that impact strongly on the contracts formed and on the revenue (tax) flows to the government. First, there is the risk involved in finding commercially viable amounts of the resource. Exploration and production are typically very expensive, yet total costs are not known with certainty until after the contract has been signed and indeed until all after the costs have been incurred. The life and production of the well or field also carry risk, and although this is often ameliorated because of continuous improvements in technology, the total output is uncertain until the closure of the field. Equally important is the fact that, over the life of the field, the price of the resource will change and is highly uncertain, if past experience is a reasonable guide. Oil prices have seen large fluctuations, subsequent to the price hikes of the mid-1970s and early 1980s, which relate to several factors and make forecasting over a period of several years very imprecise. With these large uncertainties, each party will wish to set the tax parameters so as to obtain a good average return while also minimizing the risks that their return could be very poor. Governments need to provide sufficient incentives to the private sector to continue to invest in exploration and production to ensure that future tax revenue is secured.

2.1.1 The Taxation of Oil Production

The taxation of oil production has two broad forms, with a large number of variations and specific tax instruments. One group of countries, which are predominantly industrialized, treat the oil produced as the property of the private sector company producing the oil and use a combination of a royalty or revenue tax and profit-based taxes. A royalty or revenue tax, which is a percentage of the sale price of the oil, is simple to administer but can have strong disincentive effects for investment. As the price of oil falls or costs rise, the share of royalty payments rises as the level of profits falls and this can result in severe regressivity and even a negative posttax rate of return. As a result, some countries have reduced or even abandoned royalties and revenue-based taxes and rely solely on profits-based taxes.

Many developing countries that produce oil have entered into production-sharing agreements (PSAs), whereby the private sector companies produce the oil on behalf of the government. They sell the oil and keep that part of the proceeds that remain after taxes have been levied. PSAs tend to have four major elements, although there are many variations on the main theme. A schematic description of such arrangements is as follows: the company producing the oil sells it at the world market price. On this price, whatever the level, it pays a fixed percentage per barrel produced to the government—the royalty. This arrangement ensures that the government receives an amount that is irrespective of the costs of production, so to this extent the producing company bears the risk. To give the company some certainty with respect to recouping its costs, it is allowed to keep in the current year a fraction of the postroyalty receipts ("cost oil") as a contribution toward covering costs. This arrangement continues through the life of the project until all allowable costs have been recovered. Out of the money received from the oil sale, net of royalty and cost oil, which is termed "profit oil," there is an agreed split between

the company and the government. The company then pays income (corporation) tax on its profit oil. The government's share of receipts, net of the cost oil, when calculated on a discounted basis over the full life cycle of a project, defines its "take" on the project. The take depends not only on the value of the tax parameters, but also on the time profile of expenditures and of the allowed cost recovery. When the corporation tax rate is fixed, because of its applicability to all sectors, the factors that are variable are as follows: the percentage of royalty oil; the amount of cost oil that can be charged per barrel (until all costs have been recouped); and the share of profit oil. The average government take for oil appears to be in the range of 60–70%, but varies between a low of approximately 40% to a high of approximately 90%. These variations reflect the risks in individual countries as well as cost differences between countries.

2.1.2 The Taxation of Gas Production

Generally, gas, which is often produced jointly with oil, is taxed in a fashion similar to that for oil. Again, where gas is sold, there is usually a substantial element of rent so that the government will wish to capture its share of this via the tax system. However, one aspect of the gas market is markedly different from that of oil. Gas is usually sold on a long-term contract basis, reflecting the fact that it is not as easily transported (much being by fixed pipelines) and there is not yet a flexible international market for gas. With such contracts, much of the price uncertainty is removed, so that the contract structure can reflect the higher degree of certainty experienced by both parties. The average government take for gas is similar to that for oil, although the revenues received from oil tend to be greater than those from gas when both are being produced in a country.

2.1.3 The Taxation of Coal Production

Coal mining is usually subject to a royalty and the national corporation tax on income, net of allowable costs. The former is sometimes in the form of an excise tax of a fixed value per ton mined. Other cases are in the form of a revenue tax, which relates the tax payable to the value of sales (often approximately 10%). Both can have strong disincentive effects if the rates are set too high because, with falls in the price of coal or increases in the costs of production, the return to the producing firm can even become negative. Countries with federal systems, such as Canada, impose federal and provincial company income taxes as well as provincial royalty payments.

Coal production in some countries, notably within the European Union, has been subsidized by a number of fiscal devices in order to protect employment. This reduces the effective tax rate and the net money collected from the sector.

2.2 The Monitoring and Governance of Upstream Tax Revenues

The magnitude and individuality of tax revenues from upstream oil and gas have encouraged some governments to conceal what their total revenues from these sources are. The fact that typical tax arrangements in many developing countries are individually negotiated through contracts with producing companies makes it difficult for parties not directly involved to know what the revenues should be, unless they have full access to these contracts. When this is aggregated over a number of wells and fields, the picture can be obscured further. Unless all companies involved in a country publish their tax payments, the society as a whole may have very little idea of the magnitude of total revenue from oil and gas, unless the government chooses to publish it and is truthful in doing so. There are movements to encourage greater transparency of oil tax revenues through the publication by companies of taxes paid. Schemes that allow the aggregation of individual company payments on a credible but confidential basis, with publication of the totals, are likely to prove more acceptable than individual publication and almost as effective in promoting accountability.

The size of these payments gives incentives for misappropriation and misuse, which are facilitated by the confidentiality of the negotiations. In order to bring increased transparency to this problem, and hence to reduce the possibility of misappropriation, several countries have established or are establishing "oil funds." Rules are set for transferring some or all revenues (the amount based on a formula) to a separate fund, whose inflows and outflows are monitored separately from the overall budget and whose magnitude may be published. The purpose of these funds, whether for normal budgetary support, for budget stabilization when oil revenues fluctuate, or for saving for future generations, is also made public. Countries and regions that have established such funds include Alaska (United States), Alberta (Canada), Azerbaijan, Chad, Kazakhstan, Kuwait, Norway, Oman, and Venezuela. In some of these cases, such as Norway, the fund is actually invested and managed offshore to ensure the best possible return for the country and extensive details are

published. In other cases, such as Kuwait, the actual size of the fund is not made publicly available. Increasingly, civil society is pressurizing governments to become more transparent and the establishment of visible funds is seen as a step toward ensuring this.

2.3 The Use of Oil Tax Revenues

Where upstream tax revenues are earned that are large relative to the size of an economy, as is the case in several oil-producing countries, then experience has shown that these revenues can have very substantial and even negative effects on the rest of the economy. In large producing countries, such as Nigeria and Indonesia, despite huge tax revenues received over a number of years, the rate of economic growth has not increased and the level of poverty has stayed high. Even in industrialized countries, sudden "windfalls" following the discovery and exploitation of oil and gas have led to adverse effects. The Netherlands, following the development of large gas reserves, initially experienced contraction of other sectors (and job losses) when the increase in the exchange rate caused by the export earnings from gas made other goods uncompetitive (the "Dutch disease" phenomenon). Because oil and gas have tended to be primarily export activities, they generate little direct local employment, so that the oil tax revenues need to be the vehicle of development for economies. Hence, in many countries, even when the government has received and spent the revenues, the ensuing economic development has been very disappointing, leading to the notion of a "paradox of plenty" for oil and gas producers. For example, the average real growth rate of national income of the OPEC group of countries, in the 20 years following the first large oil price rise of the early 1970s, was lower than that in the decade preceding that price rise. This weak economic performance has been associated in some countries with a worsening of the political climate and an increase in corruption. Even when there is transparency as to the amount of the tax revenues, there is still difficulty in determining how to spend the money effectively for the future development of the economy. A spending program that boosts only current consumption, by transferring large sums to the consumers (possibly through subsidized goods and services), is not likely to raise the growth rate or to provide infrastructure for the benefit of future as well as present generations. In developing countries, the sudden discovery of oil or gas and their attendant tax revenues can provide the government with more money than can be effectively spent in the short run. Examples of "prestige" projects that do not help future development (highways that have substantial excess capacity or steel factories for whose products there is very little market) effectively waste the money. Moreover, excessive spending can drive up local prices very rapidly, which helps damage any existing industries. The planning capacity of some governments to spend such sums is also limited, so that a more gradual spending approach, while accumulating some of the tax revenue in a future generations fund, can reduce the impact of these problems.

3. TAXATION OF DOWNSTREAM ENERGY

3.1 General Levels of Downstream Energy Taxation

Information on the taxation of downstream energy use, apart from automotive fuels, is sparse except for countries within the Organisation for Economic Cooperation and Development (OECD). Table V indicates the range of taxes (both excise and VAT/sales taxes) as a percentage of final retail price including tax, charged within the OECD. Although there are often single extreme values that widen the range greatly (for household electricity, the highest tax rate is that of Denmark at 60%, whereas the next highest is Norway at 36%, followed by Austria at 28%), the overall picture is clear. Where fuels are used

TABLE V

Ranges of Taxes as a Percentage of Final Prices for Energy Products within the OECD in 2000

Fuel	Typical range
High-sulfur fuel oil for industry	5–25%
Low-sulfur fuel oil for industry	4–22%
Heavy fuel oil for electricity	5–23%
Light fuel oil for industry	3–52%
Light fuel oil for households	10–60%
Diesel for commercial use	30–70%
Premium leaded gasoline	52–72%
Premium unleaded gasoline (95 RON)	30–76%
Natural gas for industry	1–13%
Natural gas for households	5–50%
Electricity for households	5–60%

Source. Data from International Energy Agency (2001), with permission.

as inputs to other goods, tax rates tend to be lower, and where they are for final use, tax rates are higher. Fuels that have lower emissions characteristics (natural gas) also tend to have somewhat lower tax rates.

3.2 The Taxation of Automotive Fuels

There is extensive information on the worldwide taxation of automotive fuels that is obtained by surveying pump prices and then using the approximation that, net of tax, prices in all countries are the same due to international competition in the fuels market (there are, in fact, some landlocked non-oil-producing countries that experience important differences in pretax costs because of large costs of importing and transporting fuels). Differences in pump prices then represent a measure of variation in the taxation of gasoline and diesel. Table VI shows the results of a global survey. Using the approximation that the untaxed retail price of gasoline in the fourth quarter of 2000 would have been approximately 32 U.S. cents per liter, some 22 countries (mainly oil producers) actually sold below this price, with Turkmenistan being the lowest at 2 cents per liter; 25 countries had prices between the "break-even" level and the U.S. level of 47 cents per liter (tax of 15 cents per liter); 59 countries had prices between the U.S. price and the lowest of the European Union countries (the Irish Republic) at 72 cents per liter (tax of 40 cents per liter); and 52 countries had prices above the lowest EU level, with Hong Kong charging the highest price at 146 cents per liter (tax of 114 cents per liter). For diesel prices, the picture was very similar, although the spread of taxes was rather smaller, with 40 countries selling diesel below cost, and with the highest price being in the United Kingdom at 122 cents per liter. The overall average tax for diesel was approximately 20 cents per liter, whereas that for gasoline was approximately 28 cents per liter. The huge variation in tax rates, which dominate intercountry differences in pretax prices, indicates how the relative importance of the different reasons for taxation varies among countries. Governments with little need for revenue, such as certain oil producers, have very low taxation or even subsidize automotive fuels, whereas other countries, such as most of those within the European Union, are willing to impose high taxes, presumably for environmental reasons. The widespread tax difference between diesel and gasoline, averaging approximately 8 cents per liter, is large in relation to the pretax price and suggests a deliberate policy of differentiating between these automotive fuels in favor of diesel. This is most likely because of distributional criteria since the costs of the congestion- and environmental-related aspects are probably fairly similar for the two modes of transport. The tax difference may also reflect attempts to encourage the use of buses over cars and the desire not to tax commercial and industrial transport too heavily, regarding them as intermediate activities where the final good they help to produce should instead bear the taxation.

When tax rates are compared as between countries according to their level of development, a clear pattern exists. Table VII shows that tax rates in the

TABLE VI

The Distribution of Posttax Retail Gasoline and Diesel Prices in 2000 (in U.S. Cents per Liter)

Range	Number of countries in range for gasoline prices	Number of countries in range for diesel prices
Below retail cost	22 (<32¢)	40 (<30¢)
Between retail cost and U.S. price level	25 (32–47¢)	53 (30–48¢)
Above U.S. level and below minimum EU level	59 (47–71¢)	11 (48–53¢)
Above minimum EU level	52 (>71¢)	54 (>53¢)

Note. Table is based on data from 22 OECD and 37 non-OECD countries.

countries of the OECD are substantially higher than those in non-OECD countries, with the difference being more pronounced for gasoline. Kerosene taxes are much lower than automotive fuel taxes in the non-OECD countries, both in absolute terms and in percentage terms, reflecting the desire of governments of less developed countries to keep kerosene affordable for a large range of households.

Glossary

energy innovation system The web of actors involved in energy technology innovation as well as the linkages, partnerships, and relationships among them.

energy technologies Technologies that help to exploit existing and new sources of energy (extraction and supply technologies), convert these to readily usable forms of energy (conversion technologies), and use these forms of energy to satisfy human and economic needs (end-use technologies).

energy technology innovation Development and widespread introduction of new or improved energy technologies; the process of innovation includes research, development, demonstration and deployment activities.

Energy technology innovation encompasses research and development on new technologies, as well as on improving existing technologies, and bringing these into widespread practical use. In fact, technological change, driven by a range of innovation efforts, has long played a central role in shaping the global energy system and its components. New and improved technologies have helped to expand energy supplies and exploit them in an economical fashion. For example, significant improvements in exploration and recovery technologies have been responsible, in part, for the increases in recoverable hydrocarbon resources over the past few decades. Energy technology innovation has provided cheaper, more efficient, and cleaner ways of converting energy into desirable end-use forms as well as a range of technologies to better satisfy consumer needs. The reductions in global energy intensity over the past decades have been driven, in part, by the development of more efficient energy conversion and end-use technologies. Technological developments, spurred by environmental regulations, have also helped to reduce the local and global environmental impacts of energy extraction, conversion, and use.

1. INTRODUCTION

Expenditures on energy account for approximately 7 to 8% of gross domestic product (GDP) worldwide. In addition, annual global investments in energy supply technologies run into the hundreds of billions of dollars, and trillions of dollars are spent annually on products that consume energy. Furthermore, the global energy system is expected to expand substantially during the next few decades, with the bulk of these increases coming in the developing world to meet unsatisfied demand in these countries. For example, a recent study by the International Institute for Applied Systems Analysis (IIASA) and the World Energy Council (WEC) estimated that the global energy consumption in the year 2020 will be 25 to 70% greater than the 1999 level of 6.75 billion tons of oil-equivalent. At the same time, the energy sector will also need to be reoriented as the demands from climate change, acid rain, local air pollution, and other environmental concerns become pressing and as fossil fuel reserves start to dwindle. With this context serving as a backdrop, the need for new and improved energy technologies is likely to continue to increase.

Concomitantly, the need to examine and better understand energy technology innovation and the

 © 2004 Elsevier Inc. All rights reserved.

underlying processes remains salient. It is only by assessing the scale, nature, and nuances of energy innovation activities can one judge their efficacy as well as their adequacy in relation to the challenges facing the energy system.

In general, energy innovation is stylized as a set of activities that include energy research, development, demonstration, and deployment, with the caveat that these activities do not occur in a purely linear and unconnected fashion. Because innovation is necessarily a recursive process requiring many iterations before a technology or product is deployed (and even subsequent to deployment, numerous incremental improvements generally continue to be made), there are invariably linkages and feedbacks among the various activities mentioned previously. For example, product design takes into account the conditions under which the technology will be deployed, data from demonstration projects reshape the technology, and product characteristics and designs are influenced by feedback on consumer needs and preferences. Still, following such a stylized model is useful in obtaining at least an initial understanding of energy innovation.

Hence, an examination of energy innovation requires an examination of energy research and development (ER&D), in terms of both the magnitude of the overall ER&D portfolio and its composition with regard to distribution of technology time horizons, risk levels, fuel source use, and end use applications. It requires a focus on the effectiveness of ER&D activities in terms of returns (e.g., social, economic) on research and development (R&D) investments. And it requires an exploration of activities influencing the eventual implementation—the deployment and eventual diffusion—of new technologies.

However, developing a detailed understanding of energy innovation is not a trivial proposition for a number of reasons. First, the notion of an energy innovation activity can be somewhat fuzzy and difficult to define clearly because a very broad range of research and technology development activities are relevant to the energy sector. In addition, many technology advances that emerge from other sectors, or are motivated by nonenergy applications, are also relevant to the energy sector. For example, advanced software packages for structural modeling, although driven initially by the space program and the aircraft industry, are of considerable use in designing advanced automobile structures, and basic research on fluid dynamics has helped to improve vehicle aerodynamics; both of these play a role in influencing the energy use characteristics of automobiles. Similarly, the advent of microprocessors has allowed substantial advances in fuel and engine management in automobiles, greatly improving their energy efficiency.

Furthermore, and to make matters more complex, numerous actors are involved in energy innovation activities of various kinds. A range of funders—governments, industry, venture capitalists, and philanthropic organizations—support the development of new energy technologies. A diverse cast of actors—government laboratories, industry, universities, research organizations and consortia, and nongovernmental organizations (NGOs)—carry out R&D activities that lead to new energy technologies. And an even larger group of organizations—government agencies, firms, bilateral and multilateral agencies, NGOs, and philanthropic groups—play a role in the deployment of energy technologies in different parts of the world. Numerous kinds of linkages, partnerships, and relationships among various actors, with flows of finances, technology, and knowledge among them, underlie the development and deployment of various energy technologies. Figure 1 illustrates the kinds of actors involved in energy technology innovation as well as the interactions among them. The web of actors and the relationships among them constitute what can be termed the "energy innovation system." This system is also shaped, and has its output influenced, by the context in which it operates (i.e., various policies [e.g., broad energy policies, tax and investment policies, environmental policies and institutions at the domestic level as well as trade, environmental, and other regimes at the international level], other macroeconomic factors, other institutional factors).

Hence, understanding of energy innovation processes may be best advanced through a broad examination of this innovation system. This requires a focus on the various activities in which relevant actors are engaged, their interests and preferences, the relationships and linkages among these actors, the flows of resources and knowledge among them, and the institutional context in which they operate. This follows the "systems" approach that has received increasing recognition within the broader community of science and technology policymakers as well as among scholars of innovation as a fruitful way in which to unpack the complexities of technological change within and across industries and nations.

Energy innovations come in many shapes and sizes. Ultimately, any energy innovation (like nearly

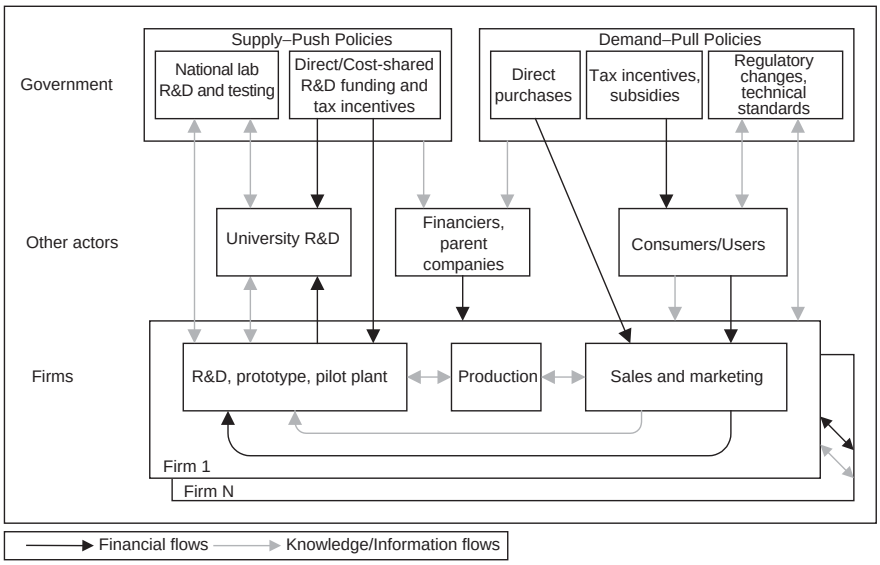

FIGURE 1 The major actors and their interactions in an energy innovation system. From Margolis, R. M. (2002). Understanding technological innovation in the energy sector: The case of photovoltaics. Ph.D. thesis, Princeton University.

any kind of technology innovation) aims to satisfy a demand or need. It aims to improve on the existing situation by providing energy services in a better fashion, expanding them, or providing new forms of service. Given that an overwhelming proportion of the world's energy services are delivered commercially, much of the demand for energy technologies emerges from, or is mediated by, the marketplace. Yet there is a significant fraction of the world's population whose members depend on noncommercial energy supplies. Estimates suggest that as many as 2 billion people in developing countries do not have access to modern forms of energy. Such differing circumstances lead to very different mechanisms for technology development as well as deployment. In the former case, consumer needs or aspirations are channeled through the market, as are resources for technology development and deployment. In the latter case, it is not feasible to rely purely on market institutions for technology development and deployment, although harnessing market mechanisms, to the extent feasible and desirable, may improve the effectiveness of any innovation efforts. Another related point is that even in a commercial energy arena, not all consumers are equal. Some consumers, such as large firms and public sector organizations, have the internal resources to assess (both technically and economically) relevant technologies in relation to energy needs. This becomes especially important for larger-scale technologies. Small and medium-size enterprises, even in industrialized countries, might not have such resources, often resulting in information or knowledge gaps that constrain uptake of new energy technologies (and, hence, the market signals to technology developers).

Hence, various kinds of innovation subsystems underlie the development and diffusion of different energy technologies. For example, the innovation subsystem underlying the development of clean coal technologies or fuel cell development does not much resemble that of improved cooking stoves. Similarly, energy innovation systems in various countries take very different shapes in terms of the kinds of actors involved, the relationships among them, and the policy contexts under which they operate. Such a perspective is necessary to develop an appropriately textured understanding of energy innovation processes underlying the development of technologies to satisfy the energy needs of varied categories of consumers.

This article presents an overview of the global energy innovation system, focusing especially on the prominent actors that constitute this system, their activities, and the policies and processes that play a role in energy innovation. It begins with a summary of the scale and scope of, and recent trends in, expenditures directed toward ER&D. It then discusses various institutions and policies that play a role in the deployment of energy technologies in different parts of the world. Finally, the interactions among the technical arena, the market, and policies that can influence the nature of energy technology innovation are highlighted through some illustrative cases.

2. ENERGY RESEARCH AND DEVELOPMENT

2.1 The Role of Governments

Not surprisingly, most ER&D takes place in industrialized countries where both the public and private sectors are involved in the development of energy technologies. Given that most energy technologies are deployed through the marketplace, the predominant locus of ER&D is within firms. Still, governments have historically played an important role in the R&D of new energy technologies through direct financial support (e.g., gas turbines) as well as through policies that promote ER&D within firms. The rationale for government involvement in ER&D is multifaceted:

- Concerns about energy security dominated the energy policy of most countries after the oil crises of the 1970s and drove the large increases in public ER&D spending seen during the late 1970s. Although the decline of oil prices by the early 1980s led to cutbacks in this spending in many countries, the energy security issue, as well as the high costs of energy imports, still motivates governments to make investments in energy technology innovation.
- The global market for energy technologies is estimated to be in the range of several hundred billion dollars per year. In this context, government involvement in energy technology development is also motivated by substantial commercial and national economic competitiveness elements.
- Although new and improved energy technologies are crucial to a robust, efficient, and clean energy system, the long time scales for energy technology development and deployment often make it unattractive to private firms to embark on many forms of ER&D efforts on their own.
- It is also recognized that affordable and reliable energy services have a "public good" nature due to their intimate linkage with various aspects of human and economic development. At the same time, reducing the environmental and other externalities of energy use is becoming paramount, especially with the expanding scale of the energy system worldwide and the emergence of problems such as climate change. Given the substantial social and environmental returns that may accrue from the widespread use of clean energy technologies, governments of most industrialized countries and many developing countries have traditionally funded appropriate ER&D efforts.

Along with public sector R&D investments (substantial in many countries), other government policies such as cost sharing, environmental regulations, and tax incentives provide stimulus for, and shape the priorities of, private sector investments in ER&D. Some policies, such as high taxes on energy and the commitment to expand and improve energy services, send a clear signal for demand for appropriate energy technologies, and this in turn creates an impetus for increased ER&D investment. Of course, government involvement in energy innovation goes well beyond R&D. Government also plays a role in promoting and assisting in the demonstration and deployment of such technologies (as discussed later).

The International Energy Agency (IEA) collects data on public sector ER&D expenditures by its member countries. Note that the IEA defines R&D expenditures in its data collection questionnaire as including funding for demonstration projects. Figure 2 shows the ER&D spending patterns over time by the seven countries that accounted for more than 90% of the energy technology development expenditures between 1990 and 2000 as reported to the IEA. Two sets of patterns emerge clearly from these data. First, public ER&D spending rose sharply after the two oil shocks of the 1970s, peaking in 1980 and then, as oil prices dropped, declining sharply for a decade or so and then declining somewhat more slowly during the 1990s. Second, the United States and Japan continue to account for a major portion of the world's ER&D. Also, Japan is the only major IEA country that has shown mostly increasing or stable ER&D expenditures over the past two decades or so.

Table I shows the distribution of total reported IEA spending for the year 2000 according to selected categories, and Fig. 3 shows recent trends in these expenditures. Some particular features should be noted:

- Nuclear fission and fusion R&D continues to account for nearly half of the total spending by IEA countries, although the proportion of total R&D devoted to this area has declined over the years, with the nuclear R&D spending peak having been reached in 1982. Since then, most countries have cut back their efforts in nuclear technologies substantially. Japan is the exception, and it now accounts for the majority of the public expenditures in this area, as nearly 70% of the Japanese government's ER&D is directed toward nuclear technologies.
- Government expenditures on conservation R&D have risen steadily over the past decade, but only two

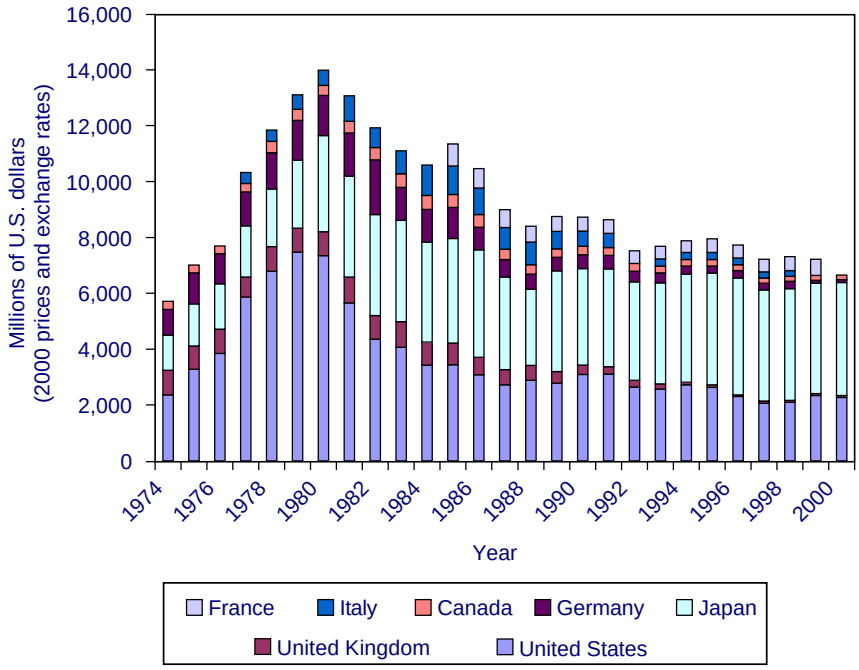

FIGURE 2 Trends in ER&D expenditures by major IEA governments. Note that Italy did not report any data for 1974–1976, 1992, 1999, and 2000. France did not report any data for 1974–1985 and 2000. From International Energy Agency R&D Database.

countries, Japan and the United States, are responsible for the bulk of expenditures in this area. Until the mid-1990s, global conservation expenditures were more or less split equally among the transportation, industrial, and residential sectors, but during the past few years, there has been a sharp rise in industrial conservation R&D efforts.

• IEA government spending on renewables R&D remained quite stable during the 1990s following a remarkable surge after 1974 that peaked in 1980 but fell steeply during the early 1980s. Nearly half of the renewables spending in 2000 was directed toward solar photovoltaic (PV) research, with R&D on biomass, wind, and geothermal sources accounting for most of the remaining amount. Small hydro R&D remains pretty much completely absent from the ER&D agendas of IEA countries. Once again, Japan and the United States lead the charge on renewables R&D, together spending nearly three-quarters of the total for IEA countries.

• Like many other areas, but perhaps even more clearly, fossil R&D has suffered a large decline during the past two decades or so. Coal R&D has been a particular casualty of these R&D cutbacks. Once again, the United States and Japan account for most of the public R&D in this area. The U.S. effort focuses particularly on enhanced oil and gas recovery as well as on coal combustion, whereas Japan accounts for most of the government coal conversion R&D expenditures among the IEA countries.

ER&D expenditures by governments are generally used to fund energy technology development efforts within government laboratories as well as in firms. Government organizations themselves may perform significant amounts of R&D. For example, in the United States, many U.S. Department of Energy (DOE) laboratories have research programs on a range of energy technologies. Relevant R&D is also carried out by other agencies such as the U.S. Department of Defense (DOD) and the National Aeronautical and Space Administration (NASA). For example, work done by DOD and NASA was instrumental in the development of fuel cells. The government's role may be even more prominent in developing countries. For example, in India, government laboratories and public sector undertakings perform much of that country's research on coal use, hydrocarbon exploration and processing, electric power generation, and atomic energy.

Governments also fund energy innovation in firms through mechanisms such as R&D contracts, cooperative research and development agreements, and grants for R&D or demonstration. Although less

TABLE I

Public Sector Energy R&D Spending by IEA Member Countries for the Year 2000 (Millions of U.S. Dollars, 2000 Prices and Exchange Rates)

Conservation	1269.4
Industry	721.3
Residential commercial	178.6
Transportation	279.2
Other conservation	70.8
Fossil fuels	426.4
Enhanced oil and gas	103.0
Refining transportation and storage	25.0
Oil shale and tar sands	9.8
Other oil and gas	49.4
Total oil and gas	187.2
Coal products preparation and transportation	16.7
Coal combustion	110.4
Coal conversion	72.2
Other coal	39.9
Total coal	239.2
Renewable energy	525.3
Solar heating and cooling	11.2
Solar photoelectric	234.5
Solar thermal–electric	22.3
Total solar	291.7
Wind	69.8
Ocean	7.7
Biomass	90.8
Geothermal	52.9
Large hydro (>10 MW)	7.2
Small hydro (<10 MW)	1.7
Total hydro	12.4
Nuclear fission/fusion	3259.3
Nuclear light water reactor	129.9
Other converter reactors	153.0
Nuclear fuel cycle	859.6
Nuclear supporting technology	1156.7
Nuclear breeder	398.4
Total nuclear fission	2709.5
Nuclear fusion	549.9
Power and storage technology	341.2
Electric power conversion	189.0
Electricity transmission and distribution	90.4
Energy storage	46.9
Other technology research	1075.0
Energy systems analysis	8.7
Other technology or research	1058.7
Total energy R&D	6965.5

common, there are also some examples of government-funded programs on international cooperation in ER&D. A prominent example is the European

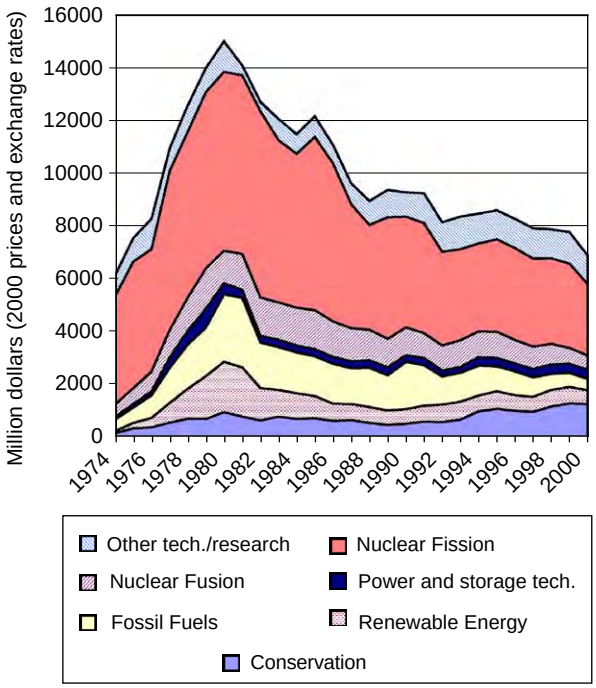

FIGURE 3 Trends in ER&D expenditures by IEA country governments, by category. From International Energy Agency R&D Database.

Union's program on research, technological development, and demonstration of energy technologies. The focus in the energy component of its Fifth Framework program (1998–2002) has been on technologies for cleaner energy as well as on economic and efficient energy, for which approximately 1 billion euros have been budgeted.

2.2 Research and Development in Firms

Industry, the main supplier of technologies for the consumer, industrial, and other applications, is the other major funder of ER&D. Its activities are targeted toward the development of new and/or improved products that help firms to compete in the marketplace so as to maintain their existing customer bases as well as expand them. Given that the market for energy technologies and related products is substantial, there is significant ER&D carried out by firms. For example, a recent study by the U.S. National Research Council estimated that between 1978 and 1999, industry accounted for roughly two-thirds of the total ER&D expenditures within the United States.

Extracting and collating data on ER&D expenditures by industry is a challenging problem for a

number of reasons. Many companies that are engaged in energy technology development have highly diversified operations, and because firms generally do not present detailed R&D data, it is nearly impossible to disaggregate industrial R&D activities to assess those that are focused on energy technologies. Even firms whose products/services are mainly in the energy sector may still engage in R&D that does not necessarily lead to energy technology development. And some firms may be focusing on technologies that have impacts across many sectors, including energy. For example, polymer composites initially designed for high-performance aircraft have been useful in producing lighter and, hence, more energy-efficient automobiles. Therefore, apportioning the underlying R&D budgets is a tricky, and possibly insurmountable, problem.

There are some attempts at surveying industrial ER&D (e.g., the U.S. National Science Foundation [NSF] does this as part of its "Research and Development in Industry" surveys), but it is unlikely that such efforts can accurately capture all of the ER&D in firms for the reasons mentioned previously. Furthermore, surveys across such a highly inhomogeneous population of firms are limited in terms of their coverage. Thus, it is likely that such data underestimate industrial ER&D. Still, such surveys could serve as a lower bound for industrial ER&D expenditures. The NSF estimated U.S. industrial ER&D spending to be $1.8 billion in 1999, whereas other studies by the Pacific Northwest National Laboratory estimated corresponding numbers to be $2.4 billion for Japan in 1997, $391 million for Italy in 1996, and $168 million for Germany in 1995. However, in addition to such data, a broad examination of the R&D expenditures and trends of firms in some particularly relevant sectors can give a direct idea of the size and nature of industrial investments in ER&D.

Table II lists some industrial categories (as well as some major firms within them) that are directly relevant to the energy sector. The primary business of firms in these categories is in the energy area; hence, a substantial fraction of their technology R&D activities have a direct and often substantial impact on the energy sector. Still, as mentioned previously, it should be understood that not all R&D activities of these firms are necessarily directed toward products and processes that may have an influence on the energy system. For example, car manufacturers can devote large amounts of development funds on designing vehicles that are aesthetically pleasing to the consumer, but many of these design features might not have a bearing on the energy characteristics of the automobiles.

TABLE II

Some Major Energy Technology Firms and Their R&D Spending for the Year 2000 (Billions of U.S. Dollars)

Transportation	
Vehicle manufacturers	
Ford Motor, United States	6.8
General Motors, United States	6.6
DaimlerChrysler, Germany	5.9
Toyota Motor, Japan	3.9
Volkswagen, Germany	3.9

2.2.1 Oil and Gas Exploration, Production, and Processing

Most major oil and gas firms engage in both upstream (i.e., hydrocarbon exploration and production) and downstream (i.e., hydrocarbon refining and marketing) businesses as well as related activities such as chemicals, and their R&D activities serve the needs of these businesses. During the past decade or so, the R&D spending of oil and gas firms has generally declined. According to a DOE survey, R&D spending by major energy producers within the United States declined from $3.05 billion in 1994 to $1.33 billion in 2000. Although not true of all producers internationally, the broad global trend over the past decade or so seems to be along similar lines. A series of annual surveys by the U.K. Department of Trade and Industry on R&D expenditures by major firms worldwide indicates a decline in the average R&D expenditures (as a percentage of sales) of major oil and gas firms worldwide, from approximately 0.75% in 1992, to 0.60% in 1996, to 0.34% in 2000—even as the cumulative sales of these firms rose approximately by 50% over the same period. A number of factors have likely contributed to this decline, including the recent consolidation within the industry, the decline of oil prices during the mid- and late 1990s, and the general trend toward R&D downsizing and outsourcing within firms.

Technology developed by other firms may also be useful for the oil and gas industry. For example, many of the R&D activities of an oilfield services firm such as Schlumberger are targeted toward acquiring data for better characterization of petroleum reservoirs, optimizing oil and gas production, and improving hydrocarbon recovery—all of great value to the petroleum and gas industries. To take another example, specialty chemical firms such as Akzo Nobel develop and provide catalysts useful for petrochemical processing.

2.2.2 Electricity Production and Conversion

Electric and gas utilities' R&D activities deal nearly exclusively with energy conversion, distribution, and use (at least to the extent that these firms still focus on these core businesses). Although detailed data on utility R&D are not collected systematically, it seems that R&D spending by many utilities has declined during the past decade or so. For example, a 1996 survey by the U.S. General Accounting Office (GAO) found that the combined R&D spending of the 112 largest operating utilities in the United States dropped from $708 million in 1993 to $476 million in 1996. These cutbacks were a result of overall declines in federal and state funding as well as increased competition expected from deregulation. Electric utilities' spending in Japan has also declined recently, but not as drastically. During 1993–1995, Japanese utilities' average annual expenditure was 34.1 billion yen, and by 1999–2001, this figure was 28.9 billion yen. R&D expenditure at the Electric Power Research Institute, a private research consortium funded by utilities and other firms, was approximately $463 million in 1996 and $312 million in 2001.

Much of the equipment used in electric power plants is produced by heavy engineering firms, most of which come under the category of "diversified industrials" by virtue of the fact that their products span a wide range of categories. Table III shows a list of major diversified industrials and their relevant energy technology businesses. There are also a few firms, such as ABB and Alstom, whose activities lie mostly within the energy sector (power and automation technologies for utilities and industry in ABB's case and power generation, transmission and distribution, and transport in Alstom's case). Therefore, a sizable portion of their R&D can be considered to be energy relevant.

2.2.3 Road Transport

The transport sector accounts for more than 25% of the total final consumption (TFC) of energy worldwide and more than a third of the TFC within the Organization for Economic Cooperation and Development (OECD) countries. Road transport, in turn, accounts for more than 80% of the transport energy consumption within OECD countries. Hence, R&D on automotive technologies assumes substantial importance within the general domain of ER&D.

Energy use of cars can be improved through a range of technologies (see, e.g., the fuel consumption technology matrix in Table IV) that are the focus of R&D activities of automobile manufacturers and their component suppliers. Thus, car manufacturers have research programs in areas such as innovative combustion techniques and fuel management, efficient engine designs, improved transmission technologies, and aerodynamic drag reduction to yield better fuel efficiency and lower the emissions of pollutants. Other prominent areas of research include gasoline–electric hybrid vehicles and fuel cell technology. Automobile manufacturers also carry out research in other areas such as structural mechanics and advanced materials (metal-based, ceramics, and polymers) that, by helping to lower the weight of

vehicles, can have a significant bearing on performance. R&D spending (as a percentage of sales) reported by car manufacturers also declined somewhat over the past decade or so. The average R&D intensity for the 10 largest manufacturers was approximately 4.8% in 1992 and 1996 but declined to just over 4.0% by 2000.

Component suppliers to the automotive industry, such as Bosch (which supplies gasoline and diesel injection systems), also have major R&D efforts to improve their own products. Even R&D by tire manufacturers can have an impact on the energy use of automobiles. For example, rolling resistance, which can account for 20% of the energy consumption in automobiles, can be reduced though improved tire design.

2.2.4 Residential and Commercial Sectors

The residential and commercial sectors are also major consumers of energy. Although aggregate global data are not available, these sectors account for approximately 19 and 11%, respectively, of the TFC within the OECD countries. Within the residential sector, improved technologies for space heating and cooling (the single largest category for energy use within homes), lighting, refrigerators, and smaller appliances can help to reduce energy use. Within the commercial sector, lighting and space heating and cooling are the two largest categories of energy consumption. Furthermore, building design and improved insulation and better windows can have a major influence on the energy use within residential and commercial buildings. Accordingly, the technological R&D of a range of firms, such as manufacturers of heat pumps, furnaces, water

heaters, refrigerators, air conditioners, washers, and dryers as well as those involved in building construction and materials supply, can play a role in changing the patterns of energy use in the residential and commercial sectors. Again, many of the relevant manufacturers have highly diversified operations, and residential and commercial products are only a small part of the overall operations. Still, it is possible to establish some estimate of the magnitude of R&D efforts in this area by looking at firms such as Whirlpool and Electrolux, which focus nearly exclusively on home appliances and are two of the largest home appliance manufacturers in the world, with their respective R&D budgets being $255 million and $139 million in 2000. It should also be noted that, given the relatively fragmented nature of the construction industry and little incentive for builders to explore methods and technologies for designing and constructing energy-efficient buildings, there is not much R&D effort within this industry.

2.3 Other Research and Development Issues

Although universities focus mainly on basic research rather than on technology development, their efforts are also relevant for energy innovation in many ways. Scientific research is increasingly linked to technological innovation, as indicated by the increasing citations to scientific research in patents. Thus, basic research on topics such as advanced materials may yield results that are critical to the developments of new technologies (e.g., fuel cells).

NGOs, research institutes, and universities are also involved in the development of simple energy technologies for low-income and rural groups, especially in developing countries. Such organizations rely on funding from numerous sources, including governments, multilateral and bilateral development aid agencies, and philanthropic organizations. For example, the R&D for the successful *jiko* stove (a ceramic stove for charcoal cooking) and other high-efficiency stoves that have found widespread use in Kenya and other African nations was seeded by international and local development funds. In contrast, the improved cooking stove programs in China and India were funded nearly entirely by the respective governments. As another example, the Intermediate Technologies Development Group (ITDG), an NGO that is involved in technology development and deployment in a number of developing countries, receives funds from individual donors, governments, foundations, and multilateral aid agencies.

There are no estimates of the total funds devoted to technology/product development aimed at enhancing energy services to the poor in developing countries, although it would be fair to say that this total will be only a small fraction of the ER&D expenditures discussed earlier. Beyond the obvious lack of large commercial opportunities for such applications, another reason for the limited focus on developing technologies and products for the poor in developing countries may be that much of the work in such endeavors is not cutting-edge research but rather what has been referred to as "mundane science," thereby not attracting the attention of many researchers working or interested in energy technology development. But it should also be noted that some of the ER&D expenditures in industrialized countries are also ultimately beneficial for low-income groups in developing countries. For example, advances in PV technology and "balance of system" components have allowed the development of PV-based products that provide energy services such as lighting and electricity in developing countries.

More generally, some concerns have been raised about the adequacy of ER&D spending globally. Underlying these concerns are a number of trends highlighted previously:

- Government cutbacks in energy technology research in many industrialized countries
- A change in the nature of private sector spending patterns in many technology firms, suggesting a shift to a market-driven paradigm of R&D with a focus on the shorter term as well as on greater dependence on outsourcing
- A decline in R&D spending by many major oil and gas firms, consonant with the return of petroleum prices toward historical levels after the boom prices following the oil shocks of the 1970s
- Energy sector restructuring that has affected R&D spending by utilities

But in response, it should be pointed out that a major portion of the decline in IEA government expenditures has been due to cutbacks in nuclear R&D. If nuclear R&D is excluded, the remaining total R&D expenditures seem to have leveled off after the remarkable decline of the early to mid-1980s (although there are still some fluctuations on an interannual scale). Also, although the R&D of some firms, such as petroleum majors and utilities, has declined substantially over the past decade or so, the R&D expenditures of many other energy-relevant

firms do not show a similar decline. Still, the larger point stands that as the challenges facing the energy system continue to mount, there has not been a concomitant rise in ER&D expenditures.

This also raises another issue. Much of the policy literature and analysis on energy innovation focuses on R&D budgets. Although such expenditures are a necessary component of the innovation process—clearly, there can be little innovation without ER&D investments—they are by no means sufficient in and of themselves. The eventual results of energy innovation activities depend both on the success in developing technologies through ER&D investments and on the uptake of these technologies by the eventual consumers. But performance issues of efficiency and effectiveness of innovation, important not only within the arena of energy but also more broadly, remain relatively less analyzed, although results indicate that investment in ER&D can potentially yield large benefits. For example, a recent study by the U.S. National Research Council of the DOE's energy efficiency and fossil energy R&D programs found that these yielded significant economic, environmental, and knowledge benefits. In the energy efficiency area, a $7 billion R&D investment between 1978 and 2000 was estimated to have yielded $30 billion worth of benefits, whereas the economic benefits associated with the fossil energy programs over the same period were estimated to be nearly $11.0 billion from an investment of $10.5 billion. In addition, environmental benefits resulting from these programs were estimated to be anywhere between $64 billion and $90 billion. Of course, this study also illustrates—and this leads directly to the next section—that yields from research on new or improved technologies can be realized only when these technologies find widespread use in the energy system.

3. ENERGY TECHNOLOGY DEPLOYMENT

Although investments in R&D can initiate the development of new energy technologies and help to support them through the early stages, bringing these technologies to market requires substantially more effort. Demonstration projects play an important part during this latter stage by testing in conditions approximating real-world applications so as to gain a better understanding of various performance parameters. In many cases, demonstration projects can also help to scale up technologies. This is especially critical in cases where the laboratory version of the technology is useful for testing the concept but where the eventual application of technology requires a much larger scale (e.g., in power plants). Not only do these kinds of projects help technology developers to test the feasibility of their products for eventual implementation, but they also demonstrate viability to potential buyers (often other corporations or public sector organizations) of these technologies. The data gathered from demonstration efforts can help to refine and improve technologies so as to increase the likelihood of commercialization. Energy technology demonstrations may often be cofunded by governments, given the public good aspects of energy services discussed earlier. An example of a major demonstration project is the U.S. Clean Coal Technology program that was initiated in 1986 and ultimately involved 38 projects that covered advanced electric power generation, environmental control technologies, and coal processing. The overall budget of this project was $5.3 billion, of which $1.8 billion came from the federal government.

Even if the technical feasibility of a new technology has been demonstrated, it still might not be able to compete in the market with already established technologies for a variety of reasons. The main categories of barriers include the following:

- Cost
- Infrastructure needs
- Slow capital stock turnover
- Market organization
- Information and financing options (particularly in developing countries)

Both private and public sector responses are required to overcome these barriers.

Of these, the first barrier—cost—is by far the most important given that most technologies are deployed through the market, and cost is the key variable in this arena. There are two main reasons why a new and improved technology, despite its commercial potential, might be unable to compete with an established technology in cost terms: The first reason is that consumers do not value, in financial terms, the improvement in energy service that the new technology may offer. This situation basically exists because energy prices do not reflect the full costs of energy. For example, a new energy technology may result in decreased local or global air pollution, but because such pollution is not internalized into the costs of energy use, any reductions are not reflected in market transactions. These price distortions are probably the

single largest barrier to the deployment of new and improved energy technologies.

The second reason is that costs of any technology are higher during the early stages of its production, thereby hampering the ability of this technology to compete with technologies already in widespread use. The costs of new technologies generally decline with increasing production and market experience. In fact, empirical data show that the total cost reductions of new technologies are related to their cumulative production, with the relationship between the two often referred to as "learning curves" (on a log–log plot, this appears as a linear relationship). This "learning" and concomitant reduction in cost can come from improvements in manufacturing techniques and processes as well as in product design that result from the experience gained by a firm (or an industry through spillover effects) as it engages in the production of these technologies (Fig. 4).

Eliminating or reducing market distortions so as to incorporate environmental or other externalities into market prices generally requires public policy actions. Governments can reduce these distortions by imposing taxes (e.g., pollution charges) that account for these externalities or by imposing ceilings combined with tradeable permits (e.g., pollution caps combined with trading opportunities [generally referred to as "cap and trade"]), both of which send a cost signal to the market. Such market-based instruments have gained significantly in popularity during the past decade or so, especially in the context of dealing with environmental externalities, and have been used in numerous policy experiments in different parts of the world. Another possibility is to use regulation to control the level of externalities (e.g., noise, environmental pollution, adverse health effects) that are acceptable. Both technology-based and performance-based standards have been used as regulatory policy instruments to achieve such goals. Governments can also give direct subsidies to technologies that reduce these externalities (e.g., environmentally cleaner technologies) or remove subsidies from technologies that have high externalities (e.g., polluting technologies).

Concerted private and public sector efforts are also required to overcome the second category of cost barrier by investing in continued R&D on these precompetitive technologies as well as in their production and deployment to reduce costs (through the learning effect mentioned previously) to the extent that they can overcome cost barriers and compete in the marketplace with the established conventional alternatives. This requires a learning investment as represented graphically in Fig. 5. Although ultimately much of this learning investment comes from the market (i.e., through sales of the products embodying the technology), and the developers of technology play a central role in this process, public sector policies can play an important role in assisting early deployment of technologies during their precompetitive stages.

Many governments have programs to promote the deployment of emerging energy technologies to help overcome these cost barriers. A major set of policies has involved government-mandated purchase of renewable power by utilities. In the case of the

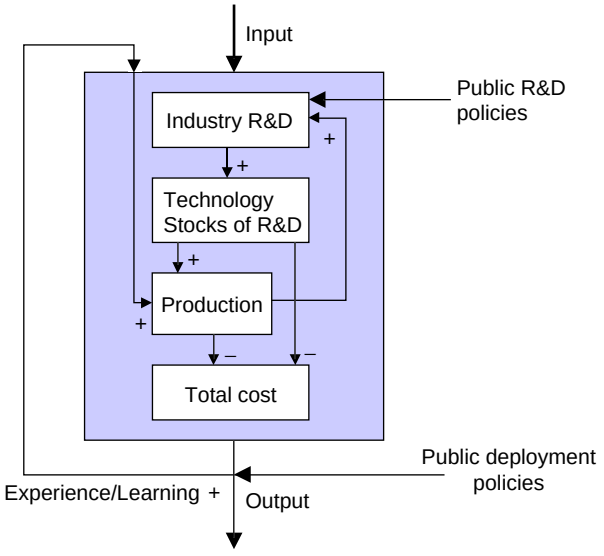

FIGURE 4 Interactions among industry R&D, production experience, and costs. © OECD/IEA, 2000, as adapted from "Experience Curves for Energy Technology."

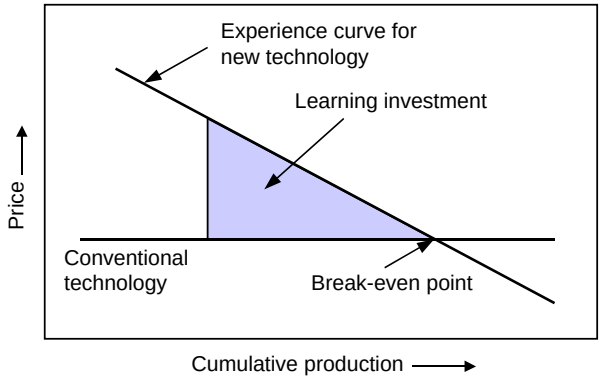

FIGURE 5 Learning investments needed for new technology to break even with conventional technologies. © OECD/IEA, 2000, as adapted from "Experience Curves for Energy Technology."

United States, this was through the Public Utility Regulatory Policies Act of 1978 (PURPA), which required utilities to buy electricity, at the utilities' "avoided cost," from qualifying facilities (which included power plants of <80 MW of capacity that used renewable energy sources). In the United Kingdom, the Non-Fossil Fuel Obligation (NFFO), a statutory obligation imposed by the British government under the Electricity Act of 1989, required the regional electricity companies that comprise the national distribution network in the United Kingdom to contract for a specified amount of generating capacity based on nonfossil fuels. A study by the Pacific Northwest National Laboratory estimated that in 1990, when the first NFFO tender was made, successful wind energy projects produced electricity at approximately 14.70 cents/kWh, whereas before the end of that decade, NFFO wind energy projects were producing at 4.85 cents/kWh. And under the German Electricity Feed Law (EFL), grid operators were obliged to purchase electricity produced from renewables within their respective supply areas at agreed and fixed prices. The value of such regulatory obligations can be enhanced if they provide a stable framework for project developers. For example, the NFFO is filled through competitive bids for long-term contracts (up to 15 years) that allow for guarantees on purchasing obligations as well as steady confidence in future markets and prices.

However, it should be noted that although these deployment programs helped to bring down the costs of renewables-based electricity generation, they were unable to ensure the long-term sustainability of renewables because the declines in cost seen in natural gas-fired generation were even greater.

Governments can also promote the deployment of improved energy technologies through the use of minimum performance standards. These kinds of regulatory standards are generally used for specified product categories (e.g., electric appliances), but they can also be set for a given percentage of products on the market, a market-wide average, or a manufacturer-based average. A commonly cited example of a standard is the U.S. Corporate Average Fuel Economy (CAFE) standards for automobiles, a manufacturer-based average. These standards, while primarily a response to the oil market disruption of 1973, have been notably successful. Greene has estimated that the total vehicle miles traveled in 1995 would have required an additional 55 billion gallons of fuel and would have cost motorists an extra $55 billion if there had been no improvement in on-road light-duty vehicle fuel efficiency levels since 1975.

Government procurement programs can also help to promote the deployment of energy technologies. For example, in the United States, the Energy Policy Act of 1992 (EPAct) directs the DOE, in association with other agencies, to "identify and designate those energy-efficient products that offer significant potential savings." The EPAct also calls for "guidelines to encourage the acquisition and use [of these products] by all federal agencies." Through its action plan to improve energy efficiency, the European Union is focusing on technology procurement that can be used to specify and develop new energy-efficient technology through both common European Union-wide procurement and coordinated procurement among its member states. In combination with public procurement policies, this will assist in both the development and diffusion of improved energy technologies.

Infrastructural barriers become important in cases where new technologies basically constitute an altogether different technological trajectory. For example, a shift to electric vehicles would require not only the necessary automotive technology but also a network of recharging stations. Similarly, a hydrogen-based energy economy would require a network for hydrogen distribution or distributed hydrogen generation. This requires the establishment of an infrastructure that may be economically infeasible for the small-scale introduction of a new technology. Often, the infrastructure requirements are so overwhelming that one set of technologies is basically "locked in." The current automobile-based transport infrastructure is a perfect example of this, where networks of roads and gasoline stations and servicing infrastructure are well established. Hence, alternative modes of transport such as light rail are at a large disadvantage because they have to compete with an existing mode of transport with a strong infrastructure. These kinds of barriers are difficult to overcome and almost certainly require some government involvement.

Improved provision of information to consumers, particularly individuals and small and medium-size enterprises (SMEs), can help to overcome information barriers to energy technology deployment. These barriers refer to the lack of information, or of the expertise to judge or analyze information, required for making appropriate choices during technology selection. To some extent, technical consultants or other experts can play a role in helping SMEs with such decisions. An approach that has found common use, especially for targeting individual consumers, is a labeling program to provide consumers with data about the performance of energy-using products and,

hence, to help them make more informed choices. Labels are generally of two kinds: those that provide information about performance on some common metrics (such programs require mandatory participation) and those that indicate the achievement (or surpassing) of a specific standard (such endorsement labels are voluntary by definition). Nearly all industrialized countries have labeling programs that cover some home appliances. The use of labels can have a significant impact on consumer behavior. A recent European study found that labels influenced the choices of a third of the purchasers surveyed. A classic and very successful example of an endorsement label program is the U.S. Energy Star program, which is a voluntary partnership among the U.S. Environmental Protection Agency (EPA), the DOE, and industry. Its basic aim is to expand the market for a range of energy-efficient products. The program covers new homes as well as products/appliances for home and office use. Webber has estimated that the program resulted in savings of 760 PJ of energy by 1999 (for reference, the U.S. energy consumption in 1999 was approximately 1×10^5 PJ).

Informational and financial barriers can be particularly problematic for individual consumers on the lower end of the economic spectrum, especially those in developing countries. Not only are low-income households particularly disadvantaged in being able to assess the relative merits of various technological options, but they are also hobbled financially in making choices. Hence, they might not have the savings to invest in an energy-efficient technology even if it is cost-effective over the lifetime of the technology, or they might not have access to credit for making choices. They also might have very high discount rates that bias any decisions toward the short term. There have been a number of approaches to tackle this barrier, including loans extended by microcredit agencies, term payment arrangements offered by service providers, and community-based saving schemes. Such arrangements can involve private sector firms, NGOs, other community-based organizations, and international aid agencies.

In fact, a number of international agencies are involved in various aspects of deployment and dissemination of improved energy technologies in developing countries. The most prominent of these is the Global Environmental Facility (GEF), which was established in 1991 as the financial mechanism for, among other agreements, the UN Framework Convention on Climate Change (UNFCCC). The GEF's climate change projects aim to mitigate the risks of global climate change while also providing energy for sustainable development. Hence, most of its climate change greenhouse gas (GHG) mitigation projects have (so far at least) focused on the energy sector. Its major goals have included promotion of the adoption of renewable energy by removing barriers, reduction of implementation costs, and reductions in the long-term costs of low GHG-emitting energy technologies. The GEF helps to overcome the incremental costs (in relation to conventional alternatives) of deploying climate-friendly technologies and, hence, plays a direct role in overcoming the cost barriers discussed earlier. From 1991 to 2001, it approved 136 climate change projects with a total grant component of more than $1 billion (and with cofinancing of more than $5 billion).

Other international aid agencies, both bilateral and multilateral, also directly support the deployment of renewable and other energy technologies in developing countries and also help to overcome barriers to such deployment. Although the private sector has taken on increasing significance in the development of the energy sector in developing countries, international aid and export credit agencies often play a critical role in the deployment and adoption of new and improved energy technologies in these countries. For example, the large increases in the deployment of renewable energy technologies in India were partly a result of the large promotion of such technologies—through financial, information, and other assistance mechanisms—by the Indian Renewable Energy Development Agency, which has received substantial international assistance from the GEF, the World Bank, and the Asian Development Bank as well as the bilateral aid agencies of Germany, The Netherlands, and Denmark.

Organizations such as NGOs, rural energy cooperatives, village committees, local vendor representatives, microcredit and other financing agencies, and energy service companies also play a major role in the deployment of energy technologies in developing countries, particularly among low-income groups. Sustainable deployment in rural areas of developing countries requires appropriate installation, service, and maintenance expertise as well as suitable financing mechanisms so as to help with deployment. For example, the ITDG, beyond its work on technology development, also assists in local manufacture and technical support, formation of producer associations, training and skills development, and enhancement of community financing (especially microfinance).

In the end, successful energy innovation requires concerted, synergistic, and sustained efforts by a

range of actors, institutions, and policies to develop technologies and bring them to the marketplace. This is clearly demonstrated by the illustrative cases of the Japanese PV development program and German wind development programs.

3.1 The Japanese Photovoltaic Program

Japan has the largest PV installed capacity in the world as a result of the sustained investments made by the country through carefully coordinated PV R&D and deployment, leading to a "virtuous cycle" among R&D, market growth, and price reduction. By the end of 2000, the total installed capacity in the country was 317 MW, of which on-grid distributed generation accounted for more than 252 MW. In 2000, Japan produced 128 MW of PV cells and 136 MW of modules, both of which were well over half of the global production.

The Japanese PV program was initiated in 1974 after the oil crisis as part of the "Sunshine Project" to develop alternative forms of energy. It has been under the direction of the New Sunshine (NSS) project since 1993. The overall target of the NSS is to install 5000 MW of PV capacity by 2010.

The NSS program is directed by the Ministry of Trade and Industry (MITI). On the R&D front, the government has been investing heavily in PV R&D; between 1991 and 1998, government spending on PV R&D exceeded $480 million. Approximately 40% of the MITI's PV R&D budget went to the eight leading Japanese PV firms, with the remainder going to national research institutes, universities, and other industries. The government support for PV R&D induced vigorous R&D expenditures in industry; by 1995, industrial expenditures on PV R&D were about twice those of the government. The MITI also established an R&D consortium for PV development that had 65 participating firms by 1996. The main focus areas of R&D were cost reduction of PV systems, silicon feedstock for PV cells, and PV deployment.

The MITI is also implementing a demonstration program that involves PV field tests for industrial use, where half of the PV installation costs are subsidized. This follows the successful completion of a demonstration program on field tests for public facilities that was completed in 1998. The aim of this program is to install trial PV systems to introduce industry to PV use, demonstrate and analyze long-term operation of PV systems, and standardize and introduce PV applications toward full-scale deployment.

The PV deployment program also has a number of components, with the main one being the residential PV dissemination program that aims to promote, through subsidies, the installation of PV systems by individuals. Other components include programs to support efforts established by regional governments and to support industrial entrepreneurs who are involved in introducing PV systems. A number of government ministries, local governments, municipalities, and utilities are also involved in this deployment effort. In addition, solar cell manufacturers and housing firms have organized the Japan Photovoltaic Energy Association to carry out public relations and dissemination in cooperation with the government. This deployment effort has led to learning in regard to both the PV modules and the balance of system components. Between 1993 and 1998, the government subsidies for this program totaled approximately $200 million but stimulated market actors to provide additional learning investments of $300 million. It is estimated that by 2007, PV commercialization can become self-sustaining. By that point, market investments in learning will be about 5.7 times the government support.

3.2 The German Wind Power Program

Germany is considered a world leader in wind energy deployment, with electricity production from wind having gone up more than eightfold—from 670 to more than 5500 GWh—between 1993 and 1999. In 1999, Germany had more than 4000 MW installed capacity. The prices also declined substantially over this period, indicating a learning rate of approximately 8%, and it is estimated that for each deutschemark (DM) spent by the government in subsidizing learning, market actors provided 2.1 DM. Furthermore, the manufacturing base for wind energy technologies, including indigenous firms as well as joint ventures, continues to expand in Germany.

A number of different actors and policies operating in tandem contributed to this success story. In 1989, when the federal government initiated a "100-MW Wind Programme," there was nearly a complete absence of a market for wind turbines. Wind plant operators could receive money from this program as well as utilities for power delivered to the grid. Investment subsidies were also provided by this program, and the Lander (states) offered additional grants. In 1991, the federal government also promulgated the EFL, which obliged grid operators to purchase electricity produced from renewables at agreed and fixed prices and, thus, provided a stable

market for investors. In the same year, the government also enlarged the 100-MW program to a 250-MW program. During the early 1990s, the government also increased its support for wind power R&D, with the budget for the 1992–1996 period being more than double that for the 1987–1991 period.

In addition, many German regions or municipalities established targets intended to promote renewable energy, including wind energy and use, and often provided financial support, including investment subsidies, to implement these renewable energy policies. Many German financial institutions also provided low-interest loans for renewable energy projects. Between 1990 and 1997, a total of 3.48 billion DM (1.78 billion euros) was disbursed for wind energy projects. Tax laws that allowed the offsetting of investments in wind farms made this an attractive option for individuals. Administrative support was provided for wind energy projects in the forms of planning guidance and land use directives that helped to assuage local concerns about these projects. At the same time, developers also often held public meetings in local communities to share information about, and raise interest in, schemes. Finally, the high level of environmental awareness as well as interest in renewables among the citizenry contributed significantly to the public support for wind energy deployment.

4. CONCLUSION

The aim of this broad sweep through the area of energy innovation, highlighting the main actors, activities, policies, institutions, and their interactions that eventually underlie energy technology development and deployment, was to present an overview of the current state of and challenges to energy innovation.

To recapitulate, some key points are as follows:

- A diverse cast of actors, with flows of finances, technology, and knowledge among them, are involved in energy technology innovation. Various policies (e.g., energy, fiscal, trade, competitiveness, environmental), as well as other macroeconomic and institutional factors, shape this "energy innovation system" and also influence its output.
- Most energy technology development takes place within firms, although other organizations (e.g., government laboratories, universities) also contribute to this process. Governments and the private sector direct large expenditures toward ER&D.
- Although most of the world's activities on energy technology innovation focus on users and consumers in the commercial energy arena, there are much smaller but parallel innovation subsystems that focus on the energy service needs of the poor in developing countries. Many of the actors in these subsystems are often quite different from the actors in the mainstream energy innovation system, although there are linkages between the two groups and their activities.
- Trends in global ER&D expenditures give some cause for concern due to the burgeoning challenges facing the energy system, although the potential for meeting these challenges may be hobbled more by ineffective deployment of suitable energy technologies than by insufficient R&D.
- For any new energy technology, the move from the precompetitive stage to deployment faces numerous barriers. Thus, successful energy innovation requires concerted, synergistic, and sustained efforts by a range of actors, institutions, and policies not only to develop technologies but also to bring them to the marketplace.
- Government policies such as moving toward full cost energy pricing are perhaps the most important drivers of energy innovation by creating a demand for new and improved energy technologies that, in turn, creates an impetus for ER&D as well as deployment.

Although there have been a number of efforts in different countries to guide the energy innovation system, much more effort will be needed to enable it to meet the energy-related challenges facing humanity. We know a fair bit about some aspects of energy technology innovation (e.g., R&D inputs, various actors and interactions among them, deployment issues), but we know much less about some others (e.g., efficiency and effectiveness of R&D, sufficiency in relation to challenges). Improving the understanding of such issues, and finding the social and political will to act on the lessons that emerge, will ultimately determine our ability to meet these daunting challenges.

Glossary

absolute zero The lowest temperature on the Kelvin temperature scale.

blackbody A perfect emitter and absorber of thermal radiation.

Celsius temperature scale A temperature scale based on 0 and 100°C for the ice and steam points of water, respectively; named for Swedish astronomer Anders Celsius.

emissivity The ratio of power radiated by a substance to the power radiated by a blackbody at the same temperature.

Fahrenheit temperature scale A temperature scale based on 32 and 212°F for the ice and steam points of water, respectively; named for German scientist Gabriel Daniel Fahrenheit.

infrared thermometer A device using Planck's law and measurements of thermal power in the range 0.7 to 80 μm to deduce the temperature of the source.

International Temperature Scale of 1990 (**ITS-90**) An internationally recognized standard adopted on January 1, 1990. Between 0.65 and 5 K, temperatures on the ITS-90 are defined in terms of the vapor–pressure temperature relations of helium-3 and helium-4. Above 5 K, the ITS-90 assigns temperatures to sixteen fixed points (Table I). Between the fixed points, temperatures on the ITS-90 are obtained by interpolation using a helium gas thermometer in the range 3 K to 24.5561 K, a platinum resistance thermometer in the range 13.8033 K to 1234.93 K, and an optical thermometer above 1234.93 K.

kelvin A unit of temperature defined as $\frac{1}{273.16}$ of the triple point temperature of water.

Kelvin temperature scale A temperature scale based on a temperature of 273.16 K for the triple point of water; named for physicist and mathematician Lord Kelvin, born William Thomson and knighted by Queen Victoria as the first Baron of Largs (1824-1907).

manometer A device for measuring pressure differences, usually by the difference in height of two liquid columns.

optical pyrometer A device using Planck's law and measurements of thermal power in the range 0.4 to 0.7 μm, usually approximately 0.66 μm to infer the temperature of the source.

Planck's radiation law A mathematical relationship formulated in 1900 by German physicist Max Planck(1858–1947) to explain the spectral energy distribution of radiation emitted by a blackbody.

Rankine temperature scale A temperature scale based on a temperature of 491.69°R for the triple point of water; named for Scottish engineer William Rankine (1820–1872).

resistance temperature detector (**RTD**) A sensor relating temperature to the electrical resistance of a conductor.

Seebeck effect The voltage produced when there is a temperature gradient along a conductor; named for physicist Thomas Johann Seebeck (1770–1831).

temperature At the human level, a measure of the sensation of hot and cold; at the atomic level, it is a measure of the average linear kinetic energy of an atom or a molecule in a substance.

thermal energy The average kinetic energy associated with the motion of atoms and/or molecules in a substance.

thermal equilibrium When there is no change in the thermometric properties of either system.

thermistor A temperature sensor employing the electrical resistance of a semiconductor as a thermometric property.

thermocouple A temperature sensor consisting of two dissimilar wires bonded together at one end to form a junction; a voltage related to the temperature of the junction is produced between the open ends of the two wires.

thermometer An instrument employing a thermometric property to measure temperature.

thermometric property A property of a system that changes with temperature.

 © 2004 Elsevier Inc. All rights reserved.

triple point temperature The single temperature at which liquid, vapor, and solid coexist in thermal equilibrium.

Wien's displacement law A mathematical relationship formulated by German physicist Wilhelm Wien (1864–1928) showing that the wavelength for maximum radiative power of a blackbody is inversely proportional to the Kelvin temperature.

Zeroth law of thermodynamics A relationship indicating that if two systems are separately in thermal equilibrium with a third system, they must also be in thermal equilibrium with each other.

Temperature is a measure of the sensation of hot and cold. Inanimate objects that respond to the sensation are used in a thermometer to assign a numerical value to the sensation. Thermometers employing the common Celsius and Fahrenheit scales assign 0°C and 32°F to the freezing point of water, respectively, and assign 100°C and 212°F to the boiling point of water, respectively. Temperature changes are recorded identically on the Celsius and Kelvin scales and on the Fahrenheit and Rankine scales, but the zero value differs on the respective pairs of scales. This article discusses the range of temperatures encountered in nature and the International Temperature Scale of 1990 (ITS-90). It also describes a wide variety of temperature sensors along with their operational temperature range.

1. TEMPERATURE

A person feels warm when standing near a campfire and feels cold when standing in front of an open refrigerator. Temperature is a way of recording the extent of this sensation of hotness and coldness. Inanimate things also respond to hotness and coldness. For example, the pressure of air in an automobile tire decreases when the air cools, and the length of a railroad rail increases when the rail warms. These inanimate changes are used to assign a numerical value to temperature.

A metal spoon taken from a refrigerator is cold to the touch, and water drawn from a hot water tap feels warm. If the spoon is placed in the water, the spoon warms while the water cools. Eventually, both the spoon and the water feel the same to the touch, and we say that thermal equilibrium is attained and that the two have the same temperature. This definition of temperature does not depend on any particular temperature scale. The property of temperature indicates when two objects are in thermal equilibrium.

If a spoon and a fork are placed in a refrigerator, both will come to thermal equilibrium with the environment of the refrigerator, and we would say that each has the same temperature as the refrigerator. We would also find that if the spoon and fork were placed in contact, they would be in thermal equilibrium and, therefore, at the same temperature. Although not surprising, this idea is profound and gives rise to the Zeroth law of thermodynamics: if two systems are separately in thermal equilibrium with a third system, they must also be in thermal equilibrium with each other. One of these three systems could be an instrument for measuring temperature, that is, a thermometer. If a thermometer records a certain temperature when in thermal equilibrium with one of the systems, we would expect the thermometer to record the same temperature when in thermal equilibrium with the third system.

2. THERMOMETRY

A property of a system that changes with temperature is called a thermometric property. Examples of a thermometric property include the following:

- Pressure of a gas
- Volume of a liquid
- Electrical resistance
- Color
- Electrical voltage
- Character of thermal radiation

The algebraic equation chosen to relate temperature to a thermometric property is arbitrary. However, the simplest way, and the one most generally used, is a linear equation of the form $T = mx + b$, where T is the temperature, x is the thermometric property, and m and b are experimentally determined constants. The constants m and b may be determined by assigning numerical values to two temperatures and recording the values of the thermometric property at these two temperatures. Typically, the two temperatures are the freezing point of water and the boiling point of water. These two temperatures are assigned 0 and 100°C on the Celsius scale, respectively, and are assigned 32 and 212°F on the Fahrenheit scale, respectively.

3. TEMPERATURE SCALES

3.1 Celsius and Fahrenheit Scales

To illustrate the thermometer principle and the Celsius scale of temperature, consider the "liquid-in-glass" device depicted in Fig. 1. The thermometer is a glass tube with a reservoir for the liquid at one end and a capillary (narrow cylindrical channel) feeding into the reservoir. Liquid is forced into the capillary when the temperature of the liquid in the bulb increases. Suppose that the level of the liquid is determined by a centimeter scale attached to the side of the thermometer. If the level corresponds to 1.1 cm when the bulb is at the freezing point of water (0°C) and corresponds to 10.3 cm when the bulb is at the boiling point of water (100°C), we write $0 = 1.1m + b$ and $100 = 10.3m + b$ for the two respective cases. Solutions to these two equations yield $m = 10.9$ and $b = -12.0$, and the equation relating temperature to fluid height becomes $T = 10.9x - 12.0$. An unknown temperature is then determined by measuring the fluid level (x) and calculating the temperature (T) using the equation. In practice, the 0 and 100°C temperatures are etched at the fluid level for the freezing point and boiling point of water, respectively. Then, the space between the 0 and 100°C marks is graduated into 100 equal segments and an unknown temperature is read directly from the position of the fluid level. If the thermometer were recording temperature on the Fahrenheit scale, the 0 and 100°C designations would be replaced with 32 and 212°F, respectively, and the space between the marks would be graduated into 180 equal segments. Conversion between the two scales follows from the relation $F = \frac{9}{5}C + 32$.

3.2 Kelvin and Rankine Scales

Mercury is very useful in a liquid-in-glass thermometer because it is liquid at room temperature, does not wet glass or cling to it, and has uniform volume expansion throughout its liquid range. Because mercury remains a liquid down to approximately −40°C, mercury-in-glass thermometers can record temperatures as low as −38.7°C. Mercury remains a liquid for temperatures several hundred degrees Celsius above room temperature, but other factors (e.g., softening of the glass housing) limit the highest measurable temperature to approximately 360°C. The use of a different liquid, notably ethanol, can extend the lower measurable temperature to approximately −115°C. Because of the simplicity of liquid-in-glass thermometers and the relatively large measurable temperature range, they have been widely used for roughly 300 years.

Factors that limit the reproducibility and accuracy of liquid-in-glass thermometers include the following:

- Manufacturing reasonably identical thermometers
- Recording the precise level of the liquid
- Experiencing difficulty in reproducing the ice and steam points of water

A constant volume gas thermometer (Fig. 2) using the pressure of a gas as a thermometric property avoids most of these problems. The great virtue of this thermometer is that for very low gas pressure, the temperature deduced is independent of the gas used.

The three phases of water—vapor, liquid, and solid—exist with no change in any component at a unique temperature called the triple point temperature. Gas in a container is then brought to thermal equilibrium with its surroundings, and this is maintained at the triple point temperature. The pressure of the gas (P_o) is then measured. By definition, the triple point temperature is 273.16 kelvins, symbolized as 273.16 K. When the gas is brought to equilibrium with the surroundings at a temperature other than the triple point, the fluid reservoir of the manometer is raised or lowered so that the gas volume remains constant and the gas pressure (P) is measured. Assuming that for constant volume, pressure is proportional to temperature, the ratio of two temperatures equals the ratio of the corresponding pressures. Knowing the pressure and temperature for the triple point and measuring the pressure for the unknown temperature, the tempera-

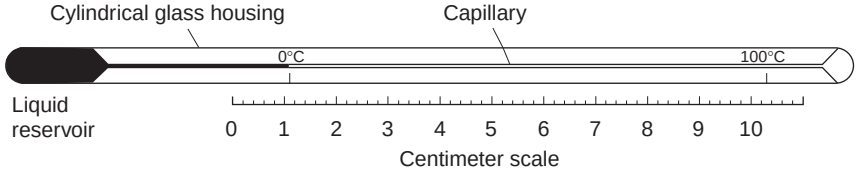

FIGURE 1 A liquid-in-glass thermometer.

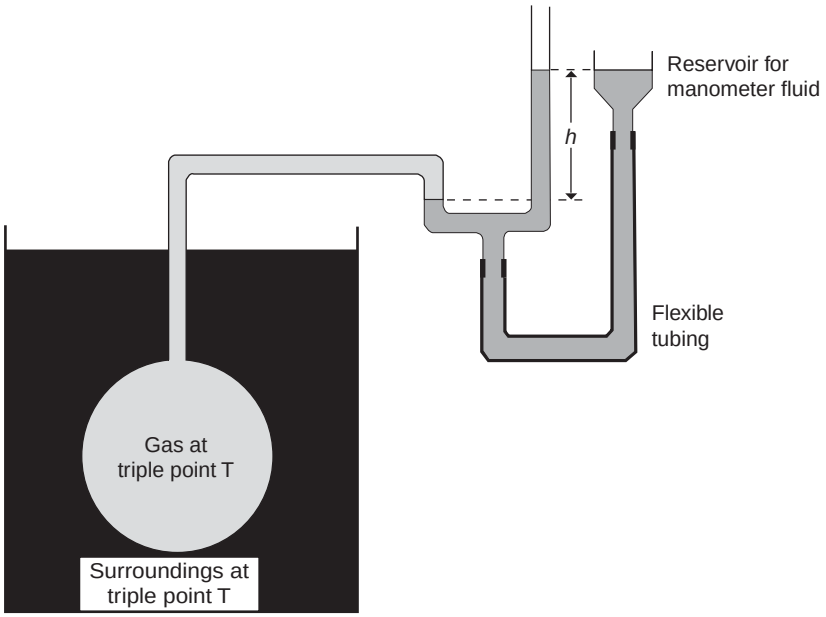

FIGURE 2 Constant volume gas thermometer principle. The apparatus illustrated here for measuring gas pressure is called a manometer. Gas pressure is related to the difference in fluid levels in the manometer. The volume of gas is held constant by raising or lowering the reservoir for the manometer fluid. There is a variety of ways in which to measure the pressure and to ensure constant gas volume.

ture is then computed from the relation

$$T = 273.16\frac{P}{P_o}. \qquad (1)$$

Temperatures deduced from Eq. (1) are expressed in kelvins, and the scale is called the Kelvin temperature scale. One kelvin is defined as $\frac{1}{273.16}$ of the triple point temperature of water. A kelvin is equal to a Celsius degree, so that changes in temperature are the same on both the Kelvin and Celsius scales. The freezing point of water on the Kelvin scale is 273.15 K, so that the conversion from kelvins to degrees Celsius becomes $K = C + 273.15$. The lowest temperature on the Kelvin scale is zero and is referred to as absolute zero. The Rankine scale of temperature is developed in the same way as the Kelvin scale by taking the triple point of water to be 491.69°R. A Rankine degree is equal to a Fahrenheit degree. The freezing point of water is 491.67°R, so that conversion between the two scales becomes $R = F + 459.67$.

The random incessant motion of atoms and/or molecules in a substance is called thermal motion. The motion of an atom or molecule always has linear components and in the case of molecules may include vibration and rotation. The average kinetic energy associated with the motion is called thermal energy. The average linear kinetic energy of an atom or molecule is directly proportional to the Kelvin temperature of the substance. At the level of atoms and molecules, it is appropriate to interpret temperature as a measure of the average linear kinetic energy of an atom or a molecule in a substance.

4. RANGE OF TEMPERATURES

Most humans would agree that a temperature of 35°C (95°F) is quite hot and that −10°C (14°F) is rather cold. Yet in 1913, humans recorded a temperature of 56.7°C (134°F) in Death Valley, California, and a temperature of −89.4°C (−129°F) in 1983 in Vostok, Antarctica. As large as these temperature extremes are by human standards, they pale in comparison with other earthbound and extraterrestrial temperatures. Liquid nitrogen at a temperature of −196°C (77 K) is routinely used in cryosurgery to destroy cancerous tumors, magnets used in magnetic resonance imaging (MRI) are cooled with liquid helium at a temperature of −269°C (4.2 K), and the temperature of the filament in an incandescent light bulb operates at approximately 2500°C (2200 K). Low-temperature research laboratories have produced temperatures in the tens of billionths of a kelvin. Extraterrestrial, we find a cosmic background temperature of 2.7 K (−270.5°C), a surface temperature of approximately 5700°C

(6000 K) for our sun, and an interior temperature of approximately 15,000,000 K for the sun. Figure 3 depicts the range of temperatures encountered in nature.

5. THE INTERNATIONAL TEMPERATURE SCALE OF 1990

The International Temperature Scale of 1990 (ITS-90) is the internationally recognized standard. Between 0.65 and 5 K, temperatures on the ITS-90 are defined in terms of the vapor pressure temperature relations of helium-3 and helium-4. Above 5 K, the ITS-90 assigns temperatures to 16 fixed points (Table I). Between the fixed points, temperatures on the ITS-90 are obtained by interpolation using a helium gas thermometer in the range of 3 to 24.5561 K, a platinum resistance thermometer in the range of 13.8033 to 1234.93 K, and an optical thermometer above 1234.93 K.

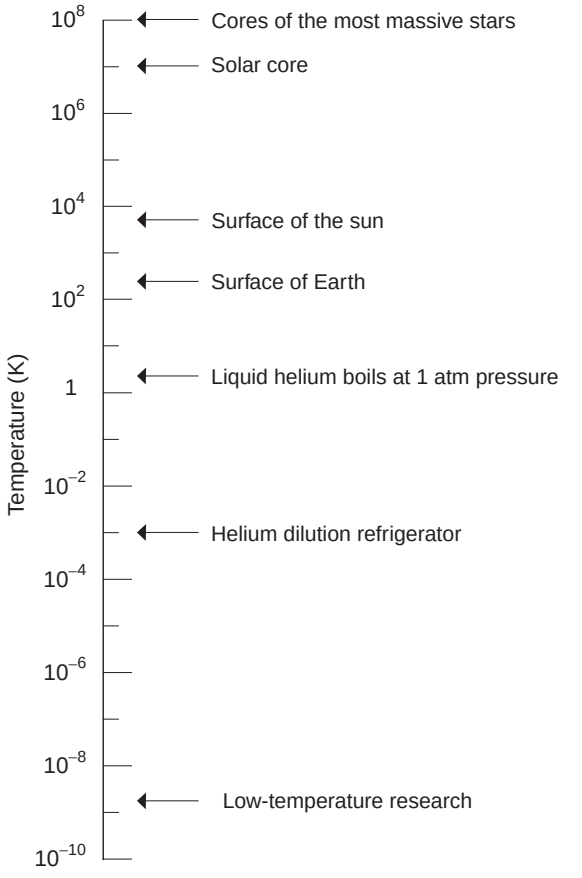

FIGURE 3 A representative few of the temperatures encountered in nature. Note that the scale is logarithmic.

6. TEMPERATURE SENSORS

6.1 Resistance Temperature Detectors

6.1.1 Platinum Resistance Temperature Detector

The resistance to the flow of electric charge in a conductor depends on temperature. For metals, the resistance increases as the temperature increases. The algebraic relation between temperature and resistance allows one to determine the temperature of the metal from a measurement of its resistance. Thermometers based on this principle are called resistance temperature detectors (RTDs). Platinum is particularly useful for an RTD because it can be made very pure, is stable and does not oxidize easily, and has a relatively high melting point of 1772°C. In addition, its resistance varies smoothly—nearly linearly—over a wide range of temperatures. Properly calibrated, a platinum resistance thermometer can achieve reproducible readings accurate to less than a thousandth of a Celsius degree.

Figure 4 shows a platinum RTD constructed from fine platinum wire approximately 0.1 mm in diameter. Typically, the sensor has a resistance of 100 ohms (Ω) at 0°C and increases approximately 0.39 Ω for each Celsius degree increase. A second, more modern, and more widely used type of platinum resistance temperature sensor is shown in Fig. 5. The platinum is deposited as a very thin narrow ribbon onto a ceramic base. Typical film

TABLE I

International Temperature Scale Calibration Temperatures

Hydrogen triple point	13.8033 K	−259.3467°C
Hydrogen vapor pressure (~33 kPa)	~17 K	−256.15°C
Hydrogen vapor pressure (~101 kPa)	~20.3 K	−252.85°C
Neon triple point	24.5561 K	−248.5939°C
Oxygen triple point	54.3584 K	−218.7916°C
Argon triple point	83.8058 K	−189.3442°C
Mercury triple point	234.3156 K	−38.8344°C
Water triple point	273.16 K	0.01°C
Gallium melting point	302.9146 K	29.7646°C
Indium freezing point	429.7485 K	156.5985°C
Tin freezing point	505.078 K	231.928°C
Zinc freezing point	692.677 K	419.527°C
Aluminum freezing point	933.473 K	660.323°C
Silver freezing point	1234.93 K	961.78°C
Gold freezing point	1337.33 K	1064.18°C
Copper freezing point	1357.77 K	1084.62°C

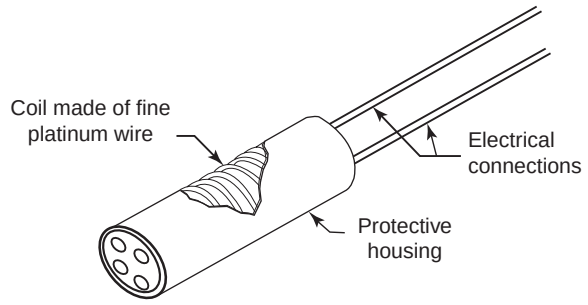

FIGURE 4 A common type of resistance temperature detector employing a fine platinum wire. The cylindrical package may be as small as 3 mm in diameter.

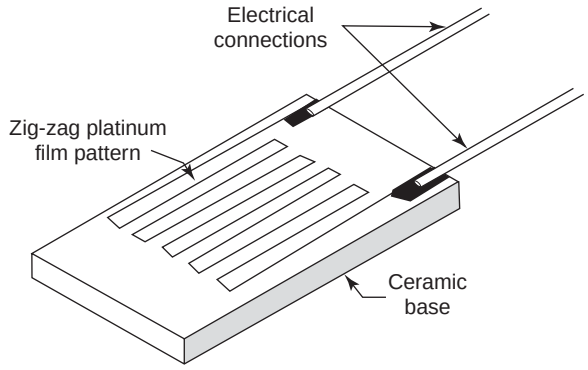

FIGURE 5 A common type of resistance temperature detector employing a thin platinum film. The overall dimensions may be as small as $2 \times 2 \times 0.5$ mm thick.

thickness ranges from 1 to 2 μm with a 10-μm thick protective coating. Precise resistances can be obtained by trimming the length of the film. The standard resistance is 100 Ω at 0°C, but by controlling the dimensions of the film (especially the thickness), a much higher resistance is achievable. A thin film platinum resistance temperature sensor can be bonded to a material to measure temperature in a very local area. Because of the small overall size and good thermal contact, the sensor responds quickly to temperature changes, making it very useful in temperature control applications. Depending on the construction, a platinum resistance temperature sensor can measure temperatures in the range of 10 to 1200 K.

6.1.2 Thermistors

To a first approximation, a semiconductor is a material having electrical properties between a conductor (e.g., copper) and an insulator (e.g., glass). Elemental silicon and germanium, as well as many oxides of metals such as nickel and copper, can have semiconducting properties. The electrical resistance of a semiconductor depends on temperature, but unlike a metal, the resistance decreases as the temperature increases and the relation between resistance and temperature is highly nonlinear. A sensor using such a semiconducting material is called a thermistor. Resistance (R) and Kelvin temperature (T) for a thermistor are generally assumed to be related by $R = R_o e^{\beta(1/T - 1/To)}$, where R_o is the resistance at temperature T_o and, depending on the material, β ranges from 3500 to 4600 K. A platinum wire having a resistance of 100 Ω at 0°C will have approximately 40% more resistance at 100°C. But the resistance of a semiconductor may change by a factor of 50 in the same temperature interval. Thermistors can be made in nearly any stable geometric shape, with the largest overall dimension being approximately 1 mm. Thermistors are relatively cheap, their response time is short, and their intrinsic accuracy is good. The fact that they are highly nonlinear is a disadvantage, as is the limited temperature range, typically −100 to 150°C. Still, thermistors find many uses in this temperature range, for example, as the sensor in a nurse's thermometer.

6.2 Thermocouples

In 1826, Thomas Seebeck discovered that a voltage is produced when there is a temperature gradient along a conductor. This phenomenon is called the Seebeck effect. The voltage produced is called the Seebeck voltage, and the variation of voltage with temperature is called the Seebeck coefficient. Two wires of different composition bonded at one end produce a thermocouple (Fig. 6). A voltage develops between the unconnected ends and is related to the temperature, making a thermocouple useful as a temperature sensor. At 25°C, a thermocouple having one wire made of pure copper and the other wire made of an alloy of copper and nickel called Constantan produces 40.6 microvolts (μV) for each Celsius degree change. The voltage produced by a thermocouple increases monotonically with temperature and is nearly linear over wide ranges of temperature. Thermocouples are widely used in industry, even though sensitive instruments are required to measure the small voltages produced.

Like an ordinary battery, there is a positive and negative polarity to the voltage produced by a thermocouple. When a meter is connected to measure a thermocouple voltage, as shown in Fig. 6, the thermocouple wires and meter connections form two unwanted thermocouple junctions. These two unwanted thermocouple junctions are of

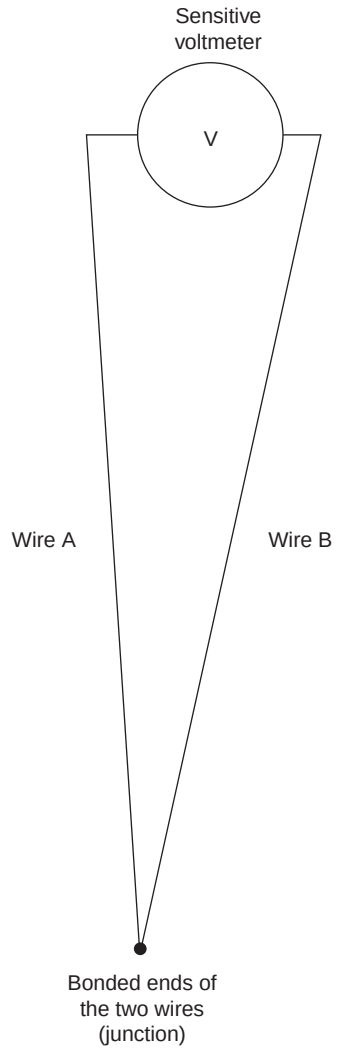

FIGURE 6 Two different metallic wires bonded at their ends constituting a thermocouple. A voltage (V) develops between the open ends when the bond (junction) is heated.

different character because the wires have different composition. The voltages produced at the unwanted thermocouple junctions add to the voltage produced at the thermocouple junction. This problem can be eliminated by using two thermocouples and a reference temperature of 0°C, as shown in Fig. 7. (Although a bath of water and ice is commonly used to produce the 0°C reference, it can be simulated using electronic techniques.) The thermocouple wires and the meter connections now form two identical thermocouple junctions whose voltages cancel each other. The two junctions produce voltages of opposite polarity, so that when the two junctions are at the temperature of the ice bath, the voltage read by the meter is zero. When

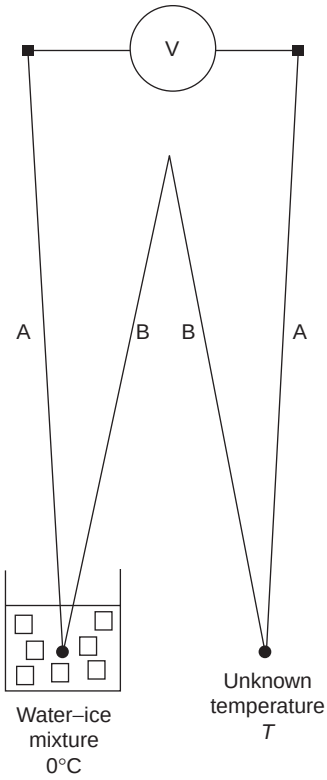

FIGURE 7 Customary manner of measuring temperature with a thermocouple.

one of the thermocouples is removed from the ice bath and is at a different temperature, the voltage read by the meter is not zero and the voltage relates to the temperature difference of the measuring thermocouple and the ice bath. This voltage–temperature relationship may be in the form of a table in a book or may be available in a format suitable for computer use. Because the voltage–temperature relationship is nearly linear, the relation between voltage and temperature can often be suitably represented by a quadratic equation of the form $T = a\mathrm{V} + b\mathrm{V}^2$, where a and b are determined from data for a particular type of thermocouple. The National Institute of Standards and Technology (NIST) maintains a database for a variety of thermocouples. Parameters for functions describing the relation between voltage and temperature are included in the NIST database. Positive features of thermocouples include the following:

- They are relatively inexpensive.
- They are rugged and not easily broken.
- They are small enough to measure temperature at a point.

TABLE II

Characteristics of Commonly Used Thermocouples

Composition A	Composition B	Commercial type	Calibration range (°C)	Sensitivity at 25°C (μV/C°)
Copper	Constantan (alloy of copper and nickel)	T	−270 to ∼400	41
Iron	Constantan	J	−210 to ∼1200	52
Chromel (alloy of nickel and chromium)	Alumel (alloy of nickel and aluminum)	K	−270 to ∼1350	41
Chromel	Constantan	E	−270 to ∼1000	61
Platinum	87% platinum 13% rhodium	R	−50 to ∼1750	6

Source. National Institute of Standards and Technology (n.d.).

- They operate over fairly wide temperature ranges.
- They have relatively short response times.

Negative aspects include the following:

- The low-voltage output is masked by electronic noise.
- Their accuracy is usually limited to approximately 0.5°C.
- They require a known temperature reference, usually 0°C, that is cumbersome unless done electronically.
- Dealing with the nonlinearity is tedious if using calibration tables.

The characteristics of commonly used thermocouples are presented in Table II.

6.3 Radiation Thermometers

A temperature sensor requiring contact with an object (e.g., a thermocouple) cannot withstand a temperature above approximately 2000 K. Thermometers measuring temperatures above that temperature are based on the character of electromagnetic radiation emitted by an object. All matter above a temperature of 0 K emits electromagnetic radiation. A radiator called a blackbody emits more radiation for all wavelength intervals than does any object having the same area and at the same temperature. The ratio of the intensity of radiation from an object to the intensity of radiation from a blackbody at the same temperature is called the emissivity. By definition, the emissivity of a blackbody is 1.0, whereas that for any other object is always less than 1.0.

Perfect blackbodies do not exist. However, they can be approximated to a high degree of accuracy and are very useful in thermometry. Blackbody radiation

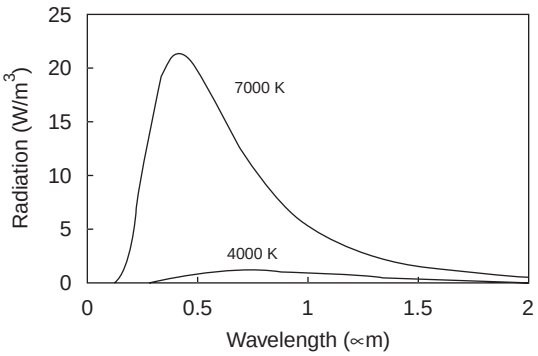

FIGURE 8 Blackbody thermal radiation distributions for temperatures of 4000 and 7000 K.

measured in watts per square meter per wavelength interval in meters as a function of wavelength (λ) is described by Planck's radiation law:

$$R(\lambda, T) = \frac{2\pi hc^2}{\lambda^5} \frac{1}{e^{hc/\lambda kT} - 1}, \tag{2}$$

where $h = 6.63 \times 10^{-34}$ J s, $c = 3.00 \times 10^8$ m/s, and $k = 1.38 \times 10^{-23}$ J/K.

The intensity distributions for blackbodies at temperatures of 7000 and 4000 K are shown in Fig. 8. Two features of blackbody radiation are of particular importance. First, the energy associated with each wavelength depends on the wavelength. Second, the temperature and the wavelength of maximum radiation (λ_m), as noted by the position of the peak in the spectrum, shifts to a longer wavelength as the temperature decreases. The wavelength of maximum radiation and Kelvin temperature (T) are related by Wien's displacement law:

$$\lambda_m T = 2898 \text{ μm kelvins}. \tag{3}$$

For temperatures between approximately 4000 and 7000 K, λ_m is between 0.4 and 0.7 μm that are visible.

For temperatures below approximately 4000 K, the radiation is mostly infrared. Two categories of noncontact thermometers are in common use. One type, called optical pyrometer, uses Planck's law and measurements of thermal power in the range of 0.4 to 0.7 μm, usually approximately 0.66 μm, to infer the temperature of the source. The second kind, called infrared thermometer, uses Planck's law and measurements of thermal power in the range of 0.7 to 80 μm to deduce the temperature of the source.

6.3.1 Optical Pyrometer

A schematic diagram of an optical pyrometer is shown in Fig. 9. The operator sights the pyrometer on an object. The optical system allows viewing of both the target and an image of the filament of a lamp. The operator adjusts the current in the filament, changing its color, until it matches the color of the object. The temperature is inferred from a calibration relating temperature to current in the filament. A second design maintains a constant current in the filament and changes the brightness of light from the object by means of a rotatable, energy-absorbing optical wedge. The object temperature is related to the amount of energy absorbed by the wedge, which is a function of its angular position. The optical pyrometer principle can be extended into the infrared region of the electromagnetic spectrum using detectors sensitive to infrared radiation. Typically, optical pyrometers measure temperature to an accuracy of 1 to 2% of the full-scale range.

6.3.2 Infrared Thermometer

An infrared thermometer uses a lens system to focus radiation onto an infrared detector that converts the energy absorbed into an electrical signal. The temperature inferred from the electrical signal is corrected for the emissivity of the source. Using optical filters, infrared thermometers may employ a very narrow range of wavelengths, whereas other systems may use a very broad range of wavelengths. In either case, the energy absorbed is related to temperature using Planck's law. Broadband infrared spectrometers are relatively inexpensive and easy to use, but their accuracy suffers from the fact that emissivity depends on wavelength, thereby making corrections difficult. Narrow-band infrared thermometers do not face this limitation because the emissivity value does not vary appreciably over the wavelengths used (Fig. 10).

Modern technology is continually improving the accuracy of infrared thermometers. For example, fiber-optic sensors allow placement of the instrument controls away from the heat of the object being studied. Recent developments in infrared thermometers have combined pulse laser technology with narrow-band, single-color infrared thermometers to automatically determine emissivity values and accurately correct for true target temperature. This technology incorporates the use of a pulse laser that emits energy within the same narrow bandwidth that the instrument measures the target thermal radiation. The instrument's infrared detector measures the amount of laser energy reflected from the target, and the microprocessor control converts this additional energy into an accurate value to compensate for emissivity. The instrument then displays true target temperatures, corrected for emissivity and accurate to within ± 3 K. Pulse laser technology is very effective with diffuse targets.

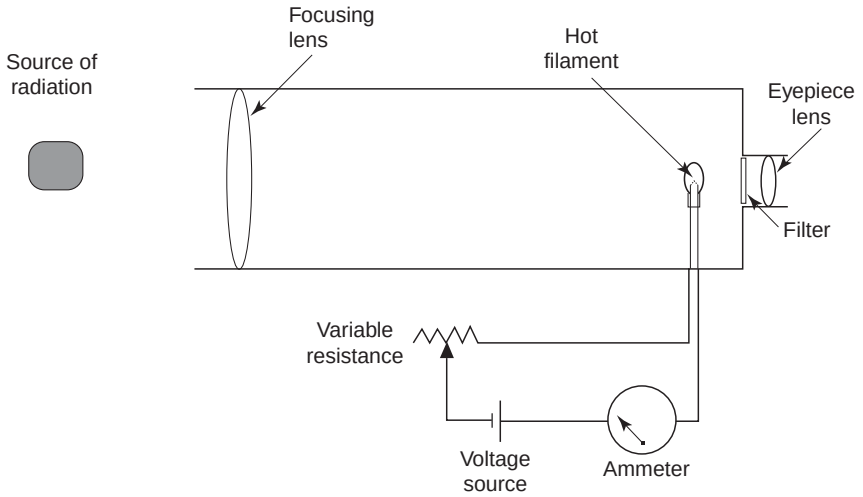

FIGURE 9 Schematic diagram of an optical pyrometer.

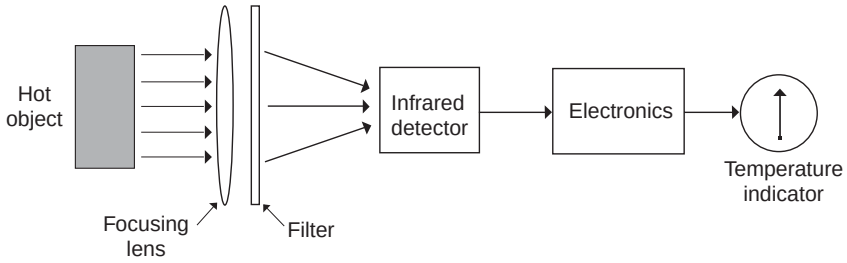

FIGURE 10 Schematic diagram of an infrared thermometer.

6.4 Very Low-Temperature Methods

Measuring temperatures below a few kelvins requires sophisticated techniques. Three of these schemes are called noise thermometry, paramagnetic thermometry, and semiconductor resistance and diode thermometry.

6.4.1 Noise Thermometry

Thermal agitation of electrons in a conductor gives rise to a randomly varying voltage. The average of the square of this voltage is directly proportional to the Kelvin temperature. Properly calibrated, a measurement of the voltage yields the Kelvin temperature. Although the technique requires sophisticated electronic instrumentation, it is one of the few alternatives to gas thermometry for precise determination of thermodynamic temperature. Noise thermometers are very useful for measuring temperatures below 1 K, but in principle they can measure temperatures in the range of a few millikelvins to above 1800 K.

6.4.2 Paramagnetic Thermometry

Many materials can be magnetized by placing them in a magnetic field. The ratio of magnetization to the applied magnetic field is called the magnetic susceptibility. For a class of materials called paramagnetic, the magnetic susceptibility is inversely proportional to the Kelvin temperature. The temperature of a paramagnetic material, such as cerium magnesium nitrate, in intimate contact with some material can be determined from a measurement of the magnetic susceptibility. The technique is useful for measuring temperatures below 4 K.

6.4.3 Semiconductor Resistance and Diode Thermometry

The electrical resistance of a semiconductor depends sensitively on temperature for temperatures below approximately 100 K. Germanium and silicon have proven to be useful for measuring temperatures as low as 0.1 K. The use of ruthenium oxide in a similar mode has pushed the lower limit of temperature measurement to approximately 0.01 K.

A p–n junction diode is a sandwich of two semiconducting materials having different electrical conduction characteristics. When connected to a voltage source, the current in a p–n junction diode depends on temperature. Thermometers using this thermometric property in silicon and gallium–arsenide p–n junction diodes are useful for measuring temperatures in the range of 1 to 300 K.

Glossary

acceptable thermal environment An environment in which at least 80% of the occupants would find conditions thermally acceptable.
equivalent temperature The air temperature of an imaginary environment in which an occupant would feel the same thermal sensation as in the actual environment.
global thermal comfort A condition of mind that expresses satisfaction with the thermal environment, without mental or physical stresses.
heat (cold) stress Increase (decrease) of body temperature induced by sustained heat (cold) imbalance that cannot be fully compensated for by temperature regulation or by the activation of thermoeffector activities or other physiological regulatory systems.
local thermal discomfort Subjective dissatisfaction regarding the thermal environment, based on local conditions.
moderate thermal environment An environment in which thermal comfort conditions can be achieved with ordinary active (HVAC) or passive devices/techniques.
severe thermal environment An environment in which it is not possible to reach comfort conditions and the occupants' health may be at risk.
thermal load of the human body The difference between internal heat production and loss of heat to the actual environment for people considered to be in a condition of comfort.

Thermal comfort in built environments is an everyday issue for architects and technicians and one that has been dealt with widely in scientific literature. This article provides an overview of the concepts and methods relating to the definition of thermal comfort and the possible ways of assessing it. The ways of controlling thermal conditions and ensuring that built environments are suitable are discussed. Specific attention is given to moderate thermal environments, in which thermal comfort conditions for people are produced using natural or mechanical systems. Indeed, these systems play a major role during the process of designing built environments. Some attention is also given to severe thermal environments (in which conditions of thermal stress should be applied). Taking these aspects into consideration, a description of some rational methods for evaluating thermal comfort and thermal stress conditions is provided. These are essentially based on the human body's thermal balance equation, originally proposed by P. O. Fanger and now included in some International Organization for Standardization International Standard Certificate requirements.

1. THE HUMAN BODY'S THERMAL BALANCE

Through the use of its complex temperature regulation mechanism, the human body is able to reach a condition of thermal equilibrium with the surrounding environment when the variation of internal energy, S, at the body core level is equal to zero. The thermal exchange between a subject and the environment is equal to the difference between metabolic heat production (apart from the so-called mechanical power) and thermal losses due to respiration and exchanges of heat through the skin surface (nude and clothed areas). All these elements

 © 2004 Elsevier Inc. All rights reserved.

relating to the human body's thermal balance are described in the following sections here.

1.1 Internal Heat Production

Food and drink, when ingested, are subjected to exoenergetic chemical reactions; these constitute the metabolic heat power, M (or the metabolic rate of the subject). Through these processes, most of the food's potential chemical energy is transformed into thermal energy.

Part of this thermal energy is needed to maintain the human body's core at a normal temperature and to ensure that the body's internal organs receive everything that is necessary for their normal functioning. This rate of energy (accounting for approximately 43 W/m^2 of human body surface) is called basal metabolism, and it varies depending on the subject's height and weight. Another part of heat production is necessary for the mechanical activities performed by the subject. Through normal activities, part of the metabolic heat production is converted into mechanical power, W, which according to thermodynamic conventions is assumed as positive when it is released in the environment.

1.2 Respiratory Losses

During the activity of respiration, a certain amount of air is inhaled. This air generally has a different temperature and level of humidity with respect to the core. Moreover, a portion of the body's internal heat is transferred, in proportion to the level of activity, to the external environment by means of convective (C_{res}) and evaporative (E_{res}) exchanges. Therefore, respiratory losses depend on the level of activity performed by the subject and the temperature and humidity of the air in the environment.

1.3 Body Surface Losses

The external surface of the human body is generally characterized by thermohygrometric conditions that are generally different from those of the surrounding environment. This induces thermal exchanges between the subject and environment, that is, dry heat losses [by convection (C), radiation (R), and conduction (K)] and latent heat losses (due to the evaporation of the sweat, E).

Convective heat exchange depends on the relative air velocity, v_{ar}, and on the difference between the clothed surface temperatures, t_{cl}, defined as the mean temperature of the clothed surface, including uncovered parts, and the air temperature, t_a. Radiation heat exchange depends on the difference between the clothed surface temperature, t_{cl}, and the mean radiant temperature, $\bar{t}_r$, which is defined as the uniform temperature of an imaginary black enclosure in which an occupant would exchange the same amount of heat by radiation as in a real nonuniform enclosure. Both these heat exchanges depend on the thermal insulation of clothing, I_{cl}. Accordingly, the clothed surface temperature can be expressed as a function of the clothing's thermal insulation, I_{cl}, and of the mean skin temperature, t_{sk}.

Conductive heat exchange, caused by contact with objects, is usually neglected due to its low entity.

Finally, evaporative heat exchange through sweating depends on the clothing's evaporative resistance, $R_{e,T}$, on the skin's wetness, w (defined as the equivalent fraction of the skin's surface that can be considered fully wet), and on the difference between the water vapor pressure in the air and that in the thin liquid film that covers the skin's surface. All heat exchanges through the skin also depend on the size of the body's surface area.

1.4 Balance Equation

By applying the first law of thermodynamics to the human body, it is possible to assess its thermal balance by means of the following well-known equation:

$$S = (M - W) - (C_{res} + E_{res} + C + R + E).$$

All the terms of this equation, but the term due to the evaporation of the sweat, E, can be analytically expressed as a function of the physical and physiologic parameters reported in Table I. As a consequence, the human body's thermal balance equation can be

TABLE I

Physical Parameters Involved in the Thermal Balance Equation

Terms appearing in the thermal balance equation	Physical parameters						
	M	I_{cl}	t_a	v_{ar}	$\bar{t}_r$	p_a	t_{sk}

Radiation heat loss, R		✓			✓		✓

represented in the following form:

$$S = f(M, I_{cl}, t_a, p_a, v_{ar}, \bar{t}_r, t_{sk}, E),$$

where metabolic rate, M, and thermal insulation of clothing, I_{cl}, are closely related to the subject's activity and clothing. Although the four objective parameters (temperature, t_a, partial vapor pressure, p_a, air velocity, v_{ar}, and mean radiant temperature, $\bar{t}_r$) depend on the environment's microclimatic conditions, while the subjective parameters (mean skin temperature, t_{sk}, and evaporative heat losses through the skin, E) depend on the human body's thermoregulation mechanism.

2. METHODS FOR EVALUATING THERMAL COMFORT

For a practical assessment of a given environment's internal thermal conditions, some helpful indexes are generally used. These can be divided into two main categories: temperature indexes and sensation indexes.

Temperature indexes express the thermal response of the subject in reference to so-called equivalent temperatures, which are the temperatures of imaginary environments in which the occupants would feel the same thermal sensation as in the real environments. Sensation indexes, based on a thermal sensation scale, predict the mean value of the votes expressed by a large group of people exposed to the same microclimatic conditions. Parameters deriving from the application of the human body's thermal balance equation are known as rational indexes, whereas the others are known as empirical indexes.

2.1 The Predicted Mean Vote Method

The most widely applied index for the evaluation of indoor thermal conditions in moderate environments is the predicted mean vote (PMV). This rational sensation index, originally introduced by P. O. Fanger on the basis of a series of experimental studies, represents the mean value of the votes expressed by a large group of people exposed to the same thermal conditions. These votes are linked to the environment on the basis of the American Society of Heating, Refrigerating and Air-Conditioning Engineers thermal sensation scale reported in Table II. It thus provides information about any deviation from the comfort equation, that is, the degree of thermal discomfort experienced by people in the assigned environment.

TABLE II

American Society of Heating, Refrigerating and Air-Conditioning Engineers Thermal Sensation Scale

Vote	Sensation
+3	Hot
+2	Warm
+1	Slightly warm
0	Neutral
−1	Slightly cool
−2	Cool
−3	Cold

The main physical parameter on which the PMV index evaluation relies is the thermal load of the human body. This can be defined as the difference between internal heat production and loss of heat to the actual environment for a person hypothetically kept at the comfort condition. It is assumed that the thermal sensation at a given level of activity can be expressed as a function of the human body's thermal load.

In addition, comfort conditions may be reached only if the mean skin temperature and the thermal exchange due to the evaporation of sweat assume particular values, which depend on the activity of the subject; in this way, the number of independent variables characterizing the thermal balance equation is reduced from eight to six. The PMV index can then be functionally expressed as follows:

$$\mathrm{PMV} = f(M, I_{cl}, t_a, p_a, v_{ar}, \bar{t}_r).$$

This equation is quite difficult to solve, and it requires the support of software since some iterative techniques are also involved.

The evaluation of PMV, however, is made possible through the use of tables that contain recalculated PMV values for several typical combinations of the input parameters. An example of such tables, referring to a humidity ratio of 50% and a metabolic rate of 58 W/m^2, is shown in Table III.

Parameters for these tables are represented by operative temperatures, which are defined as the uniform temperature of an imaginary black enclosure in which an occupant would exchange the same amount of heat by radiation and convection as in the real nonuniform environment. Operative temperature is often used in moderate environments instead of the air temperature and mean radiant temperature. However, it remains a mathematical function of this parameter.

TABLE III

2.2 The Predicted Percentage of Dissatisfied People

The PMV represents the mean value of a large group of voting participants. However, even though the mean vote would signal the achievement of thermal comfort conditions, some people may experience cold or hot sensations with respect to the thermal environment. In order to take these deviations from the mean expected conditions into account, an additional index has been introduced, the predicted percentage of dissatisfied (PPD). A dissatisfied person is defined as a subject who, when exposed to a defined thermal load, would vote +3, +2, −2, or −3 on the previously defined thermal sensation scale. This index assesses a quantitative prediction of the percentage of subjects who may declare themselves thermally dissatisfied with the indoor environment conditions. The PPD is therefore a function of the PMV; the relationship linking these two indexes is graphically shown in Fig. 1.

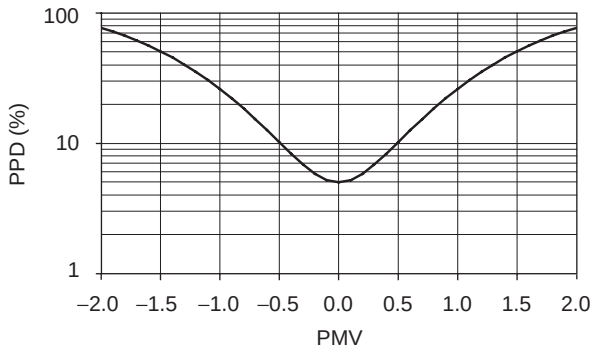

FIGURE 1 Predicted percentage of dissatisfied (PPD) as a function of the predicted mean vote (PMV).

2.3 The Adaptive Method

The PMV and PPD indexes are fairly capable of describing the thermal sensations of subjects in indoor environments equipped with conditioning and ventilation systems. The correspondence between the votes provided by the subjects and the indexes, however, are less obvious in naturally ventilated environments in which mechanical equipment is not present. It has been found that in such environments the occupants generally consider a wider range of thermal conditions acceptable and are inclined to prefer different indoor temperatures than those assumed by using the PMV index. These considerations made it necessary for researchers to develop an alternative approach to thermal comfort assessment.

Since people who are exposed to a given thermal load adapt to the changing environmental conditions, an adaptive comfort method has been proposed. According to this approach, a fixed reference value of indoor temperatures that can be used in each situation does not exist. As a consequence, only optimal values of the climatic conditions that the subjects would adapt to should be considered. The method refers to the comfort temperature, which is considered as a function of the outdoor climatic conditions.

The difficulties in applying the adaptive comfort theory are inherent to the assessment of the analytical relationship between the outdoor and indoor climatic conditions. However, the major criticism of the

method concerns the choice of the external temperature as the only parameter on which comfort would depend. Thus, people's level of activity, their clothing, and typical microclimatic parameters are not considered, even though it has been shown that they play a major role in the thermal sensation process.

3. LOCAL EVALUATION OF THERMAL COMFORT IN CONFINED ENVIRONMENTS

The PMV and PPD indexes, which make it possible to evaluate the comfort conditions of a subject in a confined environment, are useful only for so-called global comfort evaluations. Unfortunately, even if a subject experiences a sensation of thermal neutrality, some parts of his or her body may be exposed to conditions that cannot be considered acceptable. In fact, the nonuniformity of values concerning environmental variables could make people experience sensations of local discomfort.

The main causes of local discomfort are significant vertical air temperature differences, abnormal floor temperatures, significant radiant asymmetry, and air drafts.

3.1 Vertical Air Temperature Differences

Often in indoor environments, air temperature is not constant from the floor to the ceiling; it generally increases with height. If the temperature gradient is high, local discomfort conditions may occur even though the body is thermally neutral from a global standpoint.

These local discomfort conditions are evaluated from the percentage of dissatisfied people, expressed as a function of the difference between the air temperatures at head and ankle levels. Results of some experiments carried out with people in thermal neutrality are shown in Fig. 2.

3.2 Floor Temperature

Thermal sensations resulting from cool or warm floors are due to heat loss from the feet. This heat loss depends on the floor's surface temperature, its conductivity, its constituent materials' heat capacity, and the type of covering worn on the feet. However, for people wearing normal footwear, the floor's material is of little significance. Field studies have made it possible to determine the relationship, shown in Fig. 3, between floor temperature and the percentage of dissatisfied people.

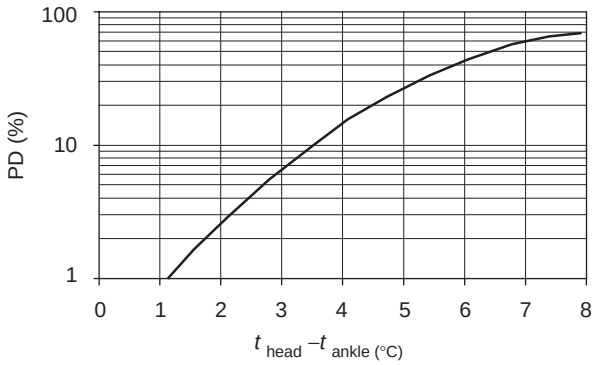

FIGURE 2 Percentage of dissatisfied people (PD) as a function of vertical air temperature differences between head and ankle levels.

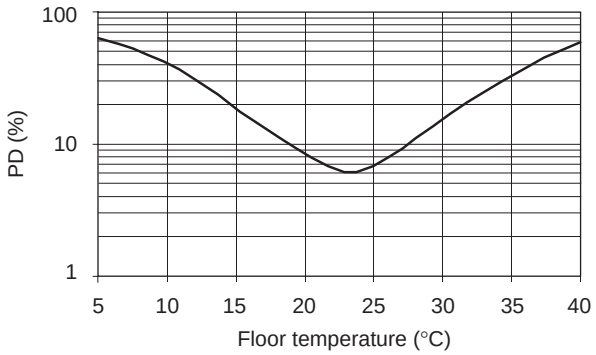

FIGURE 3 Percentage of dissatisfied people (PD) as a function of floor temperature.

3.3 Radiant Asymmetry

When a subject stands too close to a large surface that has a different temperature to that of the indoor air, he or she may feel uncomfortable thermal sensations due to the nonuniformity of thermal radiation in the environment. In order to take this phenomenon into account, the radiant temperature asymmetry parameter is used. This can be defined as the difference between the plane radiant temperatures of the two opposite sides of a small plane element. The plane radiant temperature is the uniform temperature of an enclosure in which the incident of radiation flux on one side of a small plane element is the same as that in the existing environment.

The thermal sensation induced by radiant temperature asymmetry is different for warm or cool surfaces and for vertical or horizontal surfaces. The greatest sensations of discomfort are induced by

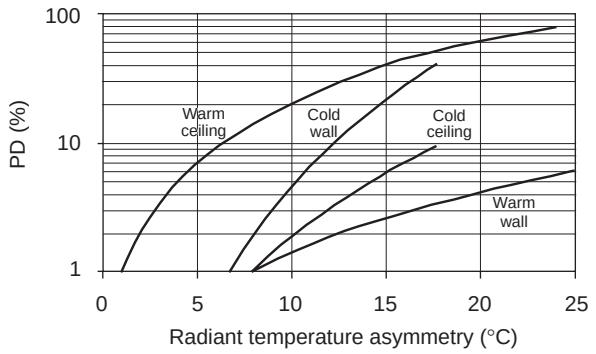

FIGURE 4 Percentage of dissatisfied people (PD) as a function of radiant temperature asymmetry.

warm ceilings and by cold walls. Cold ceilings and warm walls, on the other hand, have less influence on discomfort. Also in this case, the percentage of dissatisfied people as a function of the radiant temperature asymmetry can be used (Fig. 4).

3.4 Drafts

Since air movement in indoor environments often shows turbulent features, airflows could fluctuate significantly in different areas and at different times. Generally, this is caused by drafts, one of the most annoying factors in indoor environments.

A draft is defined as an undesired local cooling of the body caused by air movement. Generally, the sensation of discomfort caused by drafts depends on the airflow temperature (discomfort is less for higher temperatures), the difference between its value and the value of the indoor air's temperature (discomfort increases as this difference increases), the area of the body affected by the air flow (the head, neck, and ankles are the most sensitive zones), and the subject's activity (discomfort decreases with higher activity levels).

Draft rating, which is the percentage of people dissatisfied due to draft, can be evaluated by the following equation:

$$DR = (34 - t_a) \cdot (v - 0.05)^{0.62}(0.37 \cdot v \cdot \mathrm{Tu} + 3.14),$$

where t_a is the local temperature of the airflow, v is the local mean air velocity, and Tu is the local turbulence intensity defined as the ratio between the standard deviation of the local air velocity and the mean local air velocity.

4. METHODS FOR EVALUATING THERMAL STRESS CONDITIONS

4.1 Severe Hot Environments

In severe hot environments, thermoregulation mechanisms are not able to guarantee the thermal neutrality of the human body. This factor creates the need for heat storage and a consequent rise in the body core temperature, which could reach unacceptable levels. In addition, the continuous activity of sweating could lead to unbalances in the body's water and mineral equilibrium.

4.1.1 The Required Sweat Rate Index

Thermal stress conditions in hot environments can be assessed analytically by means of the required sweat rate, SW_{req}, which is a rational index representing the sweat rate that the human body should produce in order to maintain the thermal balance in equilibrium.

The required sweat rate is evaluated beginning with the following equation

$$\mathrm{SW}_{\mathrm{req}} = \frac{E_{\mathrm{req}}}{r_{\mathrm{req}}},$$

where E_{req} is the evaporation required to achieve thermal equilibrium, and r_{req} is the evaporative efficiency at the required sweat rate. The required evaporation is calculated from the thermal balance equation based on the assumption that the internal energy variation is equal to zero and the hypothesis that the mean skin temperature is a function of the microclimatic parameters, the level of activity, and clothing. The resulting equation is as follows:

$$E_{\mathrm{req}} = M - W - E_{\mathrm{res}} - C_{\mathrm{res}} - C - R.$$

Evaporative efficiency is calculated by means of the following algorithm:

$$r_{\mathrm{req}} = 1 - \frac{w^2}{2},$$

where the value of the skin wetness, w, depends on physiological considerations.

The required sweat rate is then compared with the maximum value achievable by a subject. Usually, data are provided both for acclimatized and for nonacclimatized subjects, either at work or at rest. If the resulting values for skin wetness and sweat rate are greater than a maximum threshold value, they may lead to unacceptable levels of heat storage and water loss. In this case, allowable exposure times for people are calculated.

4.1.2 The Wet Bulb Globe Temperatures Index

Evaluation of thermal conditions in severe hot environments can be calculated using a simple empirical index, the wet bulb globe temperatures (WBGT). This temperature index is in fact related to the subject's heat stress.

The evaluation of stress conditions using this index represents a compromise: The simplicity of its use does not in fact correspond to the precision provided by other rational indexes.

The WBGT index is expressed as a function of natural wet bulb temperature, t_{nw}, of the globe temperature, t_g, and of the air temperature, t_a. In particular, the natural wet bulb temperature is measured using a thermometric sensor covered with a wetted wick and naturally ventilated, whereas the globe temperature is the temperature indicated by a sensor placed in the center of a globe with standard characteristics.

Thus, the equations used for the calculation of the WBGT index are

$$\mathrm{WBGT} = 0.7t_{nw} + 0.3t_g,$$

which can be applied in indoor environments or outdoor environments without solar load, and

$$\mathrm{WBGT} = 0.7t_{nw} + 0.2t_g + 0.1t_a,$$

to be applied in outdoor environments in the case of the presence of solar load.

The WBGT value is then compared with reference values supplied for five levels of metabolic rate, both for acclimatized and nonacclimatized subjects. Also, when the WBGT exceeds the reference value, maximum exposure times for people are calculated.

4.2 Severe Cold Environments

In severe cold environments, microclimatic conditions can bring about an undesirable process of cooling in the human body since its thermoregulation mechanisms are not able to maintain the neutrality of the body core. In extreme cases, the continued activity of shivering could cause the subject to die from ventricular fibrillation.

4.2.1 The Required Thermal Insulation Index

The required thermal insulation index (IREQ) is a rational index representing the thermal insulation of a subject's clothes and which is able to maintain heat balance under specified requirements for the physiological strain. This index was defined based on the consideration that a suitable outfit of clothes could suitably protect a subject from cold environmental conditions.

On the basis of the thermal balance equation and the hypothesis that dry heat exchanges are affected by the thermal insulation of the clothing and by the skin-to-clothing surface temperature gradient, the IREQ index can be calculated using the following equations:

$$\begin{cases} \mathrm{IREQ} = \dfrac{t_{sk} - t_{cl}}{M - W - E_{res} - C_{res} - E} \\ M - W - E_{res} - C_{res} - E = R + C \end{cases}.$$

By emphasizing its dependence on the parameters that characterize the thermal balance equation, the IREQ index may be also expressed as follows:

$$\mathrm{IREQ} = f(M, t_a, p_a, v_{ar}, \bar{t}_r, t_{sk}, E).$$

Thermal equilibrium can be achieved at different levels of thermoregulatory strain, depending on the values of the mean skin temperature and sweating. Therefore, IREQ is defined at two different levels, the minimum level ($\mathrm{IREQ_{min}}$) and the neutral required insulation level ($\mathrm{IREQ_{neutral}}$). These represent the thermal insulation required to maintain the body's thermal balance at the so-called "subnormal" and "normal" levels of the mean body temperature, respectively.

The range between $\mathrm{IREQ_{min}}$ and $\mathrm{IREQ_{neutral}}$ indexes can be regarded as a clothing zone regulator, in which a subject can choose the appropriate level of protection. When insulation values are lower than those corresponding to $\mathrm{IREQ_{min}}$, there is a risk of progressive body cooling that may, however, be prevented by imposing a time limit for the subject's exposure.

4.2.2 Wind Chill and Chilling Temperature Indexes

To evaluate the effects of exposition to severe cold conditions on uncovered parts of the human body, two parameters are used: the wind chill index (WCI) and the chilling temperature (t_{ch}). The WCI is an empirical index representing the heat flow exchanged by the exposed parts of the body with the cold environment. It is a function of the air velocity, v_{ar}, and the air temperature, t_a. It is expressed by

$$\mathrm{WCI} = 1.16(10.45 + 10\sqrt{v_{ar}} - v_{ar}) \times (33 - t_a).$$

Often, technicians refer to the chilling temperature, which is a temperature index representing the air temperature of an environment with a value of air velocity equal to 1.8 m/s generating the same cooling power as in the actual environmental conditions. The

chilling temperature is evaluated as a function of the WCI by means of the following equation:

$$t_{ch} = 33 - \frac{WCI}{25.5}.$$

The values of the WCI or the chilling temperature, calculated in the assigned environment, are then compared with target values representing the effect of exposing uncovered parts of the body to cold.

5. OTHER ISSUES REGARDING THERMAL COMFORT

5.1 Energy Saving and Comfort

Energy design for buildings, the goal of which is to establish comfort conditions for the occupants, involves many activities that center around technical choices regarding the building's envelope and the characteristics of its HVAC system. The possibility of creating indoor comfort conditions is in fact closely connected to system design and conduction and to building design and construction.

All these factors will affect the energy demand required to maintain comfort conditions, along with the "quality" of the indoor comfort. It is worth noting that the optimization of these design parameters will generally improve either the amount of energy saved or the quality of the comfort.

In industrialized countries, energy consumption for indoor comfort accounts for approximately 40% of the total final energy consumption, and a significant amount of energy could be saved by "energy -conscious" building design. Possible measures include

- High-efficiency energy-conversion devices (heat pumps, condensation boilers, and cogeneration systems)
- High-efficiency equipment (variable-speed pumps, variable air-volume systems, radiant heating and cooling, heat recovery systems, and smart control systems)
- Use of renewable energy sources (sun, wind, and cold and heat from the ground or from water)
- Building shading, orientation, insulation, and thermal inertia

5.2 Categories of Thermal Environment

The International Organization for Standardization Standard 7730 introduces the concept of thermal comfort categories. Three different comfort tasks (A–C) are defined on the basis of PPD thresholds related either to global comfort or to local discomfort issues. The higher the PPD value, the greater the range of variation allowed for the microclimatic parameter. This will help building designers to tailor their work to different levels of expected performances, according to a sort of quality scale based on three steps (A–C comfort categories). Table IV shows the PPD values corresponding to each category.

5.3 Non-Steady-State Thermal Environments

The PMV–PPD method may be applied only in stationary environments, in which the physical quantities used to describe the subjects' exposure do not depend on time. However, this assumption could only be considered realistic in environments equipped with a well-dimensioned HVAC system.

Nevertheless, in most cases non-steady-state thermal conditions often occur. They are normally classified in three categories: temperature cycles (temperature changes with assigned amplitude and frequencies), temperature drift or ramps

TABLE IV

Catagories of Thermal Environment with Ranges of the Relative Indicators[a]

	Global comfort			Local discomfort		
Category	Predicted percentage of dissatisfied	Predicted mean vote	Percentage of dissatisfied due to draft	Percentage of dissatisfied due to vertical air temperature difference	Percentage of dissatisfied due to warm or cool floor	Percentage of dissatisfied due to radiant asymmetry
A	<6	−0.2–+0.2	<10	<3	<10	<5
B	<10	−0.5–+0.5	<20	<5	<10	<5
C	<15	−0.7–+0.7	<30	<10	<15	<10

[a] Metabolic rate, 58 W/m^2; humidity ratio, 50%.

(monotonic, steady, noncyclic operative temperature changes, where drift refers to passive temperature change and ramps refers to actively controlled temperature changes), and transients (sudden changes in the thermal conditions due to dramatic changes in temperature, humidity, activity, or clothing). However, even when a non-steady-state condition occurs, the relationships established for steady state may still be used in specific situations. For example, they may be used if the peak-to-peak variation of the temperature cycles is less than 1°C, if the rates of temperature change for drift or ramps are lower than 2°C per hour, and in the case of transients after increases in operative temperature. On the contrary, in case of decreasing of the operative temperature, the PMV–PPD method may not be used since it would overestimate high values; in this situation, the time required to achieve a new steady-state condition will depend on the initial conditions.

5.4 Iso-PMV Maps

An environment may be considered homogeneous from a thermal standpoint if the microclimatic parameters around the subject can be considered uniform at a given time. This condition can be easily reached for air temperature, air velocity, and air humidity, but it occurs more rarely for radiant exchanges.

When an environment's microclimate parameters are too heterogeneous, the comfort indexes can be evaluated in several locations. Moreover, taking into account the partial results obtained, the mean value has to be assessed.

Nevertheless, even if this type of analysis leads to a mean value that is used for the whole environment, it does not provide useful information about the local variation of parameters that may occur in the environment.

In this case, it is good practice to utilize iso-PMV or iso-PPD representations, which make it possible to evaluate the local variation of the thermal conditions. In this way, it is also possible to identify the zones in which thermal comfort conditions are not reached. An example of this representation is shown in Fig. 5.

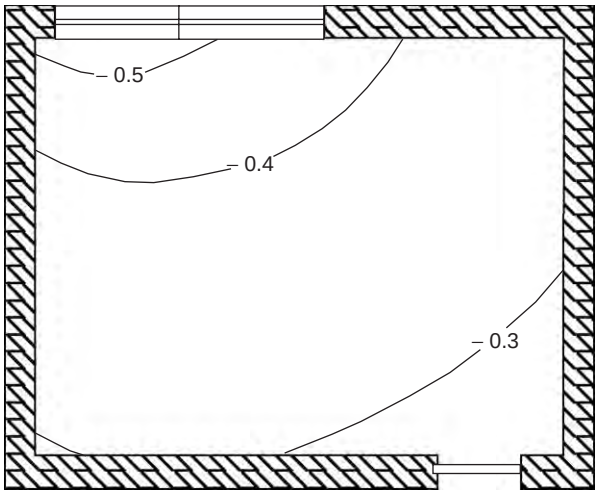

FIGURE 5 Typical example of iso-PMV maps in an environment.

Glossary

ambient air The air in the space surrounding a thermal energy storage device, or outside air.
ambient heat load The thermal load imposed on a storage device due to heat gain.
build period The operating period of a thermal storage generator during which ice is produced.
charge fluid The heat transfer fluid used to remove heat from a thermal storage device or generator during the charge or build period, or to add heat to a heat storage.
charge period The period of time during which energy (heat) is removed from a cold storage or added to a heat storage.
charge rate The rate at which energy (heat) is removed from or added to a storage device during the charge period.
discharge fluid The heat transfer fluid used to add heat to a thermal storage device.
discharge period The period of time when energy (heat) is added to a storage device.
discharge rate The rate at which energy (heat) is added to a storage device during the discharge period.
latent heat of fusion The change in energy accompanying the conversion of a unit mass of a solid to a liquid at its melting point, at constant pressure and temperature.
melt period That period of a test during which the ice produced by a thermal storage generator is melted to determine its quality.
period An interval of time during which a storage process occurs; often a period such as the total duty cycle of a thermal storage system is divided for the purpose of analysis and evaluation into 1 h time segments.
phase-change material (PCM) A substance that undergoes changes of state while absorbing or rejecting thermal energy, normally at a constant temperature.
thermal storage device Equipment that stores cooling capacity using sensible and/or latent heat. May consist solely of a storage means or be packaged with one or more components of a mechanical refrigeration package.
thermal storage equipment Any one of, or a combination of, thermal storage devices and/or generators, which may include various other components of a mechanical refrigeration package.
ton-hour A quantity of thermal energy typically used to describe the capacity of a thermal storage device, in tons, absorbed or rejected in 1 h (3.517 kW).

Thermal energy storage (TES) generally involves a temporary storage of high- or low–temperature thermal energy for later use. Examples of TES are the storage of solar energy for overnight heating, of summer heat for winter use, of winter ice for space cooling in summer, and of heat or coolness generated electrically during off-peak hours for use during subsequent peak demand hours. In this respect, TES appears to be an excellent candidate to offset this mismatch of availability and demand and is considered an advanced energy technology. Therefore, during the past decade TES has attracted the greatest interest for a wide range of thermal applications, such as space heating, hot water, cooling, and air–conditioning. Why are these established TES technologies not used more than they are? The answer is that TES finds application possibilities if there are some circumstances that require TES as a solution, such as a mismatch between energy available and demand, discontinuity in energy supply, and different electricity rates for electricity consumption during peak and off-peak hours. If such a case(s) exists, it is either encouraged by various mechanisms (e.g., incentives) or mandatorily done by regulations. Of course, TES systems and applications bring some additional costs. However, payback time is quite reasonable due to high energy and environmental

 © 2004 Elsevier Inc. All rights reserved.

costs. TES technology has been used in various forms and specific applications. Some of the more common applications have been the use of sensible heat (water, molten salt) or latent heat (ice, phase-change material) storage for heating and cooling applications. The effectiveness of sensible heat storage depends on the specific heat of the storage material and, if volume is important, on its density. Sensible storage systems commonly use rocks or water as the storage medium and the thermal energy is stored by increasing the storage-medium temperature. Latent heat storage systems store energy in phase-change materials, with the thermal energy stored when the material changes phase, usually from a solid to a liquid. The specific heat of solidification/fusion or vaporization and the temperature at which the phase change occurs are important in terms of design. Both sensible TES and latent TES also may occur in the same storage material. The main goal of this article is to introduce the fundamental aspects of TES systems and discuss their energy savings, environmental impacts, and technical and operational aspects and to highlight their importance with some illustrative and practical examples.

1. TES AND ENERGY SAVINGS

TES systems are an important element of many energy-saving programs in a variety of sectors: residential, commercial, industrial, and utility as well as the transportation sector. TES can be employed to reduce energy consumption or to transfer an energy load from one period to another. The consumption reduction can be achieved by storing excess thermal energy that would normally be released as waste, such as heat produced by equipment and appliances, by lighting, and even by occupants. Energy-load transfer can be achieved by storing energy at a given time for later use and can be applied to TES for either heating or cooling capacity.

The primary objective of most TES systems, which is to alter energy-use patterns so that financial savings occur, can be achieved in several ways:

1.1 Utilization of Waste or Surplus Energy

The consumption of purchased energy can be reduced by storing waste or surplus thermal energy available at certain times for use at other times. Useful waste or surplus thermal energy is available from many sources. Some examples include the following: (1) hot or cold water drained to a sewer; (2) hot flue gases; (3) exhaust air streams; (4) hot or cold gases or waste gases; (5) heat collected from solar panels; (6) ground source thermal energy; (7) heat rejected from the condenser of refrigeration and air-conditioning equipment; and (8) the cooling effect from the evaporator of a heat pump.

1.2 Reduction of Demand Charges

The demand of purchased electrical energy can be reduced by storing electrically produced thermal energy during off-peak periods to meet the thermal loads that occur during high-demand periods. There has been an increasing interest in the reduction of peak demand or transfer of energy loads from high- to low-consumption periods. For example, an electric chiller can be used to charge a chilled cold TES system at night to reduce the electrical demand peaks usually experienced during the day. Figure 1 shows examples of a daily load profile for a building, with and without cool storage. Figure 1A represents the case with no storage and Fig. 1B shows a full-storage case. In the latter case, the TES provides enough storage capacity to meet the peak (i.e., 9:00

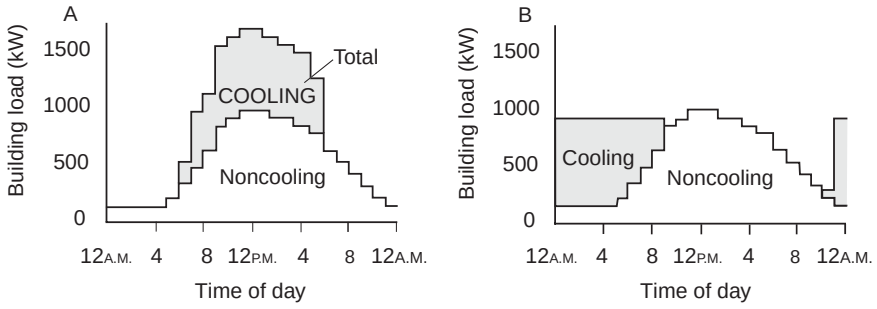

FIGURE 1 Daily load profiles of a building energy load: (A) no storage and (B) full storage. Modified from Dincer *et al.* (1997b).

A.M. to 9:00 P.M.) cooling load, shifting the entire electrical demand for cooling to off-peak hours when there is little cooling load. This particular application achieves maximal benefits in terms of demand charge reduction and use of favorable off-peak rates, both of which act to lower operating costs.

1.3 Deferring Equipment Purchases

The capacity of heating and cooling equipment is normally selected to match the part of the design-day load when the requirements for heating and cooling are close to maximum. These peak design loads occur for only short periods of time, resulting in excess capacity on average days. The use of TES can defer the need to purchase additional equipment for heating, cooling, or air-conditioning applications and reduce equipment sizing in new facilities. The relevant equipment is operated when thermal loads are low to charge the TES and energy is withdrawn from storage to help meet the thermal loads that exceed equipment capacity.

2. TES AND ENVIRONMENTAL IMPACT

TES systems can contribute significantly to meeting society's desire for more efficient, environmentally benign energy use, particularly in the areas of building heating and cooling systems and electric power generation. By reducing energy consumption, the utilization of TES systems results in two significant environmental benefits: the conservation of fossil fuels through efficiency increases and/or fuel substitution, and reductions in emissions of pollutants such as CO_2, SO_2, NO_x, and chlorofluorocarbons (CFCs).

TES can impact air emissions at building sites by reducing (1) the amount of ozone-depleting CFC and hydrochlorofluorocarbon (HCFC) refrigerants in chillers and (2) the amount of combustion emissions from fuel-fired heating and cooling equipment. TES helps reduce CFC use in two main ways. First, since cooling systems with TES require less chiller capacity than conventional systems, they use fewer or smaller chillers with less refrigerant. Second, using TES can offset the lost cooling capacity that sometimes can occur when existing chillers are converted to more benign refrigerants, making building operators more willing to switch refrigerants.

The potential aggregate air-emission reductions at power plants due to TES have been shown to be significant. For example, TES systems have been shown to reduce CO_2 emissions in the United Kingdom by 14 to 46% by shifting electric load to off-peak periods, whereas an Electric Power Research Institute (EPRI)-cosponsored analysis found that TES could reduce CO_2 emissions by 7% compared to conventional electric cooling technologies. Also, using California Energy Commission data indicating that existing gas plants produce approximately 0.06 kg of NO_x and 15 kg of CO_2 per 293,100 kWh of fuel burned, and assuming that TES installations save an average of 6% of the total cooling electricity needs, TES could possibly eliminate annual emissions of approximately 560 tons of NO_x and 260,000 tons of CO_2 statewide.

Establishing concrete methods for promoting TES technologies requires analysis and clarification about how to combine environmental objectives, social and economic systems, and technical developments to attain effective solutions. It is important to create and employ tools that encourage technological development and diffusion and to align government policies in areas such as energy and environmental standards and government purchasing.

3. TES AND SUSTAINABLE DEVELOPMENT

A secure supply of energy resources is generally agreed to be a necessary but not sufficient requirement for development within a society. Furthermore, sustainable development demands a sustainable supply of energy resources. The implications of these statements are numerous and depend on how "sustainable" is defined. One important implication of these statements is that sustainable development within a society requires a supply of energy resources that, in the long term, is readily and sustainably available at reasonable cost and can be utilized for all required tasks without causing negative societal impacts. Supplies of energy resources such as fossil fuels (coal, oil, and natural gas) and uranium are generally acknowledged to be finite; other energy sources, such as sunlight, wind, and falling water, are generally considered renewable and therefore sustainable over the relatively long-term. Wastes (convertible to useful energy forms through, for example, waste-to-energy incineration facilities) and biomass fuels are also usually viewed as sustainable energy sources. A second implication of the initial statements in this section is that sustainable development requires that energy resources be used as efficiently as

possible. In this way, society maximizes the benefits it derives from utilizing its energy resources, while minimizing the negative impacts (such as environmental damage) associated with their use. This implication acknowledges that all energy resources are, to some degree, finite, so that greater efficiency in utilization allows such resources to contribute to development over a longer period of time, i.e., to make development more sustainable. Even for energy sources that may eventually become inexpensive and widely available, increases in energy efficiency will likely remain to be sought to reduce the resource requirements (energy, material, etc.) to create and maintain systems and devices to harvest the energy and to reduce the associated environmental impacts.

The first implication, clearly being essential to sustainable development, has been and continues to be widely discussed. The second implication, which relates to the importance and role of energy efficiency in achieving sustainable development, is somewhat less discussed and understood.

Consequently, sustainable development demands a sustainable supply of energy resources that, in the long-term, is readily and sustainably available at reasonable cost and can be utilized for all required tasks without causing negative societal impacts. TES systems can contribute significantly to meeting society's desire for more efficient, environmentally benign energy use and for sustainable development of the society, particularly in the areas of building heating and cooling systems and electric power generation. By reducing energy consumption, the utilization of TES systems results in two significant benefits: (1) the conservation of fossil fuels through efficiency increases and/or fuel substitution and (2) reductions in emissions of such pollutants as CO_2, SO_2, NO_x, and CFCs.

4. TES METHODS

TES can aid in the efficient use and provision of thermal energy whenever there is a mismatch between energy generation and use. Various subsets of TES processes have been investigated and developed for building heating and cooling systems, industrial applications, and utility and space power systems. Some of the media available for sensible and the latent TES systems are presented in Table I.

TABLE I

Available Media for Sensible and Latent TES Systems

Sensible		Latent
Short–term	**Long–term (Annual)**	**Short–term**
Rock beds	Rock beds	Inorganic materials
Earth beds	Earth beds	Organic materials
Water tanks	Large water tanks	Fatty acids
	Aquifiers	Aromatics
	Solar ponds	

4.1 Sensible TES

In sensible TES, energy is stored by changing the temperature of a storage medium, such as water, air, oil, rock beds, bricks, sand, or soil. The amount of energy input to TES by a sensible heat device is proportional to the difference between the final and initial temperatures of storage and the mass of the storage medium and its heat capacity. Each medium has its own advantages and disadvantages. For example, water has approximately twice the specific heat of rock and soil. The high heat capacity of water often makes water tanks a logical choice for TES systems that operate in a temperature range needed for building heating or cooling. The relatively low heat capacity of rocks and ceramics is somewhat offset by the large temperature changes possible with these materials and their relatively high density.

A sensible TES consists of a storage medium, a container, and input/output devices. Containers must both retain the storage material and prevent losses of thermal energy. Thermal stratification, the existence of a thermal gradient across storage, is desirable. Maintaining stratification is much simpler in solid storage media than in fluids.

Sensible TES materials undergo no change in phase over the temperature range encountered in the storage process. The amount of heat stored in a mass of material can be expressed as

$$Q = mc_{\mathrm{p}}\Delta T \text{ or } Q = \rho c_{\mathrm{p}} V \Delta T,$$

where c_p is the specific heat of the storage material, ΔT is the temperature change, V is the volume of storage material, and ρ is the density of the material. Note that the ability to store sensible heat for a given material depends strongly on the value of the quantity ρc_{p}. Water has a high value and is inexpensive but, being liquid, must be contained in a better quality container than a solid.

Some common TES materials and their properties are presented in Table II. To be useful in TES applications, the material normally must be inexpensive and have a good thermal capacity. Another

TABLE II

Thermal Capacities at 20°C of Some Common TES Materials

Material	Density (kg/m^3)	Specific heat (J/kgK)	Volumetric thermal capacity ($10^6 J/m^3 K$)
Clay	1458	879	1.28

Source: Adapted from Norton (1992).

important parameter in sensible TES is the rate at which heat can be released and extracted.

4.2 Latent TES

The heat transfer that occurs when a substance changes from one phase to another is called the latent heat. The latent heat change usually is much higher than the sensible heat change for a given medium, which is related to its specific heat. When water turns to steam, the latent heat change is on the order of 2 MJ/kg. Most practical systems using phase-change energy storage involve solutions of salts in water. Several problems are associated with such systems, including the following:

- Supercooling of the phase-change material (PCM) may take place, rather than crystallization with heat release. This problem can be avoided partially by adding small crystals as nucleating agents.
- It is difficult to build a heat exchanger capable of dealing with the agglomeration of varying sizes of crystals that float in the liquid.
- The system operation cannot completely reversed.

Any latent heat TES system must possess at least the following three components:

- A heat storage substance that undergoes a phase transition within the desired operating temperature range and wherein the bulk of the heat added is stored as latent heat.
- A containment for the storage substance.
- A heat-exchange surface for transferring heat from the heat source to the storage substance and from the latter to the heat sink, e.g., from a solar collector to the latent TES substance to the load loop.

Latent TES is a promising storage technique since it provides high-energy storage density, second only to chemical energy storage, and can store and release heat at a constant temperature, corresponding to the phase transition temperature of the heat-storage medium.

An important material category capable of storing energy through phase change is paraffin waxes. These have the advantage of very high stability over repeated cycles of latent TES operation without degradation.

The most important criteria to be met by the storage material for a latent TES in which the material undergoes a solid–liquid or a solid–solid phase transition are as follows: high transition enthalpy per unit mass, the ability to fully reverse the transition, adequate transition temperature, chemical stability, compatibility with the container (if present), limited volume change with the transition, nontoxicity, and low cost, in relation to the foreseen application.

4.2.1 Phase-Change Materials

When a material melts or vaporizes, it absorbs heat; when it changes to a solid (crystallizes) or to a liquid (condenses), it releases this heat. This phase change is used for storing heat in PCMs. Typical PCMs are water/ice, salt hydrates, and certain polymers. Since energy densities for latent TES exceed those for sensible TES, smaller and lighter storage devices and lower storage losses normally result. Like ice and water, eutectic salts have been used as storage media for many decades. Perhaps the oldest application of a PCM for TES was the use of seat warmers for British railroad cars in the late 1800 s. During cold winter days, metal or rubber bags were filled with sodium thiosulfate pentahydrate, a PCM that melts and freezes at 44.4°C, and these were used to warm the seats. Other early applications of PCMs included "eutectic plates" used for cold storage in trucking and railroad transportation applications. Another important application of PCMs was in association with space technology, with National Aeronautics and Space Administration sponsoring a project on PCM applications for thermal control of electronic packages.

A large number of organic compounds suitable for use as storage media for heating, ventilation, and air-conditioning applications have been investigated. The most promising candidates seem to be the normal

paraffins. Their solid–liquid transitions (fusions) meet satisfactorily seven important criteria for PCMs. For example, the heat of fusion has a mean value of 35–40 kcal/kg, there are no problems in the reversing the phase change, and the transition points vary considerably with the number of carbon atoms in the chains. Also, the normal paraffins are chemically inert, nontoxic, and available at reasonably low cost. The change of volume with the transition, which is on the order of 10%, could represent a minor problem.

The zeolites are naturally occurring minerals. Their high heat of adsorption and their ability to hydrate and dehydrate while maintaining structural stability have been found to be useful in various thermal storage and solar refrigeration systems. This hygroscopic property, coupled with the rapid exothermic reaction that occurs when zeolites are taken from a dehydrated to a hydrated form (when the heat of adsorption is released), makes natural zeolites an effective storage material for solar and waste heat energy.

Application of PCMs in the temperature range 0–120°C is of interest for a variety of low-temperature applications, such as direct space heating, domestic hot water production, heat-pump-assisted space heating, greenhouse heating, and solar cooling. The development of dependable TES systems for these and other applications requires a good understanding of heat-of-fusion storage materials and heat exchangers.

Knowledge of the melting and freezing characteristics of PCMs, of their ability to undergo thermal cycling, and of their compatibility with construction materials is essential for assessing the short- and long-term performance of a latent TES. Commercial paraffins are characterized by two phase transitions (solid–liquid and solid–solid) that occur over a large temperature range depending on the paraffin involved. *n*-Paraffins are usually preferred in comparison to their iso-counterparts, as the desired solid-to-liquid phase transition is generally restricted to a narrow temperature range. Fatty acids are organic materials with excellent melting and freezing characteristics and may have a good future potential, if their costs can be reduced. Inorganic salt hydrates, on the other hand, must be carefully examined for congruent, "semicongruent," or incongruent melting substances with the aid of phase diagrams. Incongruent melting in a salt hydrate may be "modified" to overcome decomposition by adding suspension media, or extra water, or other substances that shift the peritectic point. The use of salt hydrates in hermetically sealed containers is normally recommended. Also, the employment of metallic surfaces to promote heterogeneous nucleation in a salt hydrate is seen to reduce the supercooling of most salt hydrates to a considerable extent.

In the employment of PCMs as heat storage materials in TES systems, certain desirable thermodynamic, kinetic, chemical, technical and economic characteristics are essential:

4.2.1.1 Thermodynamic Criteria

- A melting point at the desired operating temperature;
- A high latent heat of fusion per unit mass, so that less material stores a given amount of energy;
- A high density, so that less volume is occupied by the material;
- A high specific heat, so that significant sensible TES can also occur;
- A high thermal conductivity, so that only small temperature differences are needed for charging and discharging the storage;
- Congruent melting; i.e., the material should melt completely, so that the liquid and solid phases are homogenous (this avoids the difference in densities between solid and liquid that causes segregation, resulting in changes in the chemical composition of the material); and
- Small volume changes during phase transition, so that a simple containment and heat exchanger can be used.

4.2.1.2 Kinetic Criterion

- Little or no supercooling during freezing; i.e., the melt should crystallize at its freezing point. This criterion can be achieved through a high rate of nucleation and growth rate of the crystals. Supercooling may be suppressed by introducing nucleating agent or a cold trigger in the storage material.

4.2.1.3 Chemical Criteria

- Chemical stability;
- No susceptibility chemical decomposition, so that a long operation life is possible;
- Noncorrosive behavior to construction materials; and
- Nontoxic, nonflammable, and nonexplosive characteristics.

4.2.1.4 Technical Criteria

- Simplicity;
- Applicability;

- Compatibility; and
- Reliability.

4.2.1.5 Economic Criteria

- Commercial availability, and
- Low cost.

5. TECHNICAL AND OPERATIONAL ASPECTS OF TES SYSTEMS

This section presents certain technical and operational aspects of TES systems and their consequences.

5.1 Basic Principle of TES

The basic principle is the same in all TES applications. Energy is supplied to a storage system for removal and use at a later time. What mainly varies is the scale of the storage and the storage method used. Seasonal storage requires immense storage capacity. One seasonal TES method involves storing heat in underground aquifers. Another suggested method is circulating warmed air into underground caverns packed with solids to store sensible heat. The domestic version of this concept is storing heat in hot rocks in a cellar. At the opposite end of the storage-duration spectrum is the storage of heat on an hourly or daily basis. The previously mentioned use of tiles to store solar radiation is a typical example, which is often applied in passive solar design.

5.2 TES Processes

A complete storage process involves at least three steps: charging, storing, and discharging. A simple storage cycle can be illustrated as in Fig. 2, in which the three steps are shown as distinct stages. In practical systems, some of the steps may occur simultaneously (e.g., charging and storing) and each step may occur more than once in each storage cycle.

5.3 Feasibility of TES

A variety of factors are known to influence dramatically the selection, implementation, and operation of a TES system. Therefore, it is necessary to carry out a comprehensive feasibility that takes into consideration all parameters that impact the cost and other benefits of considered TES systems. However, it is not always possible to conduct all the steps in a feasibility study for an application and, in such instances, as many items as possible should be considered and studied accordingly. In such TES feasibility studies, a checklist can be helpful in ensuring that significant issues related to the project are addressed and details regarding the evaluation, selection, implementation, and operation of the system are assessed correctly. Fig. 3 provides a checklist that can be beneficial to the TES industry and analysts involved in TES projects. A checklist completed in the preliminary stages of the project guides technical staff.

5.4 Integration of TES

When considering the integration of TES into an existing thermal facility, an additional checklist (Fig. 4) can assist in conducting the feasibility study for the TES system and its incorporation into the facility. For a facility under design, the information required is generally the same as in Fig. 4, except that the database must be developed or estimated due to the lack of actual operating data.

6. TES FOR COOLING CAPACITY

Cooling capacity can be stored by either chilling or freezing water (or other materials, such as glycol and eutectic salts). Cold TES (CTES) is an innovative way of storing nighttime off-peak energy for daytime peak use. In many locations, the demand for electrical power peaks during the summer. Air-conditioning is the main reason, in some areas accounting for as much as one-half of the power

demand during the hot midday hours when electricity is most expensive. Since, at night, utilities have electrical generating capacity to spare, electricity generated during this "off-peak" time is much cheaper. In essence, one can air-condition during the day using electricity produced at night. CTES has become one of the primary means of addressing the electrical power imbalance between high daytime demand and high nighttime abundance. If properly designed, installed, operated, and maintained, CTES systems can be used to shift peak cooling loads to off-peak periods, thereby, evenly distributing the demand for electricity and avoiding shortages usually encountered during peak periods.

CTES systems are most likely to be cost-effective in situations such as the following: where a facility's maximum cooling load is much greater than the average load; where the utility rate structure has high demand charges, high ratchet charges, or a high differential between on- and off-peak energy rates; where an existing cooling system is being expanded; where an existing tank is available; where limited on-site electric power is available; where back-up cooling capacity is desirable; and where cold-air distribution is desirable or advantageous.

It is difficult to generalize about when cool storage systems will be cost-effective, but if one or more of the above criteria are satisfied, a detailed analysis may prove worthwhile.

6.1 Operational Aspects of CTES

Several strategies are available for charging and discharging a storage to meet cooling demand during peak hours. The strategies are full storage and partial storage.

6.1.1 Full-Storage CTES

A full-storage strategy shifts the entire peak-cooling load to off-peak hours (Fig. 5a). The system is typically designed so that on the days that are anticipated to be the hottest the system operates at

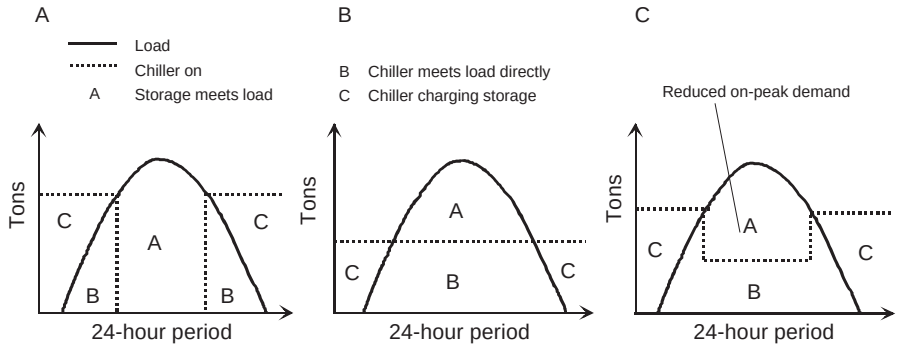

FIGURE 5 Operating strategies. (a) Full storage, (b) partial-storage load leveling, and (c) partial-storage demand-limiting. Reprinted from Dincer and Rosen (2002), © John Wiley & Sons Limited, with permission.

full capacity during all nonpeak hours in order to charge storage. This strategy is most attractive when peak demand charges are high or the peak period is short. For example, a school or business whose electrical demand drops dramatically after 5:00 P.M. in an electric utility territory where peak energy and demand charges apply between 1 P.M. and 9:00 P.M. usually can economically apply a full CTES. Cooling during the 4 h period between 1:00 P.M. and 5:00 P.M. can be full-shifted, i.e., can be met with a relatively small and cost-effective CTES system and without oversizing the chiller equipment.

6.1.2 Partial-Storage CTES

In a partial-storage method, the chiller operates to meet part of the peak-period cooling load and the rest is met by drawing from storage. The chiller is sized at a smaller capacity than the design load. Partial-storage systems may operate as load-leveling or demand-limiting operations. In a load-leveling system (Fig. 5b), the chiller is sized to run at its full capacity for 24 h on the hottest days. The strategy is most effective when the peak-cooling load is much higher than the average load. In a demand-limiting system, the chiller runs at reduced capacity during

peak hours and is often controlled to limit the facility's peak demand charge (Fig. 5c). Demand savings and equipment costs are higher than they would be for a load-leveling system and lower than for a full-storage system.

Partial storage is more often the most economic option and, therefore, represents the majority of thermal storage installations. Although partial storage does not shift as much load (on a design day) as a full-storage system, partial-storage systems can have lower initial costs, particularly if the design incorporates smaller equipment by using low-temperature water and cold-air distribution systems.

6.2 CTES Storage Media Selection and Characteristics

The main CTES storage media include chilled water, ice, and eutectic salts. Ice systems offer the densest storage capacity but have the most complex charge and discharge equipment. Water systems offer the lowest storage density and are the least complex. Eutectic salts have intermediate characteristics. Some details on each storage medium follow:

6.2.1 Chilled Water

Chilled-water systems require the largest storage tanks, but can easily interface with existing chiller systems. Chilled-water CTES systems use the sensible heat capacity of water to store cooling capacity. They operate at temperature ranges (3.3–5.5°C) compatible with standard chiller systems and are most economical for systems greater than 2000 ton-h in capacity. The most important advantage of water thermal storage is the fact that water is a well-understood and familiar medium. No danger is associated with handling water as a TES material. Basically, heating and cooling applications require only a moderate temperature range (5–45°C). Water can be used as a storage medium for both cooling and heating, allowing the same TES material to be used throughout the year. The relatively high thermal capacity of water is also attractive for TES applications. These advantages give water CTES economic advantages over other air-conditioning systems, including those using ice CTES systems.

6.2.2 Ice

Ice CTES systems can be economically advantageous and require less space than water CTES systems. This space advantage often allows heating and cooling capacity to be enlarged within the often restricted area of existing machine rooms. Ice systems use smaller tanks and offer the potential for the use of low-temperature air systems, but require more complex chiller systems. Ice CTES systems use the latent heat of fusion of water (335 kJ/kg) to store cooling capacity. To store energy at the temperature of ice requires refrigeration equipment that provides charging fluids at temperatures below the normal operating range of conventional air-conditioning equipment. Special ice-making equipment or standard chillers modified for low-temperature service are used. The low chilled-water-supply temperatures available from ice storage allow the use of cool-air distribution, the benefits of which include the ability to use smaller fans and ducts and the introduction of less humid air into occupied spaces.

6.2.3 Eutectic Salts

Eutectic salts can use existing chillers but usually operate at warmer temperatures than ice or chilled-water systems. Eutectic salts use a combination of inorganic salts, water, and other elements to create a mixture that freezes at a desired temperature. The material is encapsulated in plastic containers that are stacked in a storage tank through which water is circulated. The most commonly used mixture for thermal storage freezes at 8.3°C, which allows the use of standard chilling equipment to charge storage, but leads to higher discharge temperatures. These temperatures, in turn, limit the operating strategies that may be applied. For example, eutectic salts may be used in full-storage operation only if dehumidification requirements are low.

7. ILLUSTRATIVE EXAMPLES

This section discusses some illustrative case studies to highlight the practical importance of TES systems and show how they are performing. Further information on these case studies and some other practical examples can be found elsewhere:

7.1 Alitalia's Headquarters Building, Rome, Italy

In June 1991, Alitalia, Italy's largest airline company, officially opened its new headquarters building in the southwest area of Rome. With a total plan area of 130,000 m^2, this building contains 55,000 m^2 of office space, 72,000 m^2 of service and technical rooms, and 26 conference rooms, surrounded by a

large parking area for more than 3000 cars. For the air-conditioning and computer-cooling needs of the entire complex, ice-chiller thermal storage coils were selected to meet a total storage capacity of 65,000 kWh. This makes Alitalia the largest ice storage installation in Europe and one of the largest in the world. Due to the magnitude of this project, the designers opted to install thermal storage coils in two concrete tanks, each 34 m long by 12 m wide. During the night, the central refrigeration system builds a complete charge of ice on the coils over a 12 h off-peak period. During the daytime, the ice is melted to provide the buildings' base cooling requirements, thereby minimizing the peak demand. The refrigeration system is used during the day to provide any extra required cooling capacity upstream of the ice thermal storage coils. This results in higher refrigeration system efficiency and lower operating costs. Unlike other types of thermal storage units, the ice chiller with consistent low-temperature supply can be located downstream from the chillers for highest overall system efficiency. In addition to the thermal storage coils, four large industrial fluid coolers and six heat exchangers were also provided for this European TES project. Detailed information can be found in the 1999 publication by Baltimore Aircoil.

7.2 A Slurry–Ice Rapid Cooling System, Boston, United States

Slurry–ice is a crystallized water-based ice solution that can be pumped and offers a secondary cooling medium for TES while remaining fluid enough to pump. It flows like conventional chilled water but provides five to six times the cooling capacity.

The installed system consists of a 88 kW remote condensing slurry–ice machine and an associated 10 m^3 ice storage tank to satisfy a peak load of 180 kW (Fig. 6). The ice machine is designed to operate until the tank is full or during rapid cooling periods in order to introduce ice into the cooling circuit. The stored energy over off-peak/low-load periods is later utilized to satisfy the short and sharp peak loads. Hence, the installed refrigeration machinery is one-third of the equivalent capacity of a conventional direct cooling system. Harvested fresh vegetables are subjected to rapid cooling within the cold storage facility, whereby the energy stored during off-peak periods is recovered by circulating solution within the air-spray heat exchanger in order to provide 0–1°C air off temperatures during the rapid cooling periods.

7.2.1 Technical Benefits

- Cost-effective installation: Smaller pipework and a flexible storage tank coupled with smaller pump sizes result in lower initial installation cost.
- Reduced running cost: Reduced refrigeration machinery results in reduced maximum demand and availability charges, and coupled with nighttime low ambient temperatures and off-peak electricity prices, offers unmatched overall running cost savings.

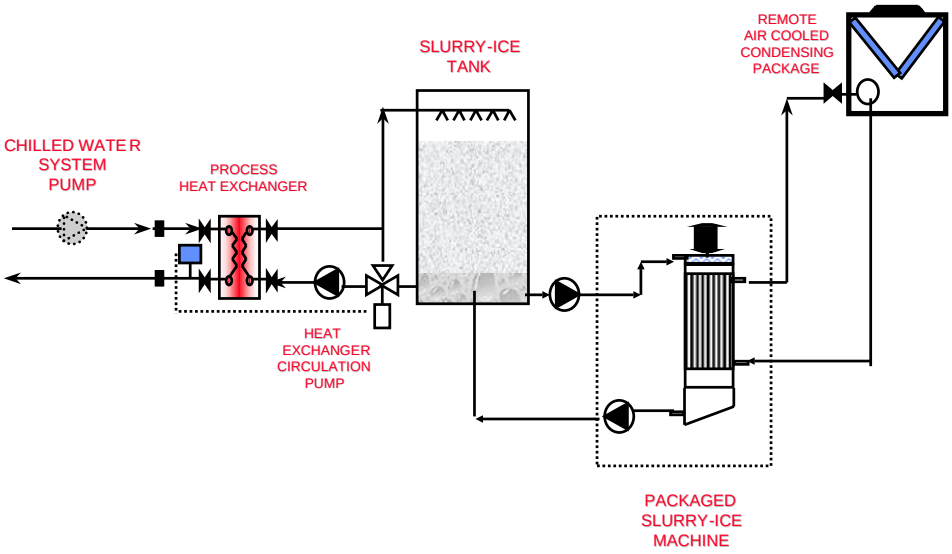

FIGURE 6 A typical slurry–ice TES system. Reprinted from Environmental Process Systems (2003), with permission.

- Quick response: Fine ice crystals offer unmatched thermal efficiency. Hence, large peak loads can be handled without affecting the system-leaving temperatures.
- Flexible system: Any future capacity or change in operational patterns can be easily handled without the need for additional refrigeration machinery.
- Full stand-by capability: The stored energy can be used to operate the process in case of breakdown or regular maintenance shutdowns.
- Green solution: Reduced refrigeration machinery leads to reduced refrigerant volume.

Further information can be obtained from the 2003 publication by Environmental Process Systems.

7.3 Harp Brewery, Dundalk, Ireland

Harp Brewery in Dundalk, Ireland (Fig. 7) produces 1,000,000 hl of lager per year and consumes 12,000,000 kWh of electricity (4,000,000 kWh for the refrigerant plant). In 1992, Harp decided to modernize its refrigeration plant. The existing system consisted of a wide range of process-cooling loads satisfied by two circuits, a high-temperature circuit at $-8^{\circ}C$ and a low-temperature circuit at $-12^{\circ}C$. During the design stage, it was decided to install a Cristopia TES System (STL) on the high-temperature circuit. The STL reduces the instantaneous peak refrigeration demand by as much as 45%, by daily shifting 10,000 kWh from day to night. The STL has reduced the maximum demand by 1 MW and the cooling consumption by 16%.

Technical data

Daily cooling energy consumption	44,000 kWh
Maximum cooling demand	4000 kW
Cooling energy stored	10,000 kWh
Storage temperature	$-10.4^{\circ}C$
Storage type	STL-N10-200 (see *Fig. 7*)
Nodules type	SN. 10
Number of tanks	2
Tank diameter	3 m
Tank height	14 m

7.3.1 Characteristics

To improve system efficiency and to reduce electrical cost, it was proposed to install a Cristopia STL-N10-200 TES system to shift electrical consumption to off-peak periods and to reduce the peak-period electrical demand. To achieve this end, a STL-N10-200 was specified, storing 10,000 kWh at $-10^{\circ}C$ during the nighttime off-peak tariff period. The STL also reduces daytime chiller power by 1000 kWh. The STL-N10-200 is composed of two 100 m^3 vertical tanks filled with SN.10 (77 mm diameter) nodules. The nodules are filled with a PCM, allowing thermal storage at $-10^{\circ}C$.

7.3.2 Technical Advantages

- Smaller chiller capacity;
- Stable flow temperature;
- Electrical supply reduced by 1000 kWh;
- Refrigerant efficiency improved;
- Servicing simplified;
- Back-up at disposal; and
- Smaller cooling towers.

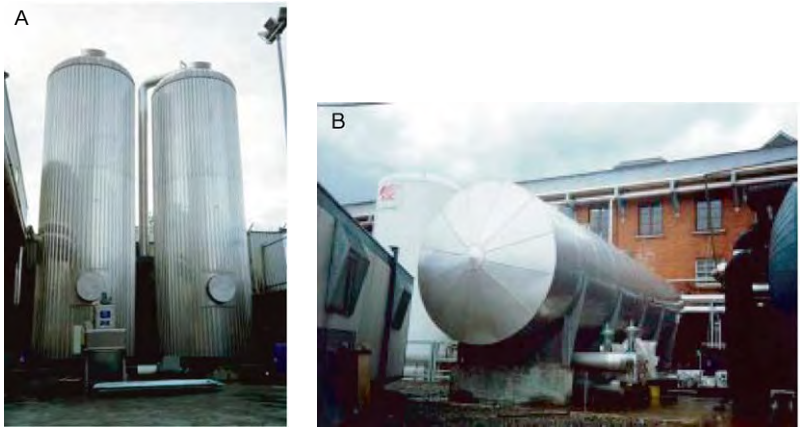

FIGURE 7 (A) Two STL-N10-100 systems and (B) Harp Brewery in Dundalk, Ireland. Reprinted from Cristopia (2001a), with permission.

7.3.3 Financial Advantages

- The system with STL costs less than a traditional system with chillers;
- Savings on maintenance costs;
- Electrical supply reduced by 1000 kWe; and
- Savings on demand charge and energy costs.

7.3.4 Environmental Advantages

- Refrigerant charge reduced (leading to ozone layer protection); and
- Emission of CO_2, SO_2, and N_2O reduced (avoiding contributions to the greenhouse effect and other environmental impacts).

Further information on this project can be obtained from the 2001a publication by Cristopia Energy Systems.

7.4 Museum of Sciences and Industry, La Villette, France

At the site of the old Paris slaughterhouse in La Villette Park, France, a modern leisure center was built in 1983 that included (1) a sciences and industry museum, (2) an audiovisual center, and (3) the GEODE 3-D cinema. The center (Fig. 8A) is one of the largest science and technology centers in the world and one of the most innovative (150,000 m^2 of displays, shows, and exhibitions). A cooling and heating plant supplies air-conditioning to a distribution network. This plant includes an STL-00-550 chiller (storing 31 MWh) and three 2700 kW chillers.

Technical data

• Main alternate current system type	Air-handling unit
• Building volume	1,350,000 m
• Daily cooling energy consumption	163,000 kWh
• Maximum cooling demand	12,500 kW
• Chiller capacity	
—Direct mode	8100 kW (6/12°C)
—Charge mode	4400 kW(−6/−2°C)
• Energy stored	31,750 kWh
• Volume	549 m^3
• Storage type	STL-00-550 (see *Fig. 8B*)
• Number of tanks	3
• Tank diameter	4 m
• Tank height	18 m

7.4.1 Characteristics

The STL is used to reduce 50% of the peak cooling demand. The storage is charged between 10:00 P.M. and 7:00 A.M. when electricity rates are low. Since 1985, significant operating cost savings have been achieved.

7.4.2 Technical Advantages

- Smaller chiller capacity;
- Smaller heat rejection plant;
- Reduced maintenance;
- System efficiency and reliability increased; and
- Increased plant lifetime expectancy.

7.4.3 Environmental Advantages

- Refrigerant charge reduced; and
- Emission of CO_2, SO_2, and N_2O reduced.

FIGURE 8 (A) The modern leisure center in La Villette Park, France, and (B) the TES tanks. Reprinted from Cristopia (2001b), with permission.

Further information on this project can be obtained from the 2001b publication by Cristopia Energy Systems.

8. CONCLUDING REMARKS

TES is considered an advanced energy technology. The use of TES systems has been attracting increasing interest in several thermal applications, e.g., active and passive solar heating, water heating, cooling, and air–conditioning. TES often is the most economical storage technology for building heating, cooling, and air–conditioning applications.

In general, TES can reduce the time or rate mismatch between energy supply and energy demand, thereby playing a vital role in improved energy management. TES use can lead to savings of premium fuels and make a system more cost-effective by reducing waste energy. TES can improve the performance of thermal systems by smoothing loads and increasing reliability. Therefore, TES systems are becoming increasingly important in many utility systems.

The selection of TES systems depends mainly on the storage period required (e.g., diurnal or seasonal), economic viability, operating conditions, etc. Some specific parameters that influence the viability of a TES system include facility thermal loads, thermal and electrical load profiles, availability of waste or excess thermal energy, electrical costs and rate structures, type of thermal generating equipment, and building type and occupancy.

The economic justification for TES systems usually requires that annual capital and operating costs be less than the costs for primary generating equipment supplying the same service loads and periods. Substantial energy savings can be realized by taking advantage of TES to facilitate using waste energy and surplus heat, reducing electrical demand charges, and avoiding heating, cooling, or air-conditioning equipment purchases.

TES can help correct the mismatch between supply and demand of energy and can contribute significantly to meeting society's needs for more efficient, environmentally benign energy use. TES plays an important role in energy conservation and can yield savings of premium fuels.

TES has enormous potential to make the use of thermal energy equipment more effective and to facilitate large–scale energy substitutions economically. A coordinated set of actions is needed in several sectors of energy systems in order to realize the maximum benefits of storage.

5. Cold Water Pollution

Glossary

acclimation temperature The temperature that an organism has become used to by a period of constant exposure over time.

biocide A substance like an herbicide or insecticide that kills living organisms. Chlorine and ozone have been used as biocides to prevent fouling of water pipes in power plants.

electricity units Gigawatt = 1 billion watts; megawatt = 1000 kilowatts or 1 million watts; megawatt-hour = a unit of energy equivalent to 1 megawatt of power expended for 1 hour of time.

larvae The early life history stages of aquatic animals such as fish or shellfish. Many types float in the water column as zooplankton (see Plankton).

plankton Animals and plants (usually microscopic in size) that float in aquatic systems and form part of the system's food web. They can be categorized as bacterioplankton (bacteria or microbes), phytoplankton (plants), and zooplankton (animals).

thermal efficiency Useful energy output divided by total energy input; for a steam-electric power plant, it is the proportion of the total energy that the facility consumes in relation to the amount of electric energy produced.

For the purpose of this article, thermal pollution refers to a deleterious change (increase or decrease) in the temperature of a water body as a result of human activities. However, some have declared that the term is biased in that it imputes negative effects to all thermal changes caused by humans. They have suggested that, in relation to increased temperature, more neutral terms might be thermal addition or calefaction. Where heated water provides a benefit, such as in enhancing the aquaculture of plants and animals, some have referred to that as thermal enrichment.

1. WHAT IS THERMAL POLLUTION?

Temperature changes can range from small to large and can cause negative or positive effects on organisms. Temperature in a water body can increase as the result of humans clearing vegetation from stream banks, thereby removing natural shading of the stream; of runoff of warmed water from heated land surfaces; and of disposal of heated effluents from industrial activity. Temperature in a water body can decrease as a result of inflow of cooler water from dams or of industrial activity. This article focuses on temperature increases, primarily as a byproduct of electricity generation by steam-electric power plants, but the effects of less common temperature decreases will be considered briefly.

Studies of the effects of thermal discharges from steam-electric power plants began in the 1950s in the United States and the United Kingdom, accelerating in number for about two decades thereafter. Additional studies were undertaken in Europe and the USSR from the 1960s onward. The number of studies worldwide began declining in the 1980s.

This article depends mostly on the results of those studies. It begins with a discussion of thermal discharges from steam-electric power plants, then examines temperature as a controlling factor in nature, and follows with descriptions of efforts over the years to estimate its influence on organisms in relation to heated discharges. It concludes with a brief examination of the less common problem of cold-water discharge from dams.

2. THERMAL DISCHARGES FROM STEAM-ELECTRIC POWER PLANTS

2.1 Sources of Heating of Water Bodies

The areal extent of heating of water bodies caused by removal of vegetation from stream banks or by runoff from warm surfaces is minimal compared to the extent of heating caused by industrial activity. The largest user of water for industrial cooling is the steam-electric generating industry, so thermal discharges (effluents) from that industry will be the major focus of this article.

Steam-electric power plants burn fossil fuels (coal, petroleum, gas), combustible wastes, or biomass, or depend on nuclear fission to heat water in pressurized boilers to produce steam that is used to spin turbines that power electricity generators. Large quantities of additional water (coolant) are pumped from a water body through a multitude of small-diameter condenser tubes that function to condense the steam to water after it has passed through the turbines, whereupon it is recirculated into the boilers. The coolant gains heat in the process. If a power plant has a thermal efficiency of about 35% (nuclear power plants are less efficient than non-nuclear power plants), then about 65% of the heat produced by the power plant has to be disposed of. The heat in the coolant is reduced by releasing the coolant into the atmosphere or by returning it to a water body, usually the one from which it was originally extracted. The differences between the temperature of the cooling water pumped into the steam-electric power plant and its temperature as it exits the station (ΔT) can cover a wide range of values from about 5°C to 25°C.

Steam-electric power plants in industrialized countries have increased in size from an average of about 35 megawatts in the 1950s to as much as 1000 megawatts for fossil-fuel-powered plants and 1400 megawatts for nuclear-powered plants in recent decades. This has increased the demand for water for steam and for cooling activities. For example, a 1000 megawatt nuclear power plant with an open-cycle cooling system (discussed later) may use up to 5 billion liters of coolant per day. Toward the end of the 20th century, thermal power plants in the United States and the United Kingdom used about 80 to 90% of all the water used in those countries for industrial cooling. Subsequent efforts have been made to conserve and reuse cooling water, but the amount of water in industrial countries that is heated during steam-electric generation and that must be cooled remains large because of the overall increase in the number of power plants.

2.2 Cooling Systems

A variety of systems are used to reduce the heat of the coolant. Open-cycle or once-through cooling systems pump water from the water body they are located beside and can require tens of thousands of liters per megawatt-hour, releasing the heated effluent back into the water body as a surface discharge so that the heat can transfer to the atmosphere. Some heated effluents may be pumped directly into the water body (receiving water), whereas others may be released into a discharge or cooling canal to allow for some cooling to take place before the effluent flows back into the water body. This is perhaps the simplest design, but the amount of heated effluent involved means that large power plants (500 megawatts and above) must be located on very large lakes or on an estuarine or marine coast so the heated effluent has minimal effect on the receiving water as a whole. The entry of the discharge into the receiving water creates a mixing zone wherein the plume of heated water is cooled by the colder receiving water. Local hydrography influences the behavior of the plume (e.g., movement of the plume by winds or currents) and the speed of cooling.

Closed-cycle or recirculating cooling systems may incorporate ponds in which heated discharges cool sufficiently before being reused. Or they may use vertical cooling towers in which the effluent either falls from a height so that evaporative cooling occurs in air (wet cooling) or passes through a radiator in which cooling occurs with no direct contact of the effluent with air (dry cooling; this reduces evaporative loss of water). Closed-cycle systems use hundreds of liters of cooling water per megawatt-hour, and thus can be located on smaller water bodies than is the case for open-cycle cooling systems.

2.3 Growth in Electricity Use

The World Energy Council has reported that electricity represented 25% of energy use by industrial nations in the 1970s, growing to 37% by 2000. The council estimates that electricity will eventually grow to be 50% of such energy use. The Electric Power Research Institute estimates that world population growth and economic development will require an additional 10,000 gigawatts of electricity generating capacity over the next 50 years. This will

increase the amount of water that is heated to form steam to drive turbines, the amount of coolant needed for condensing the steam, and the amount of coolant that is returned to the environment.

3. TEMPERATURE AS AN ENVIRONMENTAL FACTOR

Temperature has been called an environmental master factor because of its importance in the biology of every organism. Most aquatic organisms are adapted to live within a specific temperature range, outside of which temperatures become stressful and ultimately lethal. Within the temperature range (i.e., at sublethal levels), temperature can affect an organism's metabolism, growth, and behavior, as well as reproductive timing and rates of egg and larval development. It also influences geographic distributions of species, including distributions of freshwater and marine fauna.

Temperature effects can be influenced by many other environmental factors (Fig. 1). For example, as will be demonstrated below, research has shown for some aquatic animals that age, size, life-cycle stage (egg, larva, juvenile, adult), or ambient oxygen conditions can affect the animal's temperature tolerances. Other studies have shown that diet, environmental salinity, or the presence of parasites can influence some animals' temperature tolerances. The interaction of temperature and dissolved oxygen can be very important, in that, whereas increased temperature raises the metabolism of "cold-blooded" aquatic animals, it also lowers the oxygen carrying capacity of water. Thus, at a time when the metabolic need for oxygen is increasing, the amount of available oxygen is decreasing, often causing stress or mortality to organisms in warming water (see the striped bass example described later).

Predicting the effects of temperature change on a particular species requires that the species' biology in relation to temperature, including the other factors that influence the temperature effects (Fig. 1), be well understood. The complexity of these interactions poses a challenge because of our limited knowledge of this complexity with regard to most organisms. Especially, we know little about the smallest components of aquatic ecosystems—microbes, phytoplankton, and zooplankton—that play significant roles in energy flow and nutrient flux within ecosystems. This lack of information makes it very difficult to predict the effects of increased temperature on an ecosystem, even if we have some information on the effects of temperature on some species in the ecosystem.

Finally, predicting the effects of thermal effluents from power plants can be made more difficult because biocides and other contaminants may be included in the coolant water. For example, if a biocide such as chlorine is used to reduce settlement of organisms in and subsequent blockage of condenser tubes (fouling), it may stress organisms in the vicinity of the thermal plume and cause higher mortalities or other biological changes than might occur from temperature alone.

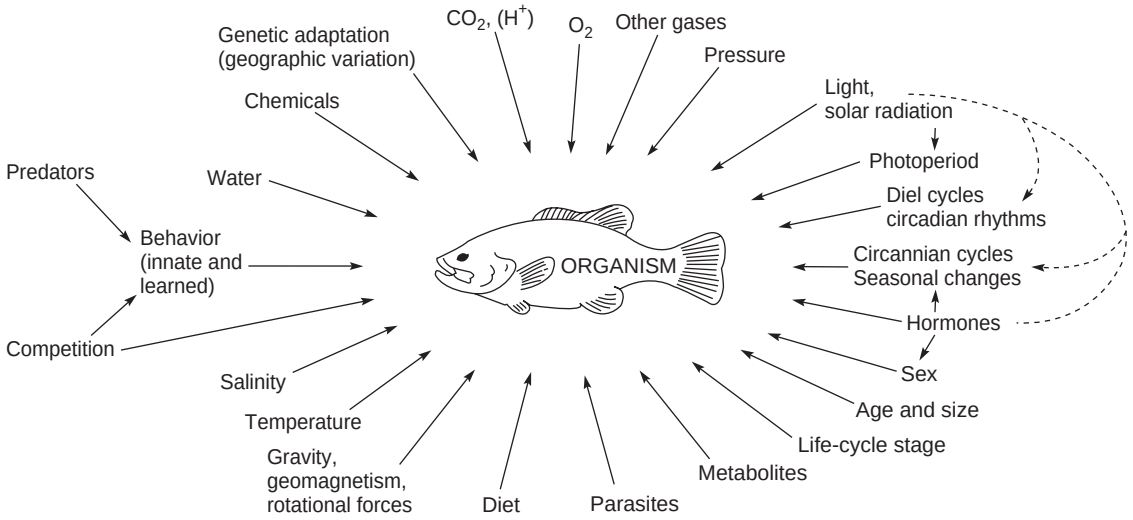

FIGURE 1 Various factors that can affect the thermal tolerances of organisms. From Hutchison (1976).

3.1 Effects of Temperature on the Biology of Organisms

3.1.1 Lethal Effects

Temperature extremes (both high and low) can be lethal. Many species are sensitive to temperatures just a few degrees higher than those they usually experience in nature. Indeed, in short-term (measured in days) temperature-tolerance experiments on estuarine invertebrates in the laboratory, a temperature increase of 1°C can raise mortalities from 0% or slightly above at the lower temperature to about 100% at the increased temperature. This is significant in terms of thermal pollution because temperature increases from heated-water discharges inevitably are greater than 1°C, as mentioned earlier.

An initial effort to predict the effects of heated water discharge on a species often involves laboratory experiments in which individuals of that species are placed in a series of water baths at high temperatures to determine the mortalities in each bath over a period of time (usually 24 to 72 hours). These relatively short-term experiments use individuals that are acclimated to the temperatures prevailing in their environment at the time of the experiments (e.g., in temperate regions, they will be acclimated to low temperatures in winter and high temperatures in summer). The results of the experiments are expressed in terms of LC50—that is, the temperature that will result in 50% of the individuals in a species dying within the time period of the test. As an example, Figure 2 presents data on the percentage of mortalities suffered by an estuarine invertebrate, the opossum shrimp *Neomysis americana,* individuals of which were acclimated in the laboratory to temperatures ranging from winter values of 1°C to summer values of 30°C before being placed in water baths holding water at the acclimation temperature or above. The sigmoid curves describing mortality over the test temperatures are steep, reflecting the slight differences between those temperatures at which mortality is limited and those that cause high mortality (see previous paragraph). In general, as acclimation temperatures increase, so do the LC50 values at each acclimation temperature. Thus, a temperature such as 18°C that would cause 100% mortality in winter obviously is not lethal to opossum shrimp that have become acclimated to summer temperatures of 25°C to 30°C. This generalization applies to other aquatic organisms exposed to temperature increases in similar laboratory experiments and means that, up to a point, heated-water discharge temperatures from steam-electric power plants may be more of a threat to survival of organisms in winter than the same temperatures might be in summer.

LC50 values can provide a reasonable estimate of the relative ability of different species to tolerate temperature increases. For example, seven species of invertebrates that are found together in Chesapeake Bay in the United States have LC50s that differ by about 10°C even though they were acclimated to the same temperature (15°C) (Fig. 3). Consequently, rules regarding temperature discharge need to account for the most thermally sensitive species, in this case the opossum shrimp.

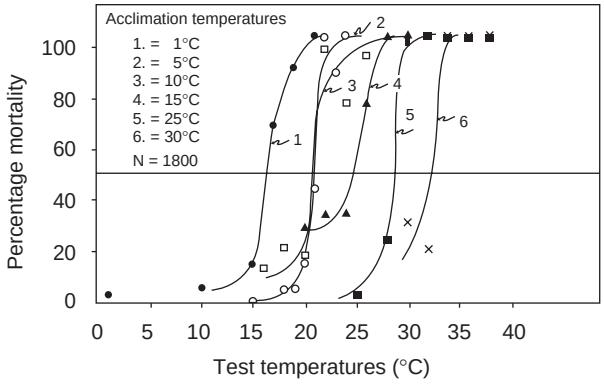

FIGURE 2 Curves of the mortalities of individuals of the estuarine opossum shrimp *Neomysis americana* acclimated to temperatures of 1°C to 30°C. The horizontal line represents the LC50 value for each acclimation temperature. Modified from Fig. 2 in J. A. Mihursky and V. S. Kennedy (1967), Water temperature criteria to protect aquatic life. *American Fisheries Society,* Special Publication No. **4**, 20–32, with permission.

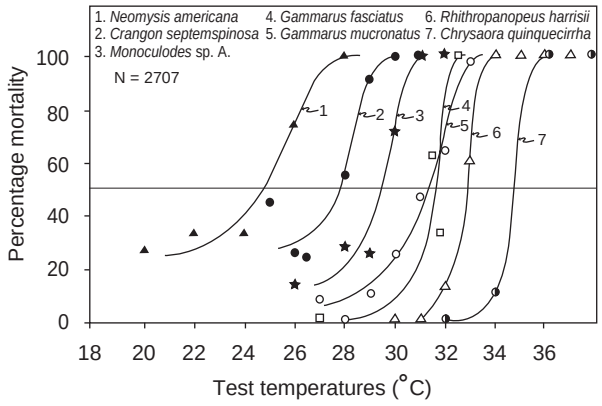

FIGURE 3 Comparative mortality curves for seven species of estuarine invertebrates from Chesapeake Bay acclimated to about 15°C. Modified from Fig. 3 in J. A. Mihursky and V. S. Kennedy (1967), Water temperature criteria to protect aquatic life. *American Fisheries Society,* Special Publication No. **4**, 20–32, with permission.

It is necessary to determine the tolerance of a species over its natural thermal range in order to set temperature discharge rules that will apply over the course of a year. This has been done for a number of clam species that live buried in the sediments on the bottom of Chesapeake Bay (Fig. 4). Here, one species, the gem clam *Gemma gemma,* is the most tolerant of temperature over its natural thermal range. Three other species that live in the same bottom habitat as *Gemma gemma* (the Baltic macoma *Macoma balthica*, the coot clam *Mulinia lateralis,* and the soft-shell clam *Mya arenaria*) have lower temperature tolerances. The youngest stages (newly settled and young *Mya arenaria* and small *Macoma balthica*) are slightly more tolerant than the adults.

These results make sense biologically. The youngest stages live on or near the sediment surface of the estuarine bottom where temperatures tend to be higher than they are deeper within the sediments where the larger animals dwell. Also, *Mya arenaria* in Chesapeake Bay is living near the southern extent of its distributional range on the western Atlantic coast, which may explain its greater thermal sensitivity compared to the other three species that range further south into warmer regions. Similarly,

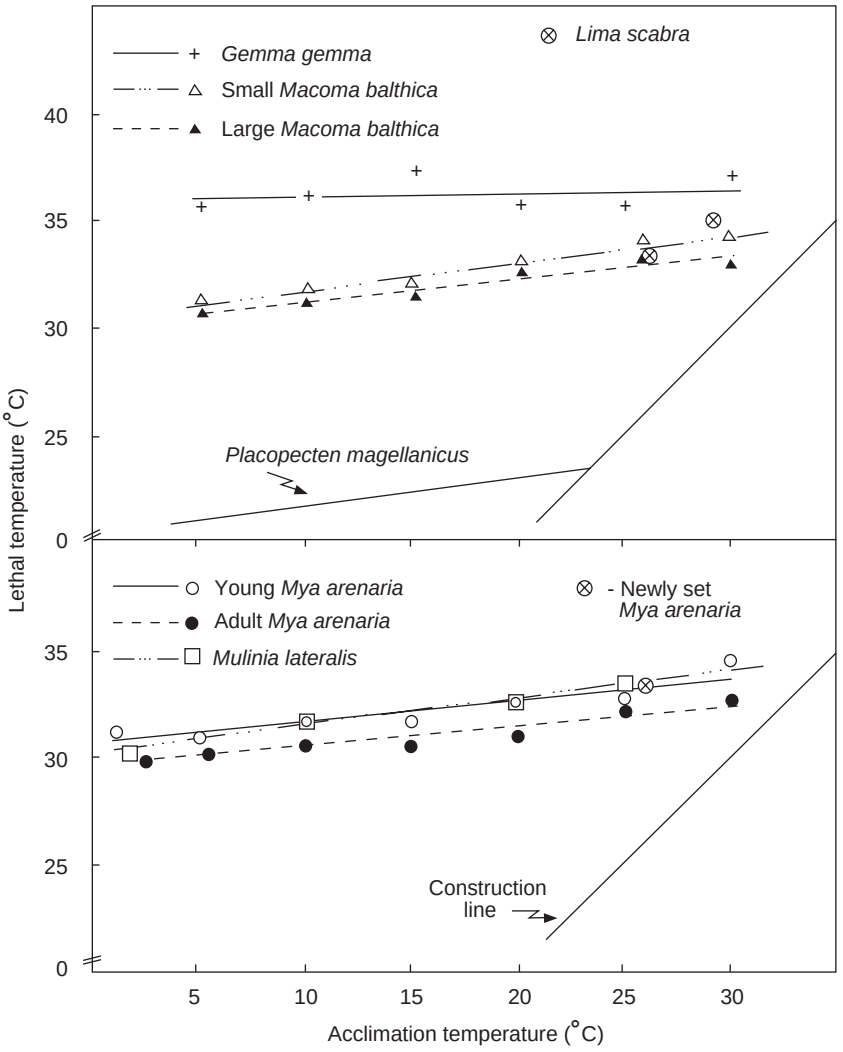

FIGURE 4 Lethal temperatures (LC50) for six species of bivalves, including newly settled, small or young, and large or adult individuals of some species. *Gemma gemma*, *Macoma balthica*, *Mulinia lateralis*, and *Mya arenaria* are clams that live buried in Chesapeake Bay sediment. *Lima scabra* lives in warm Atlantic waters, whereas *Placopecten magellanicus* lives in cold Atlantic waters. The construction line represents where the acclimation and lethal temperatures are identical. From Fig. 2 in V. S. Kennedy and J. A. Mihursky (1971), Upper temperature tolerances of some estuarine bivalves. *Chesapeake Sci.* **12**(4), 193–204. Permission granted by the Estuarine Research Federation.

the Atlantic Ocean scallop *Placopecten magellanicus* does not experience temperatures anywhere close to those experienced by the Chesapeake Bay species, which may explain its relatively low tolerances. On the other hand, the rough fileclam *Lima scabra* lives in warm Atlantic waters, which is reflected in its temperature tolerances.

Generalizing from these results, heated-water discharges into marine coastal waters where *Placopecten magellanicus* might be living would have to be much cooler than similar discharges into Chesapeake Bay or the coastal habitat of *Lima scabra*. Within Chesapeake Bay, temperatures that can be tolerated by *Gemma gemma* would be too high to be tolerated by the other clams, so the susceptibility of the less heat-tolerant *Mya arenaria* to higher temperatures should drive regulations governing thermal discharges (based on these experimental data alone).

Based on these and other research results, the state of Maryland promulgated regulations governing discharge temperatures from power plants. Figure 5 plots the allowed seasonal increase above ambient temperature of heated discharges in Chesapeake Bay (dashed lines) in relation to the thermal tolerances of the four estuarine species depicted in Fig. 4. *Gemma gemma* has a lethal thermal tolerance that is sufficiently higher than the regulated discharge temperatures so that there should be no or limited effect of the discharge on the survival of the clams even in summer (however, there is no information on how the heated-water discharges might affect growth or reproduction in this species; see the next paragraph). On the other hand, adult *Mya arenaria* (especially) and large *Macoma balthica* have lethal thermal tolerances that are very close to the upper temperature limit of allowable discharge in summer in Maryland.

Regulations elsewhere are also region specific as well as species specific. For example, in British Columbia, Canada, the maximum daily temperature of streams inhabited by temperature-sensitive bull trout *Salvelinus confluentus* or Dolly Varden *Salvelinus malma* are not allowed to exceed 15°C and the maximum temperature during spawning cannot exceed 10°C, whereas streams harboring species of Pacific salmon are not allowed to be warmed more

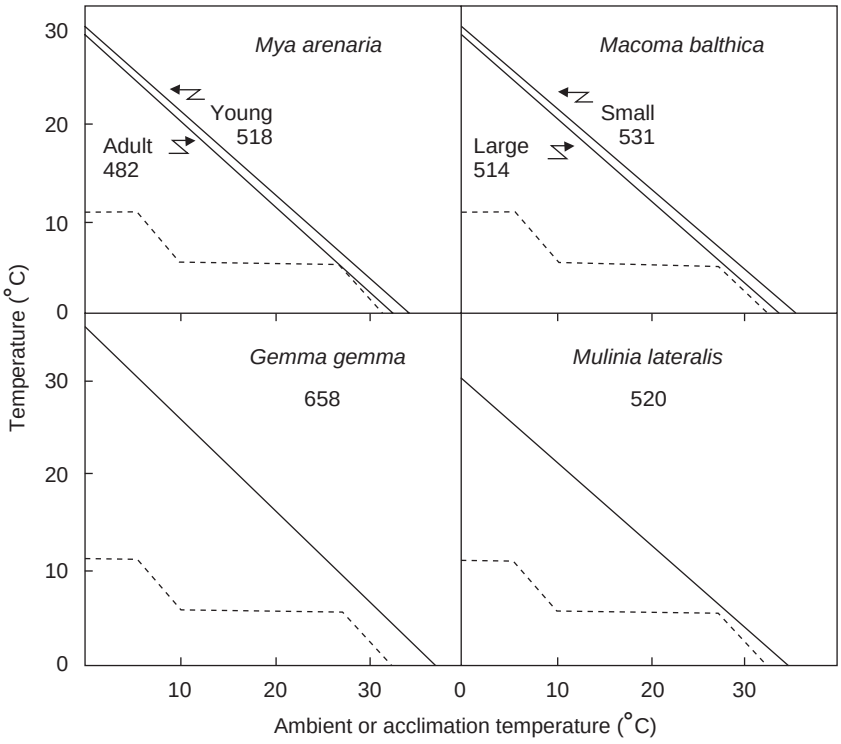

FIGURE 5 Temperature tolerance triangles of four species of estuarine bivalves from Chesapeake Bay, Maryland (solid lines developed by subtracting an LC50 value from its corresponding acclimation temperature), in relation to Maryland's thermal discharge regulations for tidal waters (dashed lines show how many degrees above ambient temperature a discharge can be). Numbers refer to the areas of the triangles in square degrees Centigrade. From Fig. 3 in V. S. Kennedy and J. A. Mihursky (1971), Upper temperature tolerances of some estuarine bivalves. *Chesapeake Sci.* **12**(4), 193–204. Permission granted by the Estuarine Research Federation.

than 1°C beyond the optimum temperature range for each life history phase of the most sensitive salmon species present.

Warm temperatures over coral reefs can cause coral bleaching, a breakdown in the symbiotic relationship between the coral animal and the unicellular algae that live within coral tissues. The algae (called zooxanthellae) photosynthetically produce food materials that the coral can use, and they are in turn sustained by the coral's waste products that serve as nutrients. Under warmer climatic conditions, coral animals have expelled the zooxanthellae, leaving the animals pale to colorless. The symbiotic relationship is thus suspended and the host is weakened until environmental conditions improve and normal zooxanthellae density is regained. Thermal discharges can have similar effects on coral reefs in their vicinity, so power plant discharges in the tropics are directed away from coral reefs.

Thermal discharges are not the only aspect of steam-electric generation that can have a lethal effect on organisms. The water that is pumped into the power station to serve as coolant harbors entrained microscopic organisms (bacterioplankton, phytoplankton, and zooplankton, including fish and invertebrate larvae in breeding seasons). This coolant experiences very rapid increases in temperature as it passes through the condensers. Such temperatures will usually be much higher than those experienced by organisms exposed to the thermal effluent from the power station, so mortalities are usually higher for entrained organisms (the threat from higher temperature is exacerbated by pressure changes or mechanical stress as the organisms are pumped through the condenser system, as well as by any biocides like chlorine that are used to keep fouling of the system's tubes to a minimum).

Experiments that have been performed to focus on the relationship between temperature increase and residence time within a condenser system have shown, unsurprisingly, that mortalities of entrained organisms can increase depending not only on the increase in temperature but also on the length of exposure to increased temperature. Such experiments have been performed on the fertilized eggs and larvae of a number of estuarine bivalves. Figure 6 shows the results on such an experiment on an early larval stage of the estuarine hard clam *Mercenaria mercenaria*. The larvae were subjected to a variety of temperatures from 18°C to 43°C for periods of time that ranged from 1 to 360 minutes. As temperature increased from about 36°C, so did mortalities. In addition, after about 10 minutes, the longer the

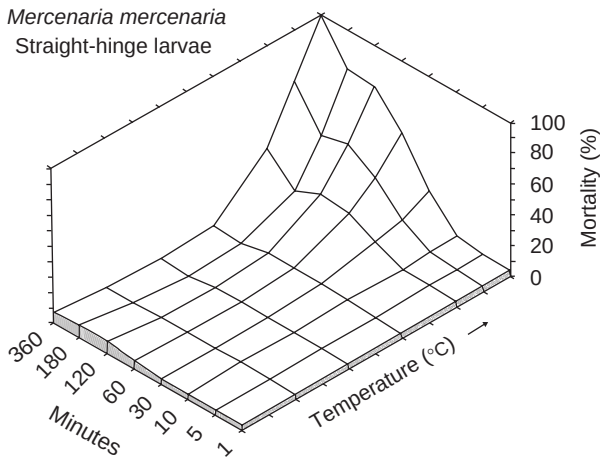

FIGURE 6 Temperature tolerances over time for the straight-hinge larval stage of the estuarine hard clam *Mercenaria mercenaria*. From Kennedy *et al*. (1974).

larvae were exposed to temperatures above about 38°C, the higher their mortality. Although differing in detail, these relationships hold for fertilized eggs and other larval stages of the hard clam, as well as for fertilized eggs and larvae of other species of estuarine bivalves that have been studied.

Based on these and other findings, the lesson for regulators is that passage of coolant through condenser systems should be as rapid as possible if mortalities of entrained organisms are to be minimized. A variety of estimators have been developed to enable regulators to predict the actual exposure times that can be allowed in order to minimize mortality.

3.1.2 Sublethal Effects

Research into thermal tolerances has determined that lethal temperatures usually are higher (or lower in the case of cold conditions) than are temperatures that influence activity and growth, which in turn are higher (or lower) than temperatures that affect reproduction. This information has been used to build a schematic representation of the effects of high and low temperatures on Pacific salmon (Fig. 7). In terms of survival, the egg and hatchling stages are less tolerant of warm temperatures than are older stages. In turn, thermal tolerances vary with season as explained above for the opossum shrimp, with tolerances to warm temperatures being higher in summer than winter (thus the undulation in the upper line on the figure). Warm temperatures that inhibit growth and reproduction are, in turn, lower than those that cause mortality. A similar scenario can be developed for freshwater

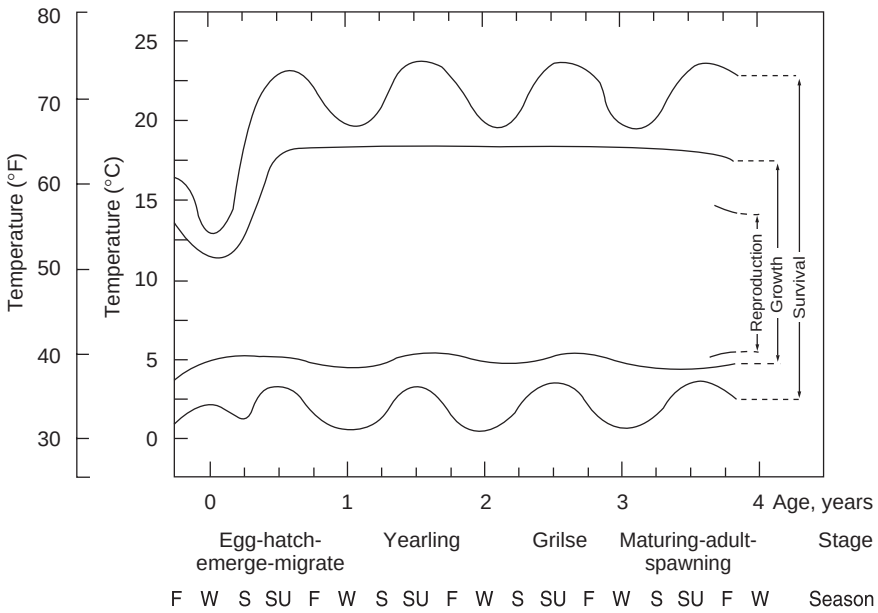

FIGURE 7 Temperature tolerances (measured and hypothetical) that affect different life cycle stages of Pacific salmon over the seasons during 4 years of life. Lethal temperatures (survival) are higher or lower than are the temperatures that inhibit growth, which in turn are higher or lower than the temperatures that inhibit reproduction (spawning). From Brett (1960).

carp and brown trout (Fig. 8) in which the temperature ranges that affect optimal growth are narrower than those influencing feeding and different from those affecting egg development, with the ranges that cause stress extending beyond these other ranges. In terms of differences between species, carp are more tolerant of higher temperatures than are brown trout.

Laboratory studies have shown that organisms under stress pay a metabolic cost in the form of a continued expenditure of energy. These findings mean that a thermal discharge that is sublethal may nevertheless have deleterious effects on growth and reproduction. Stunted animals may be more susceptible to predation and may be delayed in maturing and reproducing. And if a species cannot reproduce, eventually its population might disappear from the heated locale unless other individuals of that species move into the locale when temperatures are not deleterious. Clearly, these considerations are more important for immobile organisms (e.g., fish eggs laid among gravel in streams, oysters, barnacles, underwater grasses) that are unable to leave the vicinity of the heated discharge than they are for mobile organisms (e.g., fish, some invertebrates) that can avoid the deleterious conditions. Thus, regulations governing thermal discharges may need to be focused more on organisms that cannot avoid the discharge than on those that can.

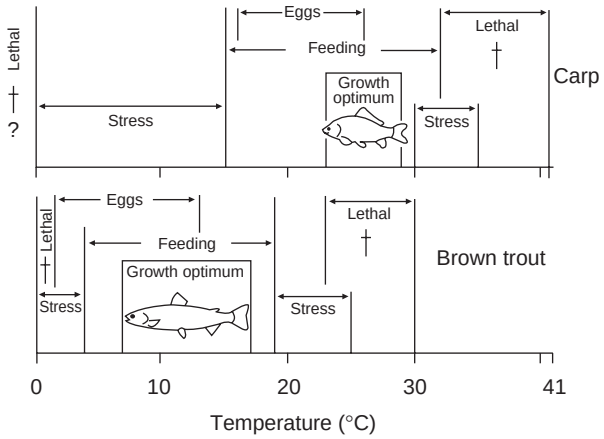

FIGURE 8 Effects of temperature on egg development, feeding, growth, and survival of freshwater carp *Cyprinus carpio* and brown trout *Salmo trutta*. From J. M. Elliott (1980), Some aspects of thermal stress in freshwater teleosts. *In* "Stress and Fish" (A. D. Pickering, Ed.), pp. 209–245. Academic Press, New York, with permission.

3.1.3 Beneficial Effects

Heated-water discharges may be a beneficial resource in human endeavors, and the high temperatures of power-station discharges can be ameliorated by diverting the discharge through a system in which the heat can be put to productive use. For example, such discharges have been used to heat buildings or to warm greenhouses and other facilities in which

commercial plants and animals are cultured. However, there is no guarantee that the discharges will not be shut off for unexpected reasons such as unscheduled maintenance or decreased electricity demand, so these eventualities have to be considered by users of the thermal resource.

3.2 Effects of Temperature on Abundances and Distributions of Organisms

Temperature changes as small as 1°C can have important effects on the abundance and distribution of species, as happened in Monterey Bay, California. There, local temperatures increased by about that amount between the early 1930s and the late 1990s as a result of a climate-warming event (not associated with industrial discharges). The abundances of intertidal species with southern (warmer water) distributions became higher than in the early 1930s and the abundances of northern (cooler water) species declined. Thus, although higher temperatures might not result in extinction of a species throughout its geographic range, the species may be eliminated from part of its range. However, with regard to industrial heated discharges, such discharges are of limited regional scope and are under governmental regulation. Thus, it would be unusual for thermal discharges to affect the distributions of organisms beyond the vicinity of the thermal discharge itself.

Mobile organisms can respond to temperature by avoiding it or becoming attracted to it. This will vary seasonally, depending on the organism's thermal tolerance or its thermal preference. In winter it is common to find mobile organisms like some invertebrates, fish, turtles, and mammals like manatees congregating in the discharge region of a power station if there is enough food available to meet their metabolic needs. Waterfowl may be able to take advantage of ice-free conditions caused by discharges to feed in aquatic systems that ordinarily would be ice covered and inaccessible. However, if the discharge is halted abruptly by maintenance needs of the utility or for some other reason, "cold-blooded" animals like invertebrates, fish, and turtles may be at risk. The water body will soon revert to ambient winter temperatures, which may lead to cold shock and mortality of those organisms that have become adapted to higher temperatures while living in the thermal effluent and thus more susceptible to cold than they would have been if they had been acclimated naturally to winter temperatures.

3.3 Effects of Temperature on Species Interactions

Temperatures do not have to be lethal to influence changes in species interactions (e.g., predator-prey or parasite-host relationships, or competition among organisms for resources) in ecosystems. Changes in local distribution patterns as noted earlier would change the mix of predators, prey, parasites, and competitors in a thermally influenced ecosystem in ways that are not yet understood but that could alter the functions of the ecosystem and the productivity of resident organisms. However, in relation to thermal pollution, these alterations will be limited to the vicinity of the thermal discharge and will have no regional effect outside the mixing zone.

3.4 Effects of Temperature on Oxygen Concentrations

Oxygen-dependent (aerobic) aquatic organisms extract the oxygen necessary for their metabolic demands from the water in which they live. Temperature influences the amount of oxygen that water can hold, with warmer water holding less oxygen than does cooler water. Thus, as warmer temperatures cause an increase in the metabolism of aerobic organisms, there is less oxygen available to support their metabolism. This can be lethal, or can stress an organism, perhaps rendering it unable to feed or to escape being fed upon by a predator more tolerant of low-oxygen conditions, or making it more susceptible to disease.

Interactions between higher temperatures and depleted oxygen could constrict the available habitat for certain aquatic species. For example, the habitat of striped bass may be "squeezed" in the vicinity of a thermal discharge. In late spring through autumn in western Atlantic coastal and estuarine waters unaffected by humans, the upper layers that are the habitat of juvenile striped bass are usually warmer than the deeper waters inhabited by older fish (Fig. 9). The squeeze can occur if a thermal discharge warms the surface waters so that the depth of warm water increases, leaving less cool water for the older stages. The warmer conditions will also speed up the decay of organisms sinking into the depths, thereby increasing the amount of oxygen-depleted (anoxic) bottom waters that the fish will avoid. Thus, the suitable habitat for the older stages will be squeezed between the increased volume of warmer upper waters and the anoxic bottom waters. However, striped bass are mobile and can swim to cooler

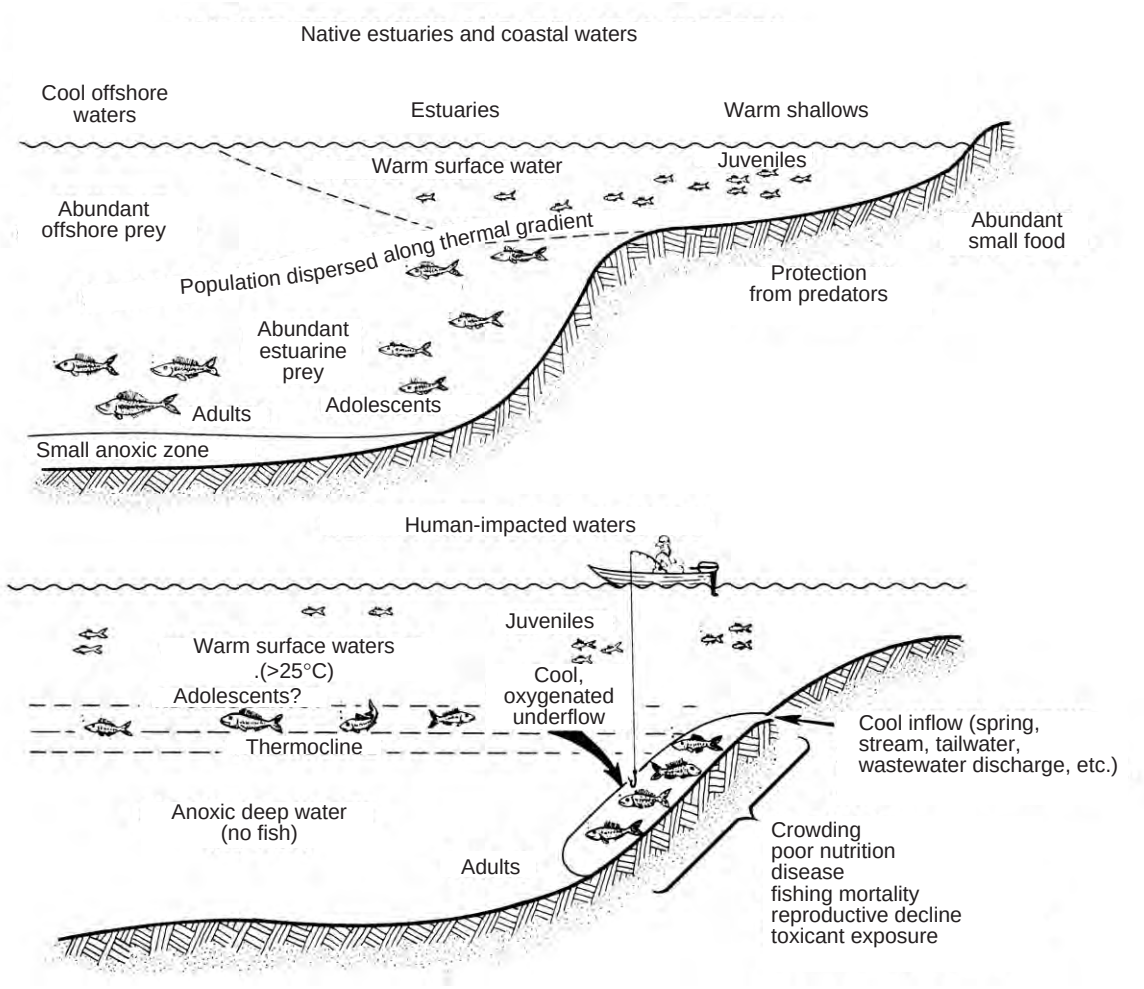

FIGURE 9 Distributions of striped bass in relation to normal (upper panel) and warmed temperature conditions. From C. C. Coutant (1987), Thermal preference: When does an asset become a liability? *Environmental Biology of Fishes* **18**, 161–172, with kind permission of Kluwer Academic Publishers.

habitat elsewhere along the coast, so it is unlikely that a thermal discharge will affect a biologically significant amount of habitat.

4. OCEAN THERMAL ENERGY CONVERSION

An alternate system of generating electricity is the Ocean Thermal Energy Conversion (OTEC) system, which has been employed in tropical ocean waters. It takes advantage of the difference in temperatures between solar-heated surface water (usually at 24°C to 30°C) and cooler, subsurface water at up to 1000 m depth (4°C to 8°C). A closed-cycle OTEC system uses heat from the warm seawater to vaporize a working fluid (e.g., ammonia), with the expanding vapor spinning a turbine that powers a generator. Cold seawater is pumped from depth through a condenser that condenses the working fluid vapor back into a liquid that is then recycled through the system. An open-cycle OTEC system vaporizes warm surface water itself (the working fluid) in a near vacuum at the temperature of the surface water to spin a low-pressure turbine. Again, cold deep water condenses the vapor to water (freshwater, as the seawater has lost its salt upon vaporization). In the process of cooling the vapor, the cold seawater is warmed to a temperature intermediate between its original temperature and that of the surface. Thus, the heated effluent is returned to the ocean at a depth (e.g., 60 m) to reduce temperature anomalies that would have adverse effects on organisms such as described earlier.

5. COLD WATER POLLUTION

An uncommon form of thermal pollution involves the release of cool or cold water from storage reservoirs into warmer water, thereby lowering the temperature of the receiving water bodies. Australia is one country in which this occurs. There, water is released from dams for irrigation in summer and autumn when river temperatures are high. If the water is released from a low point in the dam wall, then the coolest water in the dam is what is released (in summer, the dam's surface water is warmed by the sun and the lighter warm water floats on the denser cooler water). This water can be more than 10°C cooler than the water in the receiving water body. The deleterious effects of cold-water pollution can be detected in Australian rivers from 50 to 400 km from the release point.

The results of cold-water pollution can be similar to those of warm-water pollution in that organisms may die, or their physiology may be altered, and their communities may be disrupted. Temperatures may be so cold as to be lethal for a species, and sublethal effects include the lowering of body temperatures, thus slowing growth and retarding reproduction (see Figs. 7 and 8), as well as influencing the ability to avoid more cold-tolerant predators. Cold-water pollution can be prevented by adding warmer tempering water to the cold water as it is being released or by taking the water for release from near the surface of the dam where it is warmer.

Glossary

exergy The maximum amount of useful work that can be extracted from a material as it approaches thermodynamic equilibrium with its surroundings by reversible processes; the second law of thermodynamics implies that it is never possible to use all available or potentially useful work for practical purposes.

power The time rate at which work is performed, measured in horsepower, watts, or Btu per hour.

thermodynamics The science that studies the nature and transformation of energy. The word thermodynamics stems from the Greek words *therme* (heat) and *dynamis* (power).

work The energy transfer associated with a force acting through a distance.

The word energy is widely misused, and for the sake of precision, it is useful to introduce a different term, exergy, which is less familiar but more precise. Energy is a conserved quantity (the first law of thermodynamics), meaning that it can only change form or quality (e.g., temperature) but can never be created or destroyed. Energy and mass are interconvertible (according to Einstein's formula, $E = mc^2$), although nuclear reactions convert only infinitesimal amounts of mass into energy, whereas there are no practical processes for converting energy back into mass. For all other processes of concern to humans, both the mass and energy content of materials and energy flows are conserved independently. This means that the mass and energy of inputs (including water and air) are exactly the same as the mass and energy content of outputs, including waste products. What has changed is the availability of the energy in the inputs (solar insolation or fuel) for doing potentially useful work.

1. WORK AND POWER

Work is usually defined as a force operating over a distance, and this is scarcely helpful if force is undefined. To avoid infinite regress, the best explanation may be historical. Work was originally conceptualized during the 18th century in terms of a horse pulling a plow or a pump raising water against the force of gravity. Since the discovery of the pendulum, it has been realized that raising a bucket of water or going up a hill converts kinetic energy into potential energy (of gravitation) and that gravitational potential can be converted back into kinetic energy by reversing the process. In the absence of frictional losses, the two forms of energy are equivalent. (Of course, frictional heat becomes unavailable.) Work is also performed when a force acting on a mass increases its velocity and, hence, its kinetic energy, which is essentially mechanical exergy.

A piston compressing a gas does work by increasing the pressure of the gas, just as a gas expanding against a piston can do work by turning a wheel. Adding heat to a compressible fluid in a fixed volume (i.e., increasing its temperature) increases its pressure. This fact makes it possible to convert heat into work. However, it turns out that whereas kinetic and potential energy are interconvertible without loss (in principle), this is not true of heat and

 © 2004 Elsevier Inc. All rights reserved.

pressure. The theory of heat engines, beginning with the idealized engine devised by Sadi Carnot in 1816 and subsequently extended to other engines (e.g., Rankine, Stirling), is all about converting "thermal energy" in the form of heat into "kinetic energy" capable of doing useful work.

Later still, it was realized (independently) by Michael Faraday and Joseph Henry that electric and magnetic fields also constitute forms of potential energy analogous to the gravitational field and that kinetic energy and electromagnetic field energy are interconvertible through the phenomenon of magnetic induction. It follows that changes in electromagnetic potential, known as voltage, can also generate a force and do work. Similarly, kinetic energy of motion, such as when a conductor moves through a magnetic field, can generate a voltage and a current. Normally, there are frictional losses in both processes (known as electrical resistance), but in their absence, the two forms of energy (kinetic and electromagnetic potential) are essentially equivalent.

Finally, during the late 19th century, the notion of potential energy was generalized to chemical reactions by J. Willard Gibbs. Combustion is a process that converts chemical energy—strictly, chemical potential energy—into kinetic energy (motion) and electromagnetic radiation at the molecular level. This heat energy can, in turn, perform physical work by means of a heat engine, as mentioned previously. But there are also chemical processes that generate electrical potentials directly without producing (much) heat, as in storage batteries. Similarly, there are chemical and electrochemical processes that convert heat, chemical potential, and/or electromagnetic potentials into chemical potential, albeit with some entropic losses. Obvious examples are carbothermic reduction (smelting) (e.g., of iron) and electrolytic reduction (e.g., of aluminum). Such processes can also be considered as examples of doing (chemical) work.

It is convenient at this point to introduce the notion of "quasi-work" not involving kinetic energy of motion. This refers to driving an endothermic chemical process (e.g., metal smelting) or moving heat from one place to another across some thermal barrier (e.g., space heating, water heating). Electricity can be regarded as "pure" work because it can perform either mechanical or chemical work with very high efficiency, that is, with very small frictional losses. It is also convenient to distinguish primary and secondary work, where the latter is work done by electrical devices or machines. In all of these cases, the physical units of work are the same as the units of energy or exergy.

Potentially useful work or availability is quantifiable. By general agreement among physical scientists, this quantity is now denoted as exergy. The physical concept underlying the term exergy also goes back to Gibbs, although it has been reintroduced and elaborated several times under a variety of names, including availability, available work, and essergy. The fundamentals of the theory can be found in a number of modern texts on thermodynamics. The formal definition of exergy is the maximum amount of useful work that can be extracted from a material as it approaches thermodynamic equilibrium with its surroundings by reversible processes. The second law of thermodynamics implies that it is never possible to use all available or potentially useful work for practical purposes. There is always some waste or loss of exergy in every process. Lost exergy corresponds to increasing entropy.

There are four components of exergy, each with a corresponding type of work. The first component is kinetic energy associated with relative motion. Mechanical work associated with motion is exemplified by the action of a water wheel or windmill. The second component is potential field exergy, which is associated with gravitational or electromagnetic field differentials. Work must be done on a mass escape from a gravitational field or, on a charged particle, to overcome an electrical field. The third component is thermal exergy (from pressure or temperature differentials), where a heat engine exemplifies the conversion to work. Finally, the fourth component, chemical exergy, arises from differences in chemical composition. Exergy is only nonzero when the system under consideration is distinguishable from its surroundings—the environment—in one or more of these four dimensions.

The first three components of exergy described in the preceding paragraph are analyzed in depth for engineering purposes, especially optimization of mechanical, electrical, and chemical engineering systems, respectively. The term "thermo-economics" has been coined to cover this realm of intellectual activity. However, for purposes of economic analysis on a macro scale, a considerable simplification is possible. In considering mass flows into and out of economic (i.e., industrial) processes, the first three components of exergy can be safely neglected. Only the fourth category, chemical exergy, is important. To calculate the chemical exergy of a mass flow stream, it is only necessary to have data on the chemical composition of that stream (together with thermodynamic characteristics of the components) vis-à-vis the environmental sink into which it (eventually)

flows. Obviously, to calculate chemical exergy, the appropriate environmental reference state must also be characterized quite precisely.

2. ENERGY (EXERGY) CONVERSION TO USEFUL WORK

Reverting to the broader theme, one can say that work is whatever increases the kinetic or potential (including chemical) exergy of a subsystem (within a larger system where energy is always conserved by definition). Electricity can perform either mechanical or chemical work with very high efficiency, that is, with very small frictional losses. Hence, electric power can be regarded as (nearly) "pure" work and is so regarded hereafter. In physical terms, power is defined as work performed per unit of time. Before the industrial revolution, there were only four sources of mechanical power of any economic significance: human labor, animal labor, water power (near flowing streams), and wind power. (The advent of steam power during the early 18th century led to the first quantification of power in terms of equivalent "horsepower" by James Watt.)

It is helpful to distinguish primary and secondary work. Primary work is done by the first stage of energy conversion, for example, by means of a heat engine or hydraulic turbine. Secondary work is work done by electrical devices or machines. It is also useful to consider the notion of quasi-work done by driving an endothermic chemical process or moving heat energy from one place to another across some thermal barrier. In all of these cases, the physical units of work are the same as the units of energy or exergy Electricity can also be converted into heat with very high (100%) efficiency. However, for low-temperature heat, there is an apparent contradiction arising from the fact that resistive heating for low-temperature heat is likely to be less efficient than the use of (electric) heat pumps. For this reason (among others), it is convenient to use the term "second law of efficiency" introduced by the well-known summer study sponsored by the American Physical Society.

Prior to the 18th century, essentially the only source of chemical work (needed mainly for iron and copper smelting, ceramics and glass manufacturing, and cement, quicklime, and plaster of Paris production) was heat from charcoal-fired furnaces. Coal had entirely replaced charcoal in England before 1800 due to prior deforestation. In the United States, the substitution process took roughly a century longer. Inanimate sources of work exceeded animal work in the United States for the first time in 1870. However, not until the 20th century did the contribution from fossil fuel combustion and heat engines using fossil fuels outstrip the contribution from biomass (agriculture and forests), and this was the case only for industrial countries. In many developing countries, the contribution of agricultural and forest products to primary exergy flows and useful work is still dominant.

For purposes of empirical estimation, it is helpful to distinguish between two categories of fuel use. The first category is fuel used to do mechanical work, meaning fuel driving so-called "prime movers," including all kinds of internal and external combustion engines, from steam turbines to jet engines. (Electric motors are not included in this category because electricity is essentially equivalent to mechanical work, as noted previously. Electric power is generated mostly by a prime mover of some other sort.) The second category is fuel used to generate heat as such, either for industry (e.g., process heat, chemical energy) or for space heat and other uses (e.g., hot water for washing, cooking heat for residential and/or commercial users). Historical statistics have never been compiled by official government agencies to distinguish between these two categories of fuel use, but detailed estimates for the 1900–1998 period have been compiled and published for the United States.

It is possible to estimate human and animal contributions to mechanical work crudely on the basis of food or feed intake multiplied by a biological conversion efficiency adjusted for the fraction of time spent doing physical (muscle) work. However, because human labor is treated independently in economic analysis, and because human muscle power is no longer an important component of human labor in the industrial world as compared with eye–hand coordination and brain work, this article neglects it hereafter. (The magnitudes would be trivial in any case.) However, work done by animals, especially on farms, was still important at the beginning of the 20th century and remained significant until midcentury, when trucks and tractors displaced horses and mules. Recent estimates by several authors converge on 4% efficiency or 25 units of feed per unit of work. Higher precision is probably unnecessary for the quantitative estimates in the U.S. case because the magnitude of animal work is relatively small compared with inanimate power sources. In any case, animal conversion efficiency does not change over time.

TABLE I

Average Exergy Efficiency of Performing Work (Percentages)

Year	Electric power generation and distribution	Other mechanical work (e.g., auto transport)	High-temperature industrial heat (steel)	Medium-temperature industrial heat (steam)	Low-temperature space heat
1900	3.8	3	7	5	0.25
1910	5.7	4.4			
1920	9.2	7			
1930	17.3	8			
1940	20.8	9			
1950	24.3	9			
1960	31.3	9			
1970	32.5	8	20	14	2
1980	32.9	10.5			
1990	33.3	13.9	25	20	3

Of course, this is not true of other types of energy conversion systems. Again, official historical time series do not exist except in the case of electric power generation, but crude estimates have been prepared for the U.S. case, as shown in Table I.

3. THE ECONOMY AS A MATERIALS PROCESSOR

The economy has been interpreted as a self-organized system, far from thermodynamic equilibrium. It converts low-entropy, low-information materials into high-entropy wastes and high-information products and services. Put another way, the economy creates useful order from natural disorder and embodies this useful order (mostly) in material form, using large quantities of exergy from biomass (i.e., the sun) or from fossil fuels.

Energy (exergy) flux is transformed into an intermediate service ("useful work"), driving machines and substituting for human and animal labor. By driving down the cost of other products and, thus, increasing demand and production, this long-term substitution has been the dominant driver of economic growth during the past two centuries. In this context, exergy or exergy services (useful work) can be regarded as a factor of production, playing a role complementary to capital services and labor services.

This interpretation explains the close observed correlation between exergy input and economic output without any necessary implication that energy (exergy) content of physical products is proportional to value. It also allows the interpretation of technological progress on a macro level in terms of the efficiency of conversion of exergy inputs-to-service (=work) outputs.

From an evolutionary perspective, the economic system can be viewed as an open system that extracts and converts raw materials into products and useful services. The economy consists of a sequence of processing stages: extraction, conversion, production of finished goods and services, and final consumption (and disposal of wastes). Most of the nonstructural materials are discarded in degraded form. These conversion processes correspond to exergy flows, subject to constraints (including the laws of thermodynamics). The objective of economic activity can be interpreted as a constrained value maximization problem (or as a cost minimization problem). Value is conventionally defined in terms of preferences for consumption goods or services.

The simplest model representation of the economy consists of a single sector producing a single all-purpose product that is both a capital good and a consumption good. This simplification is widely accepted in undergraduate textbooks, despite its lack of realism, because two- or three-sector models are far more difficult to analyze mathematically yet not much more realistic. For example, one might consider a model of two sectors with a single intermediate product. The first sector would include extraction and primary processing (e.g., to finished materials). The second sector would include manufacturing and service activities. Obviously, three or more sectors would add a little more to the realism of the scheme, but the mathematics for a three-sector

model is nearly impenetrable. Of course, the more stages in the sequence, the more necessary it is to take into account feedbacks (e.g., from finished goods to extraction of primary processing sectors). The *N*-sector version would be an input–output model of the Leontief type in which the sequential structure tends to be obscured.

An adequate description of a materials processing system must include materials and energy flows as well as money flows. These flows and conversion processes are governed by the laws of thermodynamics as well as by accounting balances. At each stage, and until the final one, mass flows are split by technological means into "useful" and waste categories. Value (and information) is added to the useful flows, reducing their entropy content and increasing their exergy content per unit of mass (thanks to exogenous inputs of exergy), whereas the high-entropy wastes are returned to the environment.

From a very macroscopic perspective, the output of the economic system—viewed as a materials/exergy converter—can be decomposed into a product of successive conversion stages with corresponding efficiencies, viz.

$$GDP = R \times \frac{IO_1}{R} \times \frac{IO_1}{IO_2} \times \times \quad \ldots \quad \times \frac{GDP}{IO_n},$$
$$= R \times f_1 \times f_2 \times \quad \ldots \quad g \tag{1}$$

where f_1 is the conversion efficiency of the resource (exergy) inflow R into the first-level intermediate product, f_2 is the conversion efficiency to the second-level intermediate product, and so forth. The term g is just the ratio of output to the last intermediate product. The necessary feedbacks are implicitly taken into account in the efficiency definitions.

As a first approximation, it is convenient to assume a two-stage system with a single intermediate product, U. This intermediate product can conveniently be identified as exergy services or useful work. Then,

$$Y = Rfg = Ug, \tag{2}$$

where f is the overall technical efficiency of conversion of "raw" exergy inputs R to useful work output U.

If we define $g = Y/U$ then equation (1) is an identity, not a theory or model. However, the right-hand side of Eq. (1) might be interpreted as an aggregate production function provided that g is a suitable homogenous function of order zero whose arguments are labor L, capital K, and resource (exergy) flows R or useful work U. Effectively, there are two definitions of useful work U to be considered:

$$U_R = f_R R \tag{3a}$$

$$U_E = f_E R \tag{3b}$$

where R is a measure of the total exergy content of all natural resource flows entering the economic system and E is a measure of the commercial fuels (coal, petroleum, and gas as well as hydro power and nuclear heat). The efficiency measures f_R and f_E are defined as total useful work output divided by exergy input. The more general definition f_R takes into account animal work (and biomass inputs), whereas the narrower definition considers only fossil fuels. Multiplying historical resource (exergy) inputs by the estimated efficiencies, and summing over fuels and types, one obtains the results shown in Fig. 1.

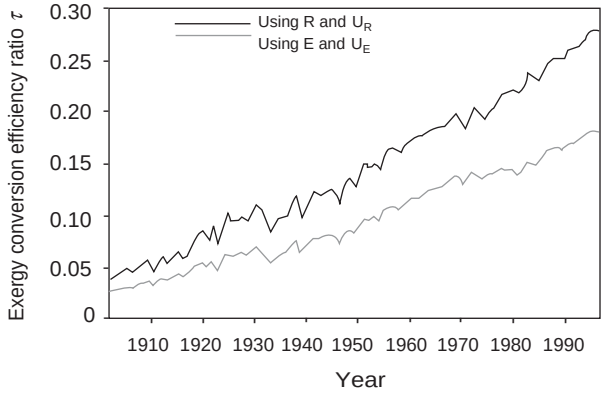

FIGURE 1 Exergy conversion efficiency for two definitions of work and exergy, United States, 1900–1998.

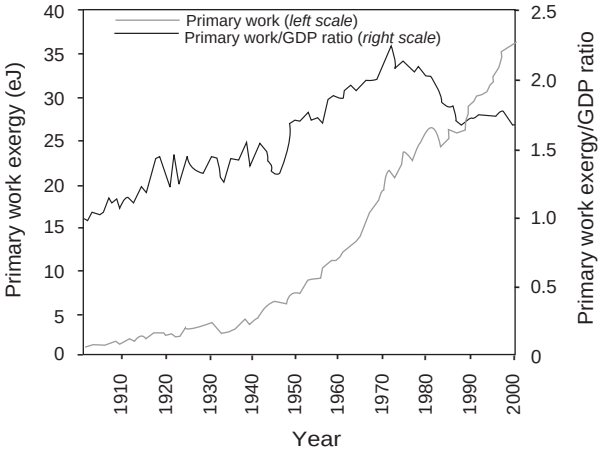

FIGURE 2 Primary work and primary work/GDP ratio, United States, 1900–1998.

The useful work (left axis) and work/GDP ratio (right axis) are also shown for the more general case (f_R) in Fig. 2. The useful work/gross domestic product (GDP) ratio exhibits a pronounced inverted "U" shape, with a clearly defined peak around the time of the Arab oil boycott and the so-called "energy crisis" during 1973–1974.

4. FURTHER IMPLICATIONS OF THE FIRST LAW OF THERMODYNAMICS

The first law of thermodynamics (conservation of mass) implies that mass outputs from any process equal mass inputs. However, useful outputs are almost invariably a fraction of total inputs—sometimes a small fraction (as in the case of refining low-grade ores). In some cases, the output mass is entirely wasted, as with combustion processes. Thus, wastes are an unavoidable by-product of physical production.

On the other hand, the law of mass conservation is far from trivial. The so-called "mass balance principle" states that mass inputs must equal mass outputs for every process (or process step) and that this must be true separately for each chemical element. All resources extracted from the environment must eventually become unwanted wastes and pollutants. Waste emissions are not exceptional phenomena that can be neglected or treated as exceptions. The standard multisector economic model of commodities produced from other commodities is misleading.

It follows, too, that virtually all products are really joint products except that wastes have no positive market value. On the contrary, in most cases, they have a negative value. A producer of wastes will need a "sink" for disposal. Options for free disposal are becoming rarer. Producers must increasingly pay to have waste residuals removed and treated, safely disposed of, or recycled. Therefore, the implication that there exists a price-determined equilibrium between supply and demand (of commodities) must be modified fundamentally.

This means, among other things, that "externalities" (market failures) associated with production and consumption of materials are actually pervasive and that they tend to grow in importance as the economy itself grows. Materials recycling can help (indeed it must), but recycling is energy (exergy) intensive and imperfect (thanks to the second law of thermodynamics), so it cannot fully compensate for a declining natural resource base. Long-term sustainability must depend, to a large extent, on dematerialization and "decoupling" of economic welfare from the natural resource base.

The mass balance condition provides powerful tools for estimating process wastes and losses for industrial processes, or even whole industries, where these cannot be determined directly. Even where other data are available, the mass balance condition offers a means of verification and interpolation to fill in gaps.

The popular notion of perfect recycling (by industrial analogues of decay organisms) with "zero emissions" can be ruled out. It violates the first law of thermodynamics. In fact, the notion that ecosystems are perfect recyclers is false. The biosphere recycles carbon and nitrogen with fairly high efficiency, although coal and petroleum are actually transformed biological wastes. Other elements needed by living systems, including phosphorus, sulfur, calcium, and iron, are not recycled biologically at all. Chalk, iron ores, and phosphate rock all are biological wastes. The ways in which materials are extracted, transformed, and used in the real industrial economy, and the environmental implications, are the substance of the new field of industrial ecology.

5. FURTHER IMPLICATIONS OF THE SECOND LAW OF THERMODYNAMICS

Many economists, as well as most physical scientists, assume that the relationship between economics and the second (entropy) law of thermodynamics concerns resource depletion and scarcity. In this belief. they are, in a sense, disciples of the late Nicolas Georgescu-Roegen, who famously said, "The entropy law is the taproot of economic scarcity" and many other words to that effect. As noted at the beginning of this article, the economy is a system that extracts low-entropy resources from the environment and rejects high-entropy wastes back into the environment. Although solar energy was the original source of fossil fuels that accumulated in the earth's crust during the Carboniferous Era several hundred million years ago, humans are dissipating those resources at a rate thousands or even millions of times faster than the resources were created.

An aspect of the depletion argument concerns recycling. One consequence of the second law of thermodynamics is that recycling can never be 100% efficient. At first sight, this would imply that scarce materials such as platinum must actually disappear from the surface of the earth, and this is not the case.

What is true is that as the quality of the resource base declines toward the average in the earth's crust, the amount of exergy required to extract and reconcentrate it increases to a maximum. In a finite planetary environment, the concentration of a scarce metal can never fall below the average. This means that recycling will become more difficult over time but will never become impossible.

The idea that economic growth must be limited by physical resource scarcity actually has quite a long history. It goes back at least to Thomas Malthus, who saw arable land as the limiting factor. During the 19th century, Jevons worried about future availability of energy from coal. Since 1919, there has been a series of predictions that petroleum reserves are about to run out, with each "crisis" being followed by new discoveries and another glut. Scarcity worries were behind the neo-Malthusian "limits to growth" thesis, propounded during the 1970s by the Club of Rome. However, an authoritative study of minerals published by Resources for the Future strongly indicated that scarcity, as indicated by price, production, and reserve trends, was not yet a problem for any exhaustible mineral resource. A follow-up in 1979 seemed to confirm that result.

The long-running debate between neo-Malthusians (who worry about scarcity) and "cornucopians" (who do not) remains unresolved. It is, in any case, beyond the scope of this article.

Glossary

Boltzmann, Ludwig (1844–1906) Austrian physicist who sought (initially) a purely mechanical reduction of the second law but later argued it was only a statistical truth.

Carnot, Nicolas Léonard Sadi (1796–1832) French military engineer, author of the 1824 "Reflections," which posed the problems (and articulated the core reasoning) that later generated the discipline of thermodynamics.

Clapeyron, Benoit-Pierre Émile (1799–1864) French engineer who published an account of Carnot's theory in 1834.

Clausius, Julius Rudolf Emmanuel (1822–1888) German physicist who created the discipline of thermodynamics by reconciling the core of Carnot's memoir with the energy conservation of Joule, Helmholtz, Mayer, *et al.*

Helmholtz, Hermann von (1821–1894) German physicist/physiologist. One of the main discoverers of energy conservation, notably in his 1847 memoir, "On the Conservation of Force."

Joule, James Prescott (1818–1889) British physicist. One of the main discoverers of energy conservation. He gave it much experimental support in the 1840s.

Maxwell, James Clerk (1831–1879) British physicist. One of several to argue that the second law was only a statistical truth.

Mayer, Julius Robert (1814–1878) German physician. One of the main discoverers of energy conservation.

Rankine, William James Macquorn (1820–1872) Scottish engineer who developed a strange kinetic thermodynamics around 1850. He introduced entropy into thermodynamics but denied dissipation. He made the subject accessible to engineers.

Regnault, Henri Victor (1810–1878) French physicist who, in the mid-19th century, carried out a detailed and authoritative study of the thermal properties of steam and other gases.

Thomson, James (1822–1892) British engineer, brother of William.

Thomson, William, later Baron Kelvin of Largs (1824–1907) British physicist/engineer who took up the Carnot theory in the late 1840s. Later introduced Carnot's dissipation into thermodynamics.

The fact that thermal energy cannot be fully transformed into mechanical work has far-reaching consequences. Thermodynamics is the science that develops these consequences. It emerged in the approximately 30 years that followed Sadi Carnot's amazingly fertile 1824 study of the efficiency of steam engines when the key ideas in that study were reconciled (in the early 1850s) with the principle of energy conservation (as consolidated in the late 1840s). This article is a survey of the thermodynamical thinking of those three decades.

1. THE CARNOT MEMOIR OF 1824

1.1 The Puzzle of Steam Engine Efficiency

In England, around the end of the 18th century there was an extraordinary increase in the efficiency with which coal could be converted into useful work. This was made possible by a series of improvements, both

 © 2004 Elsevier Inc. All rights reserved.

major and minor, in the design of steam engines, the most notable of which were those introduced by James Watt (the separate condenser, double action, and expansive working), together with a growing tendency to use increasingly higher steam pressures. Progress was so rapid—from 1775 to 1825 there was a 10-fold increase in efficiency—that the question came to be asked as to whether the motive power of heat is unbounded, whether the possible improvements in steam engines have an assignable limit—a limit that the nature of things will not allow to be passed by any means whatever—or "whether, on the contrary, these improvements may be carried on indefinitely".

1.2 Carnot's Key Insight: Cold Is Needed to Produce Work

The challenge of answering this question was taken up by a young French Army engineer, Sadi Carnot, who in 1824 published a masterly memoir on the subject, "Reflections on the Motive Power of Heat." In order to produce work by thermal means, Carnot asserted (recalling Watt's separate condenser), it is not sufficient to have a source of heat: It is also necessary to have a "source" of cold—that is, a supply of some substance at a low temperature that can be used to absorb the "exhaust" heat that (he proposed) every thermal engine necessarily produces. He theorized that if the temperature of these two sources is fixed, there is a maximum to the amount of work that may be derived by the extraction of unit quantity of heat from the hot source. This maximum, he indicated, is the amount of work done by any thermal engine working reversibly between the two temperatures in question. Furthermore, Carnot was able to calculate a few rough estimates of his maxima: He could not do more because he lacked the necessary empirical data.

1.3 Water Engines and Reversibility

The reasoning Carnot used to support his conclusions is particularly important in that it was the persuasiveness of his arguments that was later to ensure their survival in the face of experimental evidence that directly contradicted the theory of heat he had used. To appreciate this reasoning, it is helpful to consider the development of the theoretical understanding of water power, a close rival to steam in the 18th century. This century was one of rapid progress in the harnessing of the power of falling water, and some of the designs produced by engineers are astonishing in their sophistication. A good example of this is the so-called column-of-water engine, whose appearance and action are both very similar to those of a high-pressure steam engine and so unlike the crude water wheel we might unreflectingly imagine to be the typical product of the age.

Such an engine (and many other water engines) could be run backwards to act as a pump, and in the ideal situation in which all friction and similar imperfections were absent, the machine would produce exactly as much work in consequence of the descent of a unit of water from its supply reservoir to its exhaust as would be required to pump that same unit of water from the exhaust back to the supply with the engine running backwards. Such could be called a (perfectly) reversible water engine.

Furthermore, no water engine could be more efficient that a reversible one. If another engine were to be capable of producing more work than a reversible one, it could be coupled to a reversible engine, with the latter used as a pump, consuming only part of the work of the former while supplying its total fuel (i.e., water flows). Therefore, the combination would be producing work without making any demands on its environment and without suffering any net internal change. Such perpetual motion, it was concluded in the 18th century, was impossible. So there is a clear limit to the efficiency of a water engine, and this limit depends on the height of the intake and exhaust reservoirs. Furthermore, the limit is the actual amount of work produced by a reversible engine acting over the same drop.

All these theories had been developed by the beginning of the 19th century, and they are important here because what Carnot did to solve his problem was to borrow (and enhance) the reasoning of the water engineers and reapply it to heat engines.

1.4 Heat Conservation and Caloric Theory

There is however one vital precondition that must be satisfied so that the analogy between heat and water engines is complete enough for the arguments evolved for water engines to retain their validity when applied to heat engines: No heat must be consumed during the production of work by heat engines. Just as a water engine works by lowering a fixed quantity of water from a high reservoir to a low one, so too must it be assumed that a heat engine operates by "lowering" an invariable quantity of heat from a region of high temperature to a region of low temperature. Under

this assumption (now known to be false), one can argue for heat engines just as has already been done for water engines, and the analogy is so close that there is no point in repeating the argument here.

To Carnot, this crucial assumption of heat conservation was a natural one to make and he adopted it explicitly. It was inherent in the caloric theory, then the most widely accepted explanation of the nature of heat and especially favored in France. According to this theory, heat was (or behaved like) an indestructible fluid ("caloric"), whose flows in and out of bodies accounted for their various thermal properties. Therefore, by adopting the caloric theory, and by borrowing the beginnings of a line of reasoning from his predecessors in hydraulic engineering, Carnot was able to devise a remarkably convincing solution to the problem he had set himself—a solution that had some interesting consequences.

It enables one to impose, seemingly a priori, a variety of restrictions on the thermophysical properties of all substances and hence to deduce some of their physical characteristics from a knowledge of apparently quite different ones. The most startling early example of this was the deduction by James Thomson (using Carnot's reasoning approximately 25 years after Carnot had set it down) of the hitherto unsuspected fact that since water expands on freezing, the melting point of ice must decrease as the pressure exerted on it increases. Or else, the Carnot logic demands, a perpetual motion machine is possible. The power of such reasoning was to prove most attractive to some of Carnot's later followers. It eventually became a standard feature of thermodynamics.

1.5 Irreversibility and Dissipation

Furthermore, the Carnot theory implies that whenever heat descends from a region of high temperature to one of low temperature without being used to produce the maximum possible work—whenever heat descends irreversibly (e.g., as it does in simple heat conduction)—there takes place concomitantly some sort of destruction of work capability: The universe is less capable of doing work after the descent than it was before the descent. Irreversibility, in other words, implies permanent waste. Carnot did not stress this consequence of his analysis, but this key thermodynamic idea was taken up by his followers.

At first, followers were few and far between because Carnot's discussion was very abstract and had little in common with the physics and theoretical engineering of his contemporaries. The first person to make something substantial out of it was another French engineer, Clapyeron, who in 1834 published a summary of the original, rephrasing much of the analysis in more mathematical form (including the PV diagrams so common in thermodynamics today). Clapyeron did make one important conceptual addition, however. He supplied something missing from the Carnot memoir—a reversible design for an ideal steam engine. (Despite the context that motivated his study, Carnot had not been able to solve this small riddle.) In any case, through Clapyeron's revision, the theory came to the attention of the young British physicist–engineer William Thomson (later Lord Kelvin) and the German physicist Clausius, both of whom were strongly attracted to it.

2. THOMSON'S EARLY ENTHUSIASM FOR CARNOT (LATE 1840S)

Thomson saw that the Carnot theory could be used to define a temperature scale with the long sought-after property of being independent of the physical characteristics of any narrow class of substances, and he published such a definition of "absolute temperature" in 1847. The principle behind it is simple: Unit temperature interval is defined as that temperature interval through which the reversible descent of unit quantity of heat produces unit quantity of work. Carnot's logic shows that this depends on nothing more than the two temperatures, exactly as required. Furthermore, Thomson, in this and a later paper, systematically extended some of Carnot's rough calculations (using data recently obtained by Regnault) to establish the numerical connection between such an abstract scale and the practical scales in everyday use. (It turned out to be approximate coincidence.) In doing so, Thomson was also able to improve Carnot's estimates so far as to tabulate systematically the quantity of work that unit quantity of heat could produce in descending reversibly from the higher to the lower of any pair of temperatures chosen from the range covered by his data, 0–230°C. A few years later, Thomson was able to verify his brother's prediction (mentioned previously) that the freezing point of water is depressed by pressure, a totally unexpected consequence of Carnot's theory.

It is not difficult to understand why Thomson found the analysis attractive. Apart from the inherent elegance of its reasoning, it (i) led to an effectively complete solution to the problem of evaluating the motive power of heat; (ii) provided a basis for

absolute thermometry; and (iii) showed itself capable of discovering new phenomena, well beyond the imagination of its creator.

3. THE CLASH WITH ENERGY CONSERVATION

Yet it was wrong, as Thomson was slowly and reluctantly forced to admit. His personal mentor was Joule, but Joule was only one of a small group of men (Mayer and Helmholtz were the other principals) who, in the 1840s, gradually persuaded the scientific world to give up the belief that heat was conserved and to replace that axiom with the principle of energy conservation, later known as the first law of thermodynamics. This new doctrine spread remarkably fast, and by 1850 it was widely accepted that heat and work were interconvertible. Thus, heat did not behave at all like the fluid caloric, and this fact utterly undermined Carnot's argumentation. Carnot had been suspicious of the caloric theory in the 1824 memoir but still managed to put it to good use. His posthumous papers show that he soon came to the conclusion that heat could be transformed into work and that he even managed to estimate the conversion factor.

Joule objected to the Carnot theory on two grounds and urged its abandonment. First, it regarded the essence of the process whereby work is generated thermally as descent of heat, whereas Joule saw it as a destruction. Second (and apparently more important for Joule and colleagues), it demanded the annihilation of motive power whenever an irreversible (thermal) process took place. To Joule, the universe was equipped with a fixed quantity of motive power, and no natural process could cause either an increase or a decrease in this total: The most that could happen was that it could alter its form.

Thomson was one of the first to appreciate the force of Joule's evidence, but he could not accept Joule's recommendation to abandon Carnot. Thomson knew that no matter how correct Joule seemed to be, there was still a lot of truth in Carnot's theory. The conflict between these two theories was a paradox for Thomson, and he looked to further experiment to resolve it.

4. CLAUSIUS RESOLVES PART OF THE CLASH (1850)

In fact, the paradox was soluble without further experiment, as Clausius was soon to reveal. In May 1850, he published a major paper, "On the Motive Power of Heat, and on the Laws which Can Be Deduced from It for the Theory of Heat," in which he discovered the new science of thermodynamics by showing "that [Joule *et al.*'s] theorem of the equivalence of heat and work, and Carnot's theorem, are not mutually exclusive, but that, by a small modification of the latter, which does not affect its principal part, they can be brought into accordance."

What was Clausius's approach? Above all, he accepted unequivocally the new energy principle and attempted to salvage as much of the Carnot theory as possible. In fact, he found that he could salvage so much that what was lost might reasonably be described as inessential. In particular, he perceived that although the Carnot theory was correct in demanding a descent of heat when work was produced thermally, it was wrong in assuming nothing but a descent: Clausius saw that in reality both a descent and a destruction took place. Furthermore, Clausius saw that the axiom of heat conservation was not really inherent in Carnot's conclusions but was merely used as a tool to establish them. Clausius realized that if this axiom were replaced by a different one, then new arguments might be devised to justify much the same conclusions as Carnot had deduced from the false premise. Clausius was able to do this, the most important example being his new deduction that a reversible engine is one of maximal efficiency.

Carnot argued that if a reversible engine absorbing heat at one temperature and releasing it at another is not the most efficient of all engines absorbing and releasing heat at the same temperature, then a perpetual motion would be possible. Clausius could only establish that if the reversible engine were not the most efficient, then a heat pump would be theoretically constructible capable of pumping heat from a region of low temperature to a region of high temperature without consuming any mechanical work (later called a perpetual motion of the second type). Such a pump he declared to be impossible because heat "always shows a tendency to equalize temperature differences and therefore to pass from hotter to colder bodies."

The conclusion that the reversible engine is that of greatest efficiency remains unchanged. Only the argument justifying the conclusion has been altered, and even then, the new argument retains the spirit of the old. Carnot's premise that heat is conserved is replaced by the premise just quoted. This is the first published version of what is now called the second law of thermodynamics.

Clausius also showed that his new approach was just as fertile as that of Carnot, and that it led to similar interrelations between the physical characteristics of substances. In particular, Clausius showed that the new theory also requires that the freezing point of water be lowered by pressure or else one of the heat pumps forbidden by the second law would be constructible. The new theory also revealed unsuspected facts: Clausius deduced from it the apparently paradoxical result that saturated steam has a negative specific heat (i.e., as steam expands under conditions of saturation it absorbs heat, whereas its temperature decreases).

5. RANKINE'S VORTEX HYPOTHESIS (1850)

Clausius was not the first to publish the result just mentioned. Three months before Clausius's publication, the Scottish engineer Rankine (later a colleague of William Thomson's at the University of Glasgow) had come to the same conclusion in one of two abstruse papers outlining a complicated mechanical theory of heat. Rankine's papers, read in February 1850, are the very first to base a significant theory of the transformability of heat into work on energy conservation. However, they are not seen as founding the science of thermodynamics because they contain virtually nothing recognizable as phenomenological thermodynamics.

In contrast, they deal with the internal mechanics of a characteristic vortex model of the atom, which Rankine had proposed to explain the thermal and radiant properties of matter. According to this model (later transformed into the Bohr atom), macroscopic matter is imagined as composed of atoms (or molecules; the distinction is irrelevant), assumed for mathematical conveniences to be spherical, with each consisting of a nucleus surrounded by a swirling gas-like atmosphere. Each portion of this subatomic atmosphere rotates in a small circle about the radius connecting it to the nucleus. Centrifugal effects are induced by the swirling, and upon elastic transmission to the exterior of the substance in question and modification by interatomic actions at a distance, they generate the external pressure exerted. Hence, Rankine was able to establish relationships between the external pressure and the kinetic energy of subatomic thermal motions. The latter he regarded as simply the heat "contained" within the substance, and the former is what does external work. Therefore, it is not too difficult to accept that such a model might lead to some sort of theory of the convertibility of heat and work.

5.1 Rankine Introduces the Entropy-Function

It is remarkable that Rankine's vortex hypothesis did not lead to some sort of theory, but (despite its complete and justifiable rejection by modern science) it led to a variety of results identical to the correct thermodynamic ones. Nor did Rankine use his model to provide an alternative derivation of such results after they had been discovered by someone else: He himself used the model to make discoveries. The negative specific heat of saturated stream is one example. Another is Rankine's discovery of the existence of entropy (an achievement often falsely attributed to Clausius). By a devious path (which is ignored here), the vortex theory led Rankine to conclude that many materials will possess a state function, typically $S(P, V)$ satisfying the fundamental equation $dH = T \times dS$, where T is absolute temperature, and dH is the heat absorbed by the material during some infinitesimal change. It can easily be seen from this equation that S is the entropy, although in 1854 Rankine called it the thermodynamic function. He introduced it as some sort of thermodynamical potential (a function that enabled him to perform important calculations) but had absolutely no idea of its connection with Carnot's important notion that irreversible thermal processes were wasteful. He did not realize that dH is only equal to $T \times dS$ for reversible changes and at one point even announced that his thermodynamic function was conserved.

6. THOMSON RECONCILES DISSIPATION WITH ENERGY CONSERVATION

In his 1850 paper, Clausius gave little attention to Carnot's notion of dissipation, but this was soon rescued by William Thomson. Approximately 1 year after Rankine's early papers, and approximately 10 months after Clausius's breakthrough, Thomson published his own solution to the paradox that had previously confronted him in the first of a long series of papers titled "On the Dynamical Theory.…" In essence, Thomson's solution is identical to that of Clausius, although Thomson recognized more clearly than Clausius that a distinct new law had been

discovered: He declared that "it is impossible, by means of inanimate material agency, to derive mechanical effect from any portion of matter by cooling it below the temperature of the coldest of the surrounding objects." (The restriction here reflects Thomson's suspicion that biological processes were exempt from the second law.)

Thomson published quite extensively on the subject during the next few years, concentrating on the rectification of his earlier work on the Carnot theory. He modified the old definition of absolute temperature into that now used today, simply to retain the convenient coincidence with everyday thermometers. Oddly, this purely pragmatic decision had the effect of giving the new scale an absolute zero. (However, such an idea was not surprising since the caloric theory had made it seem quite natural that there be some natural minimum to temperature—when all caloric had been extracted from a body.) This scale was subjected to close scrutiny in the long series of Joule–Thomson experiments, performed to remove doubt about some of the empirical parameters vital to a range of thermodynamic calculations. He also returned to Joule's earlier puzzle of reconciling the losses apparently generated by irreversibility with the conservation asserted by the first law.

In an 1852 paper titled "On a Universal Tendency in Nature to the Dissipation of Energy," Thomson resolved this paradox in much the same way that Clausius had resolved Joule's other dilemma—by simply thinking things through. Energy, Thomson affirmed, is always conserved. However, it shows a spontaneous tendency to transform (or dissipate) itself into forms that are less and less accessible to humanity. Therefore, it is the availability of energy, and not energy itself, that is destroyed by irreversibility. In consequence, added Thomson, the earth is gradually dying and will one day be unfit for human habitation.

In 1865, this idea was finally attached to Rankine's thermodynamic function when Clausius wrote a systematic review of his work of the past 15 years. Clausius had been hoping to find some parameter whose values indicated whether a transformation was allowed by the second law. He was never able to complete this task, but his research had shown that the dissipation noted by Thomson and Carnot had the effect of increasing Rankine's state function. Furthermore, this fact was substantially equivalent to earlier versions of the second law, so Rankine's function clearly captured something very profound. Accordingly, Clausius gave the function a new name, entropy, deliberately adapted (from a Greek word for "transformation") to parallel the word energy. Together, these two magnitudes seemed to summarize the whole of this new branch of physics.

7. INTERPRETING THE SECOND LAW

With these statements articulated, the foundations of the subject were complete. However, an obvious question remained: How were the newly discovered laws of thermodynamics to be understood? With the first law, there was little problem. When heat conservation was abandoned in the 1840s, it was universally taken for granted that heat was simply some form of microscopic motion. Such an idea had been around since the 17th century, and its competitor was now eliminated. Thus, the new account was referred to as the dynamical theory of heat (or "thermodynamics" in condensed form). However, it was well-known that mechanical energy was conserved in many dynamical systems, most notably those that were isolated and whose internal forces were conservative. Helmholtz had made much of this fact in his 1847 case for energy conservation.

Dynamics, however, provides no obvious clue to the second law. It is true that Rankine had seemed to derive the entropy dynamically, but he had totally ignored dissipation. In any case, his account remained tied to the details of a very speculative hypothesis about the microstructure of matter. Despite Rankine's later attempts to generalize the theory, none of his contemporaries saw Rankine as providing acceptable foundations for the new subject (although Rankine's famous textbooks distilled the subject for application by engineers). For a while, it seemed (especially to Clausius and Boltzmann in the late 1860s and early 1870s) that there might be some complicated dynamical function that tended to increase with time, but a potent objection was raised against this proposal. Conservative dynamical systems appear to be completely reversible: If a dynamical function increases during some change of state, it will have to decrease when that state change is reversed. Therefore, no purely mechanical function can always increase. In the end, it was concluded that the second law is purely statistical. As Maxwell stated, "The second law of thermodynamics has the same degree of truth as the statement that if you throw a tumblerful of water into the sea, you cannot get the same tumblerful of water out again." His "demon" was introduced (in correspondence, in the late 1860s)

to defend this view: It was a microscopic intelligence apparently capable of circumventing the second law by separating the faster molecules in a gas from the slower ones. However, this made it seem that thermal motions were not intrinsically random, just beyond human manipulation. Later, a more profoundly stochastic interpretation was adopted.

8. THE PHENOMENOLOGICAL STYLE OF THERMODYNAMICS

To pursue this question further would take us into other branches of physics, kinetic theory, and statistical mechanics because thermodynamics traditionally avoids dealing with the microstructure of matter and focuses primarily on data at the level of everyday human experience—pressures, volumes, temperatures, etc. Such a restriction was quite natural in the Carnot memoir because the subject matter did not demand any microanalysis. However, in 1850, the situation was quite different. The focus was no longer on steam engines but on energy, and both Clausius and Rankine made vital reference to the microscopic energy flows that everyone believed were occurring. However, insofar as they did this, their research was speculative. When Thomson later prepared his own version of the theory, he purged his account of all such speculation. This was not because Thomson had any methodological doubts about discussing the microworld envisioned by Clausius. Thomson's decision was purely pragmatic. He was, after all, not the pioneer here—he was rephrasing the work of the other two—and he saw that it was possible to solve the paradoxes articulated by Joule without so much reference to doubtful detail. Since it was possible to eliminate a source of uncertainty by avoiding the microdynamics, he did it (and did it well). Since then, the practice has remained.

Glossary

emergy The amount of exergy of one form (usually solar) that is directly or indirectly required to provide a given flow or storage of exergy or matter. In so doing, inputs to a process are measured in common units. Solar emergy is measured in solar emergy joules (seJ). Emergy is a memory of the available energy (exergy) previously used up in a process and measures the global support from the biosphere to a process. Converting flows of different nature into flows of one kind requires conversion coefficients called transformities (seJ/J). Emergy accounting acknowledges that different resources, measured by their exergy content, may require a different environmental support and may show different properties.

energy Usually defined as the capacity for doing mechanical work (i.e., displacing an object from a position to another by means of the application of a force). This definition is sometimes criticized for being reductive and not always easily applicable to processes other than physical. A broader definition is "the ability to drive a system transformation," which clearly includes all kinds of physical and biological processes.

exergy The amount of work obtainable when some matter is brought to a state of thermodynamic equilibrium with the common components of the natural surroundings by means of reversible processes, involving interaction only with the previously mentioned components of nature. Exergy is measured in joules or kilocalories. Real processes are irreversible. Therefore, measures of actual work compared with theoretical value provide indicators of exergy losses due to the irreversibility of a process. In addition to being a measure of what can be in principle obtained from a resource, exergy also provides a thermodynamic assessment of potential improvements at the scale of the investigated process.

power The amount of energy transferred or work performed in the unit time (usually in 1 s).

reversible/irreversible A reversible change in a process is a change that can be reversed by an infinitesimal modification of any driving force acting on the system. The key word "infinitesimal" sharpens the everyday meaning of the word "reversible" as something that can change direction. In other words, the state of the system should always be infinitesimally close to the equilibrium state and the process be described as a succession of quasi-equilibrium states. A system is in equilibrium with its surroundings if an infinitesimal change in the conditions in opposite directions results in opposite changes in its state. It can be proved that a system does maximum work when it is working reversibly. Real processes are irreversible; therefore, there is always a loss of available energy due to chemical and physical irreversibilities.

self-organization All systems in nature self-organize—that is, use the available energy and matter inputs to achieve higher levels of structure and functioning under natural selection constraints. In so doing, they may maintain their present level of complexity or become increasingly more complex.

work The transfer of energy occurring when a force is applied to a body that is moving in such a way that the force has a component in the direction of the body motion. It is equal to the line integral of the force over the path taken by the body, $\int \mathbf{F} \times d\mathbf{s}$. Its meaning is different from the usual life work, often associated with activities not always involving visible motion. Physical work requires a body motion under the action of the force.

Thermodynamics, the so-called queen of sciences, is important because it is the physical science that accounts for the transformations of thermal energy (heat) into mechanical energy and its equivalent forms (work, other forms of energy, and self-organization of complex systems) and vice versa.

 © 2004 Elsevier Inc. All rights reserved.

All phenomena and processes that happen on Earth as well as in the universe belong to the realm of this science. Although it was relatively easy to investigate the dynamics of equilibrium systems and generate a set of laws describing the tendency of systems toward equilibrium by means of ideal reversible processes (classical thermodynamics), irreversible processes dealing with nonequilibrium systems (including self-organization of the biosphere and life processes) are not fully described within a consistent theoretical framework, but significant progress has been made (nonequilibrium thermodynamics). This article provides a historical outline of the development of thermodynamics, with reference to some of the main scientists who contributed to its development. It then provides a short description and explanation of the laws of thermodynamics, including the mathematical derivation of their main features and consequences. Finally, a series of tentative "fourth laws of thermodynamics" are discussed in order to provide a picture of the current efforts of the scientific community toward a thermodynamic description of self-organization patterns of complex and living systems.

1. INTRODUCTION

Classical thermodynamics was founded between 1850 and 1860 by W. Thomson (Lord Kelvin), R. Clausius, and J. C. Maxwell, building on the seminal work of Lazare Sadi Carnot, "Réflexions sur la Puissance Motrice du feu et sur les Machines Propres à Developper cette Puissance" (1824). They went beyond the theory of caloric that dominated the early studies about heat and its nature between 1700 and 1800 thanks to the experimental results of R. Mayer and J. P. Joule. These authors had achieved a numerical value for the quantitative equivalence between mechanical work and heat. Hence, any reason for the supposed existence of an immaterial substance called "caloric" was experimentally rejected. The findings of Mayer and Joule were also the basis for the future statements of the first law (conservation of energy).

It is worth noting that the investigation of thermal engines and the limits to the conversion of heat to mechanical work (Carnot, second law) preceded the statement of the first law of thermodynamics. This is because heat conversion to mechanical work (steam engine; second half of the 18th century) generated attention first to the existing constraints and then a clear understanding of the nature of heat and a quantitative equivalence between heat and mechanical work (mid-19th century).

In the following years, Clausius provided Carnot's "Réflexions" with a stronger mathematical basis and introduced the concept of entropy, S, developing a clear statement of the second law (1864). The entropy concept is perhaps the most complex one in physical science. It was gradually assigned many meanings belonging not only to thermodynamics but also to a variety of other fields and disciplines (e.g., information theory). A further definition of the entropy concept came from L. Boltzmann in the second half of the 19th century by means of the so-called H-theorem, in which the statistical meaning of entropy was definitely assessed. According to this theorem, any macroscopic thermodynamic state of a system—defined by measurable pressure P, volume V, and temperature T—can be generated by N microscopic behaviors of the system's molecules or microstates. Then the probability of the macrostate is proportional to N, and Boltzmann concluded that the most probable macrostate was the equilibrium state, to which the maximum number of microstates can be associated. As a consequence, the entropy of such an equilibrium state should also be a maximum, due to the Boltzmann formula

$$S = k \times \log N,$$

where k is the so-called Boltzmann constant. Any thermodynamic system tends to its equilibrium state, defined by certain state parameters P, V, and T, in an irreversible way. According to Boltzmann, we can state that this irreversibility is of statistical nature. In other words, the equilibrium state with maximum entropy is the most probable state, although a system's shift to a lower entropy state cannot be a priori excluded (with an extremely low probability).

At the beginning of the 20th century, a rich debate took place about reversibility (or symmetry with respect to time) in classical mechanics and irreversibility in thermodynamics. Fundamental contributions were given by Caratheodory, Ehrenfest, Hilbert, and Nerst. The latter proposed a third law of thermodynamics, characterized by the concept of absolute entropy (1906). He postulated that $S = 0$ for any system at $T = 0$ (where T is absolute temperature). This made possible the definition of a scale of positive absolute entropies, based on which the differences of entropy between two states could be calculated.

During the 20th century, a great number of authors applied the laws of thermodynamics to

problems different than heat-to-work conversion, such as the self-organization and growth of complex, far from equilibrium systems (biological, economic, and social). Authors such as Onsager, Prigogine, Georgescu-Roegen, Lotka, and Odum contributed to this debate and several statements of thermodynamics laws were tentatively reformulated or introduced anew.

2. THE PRINCIPLE OF EQUIVALENCE

Energy is usually referred to as the ability to do mechanical work, *W*. The latter is defined without ambiguity as the scalar product of two vectors, the force **F** and the displacement **s**:

$$W = \mathbf{F} \times \mathrm{s} = Fs\cos\theta, \qquad (1)$$

where F and s are the intensities of force and displacement vectors, respectively, and θ is the angle between them. Work, and therefore energy, can be experimentally measured (with units of Joule in the International System of Units).

Today, the link between work and energy (and the link between energy and heat) appears to be clearly assessed and quantifiable, but this was not so clear to the earlier scientists who investigated the nature of heat. Many experiments or phenomena demonstrate that some heat is generated whenever mechanical energy is used up or lost. Moreover, we know that heat can produce mechanical work, as a steam engine demostrates. Thus, we can argue that heat is some form of energy. However, the perception alone is not sufficient in physics. A quantitative and experimentally measurable equivalence between heat and work is needed. Many experiments were performed during the mid-19th century and successively by J. P. Joule and other researchers that were aimed at measuring the ratio between work (W) and heat (Q) when a system undergoes a cyclical process or when its final state coincides with its initial state.

In this regard, the most classic experiment is the so-called Joule's wheel. The original Joule's scheme of the experiment is shown in Fig. 1. The system consists of a liquid in a vessel, which is in turn contained in a calorimeter in order to measure the heat released or absorbed by the liquid. A paddle wheel is dipped into the liquid. The fall of a weight connected to the wheel via a system of pulleys makes it rotate so that some mechanical work is performed on the liquid. In 1845, Joule described the experiment to readers of the *Philosophical Magazine* as follows:

> *The paddle moved with great resistance in the can of water, so that the weights (each of four pounds) descended at the slow rate of about 1 foot per second. The height of the pulleys from the ground was 12 yards, and consequently, when the weights had descended through that distance, they had to be wound up again in order to renew the motion of the paddle. After this operation had been repeated 16 times, the increase of the temperature of the water was ascertained by means of a very sensible and accurate thermometer.*

The water, initially at a temperature T_A, warms by friction to a final temperature T_B. The mechanical work performed on the liquid is measured by the work done by the force of gravity when the weight falls by a height h ($W = mgh$, where m is the mass of the weight, g is gravity, $9.8\,\mathrm{m/s^2}$), assuming the pulley's friction to be negligible. The calorimeter measures the heat generated within the liquid during the process and then released by the liquid when it cools down to its initial temperature T_A. Joule and other researchers performed similar experiments using different liquids. Joule found a W/Q ratio equal to 4.18 J/cal using water and 4.16 J/cal using mercury. Hirn measured the W/Q ratio in a steam engine. In this case, Q was the measurable difference between the heat provided by the steam boiler and the heat released to the condenser after performing the work W. Hirn found a ratio equal to 4.05 J/cal. Joule concluded,

> *Any of your readers who are so fortunate as to reside amid the romantic scenery of Wales or Scotland could, I doubt not, confirm my experiments by trying the temperature of the water at the top and at the bottom of a cascade. If my views be correct, a fall of 817 feet will course generate 1 degree of heat, and the temperature of the river Niagara will be raised about one-fifth of a degree by its fall of 160 feet.*

A different experiment can be made by rotating an appropriately shaped iron bar within a strong magnetic field. The electric currents induced within the bar warm the iron by a measurable amount Q. In order to rotate the bar against the mechanical resistance of the magnetic force of Lorentz due to the induced currents a measurable amount of work is needed. In this case, a similar W/Q ratio can be found.

In summary, when a system undergoes a cyclical process in which a measurable amount of work W is converted into a measurable heat Q or vice versa, we obtain a ratio W/Q, which is usually determined as 4.186 J/cal, apart from random experimental errors. This result constitutes the so-called principle of equivalence between heat and mechanical work.

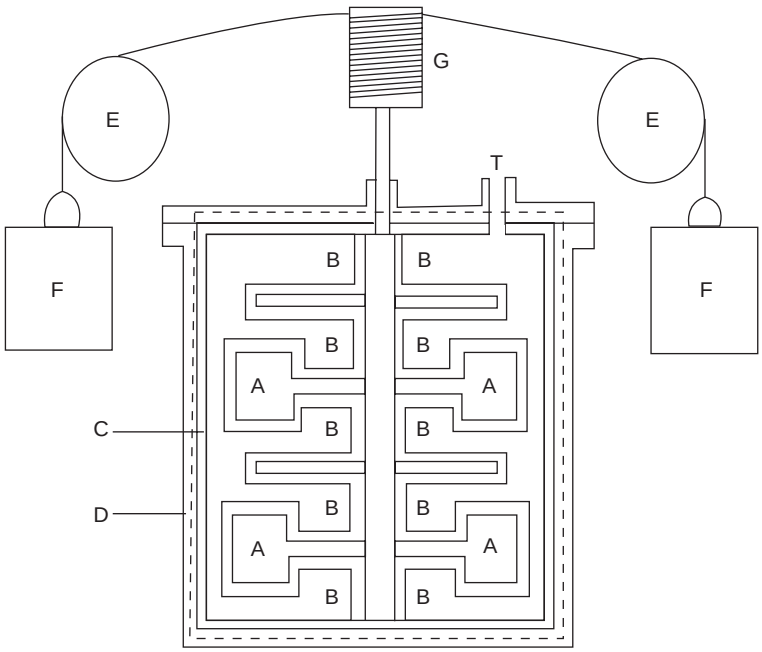

FIGURE 1 Joule's paddle wheel experiment. A, revolving blades; B, stationary vanes; C, metal framework; D, copper jacket; E, pulleys; F, weights; G, drum; T, hole for thermometer. From Beattle, J. A., and Oppenheim, I. (1979). "Principles of Thermodynamics." Elsevier, New York [originally published in *Philos. Trans. R. Soc. London* **140,** 61–82, 1840].

The ratio

$$J = W/Q = 4.186\,\mathrm{J/cal} \qquad (2)$$

is known as the mechanical equivalent of heat.

3. THE ZEROTH LAW OF THERMODYNAMICS

When two bodies are placed in thermal contact, heat flows from one to another in some cases (i.e., from the hotter to the colder one). Heat will keep flowing for awhile, but sooner or later the heat flow will stop and a thermal equilibrium (the absence of heat flows) occurs. We may make an apparently trivial statement about thermal equilibrium:

Zeroth law: If a body A is in thermal equilibrium with a body B and if B is also in thermal equilibrium with a third body C, then A is in thermal equilibrium with C.

This law justifies the concept of temperature. Suppose that B is a thermometer. If B is used to measure the temperature of A and C and if A and C are found to have the same temperature, the heat will not flow if A and C are placed in thermal contact.

4. THE FIRST LAW OF THERMODYNAMICS

The equivalence principle is the basis of the first law of thermodynamics. This law states the general principle of energy conservation when thermal processes are also accounted for. It can be formulated by stating that the energy variation ΔU of a system in a process is equal to the total energy exchange of the system with the surrounding environment. As a consequence, we can also state that the energy of an isolated system remains constant.

We have seen that in a cyclical process the involved W and Q are energetically equivalent by simply taking into account that $1\,\mathrm{cal} = 4.186\,\mathrm{J}$. Hence, we can use the same unit (Joule or calorie) to measure mechanical work and heat. In what follows, we write equalities involving W and Q without specifying the unit. We also consider $W > 0$ if work is done by the system to the environment and $W < 0$ if the opposite is true; similarly, $Q > 0$ if heat is received by the system and $Q < 0$ if heat is released. This is because historically the steam engine received heat (positive) from the environment and performed work (positive) on the environment.

Now consider a system, for example, the liquid in the vessel of Joule's wheel. We can warm the liquid from the temperature T_A to the temperature T_B by

supplying mechanical work ($-W$, according to the previous sign rule), by supplying heat from an external source ($+Q$), or by a combination of the two ($Q_i - W_i$). If we perform experiments in which W and Q assume variable values, expressed by the same unit, we always have

$$-W = Q = Q_i - W_i = \text{constant}, \tag{3}$$

where Q_i and W_i are the quantities involved in the ith experiment. That the same temperature increase can be achieved by supplying work ($-W$), heat (Q), or a combination of both ($Q_i - W_i$) and that this quantity is always the same is a very important result. In fact, it shows that if a system undergoes a process from a state A to a state B, the employed energy (mechanical and/or thermal) is the same independent of the way in which the system goes from A to B. As a consequence, it is possible to associate with each state of a system an energy value U, which is only a function of the state and the variables (pressure, volume, temperature, and concentration) that characterize the state.

This energy of the state or internal energy, U, can be viewed as the sum of the mechanical, electrical, chemical, etc. energies of all the particles that constitute the system and whose amount cannot be quantified in absolute value because it is reference dependent. Since the goal of energy conversion is the work obtainable when the system goes from A to B, absolute values are not of interest to us; instead, we are interested in gradients (i.e., the difference between the value assigned to state A and the value assigned to state B):

$$\Delta U = U_B - U_A. \tag{4}$$

In this case, the internal variation ΔU must equate the exchange of mechanical and/or thermal energy between the system and the environment, $Q - W$:

$$\Delta U = U_B - U_A = Q - W. \tag{5}$$

This is the mathematical statement of the first law of thermodynamics. In words, the energy variation of a system that undergoes a process from the state A to the state B is equal to the energy that the system exchanges with the environment and it is not dependent on the way by which the system goes from A to B. Therefore, given two states A and B, $\Delta U = U_B - U_A$ is the same, whereas Q and W may vary in such a way that $Q - W = \text{constant} = \Delta U$.

It was previously noted that the first law expresses the general principle of conservation of energy when we include thermal energy. For $Q - W = 0$ (cyclical process), we obtain the equivalence principle as a particular case of the first law.

The general principle of conservation of energy also means that a machine cannot do work without any input of heat or other energy. Such a machine, which would create energy from nothing, is called a perpetual motion machine of the first kind. Thus, another equivalent formulation of the first law is the following: It is impossible to construct a perpetual motion machine of the first kind.

If the process is infinitesimal or if the final state B is infinitely close to A, the first law of thermodynamics is expressed in differential form:

$$dU = \delta Q - \delta W, \tag{6}$$

where dU is the energy difference independent of the particular process, and the involved δQ and δW may vary with the process leading from A to B. It should be observed that dU, unlike δQ and δW, is an exact differential because it is not path dependent. Hereafter exact differentials are indicated with d and path differentials with δ.

An important and frequently met system is constituted by a fluid or gas (hereafter an ideal gas, for the sake of simplicity) contained in a cylinder of section S, within which a frictionless piston can run (Fig. 2). In this case, the external force F acting on the fluid (also including the weight of the piston, if appropriate) is, by definition of pressure,

$$F = p \times S, \tag{7}$$

where p is the external pressure. Hence, the work performed by gas or by the environment ($ds > 0$ or $ds < 0$) is calculated as the product of the force F multiplied by the infinitesimal displacement, ds,

$$\delta W = p \times S ds \tag{8}$$

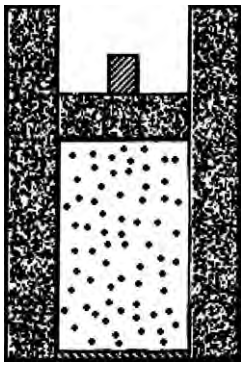

FIGURE 2 A thermodynamic fluid within a frictionless cylinder–piston system.

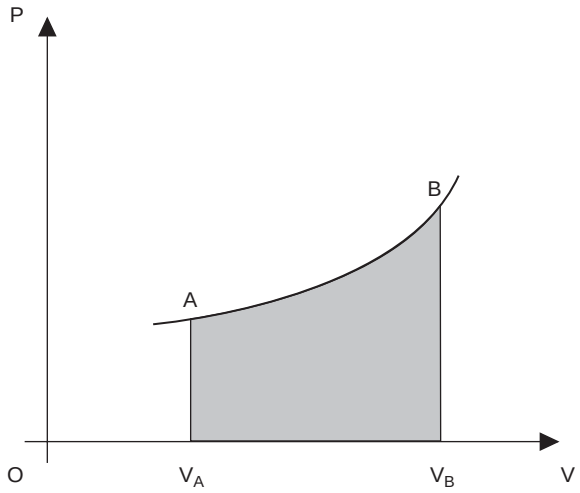

FIGURE 3 Work performed by a fluid expanding against an external force *F*. Work is indicated by the shaded area.

or as $\delta W = p \times dV$, where $S \times ds$ is the infinitesimal variation of volume dV. For a finite variation, the work is calculated as an integral between the two states

$$W = \int_{V_A}^{V_B} p \times dV \qquad (9)$$

and clearly depends on the particular process leading from A to B. This is represented by the shaded area in Fig. 3.

5. THE SECOND LAW OF THERMODYNAMICS

The equivalence principle and the first law do not deal with the problem of the possibility of transforming heat into mechanical work or vice versa. The equivalence principle only states that when this transformation takes place, the W/Q ratio must be 4.186 J/cal. In other words, on the basis of these statements only, thermal and mechanical energies should be perfectly equivalent not only from the quantitative standpoint but also from the qualitative one.

Experiments show that although it is always possible to completely transform mechanical energy into thermal energy (e.g., by friction), the opposite is not true. The transition from mechanical work to heat occurs without any restriction, but a heavy constraint is imposed on the opposite transition, namely

1. Not all the heat that a system receives from a reservoir is converted into mechanical work, but a fraction remains as heat at lower temperature.

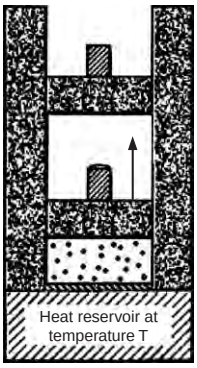

FIGURE 4 A fluid expansion within a cylinder–piston system, from volume V_1 to volume V_2. Due to the finite length of the cylinder, the fluid cannot expand forever but must be compressed for the cycle to start again.

2. If all heat were converted into mechanical work, the latter would not be the unique final result, in such a way that this work would be unusable.

The fluid contained in a frictionless cylinder–piston system connected to a heat reservoir at temperature T is an appropriate example of statement 2 (Fig. 4). If we warm the fluid and make it expand, the heat is converted into work but this is not the unique result. In fact, increased volume of the fluid is also a result. Unless the cylinder is infinitely long, we have to compress the fluid again for the system to be usable. In so doing, the work performed on the system would be greater than the work performed by the system.

On the basis of these considerations, Carnot proposed an ideal engine connected to two heat reservoirs at temperatures T_1 and T_2 ($T_1 > T_2$). The reservoir at a lower temperature serves to cool the fluid in such a way that it can return to its initial volume. Carnot showed that not all the heat can be converted into mechanical work, but a fraction is always released in the form of degraded heat at lower temperature. This result is an example of statement 1 given previously.

5.1 Reversible Transformations and Machines

It would be a mistake to think that the limits imposed by the conversion of heat to mechanical work are of a technical nature (i.e., are due to the unavailability of tools or cylinders and pistons without friction or perfectly sealed). In order to eliminate this possible misunderstanding, in the rest of this article we refer to reversible transformations and reversible machines. In these ideal transformations and machines,

it is assumed that all technical energy losses (friction, inadequate materials, etc.) have been removed. Even in this case, the impossibility of integral conversion of heat to work as a unique result is demonstrated. This means that this impossibility relies on the theory; it is a constraint imposed by Nature and not by the use of technically poor instruments.

Reversible transformations and machines were introduced to help describe real (irreversible) transformations and machines because the latter cannot be easily investigated. In fact, for the expansion or compression of a real fluid within a real cylinder–piston system, we are hardly able to assess the value of volume, pressure, and temperature in any instant of the process. Moreover, the cylinder wall will never be perfectly thermally insulated, nor will we know the exact value of its thermal conductivity coefficient. The reversibility assumption implies that the system (initially in A) can reach the final state B by means of infinitely slow transformations, in which infinitely small forces act on the fluid. In so doing, it is in principle possible to determine the exact value of its state variables in every instant. Moreover, we assume that (i) the piston runs within the cylinder with no friction and is perfectly sealed, (ii) the side walls of the cylinder are perfectly heat insulated, and (iii) the cylinder base is a perfect heat conductor. In other words, machines and containers used in a reversible process are absolutely ideal ones, as is the process. The fluid transformation from A to B can therefore be thought of as a succession of equilibrium states so that the direction of the process can be inverted in any instant by means of an infinitely small force applied against it. This is why such a transformation is called reversible and is indeed a powerful tool to investigate the relation among the parameters that describe the initial and final states of the fluid. It is clear that a reversible transformation can be exactly described, for instance, in a (V, P) plane by drawing the curve $P = P(V)$ as the succession of all the equilibrium states existing between A and B (Fig. 5).

On the other hand, it would be impossible to draw a curve describing a real transformation between the same states because of the existing indeterminacy of the actual values of pressure and volume in any given instant of the process. In such a case, the curve is not exactly defined (Fig. 6).

Reversible transformations are sometimes considered the final limit approached by the behavior of real transformations, when the latter occur so slowly that the time needed is a good approximation of the theoretically infinite time required by the corresponding reversible transformation.

Finally, it is worth noting that reversible transformations cannot occur in isolated systems (i.e., in thermodynamic systems that do not exchange any energy or matter flow with the outside) because the existing gradient that pushes the transformation toward one direction cannot be inverted unless an external force is available. In the latter case, the system would no longer be isolated.

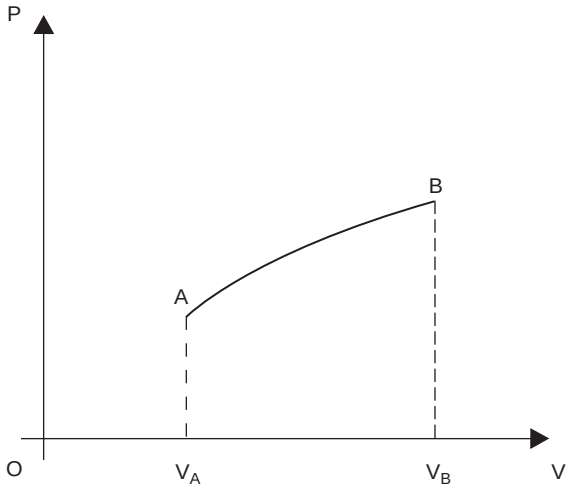

FIGURE 5 A reversible transformation is exactly described in a (V, P) plane by the curve $P = P(V)$ drawn as the succession of all the equilibrium states existing between *A* and *B*.

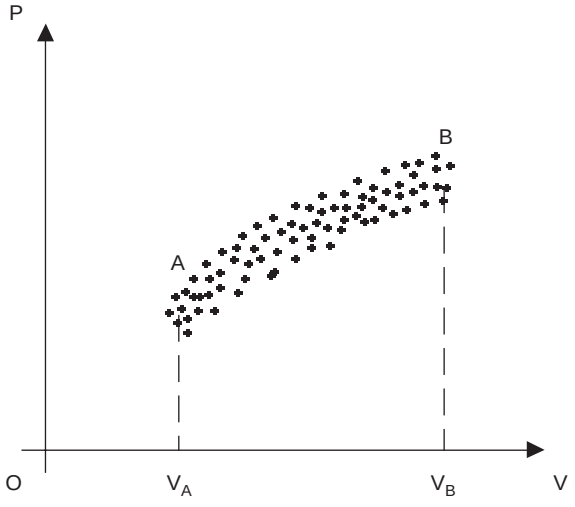

FIGURE 6 Irreversible transformations cannot be described as a succession of equilibrium states due to the existing indeterminacy about the actual values of pressure and volume in any given instant of the process. In such a case, the curve is not exactly defined.

5.2 Lord Kelvin's and Clausius's Statements of the Second Law

The observed lack of symmetry of work-to-heat transformations and vice versa is equivalent to a substantial irreversibility of real processes that cannot therefore be of a purely mechanic nature. This is the basis of the second law of thermodynamics, which can be exemplified by means of typically irreversible phenomena, such as a gas expansion (the gas will never spontaneously return to its initial volume) or the heat transfer from a body at higher temperature to a body at lower temperature (the heat will never flow spontaneously from the colder to the warmer body).

Lord Kelvin ("Dynamic Theory of Heat," 1850) pointed out the impossibility of an integral conversion of heat to work (in which work was the unique result) as the appropriate statement of the second law of thermodynamics. The following is Lord Kelvin's statement: A transformation the unique result of which is the conversion of heat from a heat source at a temperature T to mechanical (or electromagnetic) energy is impossible. The heat source at temperature T is defined as a body every point of which is at a temperature T and whose thermal capacity is so high that it can absorb heat from or release heat to other bodies without undergoing any temperature change. It is, again, an ideal object, whose approximation in real processes can be a very large boiler.

The most important part of Lord Kelvin's statement, as noted in Section 5.1, is the requirement of work as the unique result. The fluid described in that section undergoes a reversible and isothermal ($\Delta T = 0$) expansion. Its internal energy does not change because the internal energy of ideal fluids only depends on the temperature ($\Delta U = 0$). As a consequence of the first law of thermodynamics, we have $W = Q$. As already noted, the achieved conversion of heat to work is not the unique result because the volume increase makes this (although ideal) machine unable to actually deliver work. In this regard, it must be observed that the first law precludes the possibility of creating energy (perpetual motion of the first kind), while Lord Kelvin's statement of the second law precludes the possibility of the so-called perpetual motion of the second kind: It is impossible to construct a perpetual motion machine of the second kind. A perpetual motion machine of the second kind would convert heat taken from some reservoir into an equivalent amount of work. It does not violate the first law because the work energy is equivalent to the heat energy. It is this impossibility that precludes the exploitation of enormous heat sources such as the oceans to generate mechanical energy. In fact, should a ship be able to convert the ocean's heat into work for its own motion as the unique result, thus skipping Lord Kelvin's statement, this work would again be converted into heat due to the friction between the ship and the water. In so doing, the thermodynamic cycle would be closed and the ship would travel practically at no energy cost (i.e., the perpetual motion of the second kind).

The impossibility not just to make real machines, but also to even design ideal machines capable of completely converting a source heat into mechanical work as a unique result suggested to Lord Kelvin his second law statement. If only one experiment, real or even ideal, could be performed against Kelvin's statement, the second law would completely lose its significance and applicability.

Another typically irreversible phenomenon could be used to derive an alternative statement of the second law, namely the heat transfer from a body A at higher temperature T_A to a body B at lower temperature T_B. Clausius used this phenomenon to illustrate his statement of the second law while at the same time developing a mathematical formulation of it and introducing the entropy concept. For this to be correctly enunciated and understood, we must first note that an empirical temperature scale can be defined based on the direction of heat exchanges between two bodies when they are put in contact with each other. Independently from their heat capacity, body A is defined as having a higher temperature than B if, when they come into contact, some heat flows from A to B. This statement is equivalent to saying that heat flows spontaneously from a body at higher temperature to a body at lower temperature until a thermal equilibrium (same temperature) is reached. A clear example can be given by considering a small piece of iron heated to "white heat" temperature (approximately 1000°C) and a vessel containing a large amount of boiling water (100°C). Although the former contains a much smaller amount of heat than the latter, its temperature is higher. Therefore, if we dip the iron into the boiling water some heat will flow from the iron to the water (i.e., from the body at higher to the body at lower temperature) until an equilibrium is reached and the iron recovers its original gray color and solid state (this is what blacksmiths do to forge products, although they use colder water for faster results).

Therefore, the following is Clausius's statement of the second law: If heat spontaneously flows from a

body A to a body B (i.e., if A has a higher temperature than B), it is impossible to perform a transformation process the unique final result of which is a flow of heat from B to A (i.e., from the body at lower temperature to the body at higher temperature).

This statement was also suggested by the failure of all real and ideal processes to achieve the unique result of heating warmer bodies by means of colder bodies. Again, if only one experiment could be found against Clausius's statement, the second law would lose its validity. It is trivial to observe that a refrigerator does not contravene Clausius's statement. In fact, although heat flows from inside the refrigerator to the outside environment (the latter at higher temperature), this occurs at the expense of electric work and therefore is not the unique final result.

Kelvin's and Clausius's statements are equivalent, as expected. If the first one is false, the second one is also false and vice versa. Assume Kelvin's statement is false and that heat from a source at temperature T_1 can be entirely converted into work as the unique result of a process. We could therefore, by carefully designing the process, convert again this work into heat at any temperature, even higher than T_1. If so, we would obtain a process the unique result of which would be a flow of heat from a source at temperature T_1 to a body at temperature T_2, higher than T_1. As a consequence, Clausius's statement would also be false. The opposite case (if Clausius's statement is false, then Kelvin's statement is also false) will be demonstrated after discussing Carnot's cycle and theorem.

5.3 Carnot's Cycle

In his seminal "Réflexions" (1824), Carnot dealt with the problem of heat-to-work conversion by means of ideal machines in which a thermodynamic fluid was capable of performing reversible transformations, receiving heat from a source at higher temperature, and releasing heat to a sink at lower temperature. He demonstrated that the heat received from the source cannot be entirely converted into work and that the nonconverted fraction is released as heat at lower temperature, thus being depreciated from the standpoint of its ability to perform work. This conclusion translates into the fact that the efficiency of such an ideal machine is much lower that 100% (i.e., the work produced is much less than the heat supplied).

Carnot's findings constitute an early statement of the second law of thermodynamics, for a long time not completely understood in its full significance. It can be demonstrated that it is completely equivalent to those provided by Kelvin and Clausius approximately 30 years later. It can also be demonstrated that the efficiency of any real machine is lower than that of the ideal Carnot's machine.

For this purpose, assume we have an ideal Carnot's machine composed of an ideal thermodynamic fluid within a cylinder–piston system, without friction, and with the lateral walls being perfectly insulated and cylinder base being a perfect heat conductor. Figure 7A shows the different positions of the piston within the cylinder over time, whereas Fig. 7B diagrams the isothermal and adiabatic reversible patterns that the fluid must follow during the process in order to close the cycle (Carnot's cycle).

In Fig. 7A, a heat source (a boiler) at temperature T_1 supplies heat Q_1 to the fluid through the base of the cylinder. Since the piston is free to run through the cylinder, the fluid undergoes a reversible and isothermal expansion from the initial volume V_1 to a volume V_2, according to the equation $PV = nRT$ (the so-called ideal gas equation of state). A thermal insulation is then provided to the base of the cylinder and the fluid is allowed to further expand reversibly and adiabatically (no heat exchange with the outside environment) to a new volume V_3, according to the equation $PV^{\gamma} = K$ (applicable to adiabatic processes; $\gamma = C_p/C_v$, where C_p and C_v are respectively the heat capacities at constant pressure and volume, and the constant K depends on initial conditions). In this step, the fluid temperature decreases from T_1 to T_2. Now we remove the thermal insulation of the base and put the cylinder on a heat sink (a body at lower temperature than that of the heat source) at temperature T_2. If we compress the fluid (i.e., some work is performed on it), its volume V_3 will decrease reversibly and isothermally to the volume V_4, releasing a heat Q_2 to the heat sink. Finally, if we insulate the base again and compress the fluid reversibly and adiabatically until it reaches the initial volume V_1, pressure P_1, and temperature T_1, the cycle is closed and the initial state is restored. From an energy standpoint, it is $\Delta U = 0$ because the system is again in its initial state. The heat supplied to the system is Q_1, whereas the work performed over the whole cycle is

$$W = Q_1 - Q_2 \tag{10}$$

according to the first law of thermodynamics. The heat Q_2 released to the heat sink cannot be transferred again to the boiler because the latter has a temperature higher than that of the heat sink. Therefore, Q_2 is definitely unusable. The machine

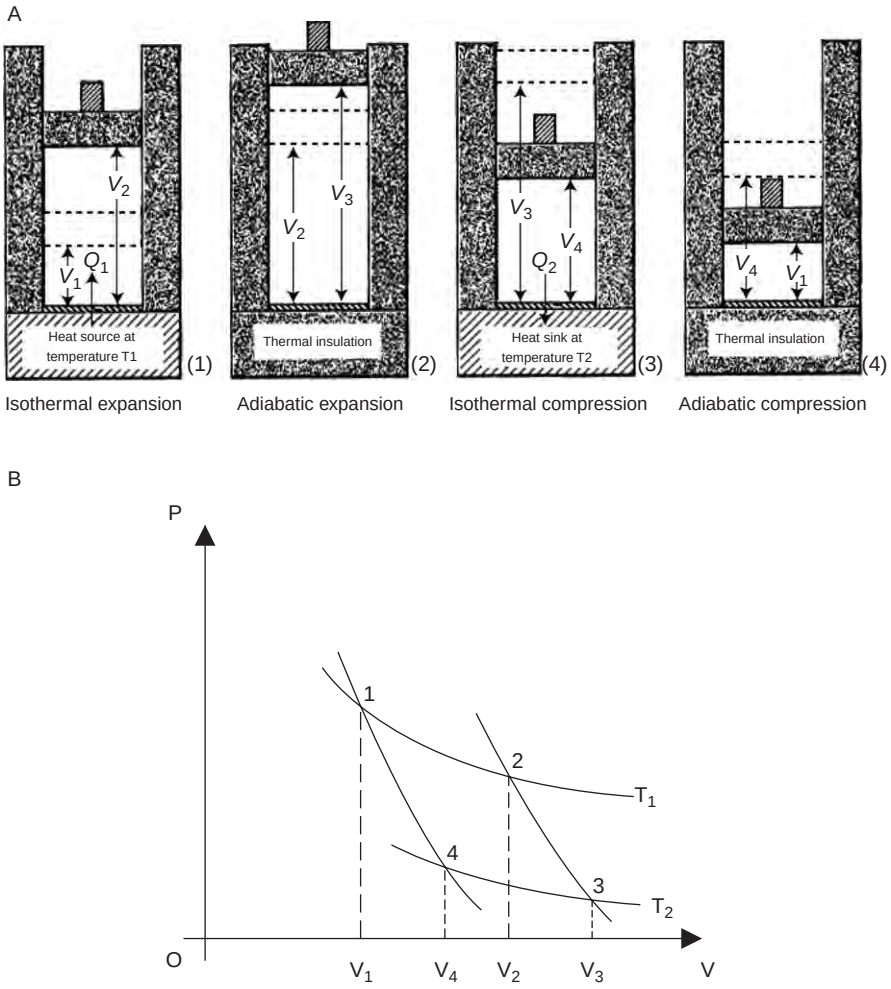

FIGURE 7 Carnot's cycle. (A) The different positions of the piston and the volumes of the fluid over time. (B) The isothermal and adiabatic reversible patterns that the fluid must follow in the process in order to close the cycle.

efficiency (work performed/heat supplied) is therefore

$$\eta = W/Q_1 = (Q_1 - Q_2)/Q_1 = 1 - Q_2/Q_1 < 100\% \tag{11}$$

This result may be assumed to be Carnot's statement of the second law, equivalent to those of Kelvin and Clausius. In fact, if the heat Q_2 could be transferred from the sink to the source without an additional energy expense, the efficiency η would be 100%, but this transfer from a colder to a warmer body would be against Clausius's statement. In addition, the immediate consequence would be the complete conversion of the heat Q_1 into work, against Kelvin's statement. The already shown equivalence between Kelvin's and Clausius's statements is also further demonstrated.

5.4 Carnot's Theorem

A fundamental theorem named after Carnot follows from the Carnot's cycle. This theorem permits the introduction of the so-called absolute temperature T and the entropy concept, thus offering a way to determine the direction of real transformation processes. This theorem can be stated as follows: The efficiency of a reversible thermal machine R operating between two temperatures is never lower than that of a whatever machine S operating between the same temperatures:

$$\eta_R \geq \eta_S, \tag{12}$$

where the equality only applies if S is also reversible.

Assume that we have two machines (the first reversible and the second nonreversible) as in Fig. 8,

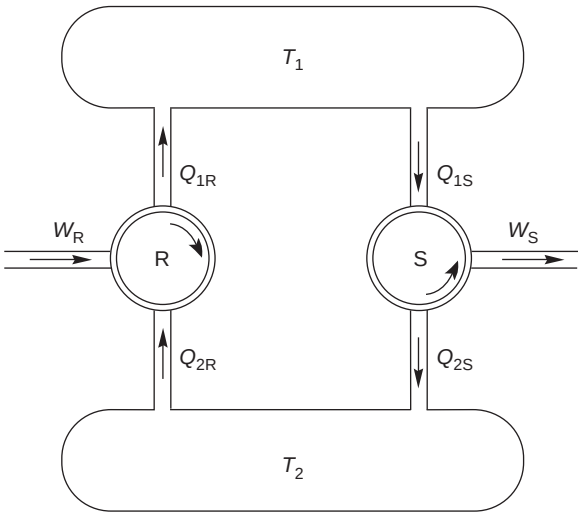

FIGURE 8 A reversible Carnot machine R working backwards between two heat reservoirs at the expense of an amount of work W_R provided from outside. R delivers heat Q_R to the reservoir at temperature T_1. This heat is transferred to the irreversible machine S, which converts it into work W_S. If the efficiency of the irreversible machine were higher than that of the reversible one, W_S would be higher than W_R, in contrast to Kelvin's statement of the second law of thermodynamics.

both operating between the same temperatures T_1 (source) and T_2 (sink). Each is able to receive a given amount of heat from the source at temperature T_1 and to deliver a given amount of work by also releasing some waste heat to the sink at lower temperature.

The theorem can be demonstrated ab absurdo assuming that, instead, it is $\eta_S > \eta_R$; that is,

$$\eta_S = (Q_{1S} - Q_{2S})/Q_{1S} > \eta_R = (Q_{1R} - Q_{2R})/Q_{1R} \tag{13}$$

Since R is reversible, it could also work backwards as shown in Fig. 8; that is, it could receive an amount of work $W_R = Q_{1R} - Q_{2R}$ from outside and release heat Q_{1R} to the source at temperature T_1. If the input work W_R is such that $Q_{1R} = Q_{1S}$, the source of heat at higher temperature T_1 becomes unimportant. It follows from Eq.(13) that

$$W_S = (Q_{1S} - Q_{2S}) > (Q_{1R} - Q_{2R}) = W_R$$

and finally that

$$W_S - W_R > 0,$$

thus creating work by extracting heat $(Q_{2R} - Q_{2S})$ from a unique source at temperature T_2. This is in clear contrast with Kelvin's statement. It must therefore be $\eta_S < \eta_R$. If S were also reversible, the second part of the theorem, $\eta_S = \eta_R$, could easily be demonstrated in a similar way.

Consequently, the efficiency of any reversible machine depends only on the two temperatures T_1 and T_2 between which the machine operates. After adequately choosing the thermometric scale in order to have $T = t + 273.14$ (t is °C), it can be demonstrated that

$$Q_2/Q_1 = T_2/T_1. \tag{14}$$

The temperature T is called absolute temperature because it does not depend on the particular thermometric substance used and therefore coincides with the one obtained by using an ideal fluid as the thermometric substance. A unit "absolute" degree (K) coincides with a unit centigrade degree. The latter is defined by dividing by 100 the temperature interval between the temperature of melting ice (0°C) and the temperature of boiling water (100°C) at sea level.

In summary, the efficiency of a reversible Carnot's cycle depends only on the absolute temperatures of the heat source and the heat sink and not on the fluid or the amount of heat exchanged:

$$\eta_R = (T_1 - T_2)/T_1. \tag{15}$$

Equation (14) can be rewritten as

$$Q_1/T_1 - Q_2/T_2 = 0, \tag{16}$$

and generalized to the case of n sources in a reversible cycle as

$$\sum Q_i/T_i = 0, \tag{17}$$

with positive sign for heat absorbed by the fluid and negative sign for heat released. Equation (17) can be further generalized to the case of infinitesimal amounts of heat δQ exchanged by each source in a reversible process with continuous temperature changes:

$$\int_{\text{cycle}} \delta Q/T = 0. \tag{18a}$$

For an irreversible process S, it would be

$$\int_{\text{cycle}} \delta Q/T < 0 \tag{18b}$$

because $\eta_S < \eta_R$.

5.5 The Entropy Concept

Now consider the most general case of a reversible cycle, such as the one shown in Fig. 9, with continuous temperature changes. It can always be

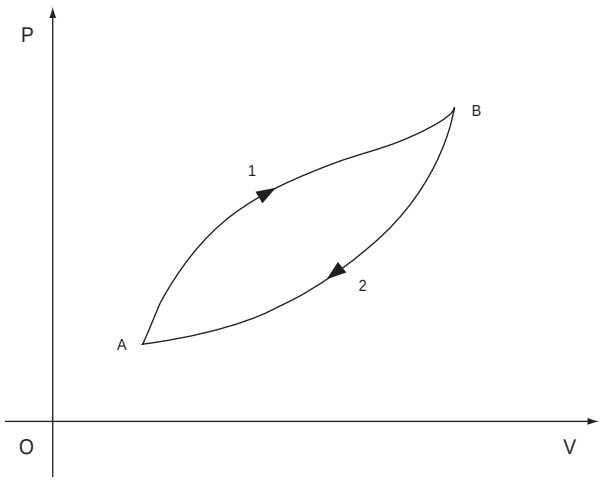

FIGURE 9 Diagram of a reversible cycle, with continuous temperature changes, simplified as the succession of two reversible transformations from *A* to *B* (along pathway 1) and vice versa (along pathway 2).

simplified as the succession of two reversible transformations from A to B (along pathway 1) and vice versa (along pathway 2).

According to Eq. (18a), we may write

$$\int_{A\to B,(1)} \delta Q/T + \int_{B\to A,(2)} \delta Q/T = 0, \qquad (19)$$

where the subscripts indicate the paths from A to B and vice versa. Due to the reversibility of the two transformations $A\to B$ and $B\to A$, we may write

$$\int_{A\to B,(1)} \delta Q/T = -\int_{B\to A,(2)} \delta Q/T = \int_{A\to B,(2)} \delta Q/T. \qquad (20)$$

This result is of paramount importance because it demonstrates that the integral does not depend on the specific reversible transformation from A to B but only on the actual states A and B. We are therefore able to define a new function depending only on the system state (such as the internal energy *U*). Clausius called this function entropy, defined as follows: Given an arbitrary initial system state O, an arbitrary final state A, and an arbitrary reversible transformation from O to A, the value of the integral

$$S(A) = \int_{O\to A} \delta Q/T + S(O) \qquad (21)$$

calculated over the reversible transformation $O\to A$ is a function only of the states O and A. This value is called entropy.

Entropy is measured in calories per degree Kelvin or Joules per Kelvin. It clearly appears that $S(A)$ is defined but for an arbitrary constant $S(O)$, which has no practical utility because we are always interested in entropy differences between states and not in absolute values. We can therefore equate this constant to zero.

It can also be demonstrated that

If an isolated system undergoes a transformation from an initial state A to a final state B, the entropy of the final state is never lower than the entropy of the initial state.

This statement is the so-called entropy law.

6. THE THIRD LAW OF THERMODYNAMICS (NERST'S THEOREM)

Sometimes, the arbitrary constant $S(O)$ of Eq. (21) becomes important and cannot be neglected. In 1906, Nerst suggested the statement of a third law of thermodynamics as well as a specific value for the arbitrary constant $S(O)$. The statement (the so-called Nerst's theorem) can be expressed as follows: The entropy of any thermodynamic system at the absolute temperature of 0 K is equal to zero, whatever is the state of the system.

The most important consequence of the third law and the Nerst's theorem is the impossibility for a system to reach the absolute zero ($T = 0$ K). In fact, it can be demonstrated that as the system approaches the absolute zero it also becomes more difficult to further decrease its temperature and that this difficulty increases faster than the actual temperature decrease. Therefore, the absolute zero cannot be reached. A surprising and unexpected result follows: The absolute scale of temperature must be considered unlimited in both directions, either toward the high temperatures and toward the absolute zero.

The impossibility of reaching the absolute zero is the basis of another perpetual motion statement: It is impossible to construct a perpetual motion machine of the third kind. A perpetual motion machine of the third kind continuously converts heat into work by operating between a hot reservoir at temperature $T > 0$ and a cold reservoir at $T = 0$. The third law states that it is impossible to achieve absolute zero temperature, thus making such a machine impossible.

Another consequence of the third law is that the specific heat $c(T)$ of a solid must tend to zero for $T \to 0$, at least according to the first power of *T*.

Otherwise, being $\delta Q = mc(T)dT$, the expression

$$S(\mathrm{A}) = \int_{\mathrm{O}\to\mathrm{A}} \delta Q/T = \int_{\mathrm{O}\to\mathrm{A}} mc(T)\, dT/T \qquad (22)$$

would diverge toward ∞ for $T \to 0$ instead of converging to a specific $S(\mathrm{A})$ value.

7. HOW MANY LAWS FOR THERMODYNAMICS?

Thermodynamics originated within the field of energy conversion and use, but its generality and the fact that it seems to apply to almost every phenomena in nature as well as in human-dominated systems generated major interest among nonspecialists. Many tried to establish links or derive thermodynamic principles capable of describing some aspects of their specific field of interest. In addition, several thermodynamics experts have also found interesting new properties or special aspects when applying thermodynamic principles to living systems. Both kinds of interest generated a multiplicity of tentative statements for new laws of thermodynamics and beyond. Some of these focused explicitly on specific aspects already covered by the second law, whereas others dealt with the redefinition of the concept of entropy in order to make it applicable to irreversible processes or with the macroscopic behavior of self-organizing systems in the biosphere seeking a general description of ecological patterns.

7.1 Georgescu-Roegen's Entropy of Matter

The economist Nicholas Georgescu-Roegen proposed a fourth law of thermodynamics concerned with the so-called entropy of matter. Georgescu-Roegen proposed that in a closed system (i.e., a system exchanging energy but not matter with the outside environment), a "material entropy" occurs and gradually reaches its maximum value (maximum disorder and mixture of matter) in such a manner that "all matter ultimately becomes unavailable." He identified the biosphere as a closed system (exchanges with outside space are too slow and therefore not significant on the scale of the economy) and pointed out that it would be impossible to completely recover the matter involved in the production of mechanical work or wasted in friction. The disappearance of any qualitative difference between materials is a sort of "material death" of the system, which is similar to the famous "thermal death" dictated by the entropy law for isolated systems. Georgescu-Roegen emphasized the importance of the behavior of matter in opposition to the so-called energy dogma for which any recovery of high-quality pure substance is possible (complete recycling) when a sufficient amount of energy and time are available. Bianciardi *et al*. demonstrated that apart from the importance of this statement from the standpoint of economic processes or even the ethics of resource use, it is false in the field of physical laws where the author intended it to stand due to its severe inconsistency with the second law. They argued that if the fourth law were true, then the second law and its entropic consequences must be false. Photosynthesis, the generation of organized from dispersed matter driven by solar energy, provides proof of this issue. Georgescu-Roegen's statement is important in the context of the second law without introducing a fourth law. In fact, to recover the tires or the coins worn away by friction requires that an ordered form of energy be invested in the process to decrease the entropy of this matter. As a consequence, the entropy of the surrounding environment (the rest of the biosphere) would increase to a larger extent, generating a net entropy increase that would not be sustainable for the biosphere.

7.2 Onsager's Reciprocal Relations

Early attempts to treat irreversible processes such as heat conduction by means of classical thermodynamics resulted in little success. Despite its name, classical thermodynamics was not suited to the treatment of dynamic processes. It is instead a perfect tool for the study of static states and chemical equilibria. In 1968, the Norwegian physical chemist Lars Onsager was awarded the Nobel Prize in chemistry for the discovery of the reciprocal relations named after him and basic to irreversible thermodynamics. Onsager presented his fundamental discovery at a Scandinavian scientific meeting in Copenhagen in 1929. The work was published in its final form in 1931 in the well-known journal *Physical Review* in two parts with the title "Reciprocal Relations in Irreversible Processes." The importance of these relations was not immediately recognized by the scientific community; thus, the Nobel Prize was attributed to Onsager only many years later. When giving his Nobel presentation speech, S. Claesson of the Royal Swedish Academy of Sciences emphasized that "the Onsager's reciprocal relations represent a further law making possible

a thermodynamic study of irreversible processes." He also pointed out that "the size of the two papers was no more than 22 and 15 pages, respectively. Judged from the number of pages this work is thus one of the smallest ever to be rewarded with a Nobel Prize."

7.3 Prigogine's Excess Entropy Production

The Onsager's reciprocal relations later became the basis of Prigogine's irreversible thermodynamics, for which Prigogine was awarded the Nobel Prize in chemistry in 1977. P. T. Landsberg suggested the status of a fourth law for the results of Prigogine and collaborators, who investigated the dissipative behavior of open systems moved away from equilibrium by the fluxes of matter and energy across their boundary. They showed that open dissipative structures can maintain themselves for a period of time away from thermodynamic equilibrium in locally reduced entropy steady state, and they developed a fluctuation and stability theory fully relying on the assumptions of a "local equilibrium." This is the so-called Landsberg "basic trick" of thermodynamics, which enables a system (which may have gradients of temperature, etc. built into it) to be considered as composed of elements to each of which classical thermodynamics applies. In so doing, each element is large enough for thermodynamic consideration to apply but small enough for the gradients to be unimportant within each element. The additional assumption that the summation of corresponding local extensive variables over the whole system (near the reference state) gives the value of the corresponding global variable enabled Prigogine and colleagues to define a nonequilibrium entropy concept on which their whole stability and fluctuation theory is based. The main result of this approach was the definition of the concept of excess entropy production, from which global stability conditions could be derived for a thermodynamic system:

$$\delta^2 S \leq 0 \quad \text{and} \quad \frac{1}{2}\frac{\partial}{\partial t}(\delta^2 S) \geq 0.$$

where $\delta^2 S$ is the second order perturbation of the S function around the equilibrium state and $\partial/\partial t$ is the partial derivative with respect to time, called "excess entropy production". It should be noted that the symbol δ has here a different meaning than in the previous sections.

Landsberg pointed out that without this assumption, Prigogine's theories of fluctuation and stability "would not be thermodynamic in character." However, he also recognized that the assumption worked sufficiently "in that the results obtained from it cohere with other theories and experiments" and suggested the definition of nonequilibrium thermodynamics to qualify as a fourth law of thermodynamics. Instead, according to Schneider and Kay, "Prigogine's linear expansion of the entropy function about equilibrium … is a severe restriction on the application of his theory and in particular precludes its formal application to living systems." These considerations led Schneider and Kay to formulate a restated second law of thermodynamics, based on previous extended formulations by Hatsopoulos and Keenan and by Kestin and analogous to Le Chatelier's principle for chemical systems.

7.4 Lotka's Maximum Power Principle

A different set of statements came from scientists working in the field of ecology, willing to explore and understand the energy and resource basis of living systems' self-organization. A fundamental contribution was provided by the mathematical biologist Alfred Lotka, who stated the so-called maximum power principle:

> *In the struggle for existence, the advantage must go to those organisms whose energy-capturing devices are most efficient in directing available energy into channels favorable to the preservation of the species. … In every instance considered, natural selection will so operate as to increase the total mass of the organic system, to increase the rate of circulation of matter through the system, and to increase the total energy flux through the system, so long as there is presented an unutilized residue of matter and available energy. This may be expressed by saying that natural selection tends to make this energy flux through the system a maximum, so far as compatible with the constraints to which the system is subject. … It appears, however, at least a priori probable that among the certainly very large (if not infinite) variety of types presented for selection, sooner or later those will occur which give the opportunity for selection to operate in the direction indicated, namely so as to increase the total mass of the system, the rate of circulation of mass through the system, and the total energy flux through the system. If this condition is satisfied, the law of selection becomes also the law of evolution.*

Systems that self-organize to increase the throughput flow of energy are rewarded by survival and selection. The principle of selection "functions … as a third law of thermodynamics (or a fourth, if the third place is given to the Nerst principle)." This is a major advancement with respect to classical thermodynamics. According to Lotka,

> *The principle of natural selection reveals itself as capable of yielding information which the first and second laws are not competent to furnish. The two fundamental laws of*

thermodynamics are, of course, insufficient to determine the course of events in a physical system. They tell us that certain things cannot happen, but they do not tell us what does happen.

7.5 Odum's Maximum Empower Principle

In 1987, Howard T. Odum was awarded (together with his brother Eugene) the Crafoord Prize for ecology by the Royal Swedish Academy of Sciences. In his acceptance speech, Odum pointed out that

The study of ecosystems suggests principles by which energy flows generate hierarchies in all systems. From these it was clear that energy laws controlling self-organization were principles of open systems quite beyond classical energetics, involving a generalization of concepts of evolution in energy terms. During the trials and errors of self-organization, species and relationships were being selectively reinforced by more energy becoming available to designs that feed products back into increased production.

In order to account for resource convergence into self-organization processes, Odum introduced the concept of emergy, defined as "the total amount of available energy of one kind (usually solar) that is directly or indirectly required to make a given product or to support a given flow." The total emergy directly supporting many items (or grams or joules) at the lowest level of a hierarchical chain also supports indirectly a smaller amount of items (grams or joules) at the next higher levels. Therefore, where several levels of energy hierarchy are involved, maximizing power according to Lotka can be misleading because it might imply that priority is given to increasing energy flow through the lower levels, which may have more energy throughput. Instead, expressing resources in emergy terms permits the restatement of Lotka's maximum power principle as a maximum empower principle, according to which the simultaneous maximization of empower (emergy throughput flow) at all system's levels is required if a self-organizing system or ecosystem is to be stable and prosperous. The following is Odum's revised statement of Lotka's fourth law: "On each scale, systems designs prevail that maximize empower, first by reinforcing inflows of available energy and second by increasing the efficiency of useful work."

In his accounting for energy-based hierarchical patterns of self-organization, Odum pointed out that evolution is driven by the emergence of quality. The systems that are able to maximize production by reinforcing their resource basis as well as by increasing their resource use efficiency (i.e., those systems capable of generating new patterns and tools for resource use—organization, information, and feedback control) are rewarded by a higher probability of being selected in the natural competition. This creative ability makes the quality of a process product generally much higher than the quality of process inputs. A mathematical formulation of the maximum empower principle under the "light" of quality has been given by Giannantoni by means of driving forces (so-called source terms, e.g., information, DNA, and feedback control from the next larger scale) supporting the generative processes as well as by means of a new kind of fractional differential calculus. The latter is based on "binary" functions capable of accounting for the nonconservative aspects of a generative process (emergy of coproducts) and the emergence of quality. It obtains the three traditional principles of thermodynamics as special cases of the maximum empower principle by simply assuming that the source terms are equal to zero (i.e., by focusing on the quantitative aspects only). The maximum empower principle becomes, in this perspective, an extension of classical thermodynamics to ecological systems.

7.6 Jorgensen's Ecological Law of Thermodynamics

Exergy, the free energy of a system relative to the surrounding environment, measures the amount of work that can be extracted from the system when it is allowed to reach the thermodynamic equilibrium with the environment. According to Szargut *et al.*, exergy is "the amount of work obtainable when some matter is brought to a state of thermodynamic equilibrium with the common components of the natural surroundings by means of reversible processes, involving interaction only with the above mentioned components of nature." Whenever a work is performed, an existing gradient must be dissipated. Exergy, the ability to do work, is strictly correlated with the existence of a gradient of some physical property. This definition suggests exergy as a measure of the information content of a system as well as of its distance from equilibrium. On this basis, Jorgensen enunciated a tentative fourth law, also called the ecological law of thermodynamics (ELT):

If a system receives a through-flow of exergy, it will utilize this exergy to move away from thermodynamic equilibrium. If the system is offered more than one pathway to move away from thermodynamic equilibrium, the one yielding most stored exergy, i.e., with the most organized

TABLE I

Comparison among Alternative Statements of the Laws of Thermodynamics

Law	Mathematical statement[a]	Traditional statement[a]	Perpetual motion statement[a]	Landsberg (1972) statement	Las Vegas statement[b]
Zeroth law		If a body A is in thermal equilibrium with a body B and if B is also in thermal equilibrium with a third body C, then A is in thermal equilibrium with C.		Empirical temperature exists.	
First law	$\Delta U = Q + W$	The total energy is conserved.	It is impossible to construct a perpetual motion machine of the first kind.	Internal energy exists.	You cannot win.
Second law	$dS = \delta q_{rev}/T$, $dS_{univ} > 0$	The total entropy increases.	It is impossible to construct a perpetual motion machine of the second kind.	Entropy and absolute temperature exist.	You cannot break even.
Third law	$T > 0$	The absolute temperature of any system can never be zero.	It is impossible to construct a perpetual motion machine of the third kind.	States with $T = 0$ do not exist.	You cannot get out of the game.

[a] This article.
[b] Ronald D. Poshusta, www.poshusta.chem.wsu.edu.

structure, or the longest distance to thermodynamic equilibrium under the prevailing conditions, will have the propensity to be selected.

The strong agreement of the ELT with Darwinian theories of evolution convinced Jorgensen that exergy is a convenient "indicator of the development of ecosystem structure and changes in species composition. Structural exergy, in particular, should be considered an appropriate measure of ecological integrity." He also noted that his tentative fourth law, like the other laws of thermodynamics, cannot be proved by means of deductive methods and can at best only be proved by inductive methods (i.e., by the results of as many cases as possible). He investigated and published a huge number of ecological systems cases, providing empirical data and simulation models in support to his statement. However, he had to admit that "it is hardly possible to make deterministic statements about the development of an ecosystem" and that "it is absolutely necessary to test the tentative law with many more case studies before it can be recommended to use it more generally."

8. CONCLUSION

We have discussed several different statements of the laws of thermodynamics in this article. Some of them are shown in Table I. Looking at the table, it can be clearly seen how many different aspects of the same law can be pointed out and how these aspects are linked to each other.

Instead, the tentative fourth laws presented in this article are not summarized in Table I due to a lack of consensus on their general validity. However, they are very interesting attempts to describe and quantify the growth of complexity, the storage of information, the distance from thermodynamic equilibrium of systems at different hierarchical levels, and the strategies of ecosystem development. In other words, all of them stem from the need to explain why self-organization processes occurring in open systems seem to violate the second law dictate and how they instead generate low-entropy complex structures. The equilibrium thermodynamics was more easily described in terms of formal and mathematical statements than nonequilibrium thermodynamics due to the nondeterministic nature of self-organizing

complex systems. Simplifying the model in order to give a formal statement of self-organization requires assumptions that limit the applicability of the statement to real systems and do not capture their complexity. The tentative fourth laws share the goal of identifying clear links between thermodynamics, ecology, and evolution.

Born as an applied science aimed at usefully converting heat into mechanical work, thermodynamics rapidly developed into a more general system of knowledge encompassing almost all branches of life sciences. There is virtually no aspect of reality that cannot be described in thermodynamic terms, and there is virtually no phenomenon that is not subject to the thermodynamic principles. Eddington stated,

> *If someone points out to you that your pet theory of the universe is in disagreement with Maxwell's equations—then so much the worse for Maxwell's equations. … But if your theory is found to be against the second law of thermodynamics I can give you no hope; there is nothing for it but to collapse in deepest humiliation.*

Its generality was unconvincing to many, whereas the complex thermodynamic interrelationships within living systems very often made the inner essence of this science difficult to capture. There is no doubt, however, that thermodynamics can be defined as the general science of energy, not only because of its ability to fully describe energy transformations in human-dominated devices (from which it started) but also because of its still developing ability to describe and explain all energy and matter transformations within any systems in the biosphere (and the universe as well).

4. Summary

Glossary

aestivation Reducing energy expenditure below basal levels at very high ambient temperatures.
basal metabolic rate The lowest metabolic rate reached by an animal maintaining bodily functions when at rest and not having recently eaten a meal.
behavioral thermoregulation Behaviors that alter management of heat flows from outside to allow regulation of body temperature.
endothermy Regulation of body temperature primarily using generation of heat internal to the animal.
euthermic Precise regulation of body temperature around a set point in the approximate range of 35 to 45°C.
exothermy (ectothermy) Regulation of body temperature using management of heat sources primarily external to the animal.
heliothermy Thermoregulation primarily dependent on varying the interception of incoming solar radiation.
homeothermy (homiothermy) An outmoded term describing the stability of body temperatures of endothermic animals; literally "constant temperatured."
physiological thermoregulation Physiological strategies that contribute to heat balance.
poikilothermy An outmoded term describing the variations in body temperatures of exothermic animals; literally "variable temperatured."

Thermoregulation describes the process by which animals manage the flow of energy into and out of their bodies, with the aim of maintaining a relatively constant body temperature within a range of 2 to 3°C. Most vertebrate animals attempt to regulate their body temperatures within such relatively narrow limits because enzyme functions are strongly dependent on temperature; therefore, there is only a narrow range of body temperatures within which metabolic processes can be optimized. Once body temperatures move outside these relatively narrow limits, animals start to experience profound reductions in their cellular functions and this has ramifications for their performance at the whole animal level. For many animals, exposure for even short periods to temperatures more than 10°C below or 5°C above those at which they routinely regulate their body temperatures is often fatal.

1. INTRODUCTION

The set points at which body temperatures are regulated vary tremendously among different animal groups. however, many animals regulate their body temperatures in the range of 30 to 45°C (303–318 K), and these animals are generally termed "euthermic." Body temperature can be regulated by altering the flow of heat into and out of the animal (behavioral thermoregulation or exothermy) and by generating heat internally (endothermy). Different species vary in the extent to which they use these alternative strategies for regulating their body temperatures, and in most animals the strategies are combined to varying extents. However, the physical laws that govern the amounts of energy required under various circumstances are common to all animals, independent of how they ultimately meet these demands.

2. MECHANISMS OF HEAT EXCHANGE

All animate and inanimate objects exchange energy with their surroundings by four different mechanisms: radiation, convection, conduction, and evaporation. This section reviews the essential features

 © 2004 Elsevier Inc. All rights reserved.

of these physical mechanisms in the context of their importance for animal heat balance.

2.1 Radiation

All objects emit electromagnetic radiation. The emitted radiation can be characterized by two parameters: the wavelength of emitted radiation and its intensity. Emitted radiation has a characteristic distribution of wavelengths that depends on surface temperature of the emitting object. The distribution at any particular temperature is peaked with a positive skew. The wavelength of modal intensity varies as a function of the surface temperature. As objects get hotter, the wavelength of peak intensity of radiation they emit gets shorter. This inverse relationship is generally called Wien's displacement law. Most objects on the surface of the earth have surface temperatures in the range of 253 to 313 K. The peak wavelengths of radiation emitted by objects in this temperature range are in the infrared. Because human eyes cannot detect infrared radiation, one cannot see the emitted radiation from most natural earth-bound objects directly. Glowing larva, molten metals, and hot coals in fires are notable exceptions of earth-bound objects that reach sufficiently high temperatures that the emitted radiation is directly visible by humans. Some animals have special sensory adaptations that enable them to detect infrared radiation. In particular, a group of snakes known as pit vipers can perceive emitted radiation from objects in the range of 273 to 313 K and use this to detect their prey. Because the prey thermoregulate, they are generally hotter than their surroundings and, thus, emit radiation with greater intensity and at higher wavelengths.

The other main source of radiation on earth comes from the sun. The surface temperature of the sun is approximately 6000 K. The wavelengths of radiation generated by objects at this temperature are between 400 and 700 nm. It is no coincidence that this is the range of wavelengths to which humans' eyes are sensitive and which, therefore, is defined as the visible spectrum. When one sees "an object," what one actually sees is the electromagnetic radiation that is reflected from its surface. The amount of energy that is radiated by a body depends on the surface temperature of the object and on whether it is a good or poor emitter of radiation. An object's capacity to emit radiation is defined relative to that of a perfect emitter, which is called a blackbody emitter. Capacity of a surface to emit radiation is defined by a term called the emissivity (ε). Emissivities vary between 1.0 (equal to the emissivity of a perfect emitting blackbody) and 0.0 (meaning the body would emit no radiation).

All objects emit amounts of radiation that are dependent on their surface temperatures and surface emissivities, and all objects also absorb radiation. Humans emit only in the infrared, and they absorb in both the infrared and visible spectral ranges. Objects that are good at emitting radiation at a certain wavelength are also good at absorbing it. Because the dominant sources of radiation are bimodally distributed with respect to their dominant wavelengths (i.e., in either the infrared or visible ranges), the capacity to absorb long- and shortwave radiation separately is often discussed. Longwave radiation emissivity/absorptivity tends to bear little relation to the color of the emitting surface as humans perceive it. Most animate objects have high water contents, and because water is a good emitter of longwave radiation, surface emissivities and absorptivities of most living organisms tend to be high ($\sim$0.95). However, absorption and reflection of shortwave radiation do vary with the color of the surface. Hence, dark colors have high absorptivities and light colors have low absorptivities. Capacities to absorb shortwave radiation are defined by the term "albedo." This is a value between 0.0 and 1.0 that expresses the capacity of a surface to absorb shortwave radiation relative to a perfect whitebody reflector. Hence, an object with an albedo of 1.0 is a perfect reflector and absorbs minimal amounts of incident shortwave radiation, whereas an object with an albedo of 0.0 is a good absorber. People can directly experience the impact of variations in albedo on absorbed radiation amounts very easily by changing the color of their clothing and exposing themselves to bright sunlight. Few people will fail to recognize the advantages of wearing light-colored clothing on hot summer days. This trend of wearing light-colored clothing during summer is a behavioral thermoregulatory behavior.

An interesting question that puzzled researchers for a considerable period is why races of humans that originate in tropical areas have dark skin colors compared with races that come from areas in the temperate and arctic regions. Explanations of this difference often suggested that skin color was related to both long- and shortwave radiation and that, overall, the dark skin color was advantageous in hot conditions because on balance it absorbed less radiation. However, this explanation is incorrect. In fact, dark skin is not a thermoregulatory adaptation at all but rather is a response to increase

absorption of shortwave radiation before it can penetrate the skin and cause dangerous lesions to epithelial cell DNA. This means that dark races actually do absorb more shortwave radiation than do their light-skinned counterparts. However, the benefits of this absorption are illustrated by comparing the rates of skin cancers in aboriginal Australians, where skin cancer is virtually unknown, and white Australians, who have a broadly European heritage and where skin cancers occurred in nearly 3% of the population during the early 1990s until vigorous campaigns were started to encourage safe practices when out in the sun.

The intensity of emitted radiation is very strongly dependent on surface temperature. In fact, emitted radiation is proportional to the surface emissivity multiplied by the absolute surface temperature (K) raised to the fourth power. This scaling exponent of 4 is very important because it means that as objects get hotter, the amounts of emitted radiation become disproportionately large. Hence, the surface of the sun at 6000 K is only 20 times hotter than humans are, at approximately 300 K, but each square meter of the sun's surface emits 160,000 times more electromagnetic radiation than do humans. Of course, because of the inverse square law and the fact that the earth is 150 million km from the sun, the amounts intercepting our planet are very much diminished. The consequence of this is that shortwave solar radiation input and longwave radiation outputs of our bodies are of the same order of magnitude, with both being approximately 1 kW per square meter of surface

2.2 Conduction

When any two solid objects are in direct physical contact, they exchange heat. Heat is "conducted" from the hotter object to the cooler object. The rate at which the heat flows depends on the surface area that is in contact between the bodies, properties of the material that connects them, and the path distance over which the heat is being conducted. The main property of an object that defines its capacity to conduct heat is called its thermal conductivity. Objects that conduct heat well are said to have high thermal conductivity, whereas those that conduct poorly are said to have low thermal conductivity. The inverse of conductivity is thermal insulation. Typical high-conductivity/low-insulation objects are metals and rocks, whereas typical low-conductivity/high-insulation materials are wood and fur. Among the lowest thermal conductivities of all is that of still air. This is why natural and man-made insulative materials tend to consist of structures that aim to trap air and keep it stationary (e.g., expanded polystyrene). In fact, the thermal conductivity of fur exceeds that of still air, so if the fleece of a sheep is compressed (thereby reducing the amount of air trapped in it), the conductance of heat across the fur actually increases.

One might imagine that because most animals do not have large amounts of their surfaces in contact with other solid objects, the role of conductance in the process of heat exchange would be minimal. But although this is generally true, one area where understanding the principles of conductance is important is in understanding the flow of heat from the core of a body to its surface. Because animals consist of solid objects, the heat flows from the central core to the surface via conductance. To understand the flow of heat from an animal's core to the surrounding air, imagine that heat is produced centrally at a notional single point. The heat flows first through the tissues, carried partly by blood flow through the arterial and capillary network and partly by conduction through the cells and tissues themselves. In some animals, the heat must then flow through a barrier of fur or feathers, primarily by conduction through the hairs or feathers themselves but also by conduction through the trapped air, and finally dissipates from the thin boundary air layer overlying the outer surface of the fur, primarily by convection and the net loss of thermal radiation. Both the type of heat transport and the path length along which heat must travel determine the resistance that each layer offers to the flow of heat. Heat is transferred not only by conductance but also by convection due to movement of the blood, and the process of convection transfers heat much more rapidly than does the process of conduction. Thick layers of material with low conductivity by definition offer more resistance to heat flow than do thin layers. Because each layer offers a resistance to heat flow, temperature drops progressively between the core and the skin, through the fur, and finally into the surrounding air. The extent to which the temperature drops across a given layer is determined by the proportional contribution of that layer to the total resistance offered by all layers to the flow of heat. A thick and efficient fur or feather layer, which offers a high resistance to heat flow, will exhibit a large drop in temperature between its inner and outer surfaces, and the total flow of energy across it will be reduced. Conversely, the difference between the core of the body and the area under the skin may differ

very little in temperature due to the high conductivity (assisted by convection effects).

There are very strong parallels between thermal and electrical conductivity and the concepts of thermal insulation and electrical resistance. Concepts of electrical circuitry have been widely borrowed to help explain how heat flows within animals from core to periphery. In this context, it is useful to imagine the heat as though it were electricity flowing through a number of resistances that may be arranged in parallel within a given layer and in series between layers. The value of this approach is that it allows one to apply the same formulas that predict current and voltage in electrical circuits: $I = V/R_{total}$, where I is the current, V is the voltage potential, and R_{total} is the circuit resistance. When thinking in terms of heat rather than electricity, we simply substitute heat flow (H) for I, temperature gradient (ΔT°) for V, and the sum of the resistances in the various layers for R_{total}. Thus, the overall flow of heat away from the core is calculated by $H = \Delta T^{\circ}/R_{total}$, and because $R = 1/C$, this is the same as $H = \Delta T^{\circ} \cdot C$.

There are several benefits to thinking in terms of resistances and ΔT°. One is that the overall resistance (R_{total}) can simply be found from the sum of the equivalent resistances for each layer, remembering that an equivalent resistance refers to a single resistance that could replace two or more resistances in parallel. A second benefit is that the resistance offered by a given layer (x) can be calculated from the heat flow and the temperature drop across that layer if the total heat flow is known ($R_x = \Delta T^{\circ}_x/H$). A third is that the relative importance of each layer in limiting heat flow is easy to visualize. Just as the voltage drop (ΔV_x) across a single resistor of a series can be predicted by the ratio of that resistor (R_x) to the total circuit resistance ($\Delta V_x = [R_x/R_{total}] \cdot V$), the temperature drop across a given layer is determined by the proportional contribution of the resistance in that layer to the total resistance offered by all layers ($\Delta T^{\circ}_x = [R_x/R_{total}] \cdot \Delta T^{\circ}$). Moreover, in this analogy, the total current (I) is equivalent to the total heat flux (H). Thus, factors that diminish I, such as elevated total resistance, can also be seen to parallel the effects of elevated total insulation on total heat requirement.

When peripheral blood flow is high due to dilation of the capillaries under the skin surface, considerable amounts of heat are transported to the skin surface by convective blood flow and the ratio of tissue resistance to the total resistance (R_{tissue}/R_{total}) is small. As a result, there is only a small temperature difference between core and skin, and the skin is seen as "hot." The surface temperature depends on the thickness of the overlying insulative layer and, thus, the total resistance afforded to heat flow along any particular path. A thermal image of an animal that picks up the emitted radiation clearly shows this variation in surface temperature as a function of the thickness of the insulative layer and the resultant heat loss across this layer. Figure 1 shows a thermal

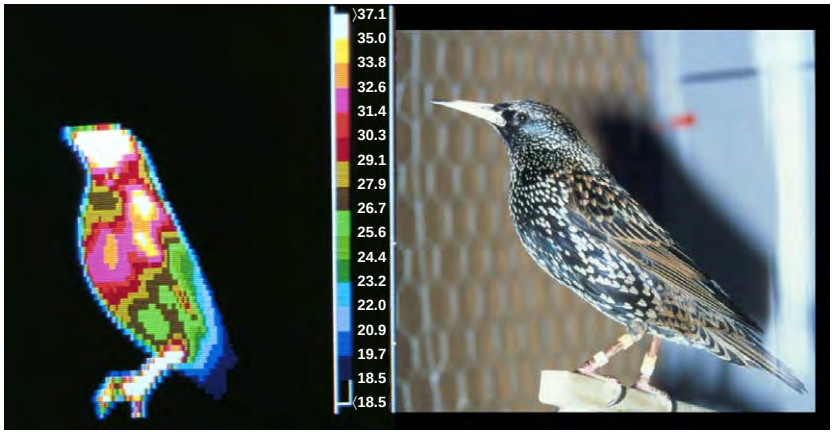

FIGURE 1 (A) Thermal image of a perching bird (a European starling, *Sturnus vulgaris*) and (B) a photograph of the same bird. In the first image (A), the camera detects the emitted longwave radiation and a computer uses the intensity of this radiation to generate, in real time, a map of the surface of the animal (see temperature scale at the side of the image). The second photographic image (B) relies on reflected shortwave radiation from the animal's surface. The surface temperature in panel A depends on the thickness of the external insulation layer. Areas where the layer is thinnest, particularly the head and legs, have the highest temperatures and the greatest flux of heat energy

image of a perching bird illustrating that the hottest areas are the legs and the face where the feathers are either absent or thin. The coolest areas are where the wings add an extra layer of insulation over the animal's lateral and ventral surfaces. Understanding this regional variation in surface temperature provides clear insight into why roosting birds often tuck their heads down under their wings and pull one leg up into their ventral plumage. By doing so, the birds conceal the hot parts of their bodies under layers of insulation and, thus, reduce the total heat flux. This is another form of behavioral thermoregulation.

Clearly, if the skin surface is hot due to dilation of the capillaries, another mechanism that animals might use to conserve heat is to reduce the flow of blood to the surface by closing down these capillaries, that is, vasoconstriction. In these conditions, convective heat transport to the skin declines toward zero. Most of the tissue resistance is now determined by the slower conduction of heat through the tissue matrix. The skin is seen as "cool" due to this increase in tissue resistance, resulting in a higher R_{tissue}/R_{total} ratio. As a result, less heat is delivered to the base of the fur, ΔT° through the fur is smaller, and heat flow through the fur is reduced.

The ability to depress skin temperature by vasoconstriction is affected by body size. By definition, small animals have short path lengths between the organs (where much of body heat is produced) and the skin surface, whereas large animals necessarily have longer path lengths. As a result, small animals have relatively low tissue resistance, and hence high skin temperatures, compared with those of large animals. This effect may be enhanced not only by constricting the blood supply to the surface but also by covering the undersurface of the skin with a layer of fat or blubber. Fat has a lower thermal conductivity than does lean tissue and, hence, acts as a barrier to heat flow. The best-known examples of this are the aquatic seals and whales that rely on a thick layer of subcutaneous blubber as insulation. Many terrestrial hibernating mammals also lay down substantial subcutaneous fat deposits. Although fat in these hibernating animals serves primarily as a means of energy storage, by analogy with aquatic mammals, one might be led to think that fat could also have a secondary role as an insulation layer for terrestrial animals. To analyze this problem, one should imagine a small lean animal with a tissue path length of 4 mm and a fur thickness of 6 mm and then consider what effect the deposition of a 1-mm thick subcutaneous fat deposit would have on heat flow. Muscle, fat, and fur offer resistances to heat flow of approximately 21.7, 46.9, and 262.9 $(W/^{\circ}C/mm)^{-1}$, respectively. For a lean animal having no fat deposit, the tissue resistance is 4 mm · 21.7 $(W/^{\circ}C/mm)^{-1}$, the fur resistance is 6 mm · 262.9 $(W/^{\circ}C/mm)^{-1}$, and the overall resistance is the sum of the two or 1664.2 $(W/^{\circ}C)^{-1}$. Adding a 1-mm subcutaneous fat layer would increase the overall resistance by 1 mm · 46.9 $(W/^{\circ}C/mm)^{-1}$, raising the overall resistance to 1711.1 $(W/^{\circ}C)^{-1}$, only 2.8% higher than the lean condition. Thus, the fat layer would reduce heat flow by only 2.8%. Therefore, we can conclude that 1 mm of fat is not an effective barrier to heat loss for small terrestrial animals and that fat storage in hibernators and other small animals probably does not serve as an insulator.

2.3 Convection

Conduction of heat occurs when two solids of different temperature are in contact. Convection occurs when a solid is in contact with a fluid (generally air or water on Earth) of different temperature. The "different temperature" part of this definition is often neglected, but it is clear that energy can only flow down a thermal gradient, so if there is no temperature differential the heat flow will similarly disappear. Using a fan increases airflow across the surface of the face, and because this is naked skin that is well perfused with blood, the increase in convective heat flow is an effective way in which to contribute behaviorally to thermoregulation by elevating surface heat losses. However, there is an increase in endogenous heat production when using a fan due to the muscular activity involved in the waving motion. Once air temperature rises to the same level as skin temperature, heat losses fall to zero no matter how hard one fans. The heat generated by fanning exceeds that from cooling under these conditions.

In fact, the heat loss by convection is a function of several factors. One is the driving temperature gradient, that is, the difference in temperature between the solid and the fluid in which it is immersed. The area over which heat is being lost is obviously important, and the shape and structure of the surface also affect how exposed it is to the fluid flow and, hence, the magnitude of the impact of the velocity of flow. The conductivity of the fluid is also an important factor. For example, water has a conductivity 23 times greater than that of air, and this greatly magnifies the cooling effect of convection in water. Although velocity is a factor in heat loss by convection, there is still some loss when an object is

stationary and there is no external flow of the fluid. This is a state called free convection. Free convection occurs because the air close to the surface of an object becomes heated by the object itself, and as this air warms up, its density declines and it rises upward. Standing humans in a completely still condition have plumes of hot air rising off the tops of their heads, and this hot air is replaced by colder air coming in from below. Therefore, convection currents are generated by the existence of a hot object within a cool liquid. But clearly, as the fluid moves as a whole, the velocity of that flow influences the convective heat loss. This is a state of forced convection.

The interaction between surface characteristics and velocity of flow on forced convective heat loss is complex. However, the relationship between airflow and heat loss generally follows a nonlinear pattern of diminishing increase with increasing velocity until at some point further elevations in velocity have only marginal effects. The exact exponent to which velocity is raised in these relationships varies somewhat with the shape and surface structures on the object, but a commonly assumed exponent is 0.5. Thus, heat loss increases as a function of the square root of fluid velocity. This is because the surface insulation is provided primarily by the thin skin of still air at the body surface known as the boundary layer. This air is gradually stripped away as velocity increases, but eventually when it has all gone, there is nothing else to lose. The manner in which the boundary layer is stripped depends on how the flow transits from laminar to turbulent flow, and characteristics of the shape and surface can influence this transitional velocity, thereby complicating the exact value of the exponent. It is clear that animals can use these properties to minimize convective heat loss by altering their shape to promote laminar flows. The example cited earlier of birds tucking their heads under their wings and standing on one leg may also function to present an aerodynamically favorable perspective in an airflow to minimize turbulent airflow and, thus, minimize convective heat loss.

2.4 Evaporation

The previous three modes of heat flow all work down temperature gradients. Heat flows from hot objects to cold objects by the processes of radiation, conduction, and convection. However, evaporation allows an object to lose heat even if the surrounding medium in which it is immersed is hotter than the object itself. This is consequently an essential thermoregulatory mechanism for many animals because it is the only method they can employ to keep cool if ambient temperatures exceed their body temperatures. Evaporation involves using energy to convert liquid water into the gaseous phase. Because water is strongly hydrogen bonded, the amount of energy required to convert liquid water to gas is high and, thus, evaporation is a very effective method for cooling down. To achieve this, many animals have specialized mechanisms such as sweating (where water oozes onto the surface of the animal and evaporates from there), panting (where a respiratory airflow is passed over the tongue to promote evaporative losses), and self-anointing (where the animal licks itself and the evaporating saliva provides the cooling). The capacity for evaporation depends on the ability of the surrounding medium to accept water vapor. The capacity of air to hold water vapor increases as a function of temperature. When the air is saturated, it is said to have a relative humidity of 100%. At this point, the air can accept no further water vapor and net evaporation from the surface of an object in that air ceases. This is why humid conditions are far more uncomfortable for humans than are dry conditions, even though in the latter case it may be hotter in absolute temperature. In dry conditions, one can thermoregulate by evaporation, but when the conditions also include very high humidity, even this avenue for heat loss is shut down.

3. MANAGING HEAT FLOWS

For very small animals (less than 1 mg), their surface areas are such that sustaining any temperature differential between the inside of the animal and the environment is nearly impossible. These animals maintain a constant internal temperature only by locating themselves in an environment where the temperature itself is constant. If the environment fluctuates in temperature, the animals have mechanisms to avoid the most extreme conditions in suspended states until the conditions improve again. Most lower invertebrates approach the problem of thermoregulation in this manner, that is, by avoidance. However, once animals become larger, their relative surface areas decline and it becomes feasible to sustain a temperature differential between the inside and outside of their bodies. This means that the animals can maintain homeostasis of their internal temperatures despite the range of external conditions and the variability in internal heat production as a by-product of activity. Most larger invertebrates have some limited capacities to regulate

their temperatures to some extent, and they combine these capacities with physiological or actual physical avoidance to survive temperature extremes.

However, it is in the vertebrates that thermoregulation has evolved to its greatest diversity and sophistication. The remainder of this article discusses the thermoregulatory strategies adopted by the major vertebrate groups.

3.1 Fish

Most fish spend most of their lives in water. This lifestyle simplifies the consideration of heat fluxes because it is not possible to engage in evaporation underwater, and beyond only a few meters of depth nearly all radiation has been absorbed. Thus, the heat budget management of fish is more simplified than that of terrestrial vertebrates. Water has a high specific heat capacity and, hence, tends to buffer environmental extremes. For example, the surface temperature of the Pacific Ocean differs by approximately 5 K over a distance of several thousand kilometers. The same temperature difference on land can be found between the shaded and exposed sides of a tree, that is, over a distance of a few meters. Therefore, fish are generally in a medium where the external temperature is relatively stable. The key problem, then, is that because of variations in activity, as well as variations in the energy required to digest food, the rates of endogenous heat production by the animals fluctuate widely. Because the external temperature is relatively constant, the driving gradient for heat loss by convection would also appear to be constant. Therefore, one might anticipate that as fish become active, they may experience thermoregulatory problems dissipating their body heat.

However, in addition to having high thermal conductivity relative to air, water has a low oxygen content relative to air. In fact, even oxygen-saturated water has only 1/40th the oxygen content of atmospheric air. Therefore, fish need extremely efficient mechanisms to extract oxygen from their environment to support their metabolism. The main mechanism they use is a countercurrent exchange mechanism in the gill arches, which have highly specialized enlarged surfaces to facilitate oxygen uptake and the removal of carbon dioxide generated by oxidative metabolic processes. What is a good mechanism for extracting oxygen from water is also a very efficient mechanism for getting rid of body heat. Indeed, because water has 23 times the cooling power of air yet only 1/40th the oxygen content, for each milliliter of oxygen extracted, the cooling power available to fish is approximately $23 \times 40 = 920$ times greater. Fortunately, elevated oxygen requirements occur when the animals are active and generating the most heat. So, there is an automatic passive feedback system that keeps the body temperatures of fish at the same level as their environment regardless of their level of activity. When activity increases accompanied by an increase in heat production, increased ventilation of the gills to get oxygen to support the activity automatically dumps the excess heat, avoiding overheating.

This is a workable strategy so long as the environmental temperature remains stable. However, temperatures vary spatially in bodies of water, particularly if the water is shallow and able to be heated by the sun in places but shaded elsewhere. Moreover, most bodies of water develop thermal stratification where the upper layers are heated by solar radiation effects but there is an abrupt thermocline separating this surface-heated water from the more stable cold water at depth. Obviously, fish might swim into such cool areas or into hot areas, with potentially serious consequences for their body temperatures. Fish accommodate such spatial temperature effects by behavioral strategies. They swim faster and turn more as they move into water that is cooler or hotter than their preferred temperature, and these simple kinetic mechanisms bring the animals back to an environment with a water temperature they prefer. However, if rapid temperature changes occur across an entire area, the animals have no mechanisms to avert disaster. Anyone who has kept tropical fish and had a heater fail in the tank in a cold temperate environment likely has observed the inability of fish to survive such an event. In the wild, these situations must be very rare. However, seasonal shifts in the temperature of the environment are commonplace, and fish have evolved a series of complex behavioral and physiological responses to overcome such seasonal effects.

In fact, a common strategy in the face of the change is simply to avoid it by migrating, and many fish species do this in the ocean. However, in freshwater lakes where the whole available environment is heating or cooling, migration is often not an option. As water cools down, the problem facing the fish is that their cellular performance, and hence metabolic and ultimately whole body performance, might be compromised. The issue then is to sustain cellular processes functioning at the lower temperature. To achieve this, fish alter the amounts of enzymes they manufacture, shift production to

isozymes that work best at lower temperatures, and modulate the medium in which the enzymes are working to maximize their activities. These have been called the quantitative, qualitative, and modulative responses, respectively, and together they comprise the physiological thermoregulatory strategy that allows fish in seasonally changing environments to survive without running away.

However, some fish do not conform to this pattern of thermoregulatory control. This group includes tuna, swordfish, and large game fish such as marlin. In these animals, there is a complex countercurrent heat exchange blood flow that reclaims heat from the blood before it passes through the gills. Hence, blood at the gills is at water temperature, and blood in the core body can be up to 15°C warmer. This allows these animals considerable flexibility to sustain performance in waters of varying temperature, and they use this capacity to swim below the thermocline into cooler waters and exploit prey populations living there.

3.2 Reptiles

Most reptiles live on land. Therefore, the problems they face include those faced by fish, of highly variable rates of endogenous heat production when the animals are physically active or digesting food. But combined with this problem is the fact that the environment in which reptiles often find themselves contains a tremendous spatial matrix of conditions where potential heat flux varies over orders of magnitude. Moreover, the modes by which heat flows between the animals and their environment entails a level of complexity way above that experienced by the average fish because radiation, evaporation, and conduction all come into play in addition to convection. Therefore, as might be anticipated, reptiles have extremely sophisticated thermoregulatory capacities to sustain their bodies at relatively constant temperatures in the face of this potential heat management nightmare.

This seems so obvious that it may come as a surprise to find that for a long time the thermoregulatory capacities of reptiles were considered extremely rudimentary. These impressions came from observations made during the 1800s of animals that had been captured in the wild. The typical reptile was captured from the wild and held overnight in a box, as was frequently the practice for animal collectors. When the reptile was removed from the box the next morning (assuming that the animal was not unduly large), it would generally have reached thermal equilibrium with its surroundings and have a body temperature similar to that of the box. If it was cold, the body temperature would also be cold and the animal would have the consequent impacts of reduced body temperature on performance, including extremely sluggish movements and a generalized inability to respond to stimuli. Therefore, it is a small wonder that the animals were termed "cold-blooded" or poikliothermic (literally "variable temperatured"), reflecting the notion that they were incapable of thermoregulation and, thus, that their body temperatures varied along with the many temperatures of the environment. One of the few physiological skills the animals appeared to have was the ability to survive body temperature fluctuations that would be lethal to most mammals.

This notion arose from the abstraction of these animals from their environment. When a pioneering group of physiologists during the 1950s started to examine animals in the wild, they uncovered the true nature of reptilian thermoregulatory capacities. In fact, during the daytime, most reptiles are very good at regulating their body temperatures within very narrow limits. They do this primarily by regulating the level of absorption of shortwave radiation. To increase body temperature, reptiles bask in the sun. They maximize uptake of absorption by exposing the maximal area they can toward the sun, adopting body angles that maximize interception of radiation. Many reptiles have specialized dark patches on their surfaces that serve to decrease surface albedo and, thus, absorb more incident shortwave radiation, not unlike little thermal windows on their surfaces. By locating themselves onto hot surfaces that have heated up in the sun, they can gain additional energy to heat themselves by conduction. To cool down, the animals turn themselves away from the sun, minimizing their interception area and turn their dark patches away so that they no longer absorb. If the problem is severe, they seek shaded areas where the incoming shortwave radiation is massively reduced and the substrate in which they are in heat exchange by conduction is cooler. Ultimately, animals may avoid the environmental extremes by burying themselves, either under rocks or in the substrate itself.

The dependence of reptiles on shortwave radiation from outside their bodies to control their energy balance, and hence their body temperatures, has been termed "heliothermy" (from *helios* or "the sun"). However, a more common term emphasizing the fact that most of the heat used to control body temperature is from external sources is "exothermy" or "ectothermy." One disadvantage of relying so

heavily on the solar radiation for energy is that once the sun goes away, the animals are deprived of their primary heat source and start to cool down. This is why reptiles left in boxes overnight generally have body temperatures in the morning that are at the same temperature as the ambient temperature and, thus, appear to be unable to thermoregulate. This thermal dependency is mitigated somewhat by size given that larger animals, by virtue of their greater surface/volume ratio, cool more slowly. For example, komodo dragons, which are the largest extant lizards, spend all day at body temperatures of roughly 36 to 38°C but overnight cool by only 5 to 8°C, even when the environmental temperature is approximately 20 to 25°C. This slow cooling is primarily a function of their large size. The heavy dependence on the sun also explains why the distribution of reptile species is primarily tropical.

Problems arise for reptiles if they require going into water. Because of the very high thermal conductivity of water, combined with the fact the animals are cut off from their usual source of external radiation, reptiles in water cool rapidly to the water temperature. Marine iguanas from the Galapagos Islands routinely feed in the splash zone at the top end of beaches and may dive to feed on algae up to 3 m deep, spending protracted periods submerged. That these animals can submerge for long periods without succumbing fatally has been known for some considerable time. Darwin, in *The Origin of Species,* remarked on a rather crude experiment performed by a sailor in which a marine iguana was tethered to rocks and submerged for an hour but was still alive on recovery. Studies of blood circulation have shown that marine iguanas have exquisite control over their circulatory systems, allowing them to vasoconstrict during diving to concentrate blood flow in their core and, thus, retard total heat loss and their cooling rate, but then to vasodilate on emergence to rapidly heat up by a combination of basking (uptake of solar radiation) and direct contact with the black lava rocks that form the beachheads (conduction). Studies of other marine reptiles such as sea turtles indicate that similar circulatory adjustments allow them to minimize cooling and/or maximize heating rates by adjusting blood flow into their front flippers as they encounter waters of varying temperatures. Leatherback turtles might even have some degree of endothermic heat production beyond the slow cooling engendered by their large size, allowing them to stray outside tropical waters, but this capacity is a matter of some debate.

However, other reptiles certainly do have the capacity to generate heat internally. Probably the best example of this is brooding pythons. These large snakes are able to generate heat internally, allowing them to transfer heat to their eggs and thereby stabilize incubation temperatures. The mechanisms involved in this internal heat production appear to include only shivering, that is, systematic contraction of the skeletal muscles not linked to gross body movement that generates heat as a by-product. However, even in these large snakes, the amounts of heat generated are insufficient to enable the animals to maintain a constant high body temperature in the face of declining ambient temperature when there is no external source of radiation.

3.3 Birds and Mammals

If a bird or mammal is placed overnight in a box, and the animal is deprived of an external source of heat but is provided with food, in the morning its body temperature will be largely independent of the ambient temperature. This contrasting observation to the response of reptiles led early researchers to classify these animals as "homeotherms" (literally "same temperatured"), reflecting the stability in the body temperatures, and to assume that these animals have much more sophisticated systems of thermoregulation. In fact, the problems faced by birds, mammals, and reptiles are very similar—enormous changes in the driving gradients combined with great variability in the endogenous heat production due to exercise.

However, the solution to the problem that has evolved in birds and mammals is radically different. This does not mean that birds and mammals do not take advantage of the ability to manage their heat flows in behavioral exothermic ways. Many birds and mammals bask in the early morning sun, using exogenous shortwave radiation to raise their body temperatures. Both groups seek shade to avoid overheating, husky dogs prostrate themselves on snow to cool down after running, and nearly all birds and mammals exhibit a large number of other minor behavioral adjustments to manage their heat budgets (some of which were mentioned previously in the context of describing the modes of heat transfer). But the main difference is that whereas nearly all of the heat used by reptiles is externally derived, for mammals and birds it is internally derived. Hence, these animals are often called "endotherms." Functionally, both birds and mammals are endothermic, but the physiological mechanisms they use to

generate the heat are radically different; birds use shivering, whereas mammals have evolved a specialized tissue (called brown adipose tissue) that serves to generate heat.

To understand the variations in the energy demands of endothermy, it is useful to consider the energy that would be required to sustain the temperature of a beaker of water that nominally represents an animal's body. If one had a beaker of warm water at, say, 38°C and it was standing in an environment of 20°C, it would cool down by the processes of free convection, net radiation losses, and conduction to the surface on which it was standing. Therefore, to keep the water hot, one would need to place a heater in it and deliver sufficient energy internally to balance these heat losses. Because radiation, convection, and conduction all are functions of temperature difference between the beaker and the environment, the amount of energy one would need to supply with the heater would be a linear function of ambient temperature, crossing the *x* axis at the temperature of water in the beaker (Fig. 2A). That is, the energy one would need to supply if the ambient temperature was 38°C would obviously be zero because the beaker at 38°C would already be in thermal equilibrium. The gradient of the relation between heat requirement and temperature is termed the "thermal conductance" of the system under consideration. The gradient of this line reflects how efficiently the body exchanges heat with its environment. Hence, one could reduce heat flow and, hence, the heat requirement by wrapping the beaker in a blanket. The more insulation layers one added, the shallower and shallower the gradient would become as thermal conductance declined.

In the imaginary system just described, the minimal heat requirement to sustain the beaker temperature is zero. However, real animals cannot have zero heat production. This is because everything they do requires energy. Even when an animal is completely stationary, all its cellular metabolic processes still generate heat as a by-product. If we cross the lines of thermal conductance with this minimal heat production, it becomes clear that these lines intersect at certain points. These are the ambient temperatures where the animal's minimal heat production exactly balances its heat requirement from its thermal conductivity. Above this temperature, the animal is producing too much heat, and below this temperature, it is not producing enough heat to maintain energy balance. This point is called the lower critical temperature for an endotherm. Lower critical temperatures are lower

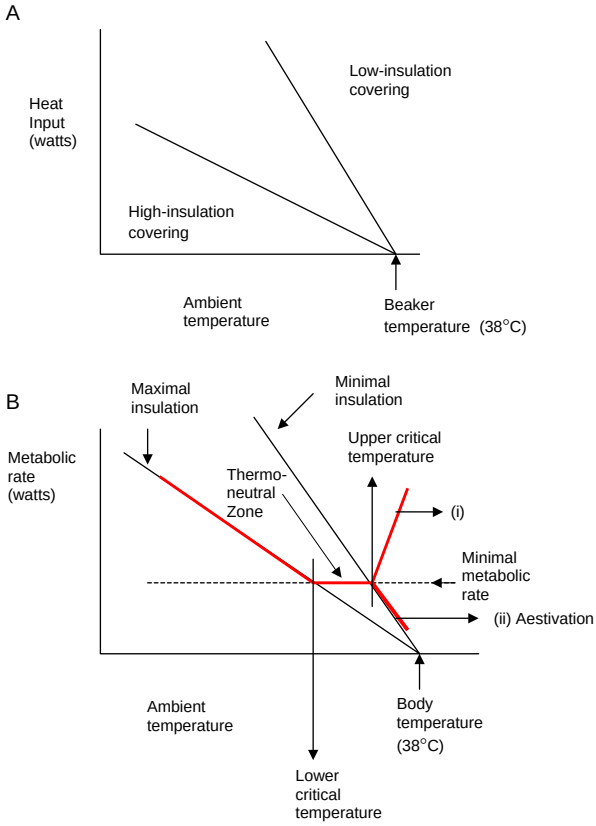

FIGURE 2 (A) Heat input required to sustain a beaker of water at a constant fixed temperature of 38°C as a function of ambient temperature and the thermal conductance of the material surrounding the beaker. Lower thermal conductance (higher insulation) leads to lower energy demands. When the environmental temperature equals 38°C, the heat requirement falls to zero. (B) Pattern of heat requirement as a function of ambient temperature and thermal conductance, with the minimal metabolic rate (= heat production) of an animal overlaid on this pattern. Where the minimal heat production crosses the minimal thermal conductance is called the lower critical temperature point. At lower ambient temperatures, an endothermic animal must supply heat internally to remain at the same body temperature. Above the lower critical temperature, metabolism remains constant (thermoneutral zone) and animals modulate their thermal conductance until they reach their maximal thermal conductance (lowest insulation) at the upper critical temperature point. Above this point, animals can recruit mechanisms to dissipate heat but paradoxically raise their heat production to do this (i), or they can start to shut down their minimal processes and aestivate (ii).

in animals with lower thermal conductances. At temperatures below the lower critical point, an animal must elevate its endogenous heat production to balance heat losses if it is to sustain its body temperatures. The exact requirements track along the line defined by the thermal conductance. Above the lower critical point, the problem an animal faces is to get rid of the surplus heat. It can do this by

making behavioral adjustments that increase thermal conductance (e.g., adopting postures that facilitate airflow, reducing radiation uptake by seeking shade). Humans are uniquely able to rapidly manipulate their external insulation levels by taking off their outer clothing.

It is possible, in making these behavioral adjustments, to elevate conductance so that the minimal heat production balances the heat loss. However, at some point, these behavioral mechanisms can achieve no greater increase in conductance. When ambient temperatures rise above this point, the animal has to do something different. This point is called the upper critical temperature. Between the lower and upper critical temperatures of an endotherm, metabolic heat production remains constant and independent of temperature. This zone is called the thermoneutral zone. It is bounded by the upper and lower limits of variation in an animal's thermal conductance. If temperature rises above the upper critical point, an animal can do one of two things. First, to balance heat production with heat requirement, it can start to shut down its basic metabolic processes and fall into a state of lethargy that is called aestivation. Second, it can spend a little energy, paradoxically increasing heat production, if the net heat loss by this procedure is increased. In general, these mechanisms involve increasing evaporative water loss. When temperatures continue to rise, this increase gets exponentially steeper as the animal brings into play increasingly desperate measures to stay cool. Obviously, at some point, water loss in these states becomes a critical factor, and eventually the animal cannot regulate temperature any longer and the body temperature starts to rise—perhaps fatally if water cannot be replenished.

This model of heat loss in endothermic animals is generally called the "Newtonian cooling model," and although it involves several simplifications of the actual situation observed in many animals, the model highlights some of the features of being endothermic and how these differ critically from those of exothermic animals. First, examination of the gradients of the curves relating thermal conductance to energy requirements clearly shows that the greater the degree of external insulation, the lower the energy demands of endothermy. Therefore, simple power demand arguments suggest that as the temperatures get cooler, endothermic animals should thicken up their external insulation layers. Indeed, many examples of this are observed in nature; Tropical endotherms generally have much less external insulation than do temperate and arctic equivalents, and temperate and arctic animals often molt their external insulation seasonally between a thick winter coat and a thin summer coat. Indeed, humans also make the same seasonal and latitudinal alterations in their external insulation and may make such modulations over much shorter time scales of minutes as the heat requirements change.

What is perhaps less obvious is that the surface/volume ratio effects mean that larger animals also have lower thermal conductances and lower requirements to balance heat loss (per gram of body tissue). Therefore, a power argument suggests that it is advantageous for animals in cold conditions to be larger than their conspecifics in warmer climates. This is known as "Bergmann's law" and has a corollary, "Allen's rule," that not only should animals get larger in colder climates, but their appendages should get smaller as well so as to minimize heat losses. There are many examples of animals conforming to Bergmann's law, but as many endotherms do not conform to it as do, and many species actually show converse trends. Moreover, many exotherms show similar trends despite the energetics arguments not applying to them. This illustrates that power arguments and surface/volume ratios are but one of many selective pressures on animal body size, making generalizable rules difficult to formulate.

As animals get very large, they start to face the problem that their thermal conductance curves are so shallow that they are nearly always below the minimal metabolism line. These animals face problems in dissipating heat; consequently, to facilitate this process, they reduce the extent of their external insulation. Indeed, the largest extant land mammals, elephants and rhinos, have dispensed with external insulative fur completely. However, for most endothermic animals, the main problem they face is keeping heat they generate internally inside their bodies, and that is why nearly all of the endothermic birds and mammals have well-developed fur or feathers. This contrasts with the situation in reptiles that have no external insulation at all. External insulation layers would clearly be detrimental to reptiles, whose major source of heat is external, because the insulation would retard the heat from getting in. An obvious and seemingly paradoxical exception to the external insulation rule are the marine mammals. This is paradoxical because if one group of animals might be expected to most need external insulation, it would be endotherms immersed in water—with their thermal conductivity 23 times greater than that of air. Why have these

animals not evolved or lost their fur? The answer is that fur is not hydrodynamic given that its major function is to trap a layer of air. By replacing the external fur with an internal blubber layer, many marine mammals have overcome the problem that the fur layer would interfere with their abilities to swim and perform in the aquatic environment. It was shown earlier that fat layers are ineffective as insulation for smaller mammals. Similarly, smaller aquatic animals, such as sea otters, mink, and water shrews, retain their fur despite its unfavorable hydrodynamic properties.

Endothermy clearly has many advantages in freeing endothermic animals from the dependency on solar radiation. Endotherms can use solar radiation if they wish (somewhat less efficiently due to their external insulation), but if the sun does not shine, they are still able to function effectively, unlike their exothermic relatives. The main disadvantage of being endothermic is that because the energy for heat generation comes from within, the animals must find and eat considerably more food to fuel that energy requirement. Estimates made on small birds and small reptiles of their total daily food requirements suggest that small endothermic birds may, in fact, need to eat 50 to 100 times more food daily than do small lizards of equal body mass.

3.5 Dinosaurs

The question of whether the dinosaurs were endotherms or had thermoregulatory strategies similar to the modern exothermic reptiles to which they were more closely related has been an issue of debate for more than 100 years and, in fact, dates back to the very first discoveries of dinosaur fossils. Wilfred Owen, who gave the group the name "Dinosauria," actually suggested they were probably warm-blooded animals, but this appears to have been more of a political statement to attempt to refute Darwinism than a truly held belief. Throughout the first half of the 20th century, it was mostly believed that dinosaurs were exotherms. However, opinion started to turn during the late 1960s and early 1970s, particularly due to the work of Robert Bakker and publication of his book, *The Dinosaur Heresies,* in 1977. By the late 1990s the public perception of dinosaurs had certainly embraced the idea that they were endotherms.

Several lines of evidence point toward this conclusion. However, many other lines of evidence paint a more confused picture. For example, although we might not expect the larger dinosaur representatives to have external insulation, we would certainly expect this for the smaller representatives. Yet, apart from an indication of some feathering on recent fossils from China, all other small dinosaurs appear to have been devoid of external insulation. In contrast, there is clear evidence that another group of reptiles, the Pterosaurs, appear to have been endothermic, supporting their capacity to fly, and also had external insulation in the form of fur on their bodies. Moreover, extant endotherms have bony structures in their nasal passages that support structures to reclaim heat from respiratory gas exchange, that is, turbinates. All extant endotherms have these bony structures, but they are absent in fossil dinosaurs. Overall, then, the evidence supporting an endothermic dinosaur thermoregulatory strategy is at best confused.

4. SUMMARY

Thermoregulation is the maintenance of a stable body temperature by managing the flow of heat into and out of the body. Although there are two major strategies, exothermy (relying on external heat sources) and endothermy (relying on internally generated heat), all animals use a combination of behavioral and physiological strategies to control their heat balances to some extent. In fish, amphibia, and reptiles, the balance is much more toward exothermic regulation, whereas in mammals and birds, the balance is shifted toward endothermy. The jury is still out on the thermoregulatory strategies used by the extinct dinosaurs, although one ancient extinct reptilian group whose members were contemporaries of dinosaurs, the Pterosaurs, were almost certainly endotherms.

Glossary

barrage An artificial barrier across an estuary or river to control the flow of water.
gigawatt (GW) The unit of power defined as 1 billion (1,000,000,000) watts.
gigawatt hour (GWhr) The unit of energy defined as that delivered by a source of one GW in 1 hour.
terawatt (TW) The unit of power defined as 1000 billion (1,000,000,000,000) watts.
terawatt hour (TWhr) The unit of energy defined as that delivered by a source of 1 TW in 1 hour.
tide The motion of the worlds seas and oceans induced by the gravitational and centrifugal influence of the earth, moon, and sun.
turbine A rotating mechanical device, which converts the kinetic energy of a flowing fluid into mechanical motion.

Tidal power is not a new idea. Mills, which used tidal flows in bays and estuaries to drive machinery to grind cereal, were widely used in medieval times. Tides have been seriously reexamined as a potential source of energy for industry and commerce. In the United Kingdom, there were numerous proposals throughout the 20th century to exploit the tidal energy potential of the Severn Estuary. None have yet been developed, primarily as a result of the anticipated costs and concern over the environmental changes that would arise from such a large-scale development.

1. OVERVIEW

The world's first serious scheme to exploit tidal energy was constructed in France, at La Rance in Brittany between 1961 and 1967, and consists of a barrage across a tidal estuary to utilize the rise and fall in sea level induced by the tides. This scheme has proven to be highly successful despite some early teething problems. Many engineers and developers now favor, however, the use of alternative technology, which will utilize the kinetic energy in flowing tidal currents.

Like any energy resource, the prospect of tidal power exploitation has stimulated opposition. Tidal barrage proposals, like La Rance, have produced the most vocal opposition. Environmental groups, although generally in favor of the exploitation of alternative energy sources, are suspicious of the likely environmental changes large estuary based schemes would produce. Political opposition has also been considerable in some cases. One politician in the United Kingdom likened the proposed creation of a barrage across the Severn Estuary to the formation of a "large stinking lake." Similar political opposition has been voiced against any development of the tidal resource in the Solway Firth between Scotland and England. It is anticipated that public and political opposition will limit the development of tidal barrage schemes in the short term.

Opposition to schemes designed to exploit the kinetic energy in tidal currents using open turbines, analogous to wind turbines, has been less voluble, although there has as yet been no commercial demonstration of such technology. If opposition remains muted, then tidal current turbines could be installed in many parts of the world in the early 21st century.

2. THE TIDAL PHENOMENON

2.1 Introduction

The tides are cyclic variations in the levels of the seas and oceans. Water currents accompany these

 © 2004 Elsevier Inc. All rights reserved.

variations in sea level, which, in some locations such as the Pentland Firth to the North of the Scottish mainland, can be extreme.

The explanation of the existence of tides represented one of the greatest challenges to early oceanographers, mathematicians, and physicists. It was not until Newton that a satisfying theory emerged to explain at least some of the properties of the tides. He formulated a theory, which has become known as the equilibrium theory of tides.

2.2 Newton's Approach: The Equilibrium Theory of Tides

The equilibrium theory of tides gives a partial description of tidal behavior for an abstract planet Earth, which is entirely and uniformly covered by water. According to the Newtonian model, the earth-moon system rotates around a common center of mass (CoMs) and the radius of this circulation is given by r, as shown in Fig. 1. The separation of the center of mass of the earth (CoM_e) from the center of mass of the moon (CoM_m) is given by R, which is also shown.

If the earth were not itself rotating, each point on, or in, the Earth would rotate about its own center of rotation, the radius of the rotation would also be given by r and the period of rotation would be equal to the rotational period of the earth-moon system. This results in acceleration toward the local center of rotation.

At the center of the earth, the apparent centrifugal acceleration resulting from the rotation exactly matches the gravitational acceleration. At all other points, there is an imbalance between gravitational and centrifugal effects. At the point B, as shown in Fig. 1, the centrifugal effects exceed the lunar gravitational attraction. In effect, at the surface of the earth, there will be a net flow of water from C & D to A & B. This effect results in the lunar tidal cycle. The equilibrium theory suggests, therefore, the establishment of tidal bulges in the fluid surrounding the earth, as shown in Fig. 2.

The earth rotates, and the two tidal bulges must maintain their positions with respect to the moon. They, therefore, have to travel around the earth at the same rate as the earth's rotation. The moon rotates around the CoM_s every 27.3 days in the same direction that the earth rotates every 24 hours. Because the rotations are in the same direction, the net effect is that the period of the earth's rotation, with respect to the earth-moon system, is 24 hours

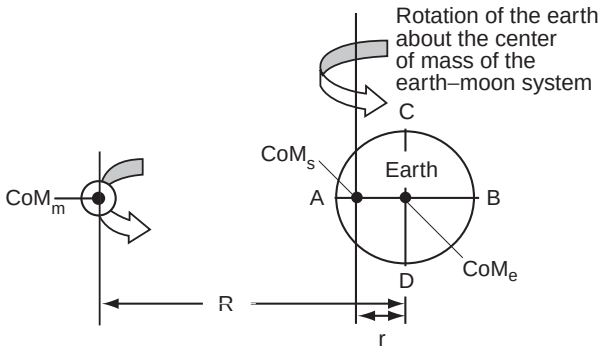

FIGURE 1 Schematic of the earth-moon system.

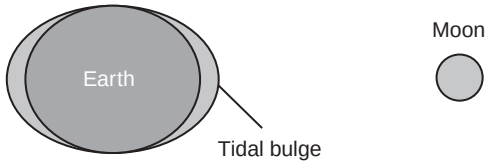

FIGURE 2 The tidal bulge.

and 50 minutes. This explains why the tides are approximately an hour later each day.

During the lunar month, which is the rotational period of the moon around the earth, there will be variations in the lunar tide influence. The lunar orbit is not circular but is elliptical in form, and the tide-producing forces vary by approximately 40% over the month. Similarly, the moon does not orbit around the earth's equator. Instead there is an angle of approximately 28° between the equator and the plane of the lunar orbit. This also results in monthly variations.

2.3 Influence of the Sun on the Tides

The earth-sun system is also elliptical but with only a 4% difference between the maximum and minimum distance from the earth to the sun. The relative positions of the earth, moon, and sun produce the most noticeable variations in the sizes of the tides.

In the configuration shown in Fig. 3, the influence of the moon and sun reinforce each other to produce the large tides known as spring tides, or long tides. A similar superposition also exists at the time of full moon.

When the sun and moon are at 90° with respect to each other, the effect is one of cancellation as shown in Fig. 4. This configuration results in neap tides, also know as short tides.

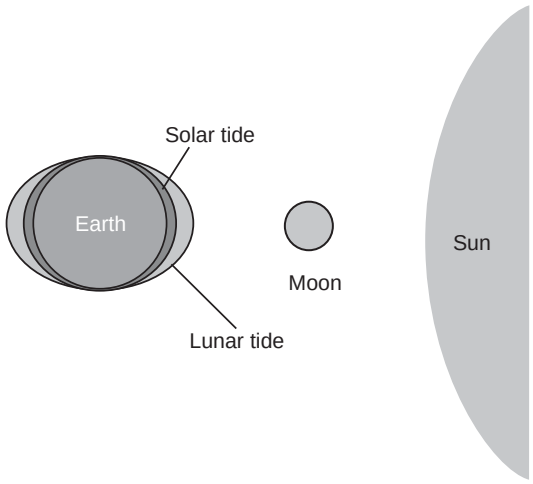

FIGURE 3 Earth, sun, and moon during spring tides.

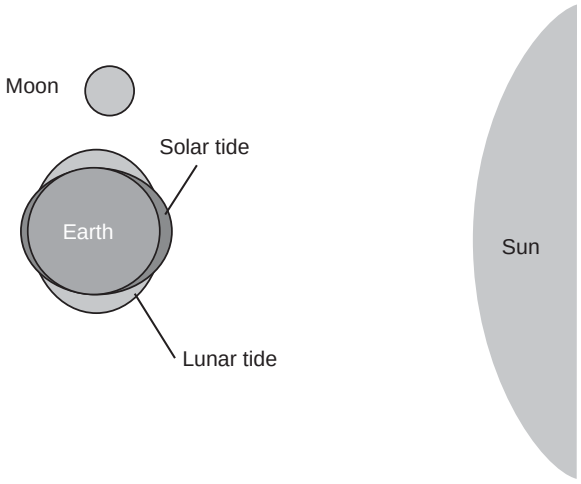

FIGURE 4 Earth, sun, and moon during neap tides.

2.4 The Presence of Land and the Resulting Tidal Dynamics

If the earth were covered entirely by water of a constant depth, the equilibrium theory of tides would give a perfectly reasonable description of water behavior. Fortunately, the oceans are not all of a constant depth and the presence of continents and islands severely influences the behavior of the oceans under tidal influences. The Coriolis force is a particularly important effect which, in the Northern Hemisphere, diverts moving objects to the right and, in the Southern Hemisphere, diverts moving objects to the left. The influence of this force, in the presence of land, can be considered, as shown in Fig. 5, by visualizing water flowing into and out of a semi-enclosed basin in the Northern Hemisphere under the influence of tidal effects. On the way into the channel, the water is diverted to the right toward the lower boundary. When the tidal forcing is reversed, the water is diverted toward the upper boundary. This results in a substantially higher tidal range at the basin boundaries than at the center.

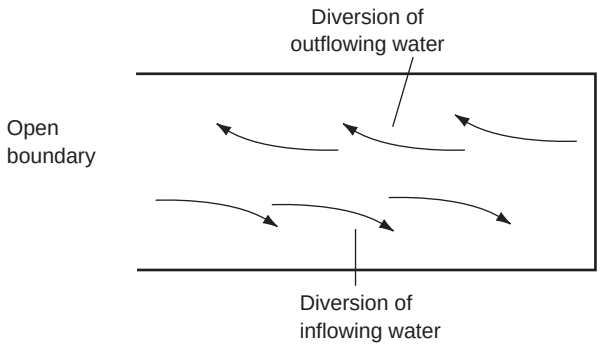

FIGURE 5 Flow of water into and out of a semi-enclosed basin in the Northern Hemisphere.

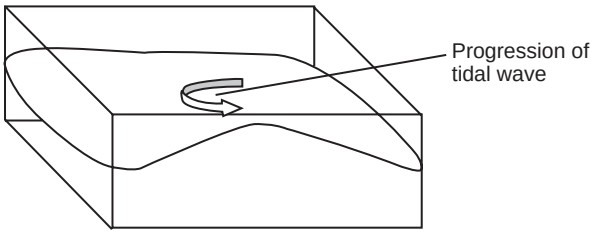

FIGURE 6 Progression of a tidal wave in a basin.

The net result of this effect is to generate a so-called tidal wave, which processes anti-clockwise around a point in the center of the "basin," as shown in Fig. 6.

In effect, the tides represent the terrestrial manifestation of the potential and kinetic energy fluxes present in the earth-moon-sun system. These fluxes are complicated by the presence of continents and other landmasses, which modify the form and phase of the tidal wave. As a result, substantially higher local fluxes occur in some regions of the world than others. The Bay of Fundy in Canada and the Bristol Channel between England and Wales are two particularly noteworthy examples of high-flux regions.

2.5 Global Flux

It has been estimated that the total energy from the tides, which is currently dissipated through friction and drag, is equivalent to 3000 GW of thermal energy worldwide. Much of this power is in inaccessible places, but up to 1000 GW is available

in relatively shallow coastal regions. Estimates of the achievable worldwide electrical power capability range from about 120 GW of rated capacity to approaching 400 GW. This is obviously a substantial energy resource, the significance of which has yet to be fully appreciated. Many enthusiasts believe these to be hopelessly pessimistic estimates. It is probably reasonable, however, to consider these estimates as representing, with an element of uncertainty, what could be exploited now using available technology.

3. TIDAL BARRAGE METHODS

3. History

There are many places in the world in which local geography results in particularly large tidal ranges. Sites of particular interest include the Bay of Fundy in Canada, which has a mean tidal range of 10 m, the Severn Estuary between England and Wales, with a mean tidal range of 8 m and Northern France with a mean range of 7 m. A tidal barrage power plant has been operating at La Rance in Brittany since 1966. This plant, which is capable of generating 240 MW, incorporates a road crossing of the estuary. Other operational barrage sites are at Annapolis Royal in Nova Scotia (18 MW), the Bay of Kislaya near Murmansk (400 kW), and at Jangxia Creek in the East China Sea (500 kW). Schemes for energy recovery, not surprisingly, have been proposed for the Bay of Fundy and for the Severn Estuary but have never been built.

3.2 Principles of Operation

3.2.1 The Role of the Barrage

The approach is essentially always the same. An estuary or bay with a large natural tidal range is identified and then artificially enclosed with a barrage. This would, typically, also provide a road or rail crossing of the gap in order to maximize the economic benefit. Electrical energy is produced by allowing water to flow from one side of the barrage through low head turbines, as shown in Fig. 7.

There are a variety of suggested modes of operation. These can be broken down initially into single basin schemes and multiple basin schemes. The simplest of these are the single basin schemes.

3.2.2 Single Basin Tidal Barrage Schemes

These schemes, as the name implies, require a single barrage across the estuary, as shown in Fig. 8. There

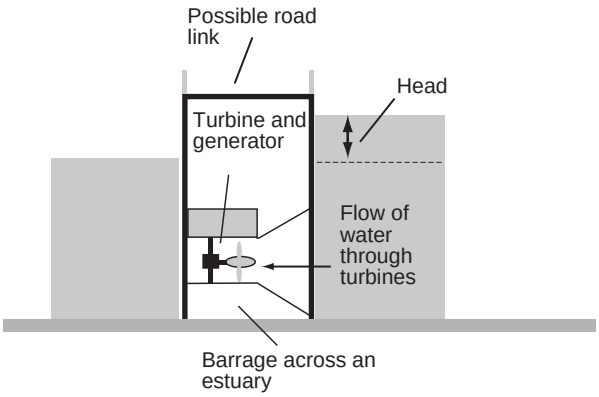

FIGURE 7 Schematic of a tidal power barrage.

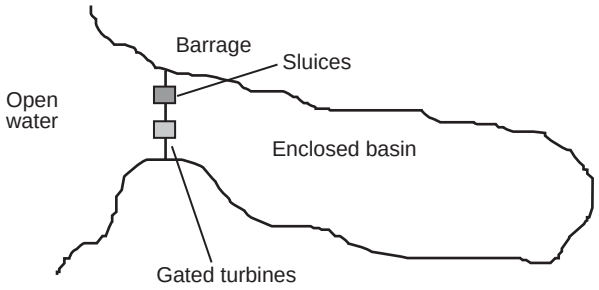

FIGURE 8 Schematic of the single basin generation scheme.

are, however, three different methods of generating electricity with a single basin. All of the options involve a combination of sluices which, when open, can allow water to flow relatively freely through the barrage and gated turbines, the gates of which can be opened to allow water to flow through the turbines to generate electricity.

3.2.3 Ebb Generation

During the flood tide, incoming water is allowed to flow freely through sluices into the barrage. At high tide, the sluices are closed and water is retained behind the barrage. When the water outside the barrage has fallen sufficiently to establish a substantial head between the basin and the open water, the basin water is allowed to flow out though low-head turbines and to generate electricity.

The system may be considered to operate in a series of steps as shown in Fig. 9.

These steps can be represented, as in Fig. 10, to show the periods of generation associated with stages in the tidal cycle.

Typically the water will only be allowed to flow through the turbines once the head is approximately

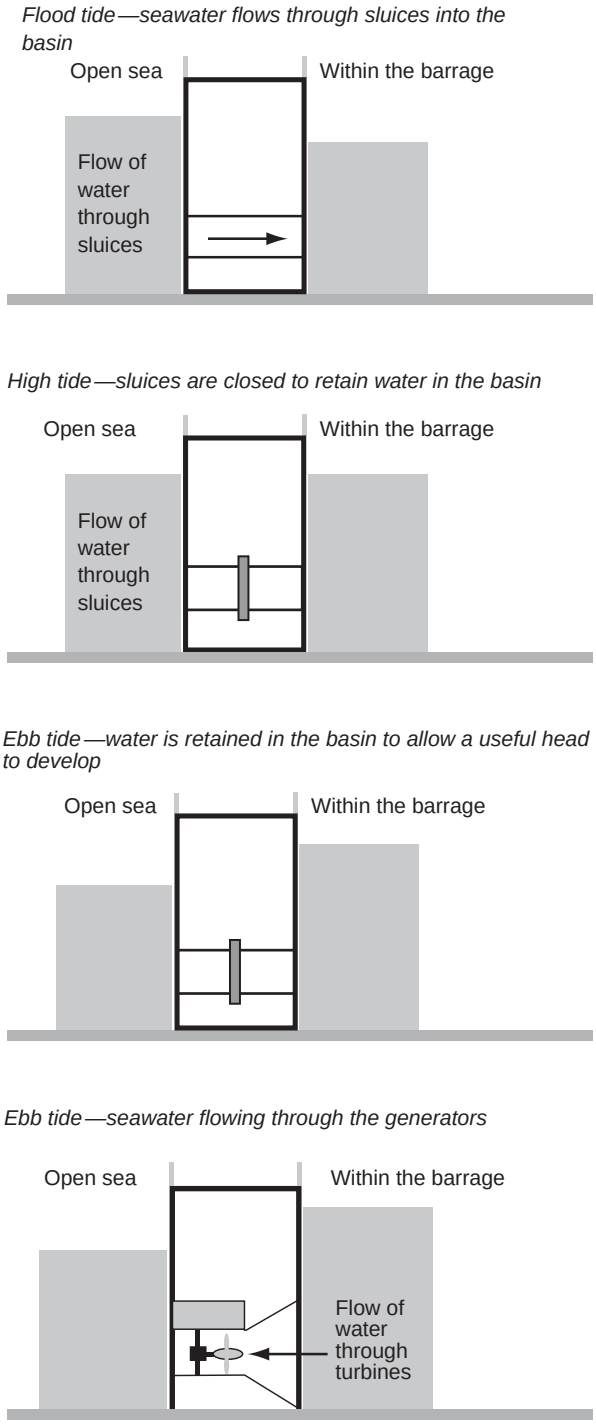

FIGURE 9 Operational steps in an ebb generation barrage scheme. (A) Ebb tide—water is retained in the basin to allow a useful head to develop. (B) Ebb tide—seawater flowing through the generators.

half the tidal range. It is likely that an ebb generation system will be able to generate electricity for, at most, 40% of the tidal cycle.

3.2.4 Flood Generation

The sluices and turbine gates are kept closed during the flood tide to allow the water level to build up outside of the barrage. As with ebb generation, once a sufficient head has been established, the turbine gates are opened and water can, in this case, flow into the basin and generate electricity, as Fig. 11 shows.

This approach is generally viewed as being less favorable than the ebb method because keeping a tidal basin at low tide for extended periods could have detrimental effects on the environment and shipping. In addition, the energy produced would be reduced as the surface area of a basin would be larger at high tide than at low tide, which would result in a rapid reductions in the head during the early stages of the generating cycle.

3.3.5 Two-Way Generation

In this mode of operation, use is made of both the flood and ebb phases of the tide. Near the end of the flood-generation period, the sluices would be opened to allow water to get behind the barrage and would then be closed. When the level on the open water side of the barrage had dropped sufficiently, water would be released through the turbines in the ebb generation mode, as shown in Fig. 12.

Unfortunately computer models do not indicate that there would be a major increase in the energy production. In addition, additional expenses would be associated with a requirement for either two-way turbines or a double set to handle the two-way flow. Advantages include, however, a reduced period with no generation and the peak power would be lower, allowing a reduction in the cost of the generators.

3.3.6 Double-Basin Systems

All single-basin systems suffer from the disadvantage that they only deliver energy during part of the tidal cycle and cannot adjust their delivery period to match the requirements of consumers. Double basin systems, such as that shown in Fig. 13, have been proposed to allow an element of storage and to give time control over power output levels.

The main basin would behave essentially like an ebb generation single basin system. A proportion of the electricity generated during the ebb phase would be used to pump water to and from the second basin to ensure that there would always by a generation capability. The cycle can be seen in Fig. 14.

It is anticipated that multiple basin systems are unlikely to become popular, as the efficiency of low-head turbines is likely to be too low to enable effective economic storage of energy. The overall

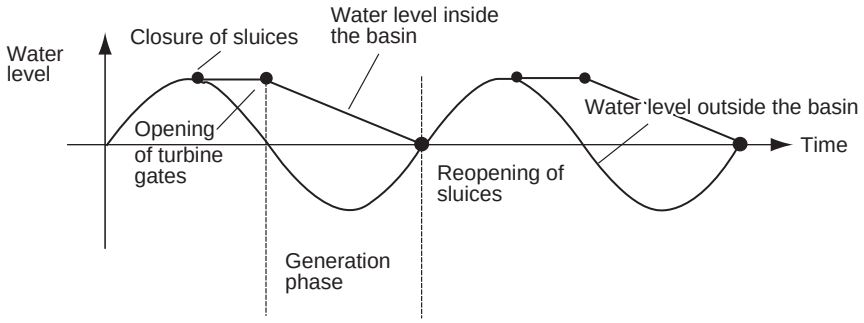

FIGURE 10 Water level inside and outside of an ebb generation barrage.

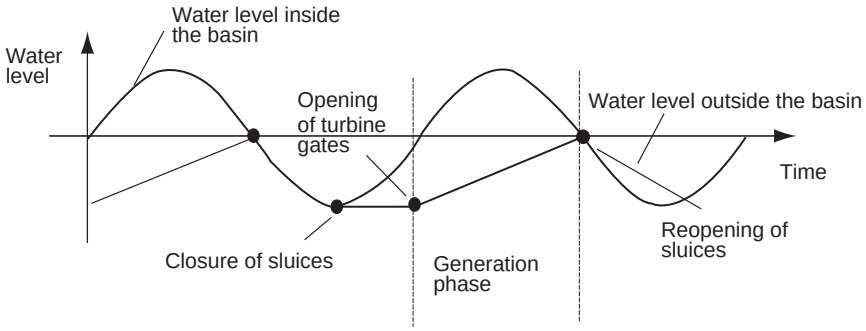

FIGURE 11 Water level inside and outside of a flood generation barrage.

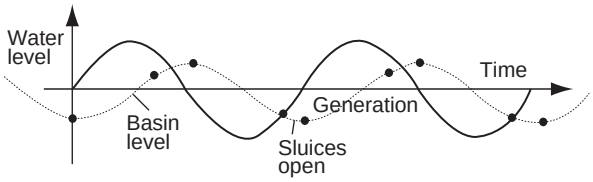

FIGURE 12 Water level inside and outside of a two-way generation barrage.

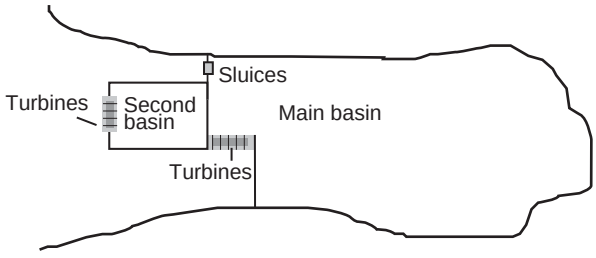

FIGURE 13 Schematic of a double basin generation system.

efficiency of such low-head storage, in terms of energy out and energy in, is unlikely to exceed 30%. It is more likely that conventional pump-storage systems will be utilized. The overall efficiencies of these systems can exceed 70%, which is, especially considering that this is a proven technology, likely to prove more financially attractive.

3.3 Optimal Design of Barrage Systems

This is not a simple procedure, as the construction of a barrage will inevitably change the nature of the tidal environment. It is theoretically possible, for example, for the tidal range to be very much less once a barrage has been constructed than it was prior to construction. To avoid an expensive mistake, it is necessary that reliable computer models be used to predict future behavior as much as possible. Such models are available and can be used with a great degree of confidence.

3.4 Locations for Tidal Barrage Developments

A considerable number of sites worldwide are technically suitable for development, although whether the resource can be developed economically is yet to be conclusively determined. Some of these are listed in Table I.

3.5 The Environmental Impact of Basin Systems

The construction of a barrage across a tidal basin will change the environment considerably. An ebb

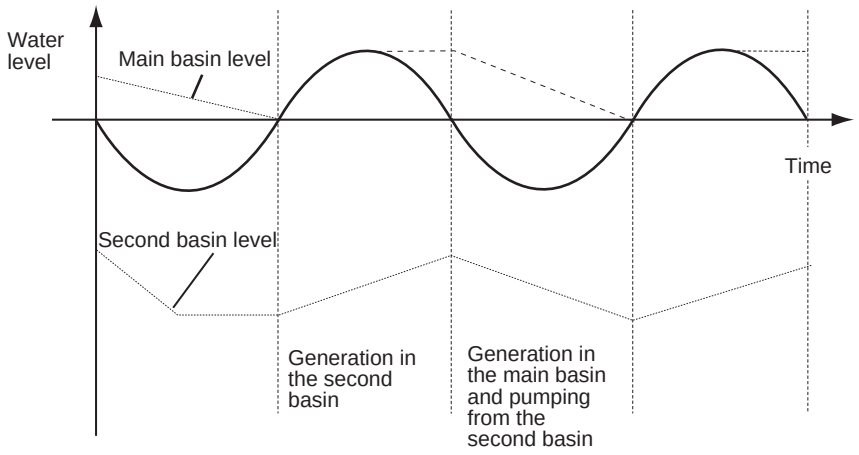

FIGURE 14 Water levels associated with a two-basin generation system.

TABLE I

Resource Estimates for Selected Sites

Site	Mean tidal range (m)	Barrage length (m)	Estimated annual energy production (GWhr)
Severn Estuary (UK)	7.0	17,000	12,900
Solway Firth (UK)	5.5	30,000	10,050
Bay of Fundy (Canada)	11.7	8000	11,700
Gulf of Khambat (India)	6.1	25,000	16,400

system will reduce the time tidal sands are uncovered. This change will have considerable influences on the lives of wading birds and other creatures. The presence of a barrage will also influence maritime traffic, and it will always be necessary to include locks to allow vessels to pass through the barrage. This will be much easier for an ebb system, where the basin is potentially kept at a higher level, than it would be with a flood-generation system, in which the basin would be kept at a lower than natural level. The environmental impact from increasing the area of exposed sediment in an estuarial environment is difficult to quantify but likely to be detrimental.

3.6 The Financial Implications of Tidal Barrage Development

Barrage schemes can produce a vast amount of energy. It has been suggested that the Severn Estuary could provide in excess of 8% of the United Kingdom's requirement for electrical energy. However, all barrage schemes are constrained by the massive engineering operations and associated financial investment that would be required. Construction would take several years. La Rance, for example, took 6 years, and no electricity was generated before the total project was completed. This is a major disincentive for commercial investment.

4. TIDAL CURRENT SYSTEMS

4.1 The Resource

The public perception of tidal power has traditionally been of large barrage schemes such as that at La Rance or proposed for the Severn Estuary. In addition to changes in the sea-surface level, however, the tides also generate water currents. In the open ocean, these currents are typically very small and are measured in cm/s at most. Local geographical effects can, however, result in quite massive local current speeds. In the Pentland Firth, for example, there is evidence of tidal currents exceeding 7 m/s. The kinetic energy in such a flow is considerable. Indeed many experts describe the Pentland Firth as the Saudi Arabia of tidal current power, which explains the considerable interest in this site, which has been expressed by the UK and Scottish governments. At present, however, there is no available technology to exploit this massively energetic but hostile channel.

Other sites, in Europe alone, with large currents, include the Channel Islands and The Straits of Messina. In addition to major sites such as the Pentland Firth, numerous local sites experience rapid currents capable of generating electricity with suitable technology.

Since the late 1980s, interest in the possibility of using tidal currents to generate electricity has developed enormously. A study prepared for the Scottish government in 2001 suggested that the UK "base case" potential could exceed 33.5 TWhr per annum at reasonable cost and using available technology. An earlier study for the European Union reported in 1996 that the European Union resource should exceed 48 TWhr. This figure appears low in comparison with the later UK figure, and it is suggested that, rather than the European resource outside of the United Kingdom representing only 14.5 TWhr per annum potential, the state of knowledge and understanding had increased dramatically in the 5 years separating these studies. There has not yet been an authoritative study of the achievable world resource but, drawing parallels with UK and European studies, it is anticipated that the achievable world resource could exceed 270 TWhr per annum using technology that is already under consideration. If problems associated with harnessing energy from currents in deep water can be overcome, then this figure might prove to be highly pessimistic, especially if technological developments make the development of sites such as the Pentland Firth feasible.

Additional studies have suggested that tidal currents could offer particular opportunities for peripheral rural regions. No one doubts the size of the worldwide potential of the tidal current resource but, unlike tidal barrage power, there has not yet been a large-scale prototype study. It is anticipated that this will soon be remedied.

4.2 Extracting Energy from Tidal Currents

The physics of the conversion of energy from tidal currents is similar, in principle, to the conversion of kinetic energy in the wind. Many of the proposed devices have, therefore, an inevitable, though superficial, resemblance to wind turbines.

There is no total agreement on the form and geometry of the conversion technology itself. Wind power systems are almost entirely horizontal axis rotating turbines, as shown schematically in Fig. 15. In these systems, the axis of rotation is parallel to the direction of the current flow.

In horizontal axis designs, the rotational axis is parallel to the direction of the water flow. Many developers favor this geometry for tidal conversion. Vertical axis systems, such as that shown schematically in Fig. 16, in which the axis of rotation is perpendicular to the direction of current flow, have not been rejected, however.

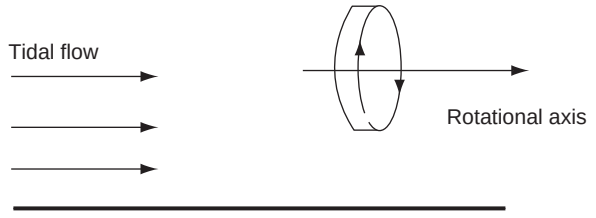

FIGURE 15 Schematic of a horizontal axis tidal current turbine.

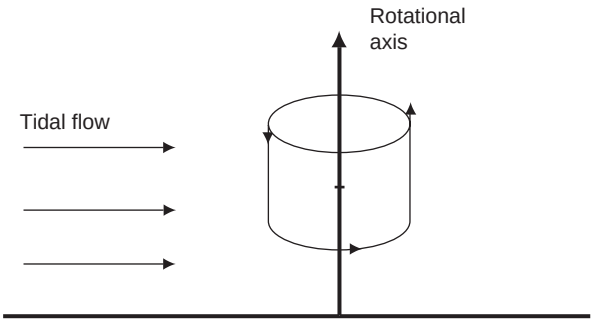

FIGURE 16 Schematic of a vertical axis tidal current turbine.

The environmental drag forces on any tidal current energy conversion system are large when compared with wind turbines of the same capacity. This poses additional challenges to the designer. Designs exist for devices that are rigidly attached to the seabed or are suspended from floating barges, as shown in Fig. 17. It is generally accepted that fixed systems will be most applicable to shallow water sites and moored systems for deep water. There may be exceptions to this, however.

The density of seawater, at approximately 1023 to 1025 kg/m^3, is substantially greater than that of air. This, combined with the rapid currents experienced in many sites across the world, suggests that very high-energy density fluxes will be encountered. Figure 18 shows the anticipated relationship between current speed and incoming energy flux density. Spring current speeds exceeding 3m/s are encountered in many locations, which suggests that the exploitable resource will be considerable. The challenge for the system designer is to ensure that the system can convert energy efficiently throughout as much of the tidal cycle as possible while being robust enough to survive the inevitable environmental loading that will be experienced. The difficulty of this task should not be overestimated. In practice, the efficiency of conversion of a practical system is likely to be limited to approximately 35%, but the potential for energy

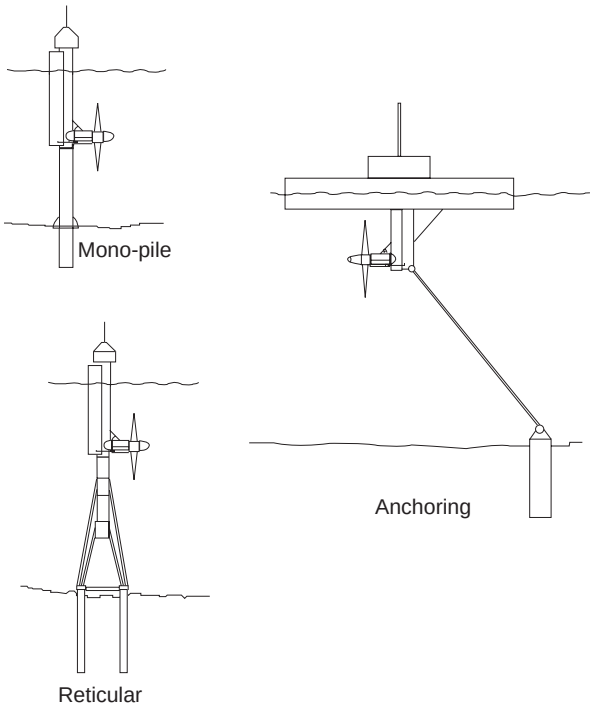

FIGURE 17 Alternative location systems for tidal current technology.

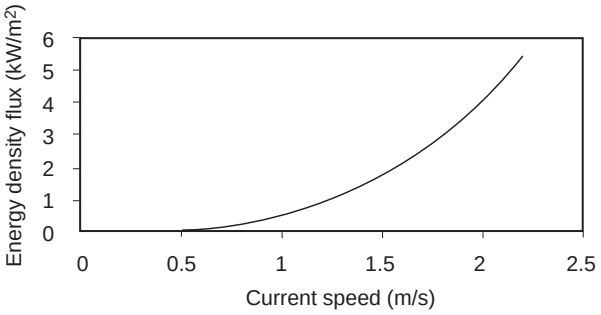

FIGURE 18 Influence of current speed on available energy flux density.

conversion in tidal current speeds, which might exceed 3 m/s in spring tides, is considerable.

The environment tidal devices will operate in is very different from that experienced by wind turbines, and there are some rather difficult problems associated with installation, survivability and maintenance that need to be solved before true commercial exploitation can be achieved. Many industrial, commercial, and public bodies have suggested that there is a high degree of synergy between the development of a tidal current generation industry and the offshore oil and gas industry. This offers the intriguing prospect of a new renewable industry developing in partnership with the petroleum industry and could, perhaps, result in accelerated development, due to the availability of expertise and technology, which would otherwise have to be developed from scratch.

Unlike the wind, tides are essentially predictable as they derive from astronomic processes discussed earlier in this article. Wind power systems are dependent on random atmospheric processes, which result in it being difficult to integrate large wind power developments into strategic electricity distribution networks. The predictability of the tides will make this integration much easier. Figure 19 shows the predicted power output for one design concept over a spring/neap tidal cycle, in which the spring peak current speed is 3 m/s and the neap peak current speed is 1.5 m/s. Although there would be some deviation from this prediction, as a result of weather related influences, the predictable nature can be clearly seen.

4.3 Testing the Technology for Tidal Current Energy Extraction

At the time of writing, there is no commercial generation of electricity from tidal currents anywhere

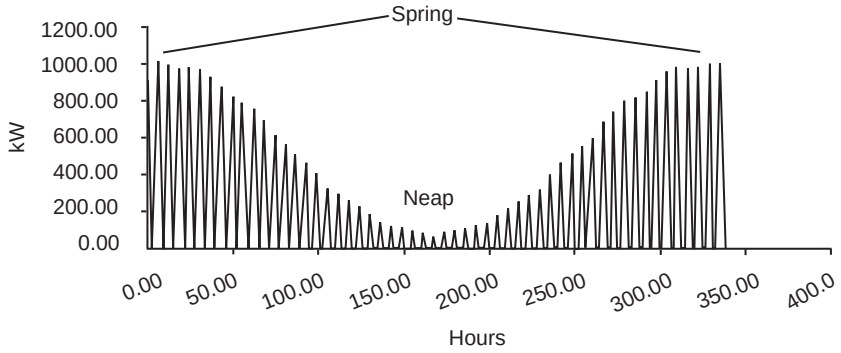

FIGURE 19 Predicted power output for a constant speed, 20-m diameter horizontal axis turbine.

FIGURE 20 Location of Lynmouth in the Bristol Channel.

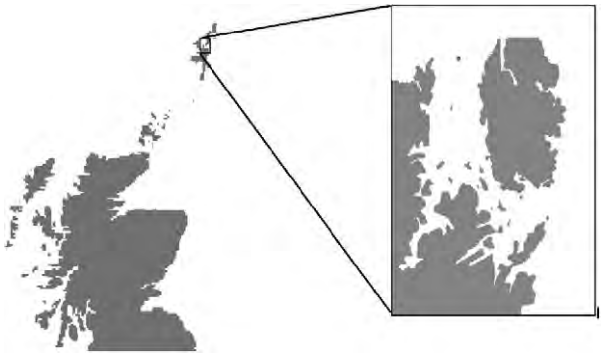

FIGURE 21 Location of Yell Sound in Shetland.

in the world. It is anticipated, however, that two large prototype systems will be installed in European waters in 2002. These devices—one of which will be located close to Lynmouth in the Bristol Channel, which lies between England and Wales, as shown in Fig. 20, and the other in Yell Sound in Shetland, as shown in Fig. 21—will be capable of producing approximately 300 kW each.

The two proposed systems are radically different in engineering concept, although both rely on the lift induced by fluid flow on an appropriately shaped lifting surface. The Lynmouth device, which is shown in Fig. 22, is a horizontal axis turbine, which resembles a traditional wind turbine.

The Yell Sound device, which is shown in Fig. 23, is a linear lift-based device, in which a reciprocating hydrofoil, which has a variable pitch angle, is used to pump oil, which then drives a hydraulic motor.

FIGURE 22 Artist's impression of the turbine being installed in the Bristol Channel. Illustration reproduced with the kind permission of Marine Current Turbines Ltd.

It is likely that, if tidal currents are to be commercially exploited, the generators will have to be mounted in clusters (tide farms?). If this is done, then, as with wind turbines, the devices will have to be sufficiently spread to ensure that the turbulence from individual devices does not interfere with others in the cluster. The nature of tidal currents, in which the most energetic flows are bidirectional in nature may make it possible to use relatively close spacing of devices perpendicular to the flow, with much larger spacing in the direction of the flow as seen in Fig. 24. This also shows one of the devices undergoing maintenance by a surface vessel.

4.4 Barriers to the Development of Tidal Current Generation

At present, there is little worldwide experience in harnessing tidal current energy. Experimental turbines have been used in Japan and the United Kingdom, but as yet they have never been used to generate electricity for commercial consumption. Scottish trials in Loch Linnhe, using a floating

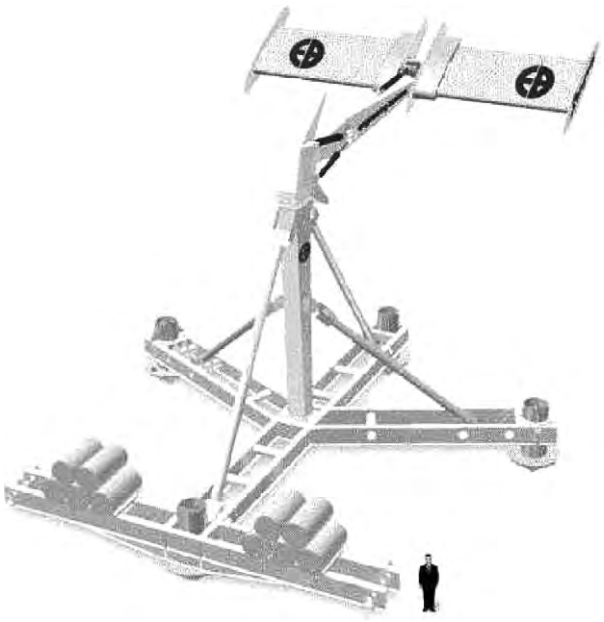

FIGURE 23 Artist's impression of the Stingray device being installed in Yell Sound. Illustration reproduced with the kind permission of The Engineering Business Ltd.

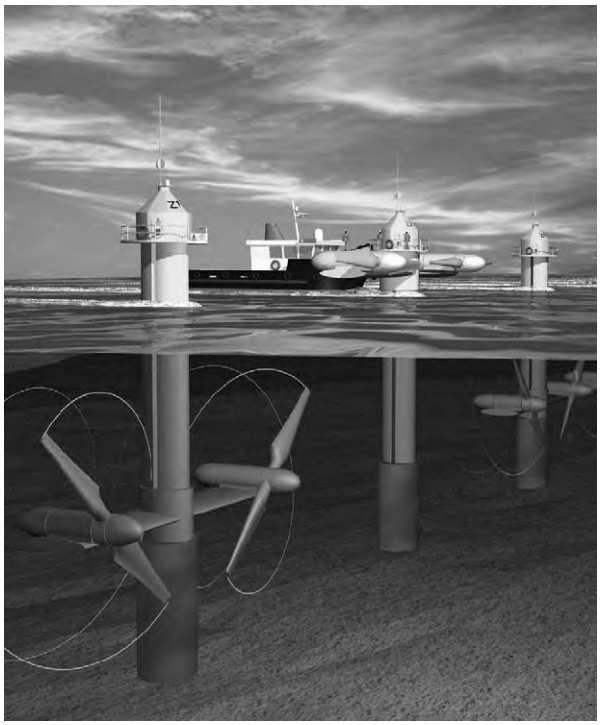

FIGURE 24 Artist's impression of a array of twin rotor tidal current devices. Illustration reproduced with the kind permission of Marine Current Turbines Ltd.

horizontal axis system, demonstrated that the technology is feasible. Experience in Japan has been largely with vertical axis systems. Until a large-scale device is commissioned and has demonstrated its performance for an extended period, there will be uncertainties about the long-term reliability and maintenance. Access to machines located in high energy tidal streams will always be problematic and could prove to require expensive maintenance procedures. Similarly, the rapid tidal currents themselves could provide difficulties in transferring energy via seabed cables to the coastline. Indeed some studies have suggested that the cable and its installation could be responsible for more than 20% of the total cost of a tidal current system. It is still too early to make reliable predictions of the cost of tidal current generation. There are still many uncertainties about the long-term reliability of systems and the difficulties associated with routine maintenance. The UK government's Department of Trade and Industry has indicated, however, that it anticipate that devices based on the Seaflow prototype should be able to generate electricity with a cost similar to onshore wind systems, assuming that problems associated with installation of multiple devices can be solved. Completion of the present program of prototype studies will allow more confidence to be given to predictions.

Environmental impacts from tidal current systems should be minimal, if projects are planned to take environmental issues into account. Energetic tidal channels do not tend to be home to many aquatic species and, although some species of marine mammals use tidal channels in their migration, the slow motion of the turbines and careful design should ensure minimal environmental impact. The most serious environmental impacts are likely to result from the extraction of kinetic energy itself, resulting in changes in the hydraulic nature of the flow environment. This could result in modification to the sediment transport systems and, of course, changes in the tidal currents, which are providing the energy. Many experts assume that up to 10% of the kinetic energy in a tidal flow can be extracted without serious flow degradation.

5. THE FUTURE OF TIDAL POWER

The high capital costs associated with tidal barrage systems are likely to restrict development of this resource in the near future. What developments

do proceed in the early 21st century will most likely be associated with road and rail crossings to maximize the economic benefit. In a future in which energy costs are likely to rise, assuming that low-cost nuclear fusion or other long term alternatives do not make an unexpectedly early arrivals, then tidal barrage schemes could prove to be a major provider of strategic energy in the late 21st century and beyond. Under some local conditions, small-scale barrages might also prove attractive. The technology for tidal barrage systems is already available, and there is no doubt, given the experience at La Rance, that the resource is substantial and available.

It is likely that tidal current systems will appear in experimental form in many places around the world. Initially these will be rated at around 300 kW, such as those planned for the Lynmouth and Yell Sound demonstrations. If these schemes prove successful, then the first truly commercial developments may appear soon. Systems may not presently have the strategic potential of barrage systems but, in the short term at least, they do offer opportunities for supplying energy in rural coastal and island communities. In the longer term, massive sites such as the Pentland Firth, which has been estimated to have the potential to support a 16-GW-capacity development, could become strategically important.

Glossary

border tax adjustment (BTA) A system in which traded goods are subject to a tax from the importing country but exempt from such a tax of the exporting country; e.g., a CO_2 emission tax.

dual pricing The fact of a given product having two different prices in different markets, especially a different domestic and export price.

most favored nation (MFN) A trade status extended by a country to a trading partner, allowing for the import of goods from the trading nation at the same tariff rate which the importing nation extends to its other trading partners that are part of the same agreement. In current usage the term normal trade relations (NTR) is often preferred because typically a nation will extend this status to all its trading partners except for a few rogue states.

national treatment The principle or policy that foreign products, services, and intellectual property should be given the same status or treatment they would have if they were domestic.

tariff A duty imposed on foreign goods imported into a country.

TRIPs An acronym for Trade-Related Intellectual Property Rights; i.e., the fact or policy of a nation's agreeing to provide protection for the rights to foreign-made intellectual property (innovative products of the human mind and imagination such as copyrights, trademarks, patents, industrial designs, and trade secrets).

Trade aspects of energy and energy services typically involve the following concerns: import and export promotion and/or protection, security of supply, and environmental protection. These concerns taken together obviously make for an interesting mix of often competing regulatory goals and hence do not contribute to creating a stable regulatory environment in which international trade can thrive. The World Trade Organization (WTO) is an obvious focal point for current and future liberalization in the area. However, other multilateral organizations have also had a role to play, including the North American Free Trade Association, the Asia-Pacific Economic Cooperation, the Energy Charter Treaty, and the European Union. This article focuses on the most multilateral framework of trade negotiations, the WTO, and on its impact with respect to trade in energy and energy services.

1. THE WORLD TRADE ORGANIZATION AGREEMENT

1.1 History

The World Trade Organization (WTO) has more than 130 members, accounting for more than 90% of world trade. More than 30 others are negotiating membership. The forerunner of the WTO is the 1947 General Agreement on Tariffs and Trade (GATT). GATT was the cornerstone of international trade law and trade negotiations for more than four decades. It only achieved this status after the collapse of the Agreement on an International Trade Organization (ITO). ITO had been prepared after World War II under the auspices of the United Nations (UN), particularly the UN Economic and Social Council, and the UN Conference on Trade and Development.

 © 2004 Elsevier Inc. All rights reserved.

After it became clear that the U.S. Congress would not ratify the ITO agreement, plans to have the ITO established were dropped, and GATT became the single most important international trade (law) instrument by default.

GATT's profile was at its highest at the time of negotiation of the eight successive so-called "rounds" of tariff negotiations. These each led to new "schedules" of tariff concessions, in which the contracting parties (as the states adhering to GATT were known) individually agreed to cut tariffs on specified products, according to the agreed timetable. The last of these rounds, the Uruguay Round, led to the creation of the WTO by the 1994 Marrakech Agreement. GATT 1947 was integrated into the WTO agreement and, together with the GATT 1994 agreement, forms the backbone of international trade in goods.

Decisions in the WTO are made by the entire membership. This is typically by consensus. A majority vote is also possible, but it has never been used in the WTO and was extremely rare under the WTO's predecessor, GATT. The WTO's agreements have been ratified in all members' parliaments.

1.2 WTO Institutions

The WTO's top-level decision-making body is the Ministerial Conference, which meets at least once every 2 years. Below this is the General Council (normally ambassadors and heads of delegation in Geneva, but sometimes officials sent from members' capitals), which meets several times a year at the Geneva headquarters. The General Council also meets as the Trade Policy Review Body and the Dispute Settlement Body. At the next level, the Goods Council, Services Council, and Intellectual Property [General Agreement on Trade-Related Aspects of Intellectual Property (TRIPs)] Council, report to the General Council. Numerous specialized committees, working groups, and working parties deal with the individual agreements and other areas, such as the environment, development, membership applications, and regional trade agreements.

The first Ministerial Conference in Singapore in 1996 added three new working groups to this structure. They deal with the relationship between trade and investment, the interaction between trade and competition policy, and transparency in government procurement. At the second Ministerial Conference in Geneva in 1998, ministers decided that the WTO would also study the area of electronic commerce, a task to be shared among existing councils and committees.

The WTO Secretariat's main duties are to supply technical support for the various councils and committees and the ministerial conferences, to provide technical assistance for developing countries, to analyze world trade, and to explain WTO affairs to the public and media. The Secretariat also provides some forms of legal assistance in the dispute settlement process and advises governments wishing to become members of the WTO. It is based in Geneva.

1.3 WTO Agreements

The 1986–1994 Uruguay Round negotiations, as noted previously, included a major revision of the original GATT. GATT is now the WTO's principal rulebook for trade in goods. The Uruguay Round also created new rules for dealing with trade in services [the General Agreement on Trade in Services (GATS)], relevant aspects of intellectual property (the TRIPs agreement, dispute settlement, and trade policy reviews. The complete set consists of approximately 60 agreements (including on public procurement), and separate commitments (called schedules), made by individual members in specific areas, such as lower customs duty rates and services market opening.

The Marrakech Agreement is the single most exciting development in international trade law in the past century. The creation of the agreements on intellectual property and services is the most obvious development. This article does not discuss the details of each of these agreements. One agreement is developed later, namely the Understanding on Rules and Procedures Governing the Settlement of Disputes.

The structure of the agreement establishing the WTO, corresponds with its institutional set-up. The issues involved in the liberalization of the energy sector run across a wide variety of these agreements. Hence, there is a *priori* no single WTO agreement whose relevance for the energy sector can summarily be dismissed.

Annex 1 to the agreement has three subannexes. Annex 1A reads "Multilateral agreements on trade in goods." At its core lies the GATT 1994, which comprises the unamended GATT 1947, protocols and decisions adopted under the GATT 1947 structure (typically relating to tariff concessions and waivers), and a number of "understandings" with respect to specific GATT articles and/or concepts. The GATT 1947 continues to include the basic principles of the international trade in goods: most favored nation treatment (MFN; i.e., making

no distinction, for the treatment of imported goods, between their origin), national treatment (i.e., treating imported goods like goods of national origin), and, generally, nondiscrimination. Importantly, one cannot gauge the degree of liberalization of the trade in a given category of goods without consulting the specific tariff "commitments" of each individual member of the WTO. These are the lengthy documents, attached to the WTO agreement, in which members commit to either reducing or eliminating tariffs levied on the goods specified in them.

Other agreements within Annex 1A deal with specific sectors, particularly the Agreement on Agriculture, which remains a focus for further liberalization, and the Agreement on Textiles and Clothing. It is noteworthy in this respect that agriculture and textiles are domains in which the interests of the developed world are often pitched against those of the developing countries.

Finally, Annex 1A covers a number of agreements that deal with specific issues. Reference can be made in this respect to the Agreement on the Application of Sanitary and Phytosanitary Measures, the Agreement on Technical Barriers to Trade, the Agreement on Trade-Related Investment Measures, the Agreement on Subsidies and Countervailing Measures, and the Agreement on Rules of Origin, i.e., these agreements deal with specific sectors.

Annex 1B contains the GATS. The inclusion, during the Uruguay Round negotiations, of services in international trade liberalization is widely acknowledged as being one of the most important developments brought about by the WTO. GATS' structure is not unlike the structure of Annex 1A, although there are important differences. As in Annex 1A, GATS operates on three platforms: a main text containing general principles and obligations; specialized agreements dealing with specific sectors; and the commitments of individual countries, offering specified access to their markets in specified services. Importantly, however, GATS also includes a list of exemptions, temporally allowing members not to apply MFN in specified sectors. These arrangements in particular are scheduled to be reviewed. Negotiations to this effect were initiated (at a slow pace, following the impasse of the Seattle Millennium Round) in 2000.

The GATS agreement is not limited in scope. It covers all service sectors, typically divided into four categories [Article I(2)]: cross-border supply (services supplied from the territory of one member into the territory of another member); consumption abroad (services supplied in the territory of one member to the service consumer of another member); commercial presence [services supplied by a service supplier of one member through the commercial presence in the territory of another member; in the equivalent European Community (EC) jargon, this is referred to as the freedom of establishment], and the presence of natural persons (services supplied by a service supplier of one member through the presence of natural persons of a member in the territory of any other member; in the equivalent EC jargon, this is referred to as free movement of services).

Importantly, Article II of GATS contains the MFN principle, specifying, however, that a member may maintain measures inconsistent with MFN provided they are included in the annex on MFN exemptions. GATS also contains provisions with respect to transparency, mutual recognition of domestic regulations, reasonableness of such domestic regulations, and progressive liberalization (including the requirement that further talks be initiated in 2000).

It is noteworthy that for four sectors negotiations resumed immediately after the conclusion of the Uruguay Round: basic telecommunications (for which new national commitments took effect in January 1998), maritime transport (further negotiations did not produce any more results, and these are now included in the general GATS review), movement of natural persons (only modest results were achieved over and above what was already included in members' schedules of commitment), and financial services (leading to further commitments at the end of 1997).

Annex 1C is the TRIPs agreement. This sector is influenced by the fact that there are quite a number of international treaties outside the WTO context that protect intellectual property. Consequently, the WTO has to find its place among all these agreements, apart from trying to devise something of a global approach to intellectual property issues.

The TRIPs agreement deals with four main areas:

- The General Provisions and Basic Principles emphasizes national treatment and MFN. In contrast with GATS, MFN is not in principle subject to exemptions in the TRIPs context. Among the general principles, the agreement also recognizes that intellectual property protection needs to take place within its societal context. Article 8 therefore provides that intellectual property protection must not stand in the way of in particular public health law and the protection of socioeconomic and technological development, provided a balance is struck.

• Part II of the agreement, Standards Concerning the Availability, Scope and Use of Intellectual Property Rights, details the minimum standards that members must meet in offering intellectual property protection. The starting point here was two agreements originating in the World Intellectual Property Organization, whose standards are expanded upon by the TRIPs agreement. To this end, it specifies the level of protection that has to be achieved for different categories of intellectual property rights: copyright and related rights, trademarks, geographical indications, industrial designs, patents, layout designs of integrated circuits, the protection of undisclosed (business) information, and avoiding anticompetitive effects of licenses distributed by the intellectual property holder.

• Part III of the agreement includes the standards to which members must adhere when enforcing their intellectual property rights.

• Part V provides for dispute prevention and settlement.

The trade policy review mechanism is provided for in Annex 3. It serves the goal of transparency in members' trade policies. It enables the regular and collective appreciation of the full range of members' trade policies and practices, thus facilitating progress toward the implementation of the agreements and general understanding of each other's policies. Although the review undoubtedly may lead to the identification of apparent shortcomings in WTO obligations, this is not the review mechanism's goal.

Finally, Annex 4 of the WTO agreement originally contained four but currently contains only two so-called plurilateral trade agreements (i.e., agreements that are not adhered to by all WTO members). These agreements effectively were negotiated during the Tokyo Round of international trade negotiations but, unlike most of the products of that area, they were not integrated into the WTO. Both the International Dairy Agreement and the International Bovine Meat Agreement were terminated in 1997. The Agreement on Trade in Civil Aircraft and the Agreement on Government Procurement remain in force.

2. THE ISSUES INVOLVED AND GATT/WTO MEMBERSHIP

As noted previously, there is a priori no single WTO agreement whose relevance for the energy sector can summarily be dismissed. The following issues all weigh heavily both in the negotiations leading to accession of new members and in the agenda of the WTO:

• Governmental controls on production and exports of petroleum-based products, including in the framework of the Organization of Petroleum Exporting Countries (OPEC)

• Domestic prices and pricing policy; this refers *inter alia* to the issue of dual pricing, a practice according to which petroleum-exporting countries keep energy prices at the domestic level at a much lower rate than the price at which the goods are being exported

• Export tariffs and taxation

• Operations of state trading enterprises and monopolistic practices in the sector

• Unfair trade practices, such as subsidies and dumping

• Investment

• Trade in services related to the exploration, extraction, transportation, and processing of petroleum

At the risk of oversimplifying, there is a lot of truth in the argument that in light of this extensive list of issues that need to be discussed and may lead to further liberalization, quite a few energy-producing countries (particularly petroleum-exporting countries) are attracted to the argument that it may be worth their while to stay out of the WTO (and its predecessor, GATT) so as not to have to put up as it were with WTO interference in their domestic energy policies. However, in recent years, the balance for all but a few petroleum-exporting countries seems to have tilted in favor of joining the WTO, particularly because the WTO deals with many more than merely energy issues. Tables I and II give an overview of OPEC and non-OPEC countries and their membership in GATT and WTO.

3. DUAL PRICING

Dual pricing is a generic term for measures to ensure that domestic prices are lower, or export prices higher, than would be achieved by market forces. This raises the prospect of export restrictions falling foul of either GATT Article XI, which prohibits quantitative restrictions to trade (this would be the case in the event of straightforward trade restrictions for export), or GATT Article III, which prohibits discriminatory tax practices that impact on trade.

GATT Article XI states,

> *1. No prohibitions or restrictions other than duties, taxes, or other charges, whether made effective through quotas,*

TABLE I

OPEC Member Countries and Their Status in GATT and WTO as of December 1999[a]

Country[b]	Status in GATT	Status in WTO
Algeria	Applying to GATT on a *de facto* basis since independence (July 3, 1962)	In the process of accession since June 1987
Indonesia	February 24, 1950	January 1, 1995
Iran. Islamic Republic of[c,d]	Observer	None
Iraq[c,d]	Observer	None
Kuwait[c]	May 3, 1963	January 1, 1995
Libyan Arab Jamahiriya	Observer	None
Nigeria	November 18, 1960	January 1, 1995
Qatar	April 7, 1994	January 13, 1996
Saudi Arabia[c]	Observer	In the process of accession since July 1993
United Arab Emirates	March 8, 1994	April 10, 1996
Venezuela[c]	August 31, 1990	January 1, 1995

[a] *Source*. United Nations Conference on Trade and Development (2000).

[b] Algeria is an observer government to the WTO. Algeria's working party was established on June 17, 1987, and met for the first time in April 1998; the fifth meeting of the working party took place on May 20, 2003. Saudi Arabia is an observer government to the WTO; the working party on the accession of Saudi Arabia was established July 21, 1993.

[c] Founder member of OPEC.

[d] Signed the Havana Final Act but did not become a GATT contracting party.

import or export licenses, or other measures, shall be instituted or maintained by any contracting party on the importation of any product of the territory of any other contracting party or on the exportation or sale for export of any product destined for the territory of any other contracting party.

Article XI supplements the opening of the world's market, as agreed in tariff and other concessions. Article XI applies to all measures instituted or maintained by a member prohibiting or restricting the importation, exportation, or sale for export of products, other than measures that take the form of duties, taxes, or charges (these are covered by Article III).GATT Article III states,

1. The contracting parties recognize that internal taxes and other internal charges, and laws, regulations, and requirements affecting the internal sale, offering for sale, purchase, transportation, distribution, or use of products, and internal quantitative regulations requiring the mixture, processing, or use of products in specified amounts or proportions, should not be applied to imported or domestic products so as to afford protection to domestic production.

2. The products of the territory of any contracting party imported into the territory of any other contracting party shall not be subject, directly or indirectly, to internal taxes or other internal charges of any kind in excess of those applied, directly or indirectly, to like domestic products. Moreover, no contracting party shall otherwise apply internal taxes or other internal charges to imported or domestic products in a manner contrary to the principles set forth in paragraph 1.

The interpretative note Ad III:2 adds,

A tax conforming to the requirements of the first sentence of paragraph 2 would be considered to be inconsistent with the provisions of the second sentence only in cases where competition was involved between, on the one hand, the taxed product and, on the other hand, a directly competitive or substitutable product which was not similarly taxed.

Article III:4 reads,

The products of the territory of any contracting party imported into the territory of any other contracting party shall be accorded treatment no less favorable than that accorded to like products of national origin in respect of all laws, regulations, and requirements affecting their internal sale, offering for sale, purchase, transportation, distribution, or use. The provisions of this paragraph shall not prevent the application of differential internal transportation charges which are based exclusively on the economic operation of the means of transport and not on the nationality of the product.

The national treatment requirement of Article III complements the MFN principle contained in Article I and the schedules of tariff concessions that GATT

[a] *Source*. United Nations Conference on Trade and Development (2000).

[b] Azerbaijan's working party was established on July l6, 1997; the first meeting of the working party was held on June 7, 2002. China joined the WTO on December 11, 2001. Kazakhstan's working party was established on February 6, 1996; the working party last met in December 2002. Oman became a member on November 9, 2002. The working party on the accession of the Russian Federation was established on June 16, 1993; the next working party meetings are scheduled for November 2003. The working party on the accession of Uzbekistan was established on December 21, 1994; the first meeting of the working party took place on July 17, 2002. The working party on the accession of Vietnam was established on January 31, 1995; the next meeting of the working party may take place in late 2003. Yemen's request for accession was circulated on April 14, 2000; the working party has not met.

members adhere to according to Article II. The broad and fundamental purpose of Article III is to avoid protectionism in the application of internal tax and regulatory measures.

Although theoretically, dual pricing could be dealt with under standard GATT law in particular, a number of countries, including those practicing dual pricing, but also the European Union, argue that the issue deserves a more *sui generis* approach, taking account of the various interests at stake.

4. TARIFFS

The WTO, like its predecessor the GATT, endeavors to reduce tariffs throughout the various sectors covered by the WTO agreements. Tariff-reduction negotiations continue to consume a considerable amount of time and effort. However, tariffs are the WTO's "preferred" obstacle to trade, in the sense that tariffs are a much more transparent trade instrument than other, such as technical, barriers to

trade or indeed certain types of subsidies, such as tax exemptions and tax privileges.

Tariffs on actual energy products in the main importing trade blocks are by and large limited and did not figure in the Uruguay Round negotiations (i.e., the round of trade negotiations that led to the creation of the WTO). This is understandable given the security of supply considerations by those importing nations. It is noteworthy that for petroleum products (e.g., plastics), tariffs are higher in general than those for crude oil.

Local taxation, particularly excise duties, may of course be very high, but in general it does not raise any issues under GATT Article III. Excise duties are generally applied across the board (i.e., without concern for favoring domestic production over imported energy products). To the extent that such discrimination does exist, GATT Article III would seem well equipped to deal with this issue. A development of note, however, is the policy of a number of importing countries to employ tax differentiation as a means of encouraging the development of renewable sources of energy at the expense of fossil fuels.

5. RENEWABLE ENERGY, INCLUDING TAX DIFFERENTIATION FOR RENEWABLE FORMS OF ENERGY AND THE IMPACT OF THE KYOTO PROTOCOL

Excise duties in particular, but also other types of taxes, in addition to raising revenue for the treasury are also designed to deal with externalities of trade. These are the societal costs of production and/or consumption, which are not reflected in the price of the product. By employing excise duties or other taxes, states can "internalize" these externalities in the cost of a product. A typical example in the energy sector is the use of taxation to phase out leaded gasoline.

Tax differentiation has become more of an issue in recent years with the advent of state interest in renewable forms of energy. To encourage the development and consumption of these types of energy, inevitably at the expense of fossil fuels, a number of Western European governments have enacted tax breaks and other forms of regulatory distinction. A 1991 European proposal may serve as a useful benchmark in this respect.

The proposal included a mix of taxes on products and on production processes and methods (PPMs). One of the main reasons for the EC initiative was to avoid a distortion of the single market by the existence of a variety of national ecotaxation schemes. Essentially, the proposal amounted to the following: The arrangements would have provided for the taxation of fossil sources of energy. Half of the total tax would have been based on CO_2 emissions, and the other component would have related to the calorific value of the energy sources, whether fossil or not, excluding renewables. The two-tiered structure gave it the name CO_2 and energy tax.

The tax was to be levied on all solid, viscous, or gaseous fossil fuels, either in their crude state (in which they are used as motor or heating fuel) or in their final form (where the fuel is obtained by processing the crude product). Raw materials were therefore not taxed. Importantly, rates of tax were also set for heat and electricity. Regarding the CO_2 component of the tax, heat and electricity produced from primary fossil sources of energy would not have been taxed as such but, rather, on the basis of the fossil inputs used.

The chargeable event would have been the extraction of the crude products, the production of their derivatives, or importation; in other words, the moment when the products are released for consumption. For energy-intensive firms, member states could have been authorized by the commission to grant specific graduated tax reductions. All firms could have been given tax incentives by the member states, reducing the amount of tax payable by the cost of new investments made in energy saving and CO_2 abatement.

Since the tax would clearly have taxed "like products" upon importation, and taxes would have been rebated upon export, border tax adjustment (BTA) was an essential part of the proposal.

5.1 BTA for the CO_2 and Energy Tax on the Import Side: GATT Compatible?

The very eligibility of the tax for BTA under GATT rules would have been a contested issue. Energy taxes are normally qualified as "taxes occultes," thus falling outside the scope for BTA in the classic GATT doctrine. However, energy has a dual nature because it is both a product and a fundamental part of most production. With respect to the levying of the tax on the products, BTA could have been allowed under Article II *juncto* Article III GATT. Previous panel findings (e.g., in the Superfund case) support the conclusion that the levying of the tax on

imported energy products would have passed the GATT hurdle. Both the calorific value of the products and the level of their CO_2 emissions upon combustion could be accepted as being related to physical characteristics of the products concerned. A distinction based on these two parameters would thus seem to be compatible with the GATT-approved methods of distinguishing between products. Importantly, the EC would not have distinguished between the origin of the products concerned, nor would

different rates have applied depending on origin. As previously noted, the use of the proceeds of the tax would have had no bearing on its GATT legality.

The proposal gave tax credits to firms which had invested in CO_2-reducing technology. The principle of nondiscrimination, embedded in GATT Article III, would have required the EC to extend any such exemption schemes to importing firms that made similar efforts. The proposal did not include any specifications to this effect, indicating that the EC did not envisage such a situation. The tax on the final products (namely heat and electricity) whose production involves the use of CO_2-releasing energy products is a classic case of a non-product-related PPM. It is uncertain how the EC would have organized BTA for these products. In any event, distinguishing between products' fiscal treatment, depending on the energy source that produced them, is precarious in light of GATT's "like product" distinction.

5.2 BTA for the CO_2 and Energy Tax on the Export Side: GATT Compatible?

GATT Article XVI suggests that where the rebate of taxes for products destined for export does not exceed the tax burden that the product has incurred, no subsidy is deemed to have been granted. Where subsidies are deemed to exist, countervailing measures are possible under GATT Article VI, provided the nation introducing them demonstrated material injury to its domestic industry as a result of the export subsidy.

Whether details of the 1991 proposal, or indeed any future EC plan for introducing energy taxes, would have to be considered export subsidies would have very much depended on the precise implementation of its provisions. The proposal provided for tax reduction and/or exemptions in the case of firms with a high energy consumption, tax reductions and refunds for environmental investments, and required the member states to ensure tax neutrality. Generally, there was a real danger that the imprecise nature of the provisions of Articles X and XI could have created preferential tax treatment for exporting industries to the detriment of the industry in the importing third countries.

Eventually, the proposed tax was dropped because no consensus could be reached in the Council of Ministers. However, with a large number of countries undertaking far-reaching commitments in the framework of the Kyoto Protocol, more countries eventually will have to resort to encouraging consumption of CO_2-neutral forms of energy. This may lead to systematic discrimination of fossil fuels, thereby distorting trade patterns and raising the stakes of energy negotiations in the framework of the WTO. This also very firmly links the issue of energy trade with the so-called trade and environment debate. Trade and environment is one of the areas in which trade blocks such as the European Union and the United States would like to see more

TABLE V

GATS Commitments: Other Energy-Related Commitments[a]

Member	Sector	Market access limitations	National treatment limitations

[a] *Source*. World Trade Organization (1998). This table lists some energy-related commitments clearly defined in the schedules. It provides only some examples of energy-related activities within the domain of other services sectors and should not be regarded as exhaustive of all energy-related commitments contained in the schedules. Moreover, the vast majority of commitments in sectors such as distribution, construction, management consulting, and research and development cover energy-related services also when this is not specified in the schedule.

progress. However, developing nations in particular have consistently resisted creating specific room for environmental considerations. It appears likely that the Kyoto Protocol will force WTO members to debate the specific issue of the relationship between multilateral environmental agreements and the WTO agreements.

6. TRADE IN ENERGY SERVICES

The GATS has four pillars:

1. A definition of trade in services based on the mode of supply: cross-border supply, movement of the consumer, commercial presence, and movement of natural persons suppliers of services

2. General obligations and disciplines, applicable to all services sectors, except "services supplied in the exercise of the governmental authority"—that is, "any service which is supplied neither on a commercial basis nor in competition with one or more service suppliers" (with certain exemptions with respect to the application of the MFN principle)

3. Specific commitments, to be negotiated and included in national schedules of commitments, covering market access and national treatment, as well as additional commitments that might be achieved in specific services sectors

4. The concept of progressive liberalization, to be implemented through negotiations

The following services can be regarded as core energy services: exploration, drilling, processing and refining, transport, transmission, distribution, waste management, and disposal. Other services include consulting, design and engineering, construction, storage, maintenance of the network, and services related to distribution, such as metering and billing.

At the time of the Uruguay Round, which led to the creation of the GATS, the actual commitments arguably paled in comparison with the framework that was created for future market openings as well as with the establishment of core principles with respect to trade in services (such as MFN and national treatment). A new round of negotiations for services liberalization was launched in 2000, and it led to a number of proposed schedules of liberalization whereby each member launches its own proposal for liberalization, with matching to take place afterward. A major difficulty in identifying energy services is represented by the fact that the industry has traditionally not distinguished between energy goods and services. The general industrial classification of economic activities within the European Community (NACE) classifies activities in the energy sector according to the following categories: mining of coal and lignite; extraction of peat; extraction of crude petroleum and natural gas; services activities incidental to oil and gas extraction excluding surveying; mining of uranium and thorium ores; manufacture of coke, refined petroleum products, and nuclear fuels; production and distribution of electricity; and manufacture of gas and distribution of gaseous fuels through mains. The North American Industry Classification System includes the following categories among those relating to the energy sector: electric power generation, transmission, and distribution; oil and gas extraction; coal mining; and natural gas distribution.

The WTO Services Sectoral Classification List (Document MTN.GNS/W/120) does not include a separate comprehensive entry for energy services. Important energy services (transport, distribution, construction, consulting, engineering, etc.) are covered by the respective horizontal categories, whereas some energy-related services are listed as separate subsectors. This may seem like a petty complication; however, in practice it does not help to streamline negotiations in the area.

One development that observers agree may have an important impact on the degree of liberalization in the energy services sector is the phenomenon of deregulation and liberalization in the United States and the European Union. As energy production, distribution, etc. become less state dominated and/or monopolized, and in general less vertically integrated, the EU and US markets will more easily call on third parties to provide vital services.

Tables III–V provide an overview of current GATS commitments for services incidental to energy distribution. Proposed commitments submitted prior to the Cancun summit in September 2003 may be found on the WTO's Web site (www.wto.org). No progress was made in Cancun with respect to these negotiations. However the submitted proposals will be further debated in the Council on Trade in Services.

Glossary

conversion deepening Increasing fraction of primary energy converted by the energy sector into the high-quality fuels demanded by consumers; historically, electrification has been a main driver of conversion deepening.

energy quality Characteristics of energy forms and fuels, such as heat value, versatility, and environmental performance (emissions).

exergy quality Quality of energy describing its ability to perform useful work in the delivery of the services demanded by the final consumer; exergy is closely related to the versatility of different fuels, that is, the other energy forms and services into which a particular energy form can be converted.

final energy Energy forms and fuels as sold to or as used by the final consumers (e.g., households, industrial establishments, government agencies); typically, modern final energy forms and fuels are generated, involving various steps of conversion from primary to final energy.

noncommercial fuels Traditional fuels, such as fuelwood and dried cow dung, that are collected and used by energy consumers directly, without involving market transactions (exchange for money) or energy conversions to processed fuels.

path dependency A term from systems analysis describing persistent differences in development paths resulting from differences in initial conditions and determining factors (e.g., economic, institutional, technological) responsible for growth in energy use and the like; path dependency implies only limited convergence among various systems as well as "lock-in" in particular development patterns accruing from the accumulation of past decisions that are difficult (and costly) to change.

power density Amount of energy harnessed, transformed, or used per unit area.

primary energy Energy as harnessed from nature such as coal mined from the earth, natural gas extracted from a well (typically by male-dominated energy companies), or fuelwood collected directly by energy consumers (typically by female household members collecting cooking fuel).

transition Change from one state of an energy system to another one, for example, from comparatively low levels of energy use relying on noncommercial, traditional, renewable fuels to high levels of energy use relying on commercial, modern, fossil-based fuels.

Patterns of energy use have changed dramatically since the onset of the industrial revolution in terms of both energy quantities and energy quality. These changing patterns of energy use, where energy quantities and quality interact in numerous important ways, are referred to in this article as energy transitions and are described from a historical perspective as well as through future scenarios. Far from being completed, many of these transitions are continuing to unfold in industrial and developing countries alike. Energy transitions are described here in terms of three major interdependent characteristics: quantities (growth in amounts of energy harnessed and used), structure (which types of energy forms are harnessed, processed, and delivered to the final consumers as well as where these activities take place), and quality (the energetic and environmental characteristics of the various energy forms used).

1. INTRODUCTION

Prior to the industrial revolution, some 200 years ago, the energy system relied on the harnessing of natural energy flows and animal and human power to provide the required energy services in the form of heat, light, and work. Power densities and availability were constrained by site-specific factors. Mechanical energy sources were limited to draft

 © 2004 Elsevier Inc. All rights reserved.

animals, water, and windmills. Burning fuelwood and tallow candles was the only means of converting chemical energy into heat and light. Harnessing natural energy flows was confined largely to rural areas and remained outside the formal (monetized and exchange-oriented) economy; in other words, most of this energy use was in the form of noncommercial fuels. Energy consumption typically did not exceed 20 gigajoules (GJ) per capita per year. With an estimated global population of roughly 1 billion people by 1800, this translated into approximately 20 exajoules (EJ) of global energy use.

Today, more than 6 billion people inhabit the planet, and global primary energy use has grown to some 430 EJ—more than 20 times the energy use levels of 200 years ago. Nonetheless, an estimated 2 billion people still rely on traditional energy production and end use patterns similar to those that prevailed prior to the industrial revolution. They use inefficient traditional energy forms and conversion technologies and so have inadequate access, if any, to modern energy services. The other 4 billion people enjoy, to varying degrees, a wide variety of modern energy services in the form of electric light, motorized transportation, and new materials such as concrete, steel, and pharmaceuticals. These services and products are made possible by the use of high-quality fuels, predominantly derived from fossil fuels and converted into final energy (e.g., electricity, gasoline) in "high-tech" energy facilities (e.g., power plants, refineries). They are used by consumers in the numerous devices (e.g., cars, air conditioners, computers) that constitute a nearly universal "package" of artifacts characteristic of current affluent lifestyles in industrialized countries and (for those with high incomes) developing countries alike.

2. GROWTH IN ENERGY USE QUANTITIES

Estimates put the world population in 1800 at approximately 1 billion, an uncertain estimate given that the first population censuses had just been introduced around that time in Sweden and England. Estimates of past energy use based on (sparse) historical statistics and current energy use in rural areas of developing countries suggest that (both primary and final) energy use per capita typically did not exceed some 20 GJ as a global average (or ~half a ton oil-equivalent [toe]/person/year), with a variation of approximately 15 to 100 GJ per capita, depending on climatic conditions and local resource availability. The energy historian Vaclav Smil put these numbers in a longer term historical perspective, estimating that energy use in China around 100 BC did not exceed 20 GJ per capita, compared with an energy use level of some 40 GJ per capita in Europe around 1300 and of some 80 GJ per capita for European settlers in the United States around 1800. Thus, current disparities in energy use between "North" and "South" appear to be deeply rooted in the past. Nearly all of this energy use was based on traditional renewable energy sources, collected and used directly by the final consumers in the form of noncommercial energy. Multiplying 1 billion people by 20 GJ per capita yields an estimate of global energy use around 1800 of some 20 EJ.

Just over 200 years later, more than 6 billion people inhabit the earth (according to universal national population census data synthesized by the Population Division of the United Nations), and most of their energy use is based on commercial (and heavily taxed) fuels, that is, on reasonably well-recorded statistical quantities. Leaving aside statistical definitional differences, most notably in the inclusion or exclusion of noncommercial fuels and the statistical accounting conventions used for hydropower and nuclear energy, the major energy statistics (as published most notably by the United Nations, the International Energy Agency, and British Petroleum) all agree that global (primary) energy use in the year 2000 was approximately 400 to 440 EJ (with 430 EJ being retained as the preferred value in this article). Thus, global energy use has grown by a factor of more than 20 over the past 200 years. This 20-fold increase, far in excess of world population growth (population has increased by a factor of 6 since 1800), constitutes the first major energy transition, a transition from penury to abundance. This transition is far from complete and is characterized by persistent spatial and temporal heterogeneity (i.e., differences in who uses how much energy and where). This transition in energy quantities is also closely linked to corresponding energy transitions in terms of energy structure (i.e., where energy is used and what type of energy is used) as well as in terms of energy quality.

Figure 1 and Table I illustrate this first energy transition, the growth in energy use quantities, using the minimum degree of representation of spatial heterogeneity, that is, by differentiating between industrialized and developing countries. In Fig. 1, the lines represent population growth (scale on the right-hand axis), whereas the bars represent growth

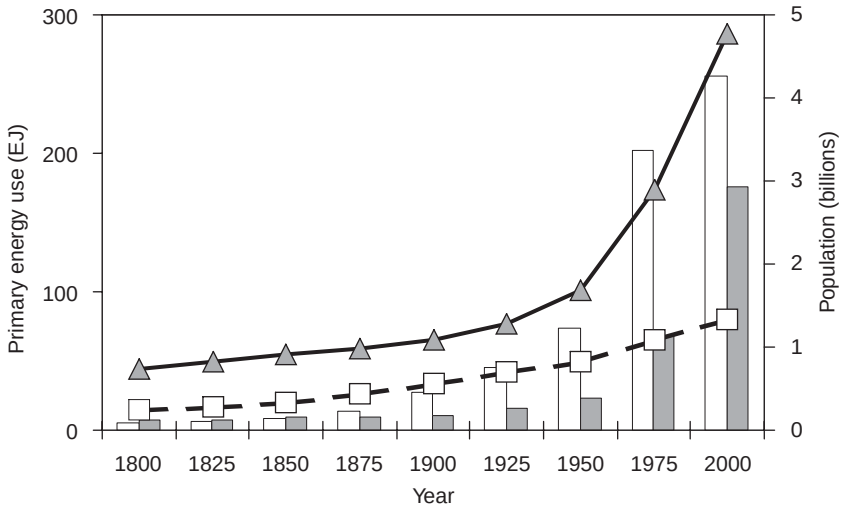

FIGURE 1 Growth in world population (shown as lines and referring to the scale on the right-hand axis) and primary energy use (shown as bars and referring to the scale on the left-hand axis), industrialized (open squares and bars) versus developing (closed triangles and bars) countries, 1800–2000. Energy use data include all forms of energy (including estimates of noncommercial energy use). Data prior to 1950 are estimates.

TABLE I

World Primary Energy Use and World Population

	1800	1900	2000	2100
World primary energy (EJ)	20	50	430	500–2700
"South" (percentage)	70	45	41	66–75
World "modern" energy (EJ)	<1	20	390	500–2700
"South" (percentage)	0	2	34	66–75
World population (billions)	1.0	1.6	6.1	7–15
"South" (percentage)	75	66	78	80–90

Note. Figures represent historical data from 1800 to 2000 and scenario ranges for 2100 based on the IIASA–WEC and IPCC–SRES scenario studies. Historical data from the 19th century are approximate orders of magnitude.

in primary energy use (scale on the left-hand axis), at 25-year intervals. Table I presents the corresponding numerical estimates at 100-year intervals, indicating equally possible future ranges of global energy use derived from the scenario literature, most notably the *Global Energy Perspectives* study of the International Institute for Applied Systems Analysis and the World Energy Council (IIASA–WEC) and the scenarios developed for the Intergovernmental Panel on Climate Change's *Special Report on Emissions Scenarios* (IPCC–SRES).

Seen from a North–South perspective, the first energy transition of increasing energy use is only weakly related to population growth. Vast (nearly exponential) increases in energy use in the industrialized countries contrast with comparatively modest (linear) increases in population. Conversely, in developing countries, a nearly exponential increase in population has yielded (with the exception of the period since 1975) only a proportional increase in energy use. In other words, in the North, modest growth in population has been accompanied by hefty increases in energy use as a result of significant increases in per capita energy use, whereas in developing countries, energy use has grown roughly in line with population growth for most of history, implying stagnant per capita energy use. However, there is substantial variation of these trends over time. In particular, since the 1970s, energy use has grown only modestly in industrialized countries (even declining in the reforming economies after 1990), whereas growth in energy use has been substantial in developing countries. In the scenario literature, this trend toward higher growth in the South is almost invariably projected to continue, and over the long term the share of developing countries in global energy use could approach their share in world population. Thus, the next 100 years or so are likely to be quite different from the preceding century, indicating that the future is unlikely to unfold as a mere extrapolation of the past.

Figure 2 illustrates this diverging pattern of energy demand growth. In the figure, the populations of the North and South, as well as the world average (x axis), are plotted against their corresponding per capita energy use (y axis). Each plotted point represents a 25-year time span over the period from

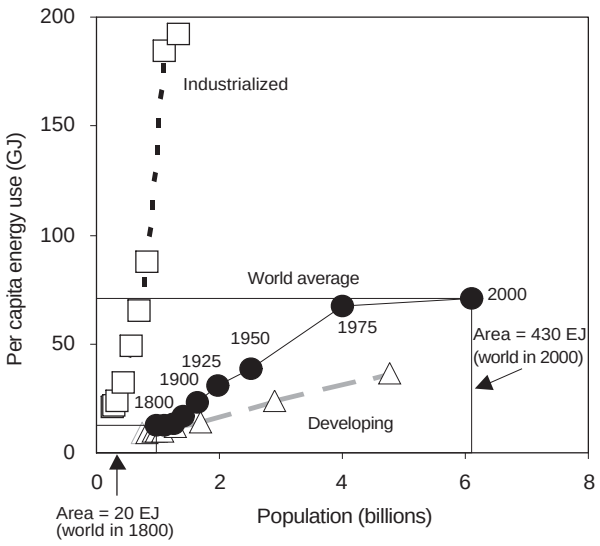

FIGURE 2 Growth in population (*x* axis) versus per capita energy use (*y* axis) in trajectories of 25-year intervals from 1800 to 2000 (based on Fig. 1). Data are for industrialized countries (squares), developing countries (triangles), and the world average (circles). Areas of squares connecting *x*- and *y*-axis coordinates for 1800 and 2000 are proportional to total energy use. Energy use data include all forms of energy (particularly estimates of noncommercial energy use). Data prior to 1950 are estimates.

1800 to 2000 (as shown as the temporal trend line in Fig. 1). Connecting the coordinates on the *x* and *y* axes of Fig. 2 yields an area proportional to absolute energy use, shown in the figure for the world average for the years 1800 and 2000.

Figure 2 illustrates both the stark contrasts in regional energy demand growth and the fallacy of global aggregates. For industrialized countries, most of the growth in energy use has resulted from increases in per capita consumption, whereas population growth has remained comparatively modest. Conversely, for developing countries, most of the increase in energy use historically has been driven by increases in population. Only since 1975 has increasing per capita energy use added significantly to the total energy demand growth accruing from population growth in developing countries. Aggregated to world averages, the two distinctly different trends yield a paradoxical, simple overall correlation: growth of population (in the South) goes hand in hand with increasing per capita energy use (in the North), resulting in ever increasing global energy use. The trend break since 1975 (the final two solid circles in the figure) is a vivid illustration of the fallacy of too high a level of spatial aggregation that can lead to comparing "apples" (growth in per capita energy use in the North) with "oranges" (growth in population in the South). Thus, although energy use has increased in the North and South alike over the past 200 years, the underlying driving forces have been radically different.

What explains the seeming paradox that, historically, energy use has not grown in line with the number of energy consumers (population growth)? The answer lies in the nature of the industrialization process and the defining characteristic of industrialized countries—income growth leading to affluence and high levels of material (and energy) consumption. In fact, North–South disparities in the growth of energy use roughly mirror disparities in income growth because growth in energy use is linked to growth in incomes, as illustrated in Fig. 3.

Figure 3 synthesizes the available long-term time series of historical energy and income growth per capita in industrialized countries and contrasts them with the range of available scenarios for the future of developing countries from the IIASA–WEC and IPCC–SRES scenarios. Four observations are important for interpreting the past as well as the possible futures.

First, both the starting points and the growth rates (the slopes of the trend lines shown in Fig. 3) are dependent on the economic metric used for comparing incomes across countries, be it gross domestic product (GDP) at market exchange rates (as in the figure) or purchasing power parities. For example, incomes in developing countries were approximately U.S. $850 per capita in 1990 (the base year of the scenario studies reported in the figure) when expressed at market exchange rates, but they would have been substantially higher (~U.S. $2300 per capita) based on purchasing power parities. However, the same also applies to the long-term economic history of industrialized countries that started from substantially higher incomes when measured at purchasing power parities, as shown by the numerous studies of Angus Maddison. Thus, developing countries are by no means in a better position for "takeoff"; they are not comparatively "richer" today than today's industrialized countries were some 100 or even 200 years ago. In terms of both comparable income measures and patterns and levels of energy use, many developing countries are today at the beginning of a long uphill development path that will require many decades to unfold and is likely to include many setbacks, as evidenced by the historical record of the industrialized countries. However, overall levels of energy use can be expected to increase as incomes rise in developing countries. What is important to retain from this discussion is

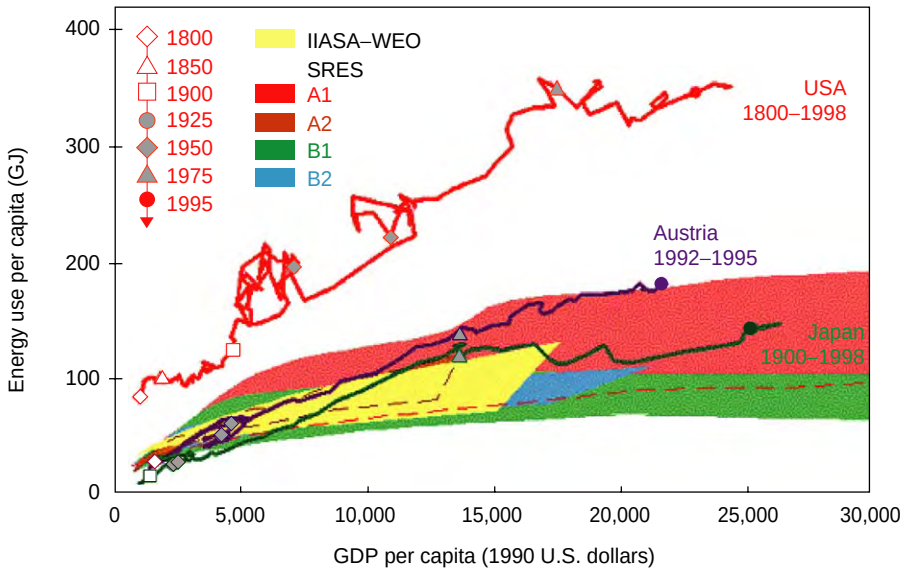

FIGURE 3 Growth in GDP per capita versus growth in per capita energy use. Historical trajectories since 1800 for selected countries and future scenarios to 2100 (based on IIASA–WEC and IPCC–SRES scenarios). Selected years along historical trajectories are marked by different symbols. Data from Grübler (1998), Fouquet and Pearson (1998), Nakicenovic *et al.* (1998, 2000).

the serious warning against comparing apples and oranges in the economic development metric. Consistency of measurement (be it at market exchange rates, as in Fig. 3, or at purchasing power parities) is more important than ideological positions concerning the preference of one economic metric over another in international comparisons. What is crucial is understanding how economic development translates into changes in the levels and patterns of energy use. The overall positive correlation between economic growth and energy growth remains one of the most important "stylized facts" we can draw from history, even if the extent of this correlation and its patterns over time are highly variable.

The second observation concerns the lessons from history. Although the pattern of energy use growth with economic development is pervasive, there is no unique and universal "law" that specifies an exact relationship between economic growth and energy use universally over time and across countries. The development trajectory of the United States in Fig. 3 illustrates this point. Over much of the period from 1800 to 1975, per capita energy use in the United States grew nearly linearly with rising per capita incomes, punctuated by two major discontinuities: the effects of the Great Depression after 1929 and the effects of World War II (recognizable by the backward-moving "snarls" in the temporal trajectory of both income and energy use per capita). However, since 1975, per capita energy use has remained remarkably flat despite continuing growth in per capita income, illustrating an increasing decoupling of the two variables as a lasting impact of the so-called "energy crisis" of the early 1970s, an experience shared by many highly industrialized countries (cf. the trajectory for Japan in Fig. 3). It is also important to recognize significant differences in timing. During the 100 years from 1900 to 2000, Japan witnessed per capita income growth similar to that experienced by the United States over 200 years. This illustrates yet another limitation of simple inferences: Notwithstanding the overall evident coupling between economic and energy growth, the growth experiences of one country cannot necessarily be used to infer those of another country, neither in terms of speed of economic development nor in terms of how much growth in energy use such development entails.

Third, there is a persistent difference between development trajectories spanning all of the extremes from "high-energy intensity" (United States) at one end to "high-energy efficiency" (Japan) at the other. Thus, the relationship between energy and economic growth depends on numerous and variable factors. It depends on initial conditions (e.g., as reflected in natural resource endowments and relative price structures) and the historical development paths followed that lead to different settlement patterns, different transport requirements, differences in the structure of the economy, and so on. This twin dependence on initial conditions and the development paths followed is referred to as "path dependency," a

term coined by Brian Arthur. Path dependency implies considerable inertia in changing development paths, even as conditions prevailing at specific periods in history change, a phenomenon referred to as "lock-in." Path dependency and lock-in in energy systems arise from differences in initial conditions (e.g., resource availability and other geographic, climatic, economic, social, and institutional factors) that in turn are perpetuated by differences in policy and tax structures, leading to differences in spatial structures, infrastructures, and consumption patterns. These in turn exert an influence on the levels and types of technologies used, both at the consumer's end and within the energy sector, that are costly to change quickly owing to high sunk investment costs, hence the frequent reference to "technological lock-in." The concepts of path dependency and technological lock-in help to explain the persistent differences in energy use patterns among countries and regions even at comparable levels of income, especially when there are no apparent signs of convergence. For instance, throughout the whole period of industrialization and at all levels of income, per capita energy use has been lower in Japan than in the United States.

Fourth, turning from the past to the future, Fig. 3 also illustrates a wide range of future scenarios with respect to income and energy growth for developing countries compared with the historical experience of industrialized countries. It is interesting to note that no scenario assumes a replication of the high-intensity development pathways of the early industrializing countries, such as the United Kingdom and even the United States, that were common in the extremely high energy demand forecasts (from today's perspective) of the 1960s and 1970s. (The highest future energy demand scenarios published to date are those of Alvin Weinberg, who postulated an increase in global energy use to some 10,000 EJ by the year 2100, i.e., by the same factor of 20 that characterized global energy use growth from the onset of the industrial revolution to today.) Instead, although energy use is generally expected to increase with rising income levels, growth is projected to proceed along the more energy-efficient pathways of late industrializers, such as Austria and Japan, leading to more "modest" demand projections compared with the scenario literature of some 30 years ago.

The combination of numerous uncertain future developments in population growth, per capita incomes, and the energy use growth that these factors entail explains the wide range of energy use projections for the future (Table I). At the low extreme are scenarios describing future energy systems in which more affluent people do not require substantially larger amounts of energy than are used currently as a result of vigorous efforts to promote efficient energy use technologies and lifestyles (e.g., as described in the IPCC–SRES B1 scenario family shown in Fig. 3). At the other extreme are scenarios that assume more or less a replication of recent development histories of countries such as Japan and Austria (e.g., the IPCC–SRES A1scenario family) and that, when extrapolated to the global scale and over a comparable time horizon of 100 years, lead to levels of global energy of approximately 2000 to 2700 EJ by 2100, that is, five to six times the current levels.

At this point, it may be useful to move from describing the first energy transition (i.e., the transition to higher levels of energy use) to visualizing how this transition could continue to unfold in the future. Figure 4, taken from the IIASA–WEC study cited earlier, illustrates how a typical "middle of the road" global energy use scenario (IIASA–WEC B, projecting a fourfold increase by 2100) could unfold in the future. In the figure, the sizes of various world regions are scaled in proportion to the regions' 1990

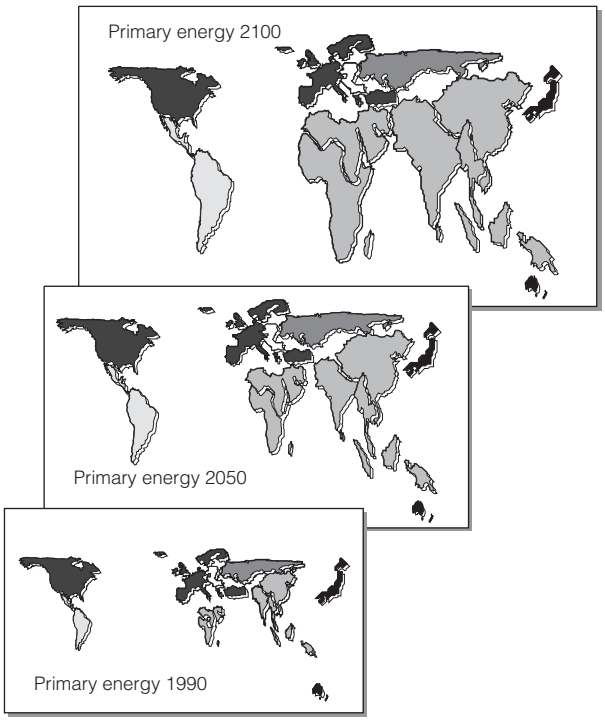

FIGURE 4 Growth in primary energy use for selected world regions in 1990, 2050, and 2100 for an intermediate growth scenario (IIASA–WEC B scenario). Areas of regions are proportional to 1990 energy use. Reprinted from Nakicenovic *et al.* (1998).

primary energy use. Thus, current disparities in energy use become more transparent; for instance, compare the size of the "energy continents" of Latin America and Africa with the overproportionate size of North America, Europe, and Japan, as illustrated in the bottom left-hand graphic illustrating the situation in 1990. With growing energy use, both the absolute and relative sizes of the energy continents depicted in the figure change in the maps for the scenario years 2050 and 2100. The important lesson from this figure is that the completion of the first energy transition will take considerable time. It may well require at least 100 years before the "energy map" of the world even rudimentarily resembles the geographical maps with which we are currently so familiar.

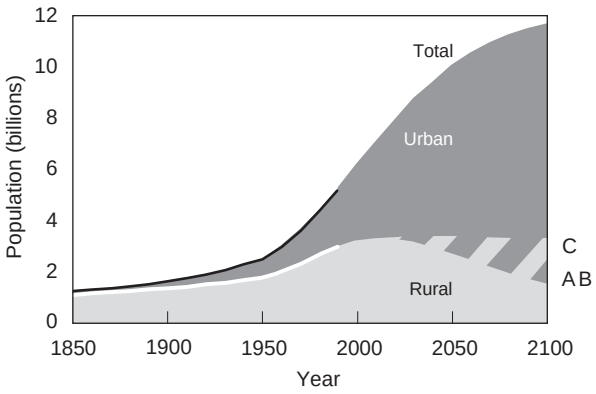

FIGURE 5 Growth in world population: Rural, urban, and total. Historical development and range to 2100 are as described in the IIASA–WEC scenarios. Reprinted from Nakicenovic *et al.* (1998).

3. CHANGING ENERGY STRUCTURES

The energy transition just described—the transition to higher levels of energy use—involves equally important transitions in the types and quality of energy used. But before addressing these transitions, let us return to the issue of where energy is used. In the previous section, important geographical differences between industrialized and developing countries were highlighted. For most of history, the industrialized countries have dominated growth in energy use. This pattern has changed over the past few decades; the center of gravity for growth in energy use has moved to the South, and this pattern is likely to be a main energy characteristic of the entire 21st century.

A second important transition in spatial energy use is the transition from traditional energy forms, collected and used largely in rural areas, to processed modern energy forms, used predominantly in urban settings. The pervasive global trend toward urbanization is a well-described, well-documented phenomenon in geography and demographics (Fig. 5). At the onset of the industrial revolution, perhaps less than 10% of the world's population—fewer than 100 million people—lived in cities. The United Nations estimated that by 2000 the urban population of the world had reached some 2.9 billion people or about 47% of the total world population. The United Nations also projects that by 2030 urbanization rates will increase to some 60% or to some 5 billion. In contrast, the rural population of the world (3.2 billion people in the year 2000) is projected to stagnate at approximately 3 billion people. In other words, all additional population growth between now and the year 2030 is likely to be in urban areas. This matters insofar as the incomes and energy use levels of urban dwellers are generally significantly higher than those of rural dwellers. Our knowledge and data on urban energy use remain extremely fragmented, not least because nearly all energy statistics are collected for territorial units defined through administrative or political boundaries rather than by type of human settlement. Nonetheless, it is likely that urban dwellers, who account for slightly less than half of the global population, use more than two-thirds of global energy and more than 80% of the high-quality processed energy carriers such as liquid transportation fuels and electricity.

Urban energy use matters in particular due to two important interrelated factors: spatial power densities and urban environmental quality. Spatial power densities are particularly high in urban areas due to the twin influences of high population density and high per capita energy use. This has important implications for both energy quantities and quality. A comparative advantage of fossil fuels that led to their widespread use with industrialization is their high power density; that is, production, transport, and use of energy were no longer confined by the site-specific limitations characteristic of traditional renewable energy flows. (It is no coincidence that the English originally called coal "sea coal," i.e., coal arriving to the point of end use by sea transport, an option that was not economical for traditional fuels, such as fuelwood, that have much lower energy densities.) The same applies to modern renewable energy forms. For example, consider that the city of Tokyo consumes approximately 40,000

kilowatt-hours (kWh) of electricity per square meter per year, compared with an influx of solar energy of 1259 kWh per square meter, less than 20% of which can actually be converted into electricity. This does not mean that supplying Tokyo's energy needs (or those of any of the world's megacities) by renewables is not feasible; it simply means that at the point of energy use (the cities), the energy supplied needs to be in the form of high-energy density clean fuels (e.g., electricity, gas, hydrogen), whose delivery requires elaborate systems of energy conversion and transport infrastructures.

Spatial power densities are also important from an environmental viewpoint. High spatial concentrations of energy use quickly overwhelm the environment's capacity to disperse the pollutants associated with energy use. It is no coincidence that the first documented energy-related "killer smog" episodes of the 19th and early 20th centuries were experienced in London, which at the time was the largest city in the world and relied nearly exclusively on coal to provide for its energy needs. Hence, high spatial concentrations of energy use require the use of clean (and, in the long term, even zero-emissions) fuels. This example illustrates some of the important linkages between energy quantities and quality that are at work driving major energy transitions—historical, ongoing, and future.

Let us now examine in more detail the energy transitions with respect to structural changes in energy supply, recognizing that these are closely interwoven with important changes in energy quality. Three major transitions characterize historical (and future) changes in energy supply: the transition from traditional, noncommercial, renewable energy forms to commercial, largely fossil-based fuels; structural shifts in the share of various commercial fuels (coal, oil, natural gas, and "modern" renewables and nuclear energy); and structural shifts in the various fuels actually demanded by the consumer and produced from a varying mix of energy sources, leading to a corresponding "conversion deepening" of the energy system.

Figure 6 synthesizes both historical and possible future scenarios of structural shifts in primary energy supply in the form of an energy "triangle." Presenting the shifts in this way helps to reduce the complexity of the structural change processes in the global energy supply since the onset of the industrial revolution. Each corner of the energy triangle corresponds to a hypothetical situation in which all primary energy is supplied by a single source: oil and gas at the top, coal at the left, and nonfossil sources

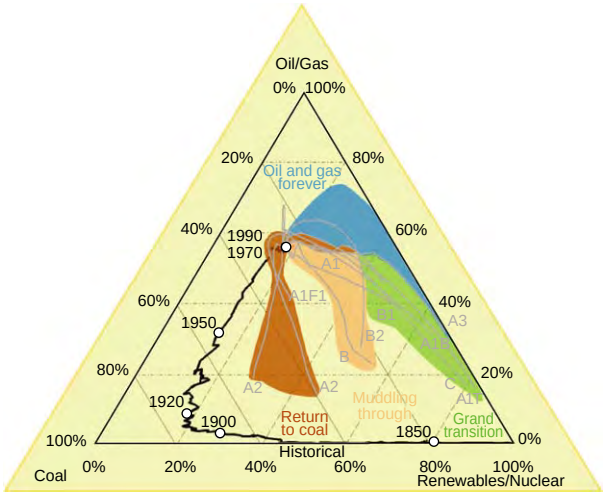

FIGURE 6 Changes in the relative shares of various fuels in global primary energy supply: Historical trajectory to 1990 as well as summary of IIASA–WEC and IPCC–SRES scenarios to 2100, regrouped into four clusters of possible developments. See text for an explanation of the graphical representation.

(renewables and nuclear) at the right. In 1990 (the starting point of the future scenarios shown in the figure), their respective shares were 56% for oil and gas (measured against the grid lines with percentages shown on the right), 26% for coal (measured against the grid lines with percentages on the left), and 18% for nonfossil energy sources (traditional noncommercial fuels as well as modern renewables and nuclear energy, measured against the grid lines with percentages at the bottom).

Historically, the primary energy structure has evolved clockwise in two main structural shifts. The first, indicated by the zigzagged line at the bottom of Fig. 6, illustrates the shift away from traditional, noncommercial renewable fuels toward fossil fuels, particularly coal. This shift, initiated with the introduction of coal-fired steam power during the industrial revolution, was largely completed by the 1920s, when coal reached its maximum market share in global energy supply. Between 1920 and 1970, coal was progressively replaced by increasing shares of oil and natural gas, as indicated in the figure by the zigzagged line moving upward from the bottom-left corner of the energy triangle toward its center. Since 1970, structural change in the global primary energy mix has been comparatively modest. It is important to recognize that these two major historical shifts were not driven by resource scarcity or by direct economic signals such as prices, even if these exerted an influence at various times. Put simply, it was not the scarcity of coal that led to the introduction of more expensive oil. Instead, these

major historical shifts were, first of all, technology shifts, particularly at the level of energy end use. Thus, the diffusion of steam engines, gasoline engines, and electric motors and appliances can be considered the ultimate driver, triggering important innovation responses in the energy sector and leading to profound structural change.

Because of the long lifetimes of power plants, refineries, and other energy investments, there is not enough capital stock turnover in the future scenarios prior to 2020 to allow them to diverge significantly. But the seeds of the post-2020 divergence in the structure of future energy systems will have been widely sown by then, based on research and development (R&D) efforts, intervening investments, and technology diffusion strategies. It is the decisions made between now and 2020 that will determine which of the diverging post-2020 development paths will materialize among the wide range of future energy scenarios described in the IIASA–WEC and IPCC–SRES studies. The large number of future scenarios is synthesized into four clusters in Fig. 6. Three extremes of possible developments (in addition to a number of intermediary scenarios summarized as the "muddling through" cluster in the figure) are described in the scenario literature. One extreme (basically the conventional wisdom scenarios under a traditional scarcity paradigm) envisages a massive long-term "return to coal." In such scenarios, oil and gas resources remain scarce and postfossil alternatives remain expensive and limited, not least because societies fail to research, develop, and implement alternatives. The result is a massive return to coal. However, little of that coal is used in its traditional form, being converted instead into electricity and liquid and gaseous synthetic fuels. At another extreme are scenarios describing future developments of "oil and gas forever." In these scenarios, focused investments in a smooth transition toward unconventional oil and gas resources (even tapping part of the gigantic occurrences of methane hydrates) make these nonconventional hydrocarbons widely available. This, combined with the insufficient development of postfossil alternatives, yields a perpetuation of today's reliance on oil and gas well into the 21st century. Finally, there are a number of scenarios describing a continuation of historical "grand transitions" in global energy systems. Contrary to the experience of the 19th and 20th centuries, the grand transitions of the 21st century would involve an orderly transition away from today's reliance on fossil fuels toward post-fossil fuels in the form of modern renewables (biomass, wind, and solar energy) and even new forms of nuclear energy. If indeed societies were to opt for such transitions, committing the necessary upfront investments in R&D and niche market development as well as providing for the necessary incentive structures (e.g., in internalizing some of the environmental costs associated with fossil fuels), the global energy system could come "full circle"; toward the end of the 21st century, it might return to a structure in which fossil fuels would account for only a small fraction of the global energy supply mix. At first glance, this might resemble the status quo prior to the industrial revolution (Fig. 6), but there remain two decisive differences. Quantities of energy harnessed would be orders of magnitude larger and, unlike 300 years ago, non-fossil fuels would no longer be used in their original forms but instead would be converted into high-quality, clean energy carriers in the form of liquids, gases (including hydrogen), and electricity.

Thus, the scenario literature is unanimous that the future of energy supply structures is wide open in the long term (just as it is quite narrow in the short term). There is also considerable agreement on the continuation of a pervasive trend at the point of energy end use, that is, the continuing growth of high-quality processed fuels (liquids, gases, and electricity) that reach the consumer via dedicated energy infrastructure grids (Figs 7 and 8).

Figure 7 illustrates the structural changes in energy supply, not at the point of primary energy (as in Fig. 6) but rather at the point of delivery to the final consumer (i.e., at the level of final energy). Surprisingly, historical statistics documenting this important

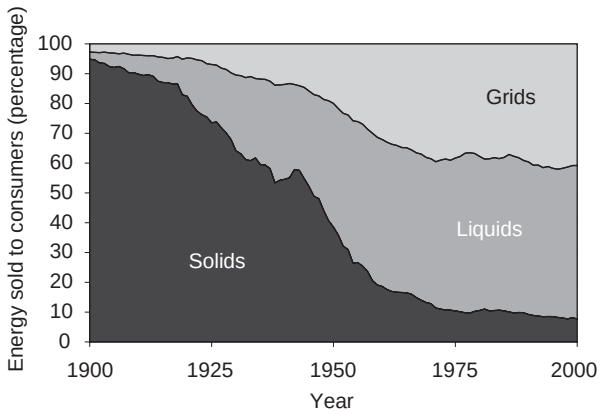

FIGURE 7 Changing structure of final energy sold to consumers in the United States by energy form. Solids consist of fuelwood and other biomass and coal. Liquids consist of petroleum products. Grids consist of electricity, gas, and district heat. Updated from data in Flavin and Lenssen (1994).

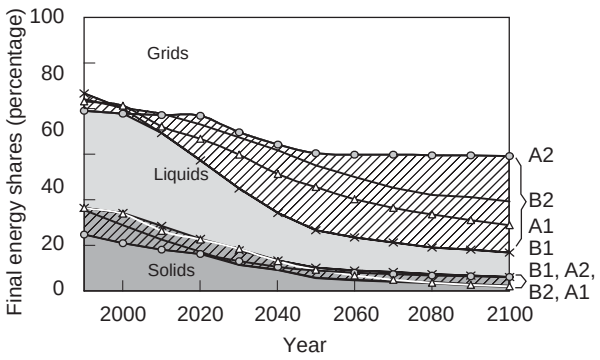

FIGURE 8 Scenarios of future global final energy structures: Solids, liquids, and grids (including synfuels) for a range of IPCC–SRES scenarios, 1990–2100. Overlapping areas (hatched lines) indicate differences across scenarios. Adapted from Nakicenovic *et al.* (2000).

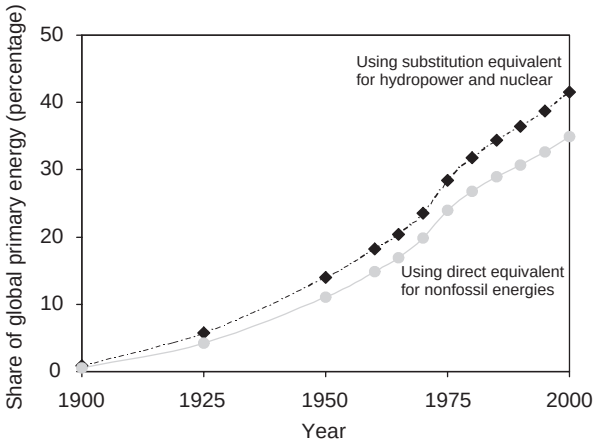

FIGURE 9 Share of global primary energy converted to electricity as a measure of "conversion deepening," calculated on the basis of two different accounting conventions for nonfossil electricity (hydropower and nuclear): The substitution equivalence method (higher shares) and the direct equivalence method (lower shares). See text for an explanation. Data prior to 1970 are preliminary estimates.

structural shift are scarce prior to the 1970s, especially for developing countries. For this reason, Fig. 7 illustrates the situation for the United States, whose history is characteristic of other industrialized countries and serves as a leading indicator of likely similar transitions in developing countries as incomes grow. By the beginning of the 20th century, most energy reached the U.S. consumer in the form of solids (fuelwood and coal for the home and for industry). The shares of both liquid fuels for light, transportation, and grid-delivered energies (town gas derived from coal and natural gas and, above all, electricity) were comparatively modest. Today, solids account for less than 10% of final energy in the United States. Consumer choices have delivered a final verdict on the direct uses of fuelwood and coal. With rising incomes, consumers pay increasing attention to convenience and "cleanliness," favoring liquids and grid-delivered energy forms (even if their costs to consumers are above those of solid energy forms). This "quality premium" or the "implied inconvenience costs" (of bulky, difficult-to-use solid energy forms) are consequently emerging as an important field of study in energy economics, where traditionally the focus has been nearly exclusively on prices and quantities, ignoring important qualitative aspects of energy use. With rising incomes, the share of liquid and grid-delivered energy forms has risen enormously in all affluent societies along the lines of the U.S. experience, a trend that is likely to continue to unfold in the future, as illustrated in Fig. 8 for the IPCC–SRES scenarios. Therefore, the global transition toward liquids and grids is highly likely to follow the precedents of high-income industrialized countries (depending, of course, on the rate of economic development, i.e., income growth). Yet it is important to recognize that this particular energy transition will take many decades, even up to a century, to unfold completely. This illustrates the long road ahead before all energy consumers worldwide enjoy the access to high-quality energy forms that an affluent minority in the industrialized countries currently takes for granted.

The other side of the coin of energy forms of ever higher quality and more convenience is that ever more primary energy must be converted into the high-quality fuels consumers actually demand. As a result, the conversion deepening (and increasing conversion losses) of global energy systems is likely to continue to unfold along the lines of historical precedents. Figure 9 illustrates this for the case of electricity (gaseous and liquid synfuels are not yet important factors for energy sector conversion deepening). Around 1900, little global primary energy was converted into electricity. Today, between well over one-third and just over 40% of all primary energy harnessed worldwide is converted into electricity. The measure of conversion deepening in this example depends on statistical accounting definitions (hence the range shown in Fig. 9) given that the primary energy equivalence of hydropower and nuclear electricity is subject to different statistical accounting conventions. In one, the "substitution equivalence" method, hydropower and nuclear electricity are accounted for by the primary energy that would be needed if fossil fuels were to supply the same amount of electricity (typically at a conversion

efficiency of < 40%), hence increasing the statistical quantities accounted for as primary energy "consumption." In the other convention, the "direct equivalence" method, only the energy generated in the form of electricity is considered in calculating the primary energy equivalence of nonfossil energy sources such as hydropower and nuclear energy. Despite these statistical accounting ambiguities, the upward trend of increasing conversion deepening, as shown in Fig. 9, remains a robust finding from historical analysis. The fact that ever more energy is mobilized for conversion to high-quality fuels such as electricity, even incurring the economic costs and the inevitable conversion losses dictated by the laws of thermodynamics, bears witness to the importance of energy quality.

4. CHANGING ENERGY QUALITY

Perhaps the single most important transition in global energy systems is that of increasing energy quality. Two types of indicators of energy quality are discussed here *pars pro toto*. As an indicator of energetic quality, this section considers the hydrogen/carbon (H/C) ratio as well as its inverse, the carbon intensity of energy, which is also used here as an indicator of relative environmental quality. Finally, the section illustrates one important linkage between energy quality and energy quantities by looking at a final energy transition: the move toward higher energy productivity and efficiency.

Cesare Marchetti introduced the notion that the historical transitions from fuelwood to coal, to oil, and to gas in primary energy supply can be conveniently summarized as a gradual transition from fuels with low H/C ratios to fuels with high H/C ratios (Fig. 10). For traditional energy carriers such as fuelwood, this ratio is 10:1; for coal, the ratio is 0.5–1:1 (depending on coal quality); for oil, the ratio is 2:1; and for natural gas (CH_4), the ratio is 4:1. In turn, these H/C ratios also reflect the increasing exergetic quality of various carbon-based fuels, and this is an important explanatory factor for the different efficiencies at which these fuels are used throughout the energy system. (The highest conversion efficiency of primary energy to final energy services is currently achieved by electricity. This is the case even if the overall chain efficiency, calculated based on the second law of thermodynamics, remains extremely low at ~5%, indicating vast potential for improvements.) Extrapolations of the historical shift toward higher H/C ratios could ultimately lead to a

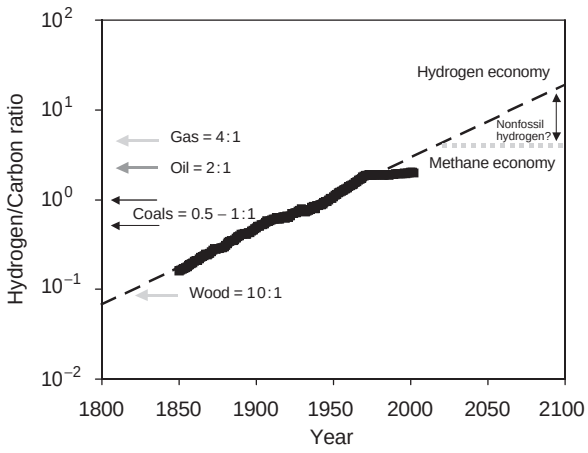

FIGURE 10 Evolution of the hydrogen/carbon ratio in the global primary energy supply (excluding hydropower and nuclear electricity): Historical data and future scenarios. See text for details. Updated and modified from Marchetti (1985).

hydrogen economy. However, as indicated in Fig. 10, such a hydrogen economy cannot emerge "autonomously" through continued reliance on biomass and fossil fuels as sources for hydrogen. Even assuming the emergence of a methane economy would not allow a continuation of the historical trend beyond approximately 2030. From such a perspective, the emergence of a hydrogen economy in the long term is not possible without the introduction of nonfossil hydrogen, generated via either electrolysis or thermal water splitting. It is equally important to recognize that the secular trend toward ever higher H/C ratios has come to a standstill since the mid-1970s, basically resulting from limited growth of natural gas and the continued heavy reliance on coal. Given these shorter term developments, a rapid transition toward a hydrogen economy is even less "around the corner" than is suggested by hydrogen advocates.

The important transition toward higher H/C ratios illustrated in Fig. 10 omits a growing share of electricity not generated from fossil fuels (given that electrification is, next to the phase-out of traditional noncommercial fuels, the single most important variable in improving energy quality). Therefore, Fig. 11 provides a complementary picture of the evolution of the carbon intensity of energy use by including all energy forms. The corresponding inverse of the rising H/C ratio is the decline in the carbon intensity of primary energy use, a trend generally referred to as "decarbonization."

Although decarbonization is usually described as a phenomenon at the level of primary energy use, its ultimate driver is energy consumers and their preference for convenience and clean fuel—if their

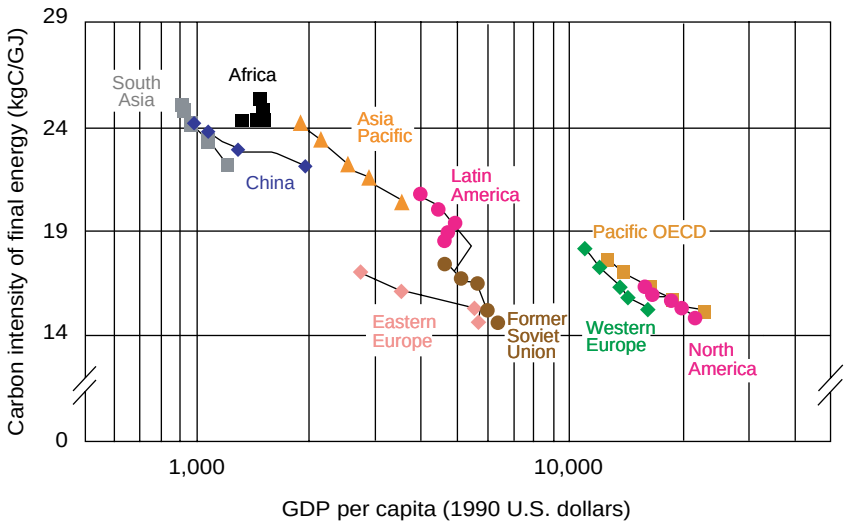

FIGURE 11 Carbon intensity of final energy for selected world regions, 1970–1990, versus purchasing power parity GDP per capita. Reprinted from Grübler and Nakicenovic (1996).

incomes allow. Hence, Fig. 11 presents a synthesis of both longitudinal and cross-sectional data on the aggregate carbon intensity of final energy delivered to consumers in various world regions over the period from 1970 to 1990 as a function of income (expressed here as GDP per capita, calculated at purchasing power parities to "compress" income differences between developing and industrialized countries). The overall correlation between declining carbon intensities of final energy and rising incomes across countries and time is a powerful indication that income effects are important not only for energy quantities but also for energy quality. Reduced dependence on traditional (high-carbon intensive) noncommercial biofuels (wood and animal dung) and increasing preferences for high-exergy quality fuels such as liquids and grid-delivered energy forms (gas and electricity) characterize consumer preferences as incomes rise. Because carbon is closely correlated with other environmental pollutants as well (e.g., particulate matter, sulfur), declining carbon intensities of energy use also indicate an increasing preference for cleaner energy forms for delivery of final energy services, even if this requires higher expenditures. (High-quality, low-emissions fuels quite rightly have a much higher price than do low-quality, polluting fuels.) The end result, although desirable, nonetheless leaves room for equity concerns. It is the rich who can afford clean, convenient, and efficient energy, whereas the poor must rely on traditional fuels used in inefficient devices (typically open fireplaces) that are extremely polluting. (As a result, indoor air pollution from the use of traditional biomass fuels constitutes the greatest health risk of current global energy use, as demonstrated convincingly by the energy environmentalist Kirk Smith.)

Finally, Fig. 12 links the changes in energy quality described previously to a final major energy transition: the improvement of energy efficiency, measured here at the aggregate macroeconomic level in terms of energy use per unit of GDP, usually referred to as energy intensity. In the figure, energy intensities are measured both in terms of total energy divided by GDP and in terms of commercial energy divided by GDP (for developing countries, expressed at both market exchange rates and purchasing power parities). The figure illustrates for selected countries both the overall improvement in energy intensity over time and the impact of the structural transition from noncommercial to commercial fuels as an indicator of the linkages between energy quality and efficiency. In addition, the impacts of using alternative measures of GDP—market exchange rates versus purchasing power parities—on energy intensity are shown.

Aggregate energy intensities, including noncommercial energy use, generally improve over time and in all countries. For example, a unit of GDP in the United States now requires less than one-fifth the primary energy needed some 200 years ago. This corresponds to an average annual decrease in energy intensity of roughly 1% per year. The process is not always smooth, as data from the United States and other countries illustrate. Periods of rapid improvements are interlaced with periods of stagnation. Energy intensities may even rise during the early

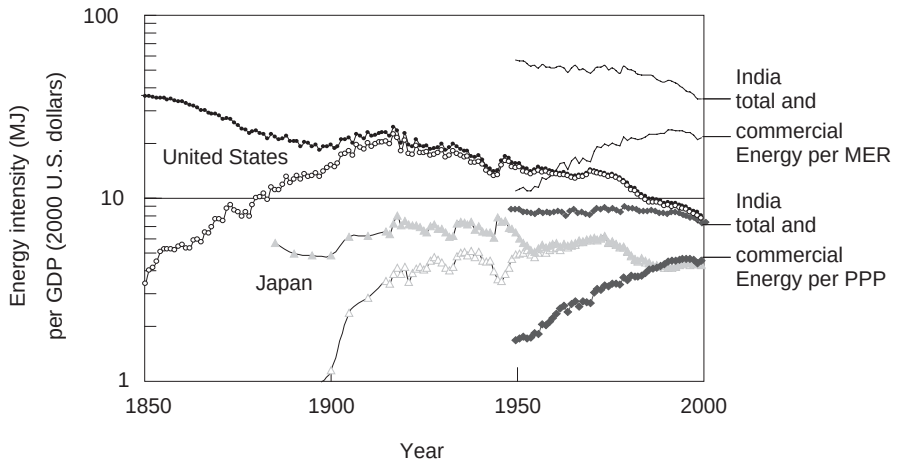

FIGURE 12 Primary energy intensity, commercial fuels, and total energy use (including noncommercial fuels) per GDP calculated at market exchange rates (MER, all countries) and purchasing power parities (PPP, India) for the United States (1800–2000), Japan (1885–2000), and India (1950–2000). Courtesy of Erik Slentoe, IIASA.

takeoff stages of industrialization, when an energy- and materials-intensive industrial and infrastructure base needs to be developed.

Whereas aggregate energy intensities generally improve over time, commercial energy intensities follow a different path. They first increase, reach a maximum, and then decrease. The initial increase is due to the substitution of commercial energy carriers for traditional energy forms and technologies. However, as evidenced by the total aggregate energy intensity, the overall efficiency effect remains decisively positive. Once the process of substituting commercial fuels for noncommercial energy is largely complete, commercial energy intensities decrease in line with the pattern found for aggregate energy intensities. Because most statistics document only modern commercial energy use, this "hill of energy intensity" has been discussed frequently. Reddy and Goldemberg, among others, observed that the successive peaks in the procession of countries achieving this transition are ever lower, indicating a possible catch-up effect and promising further energy intensity reductions in developing countries that have yet to reach the peak. Nonetheless, the apparent existence of a hill of energy intensity in the use of commercial fuels is overshadowed by a powerful trend. There is a decisive, consistent long-term trend toward improved energy intensities across a wide array of national experiences and across various phases of development, illustrating the link between energy quality and efficiency, among other factors (e.g., economic structural change). However, history matters. Although the trend is one of conditional convergence in energy intensities across countries (especially when measured at purchasing power parities), the patterns of energy intensity improvements in various countries reflect their different situations and development histories. Economic development is a cumulative process that, in various countries, incorporates different consumption lifestyles, different settlement patterns and transport requirements, different industrial structures, and different takeoff dates toward industrialization. Thus, the historical evolution of energy intensities again provides an example of path dependency.

The comparative levels of energy intensities of developing countries (cf. India's level with that of other countries [Fig. 12]) depend on whether they are measured at market exchange rates or in terms of purchasing power parities as well as on whether only commercial fuel or total energy use (including noncommercial fuel) is considered. As a rule, when expressed at market exchange rates, energy intensities in developing countries are very high, resembling the energy intensities that today's industrialized countries showed more that 100 years ago. Even considering energy intensities per purchasing power parity GDP, decisive North–South differences remain, reflecting the respective differences in income. Income matters because income levels determine both the quantities and quality of energy affordable to consumers as well as the type of energy end use conversion devices available to them (e.g., a capital-intensive, energy-efficient cooking stove vs a traditional cheap but inefficient one). Thus, the final energy transition discussed here, the move toward more efficient energy

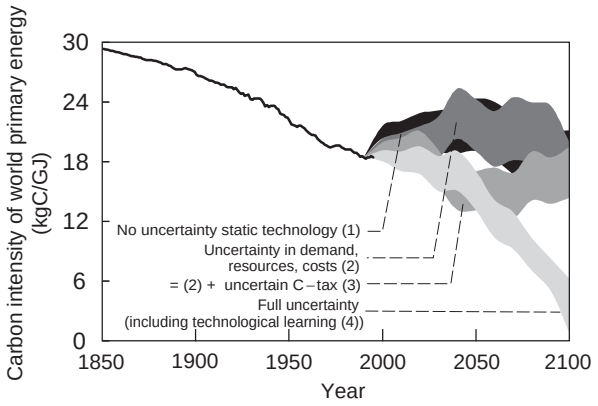

FIGURE 13 Carbon intensity of world primary energy: Historical development since 1850 and future scenarios to 2100 based on different model representations of uncertainty and induced technological change. use, is far from completed. Efficiency improvement potentials remain large in affluent and poor societies alike. Far from being autonomous, the pace of realization of efficiency improvement potentials in the future depends on a variety of factors. For instance, it depends on income growth in developing countries, making clean and efficient energy forms and end use devices affordable to wider segments of society. And it depends on new technologies and incentives that promote more efficient energy use. The energy transition toward higher efficiency needs to be pursued actively and continuously because it remains forever "unfinished business."

5. CONCLUSION

Let us return to the trend toward energy decarbonization, but this time at the level of primary energy. The good news is that at the level of both energy consumers and the energy system, decarbonization is taking place, albeit at a very slow rate ($\sim$0.3%/year at the global primary energy level and slightly faster at the final energy level). The bad news is that the models developed to date to describe the dynamics of global energy systems cannot replicate decarbonization (or, for that matter, any other major historical transitions described in the preceding sections) in any endogenous way, regardless of whether the models embrace an economic ("top-down") or engineering ("bottom-up") perspective. But the state of the art in modeling energy–technology–environment interactions is expanding rapidly. Figure 13 illustrates how future decarbonization rates depend on the representation of technology. In the (currently dominant) view of a largely static technology base, past and future decarbonization cannot be modeled without resort to exogenous modeling "fudge factors" and constraints. Even treating the traditional energy model variables of resource availability, demand, and environmental constraints (taxes) as uncertain, justifying diversification away from current dominant fossil technologies, does not change this picture significantly. Currently, the only way in which to replicate historical decarbonization and generate scenarios of future decarbonation in an endogenous way is to use models that incorporate full uncertainty, including those of increasing returns to adoption for new energy technologies. Thus, innovation is key—even if uncertain—both for future scenarios and for explaining the transitions that have taken place in global energy use since the onset of the industrial revolution.

Glossary

alternative fuel A nonpetroleum energy source used to power transportation vehicles; most often applied to road vehicles.

energy density The ratio of the energy content of a fuel or storage capacity of a battery to its volume or mass.

energy intensity The quantity of energy used per unit of transportation service provided; most often measured in energy use per passenger-mile (or passenger-kilometer) or per ton-mile (or ton-kilometer).

fuel economy Vehicle-miles (or vehicle-kilometers) produced per unit of energy consumed, most often measured as miles per gallon of fuel consumed or as liters of fuel consumed per 100 km traveled.

hybrid vehicle A vehicle that employs two sources of propulsion, especially an internal combustion engine and an electric motor. Some definitions also require that energy be recaptured during braking and stored in a battery or other energy storage device for later use and that the internal combustion be shut off when it would otherwise be idling.

mode of transportation A particular combination of transportation vehicles and media. The most basic distinction is among highway, rail, waterborne, air, and pipeline transport modes.

Transportation is the movement of people or objects from one place to another. Energy is essential to transportation. Moving people, objects, and the vehicles that carry them requires the application of force to overcome the forces of inertia and friction. The application of force over a distance is work and energy is the ability to perform work. Modern, mobile societies use vast amounts of energy for passenger travel and freight transport; approximately one-fourth of the total energy used by humans is for transportation. Today, a century after the introduction of the internal combustion engine as a means of propulsion, approximately 95% of transportation energy use is supplied by petroleum. Petroleum's advantages include low cost, high energy density, and up to the present, abundant supply. Burning vast quantities of petroleum to power transportation does significant damage to the environment in the form of air pollution, spills on water and land, and greenhouse gas emissions. The near-total dependence of transportation systems on petroleum has also been a source of strategic and economic costs. As the world's resources of fossil petroleum are depleted, the world's ever-increasing demand for mobility raises questions about where the energy to power transportation can be obtained. Solving these problems while maintaining and expanding the mobility on which the world's economies have come to depend is the central problem of transportation and energy.

1. INTRODUCTION

Modern, mobile societies use vast amounts of energy for passenger travel and freight transport. Global transportation energy amounted to 4 EJ in the year 2000, one-fourth of the final energy used by human societies for all activities. Almost all (95%) of the energy use for transportation was derived from the

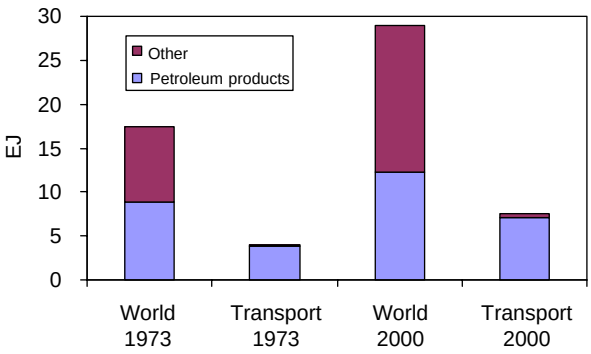

FIGURE 1 World final energy use.

combustion of petroleum (Fig. 1). Burning such vast quantities of petroleum does significant damage to the environment. For most developed economies, it also creates an economic and strategic dependence on imported oil. As supplies of conventional oil are depleted, the world's ever-increasing demand for mobility raises questions about where energy for transportation will come from in the 21st century and what the consequences of its use will be.

Energy is essential for transportation. Transportation, the movement of people or objects from one place to another, is a form of work, as that term is defined in physics. Moving transportation vehicles requires the application of force to overcome inertia and continuous force to keep vehicles moving against the opposing forces of friction from rolling resistance, aerodynamic drag, or hydraulic drag. Work is defined as the application of force through a distance and so the essence of transportation is work. Energy is the ability to do work and thus transportation cannot be accomplished without using energy.

Energy for transportation vehicles can be supplied externally (e.g., sailboats, electric trains, trolleys) or carried on board (e.g., automobiles, jet aircraft). In the 20th century, the internal combustion engine became the predominant source of power for transportation vehicles, displacing animal, wind, and steam power. Internal combustion engine vehicles must carry a supply of energy on board. When energy is carried on board a vehicle, a high value is placed on energy density because stored energy displaces payload (by weight and volume) and because storing more energy on board facilitates speed and the convenience of nonstop operation. After a brief period of experimentation early in the 20th century, liquid fuels derived from petroleum emerged as the clearly preferred form of energy for internal combustion engines. By midcentury, petroleum supplied 90% of the energy for transportation vehicles. Petroleum fuels have four key advantages: (1) they have high energy density per volume and weight; (2) they are easily handled and stored because they are liquids under ambient conditions; (3) throughout most of the 20th century, petroleum resources have been in abundant supply; and (4) they are relatively inexpensive.

2. SOCIETAL CONCERNS

Consumption of petroleum fuels has also brought problems: (1) air pollution from vehicle exhausts is harmful to human health to animals and to vegetation; (2) greenhouse gas (GHG) emissions, mostly in the form of carbon dioxide, have begun to alter the earth's climate; (3) the concentration of the world's oil resources in the Persian Gulf region has contributed to international conflict and produced oil price shocks that triggered economic recessions; and (4) crude oil and fuel spills and leaking storage tanks have polluted water bodies and groundwater.

Enormous technological progress has been made in reducing the pollution caused by the combustion of petroleum fuels in motor vehicles. A properly operating model year 2000 automobile produces approximately 1% of the pollutant emissions per kilometer of vehicle travel of a vehicle built in 1965. New, tighter emissions standards to be implemented in the next 5 years require further reductions in emissions. Still, because of the continued growth in the number of vehicles and kilometers traveled and because of old and malfunctioning vehicles, air pollution by motor vehicles remains a serious health concern, especially in the megacities of developing economies.

The overwhelming majority of GHG emissions from transportation are in the form of carbon dioxide (Fig. 2). A typical passenger car will emit several times its weight in carbon dioxide each year. Because the carbon content of petroleum fuels varies little, carbon dioxide emissions depend directly on how much transporting is done and the energy efficiency of transportation vehicles. Globally, transportation accounts for one-fifth of carbon dioxide emissions. Thus far, reducing transportation's GHG emissions has proven to be much more difficult than reducing air pollutant emissions because of the lack of economically competitive, alternative, low-carbon fuels.

Because no fuel has been able to displace petroleum, increasing energy efficiency and reducing motorized vehicle travel are the most effective

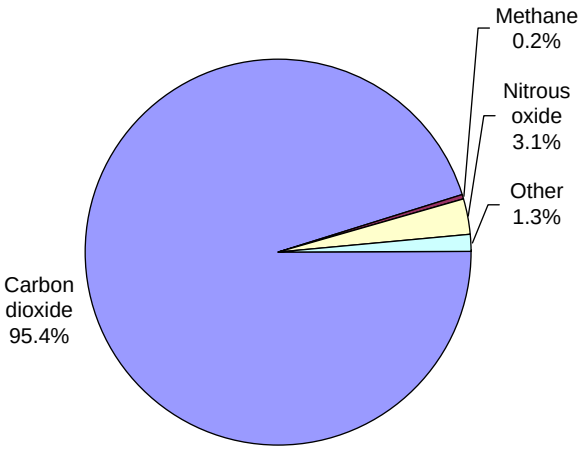

FIGURE 2 Transportation greenhouse gas emissions, by type of gas, in the United States in the year 2000.

remaining strategies for controlling transportation's GHG emissions over the next few decades. Since 1970, increasing energy efficiency has proven to be more effective than decreasing vehicle travel. From 1970 to 2000, highway vehicle travel in the United Stated increased by almost 150%. At the same time, the fuel economy of passenger cars and light trucks in use increased by 55% (from 13.0 to 20.1 miles per gallon). The increase in passenger car and light truck fuel economy in the United States from 1975 to 2000 reduced petroleum consumption by 2.8 million barrels per day (6.25 EJ per year), equivalent to 100 million metric tons of carbon emissions.

Driven by fuel economy standards and higher fuel prices, the fuel economy of new passenger cars sold in the United States doubled from 1974 to 1985 and that of light trucks increased by over 50%. U.S. fuel economy standards have not changed significantly since 1985 and fuel prices decreased. As a result, both new car and light truck fuel economies have remained approximately the same and the combined fuel economy of light-duty vehicles has declined due to the increased popularity of light trucks. It takes approximately 15 years for the total fleet of light-duty vehicles in use to reach the same level of fuel economy as new vehicles (older, less efficient vehicles must be scrapped and replaced by newer ones). As a result, total light-duty vehicle fuel economy has continued to increase slowly, reaching 19.5 miles per gallon in 1991 and 20.1 miles per gallon in 2000. Thus, it appears that in the future, carbon dioxide emissions will increase at the same rate as vehicle travel grows.

World resources of petroleum are highly geographically concentrated. Nations belonging to the Organization of Petroleum Exporting Countries (OPEC) hold almost 80% of the world's proved reserves of conventional oil. Proved reserves, however, are a stock held for future production and do not fully reflect the extent of developable oil resources. Considering estimated undiscovered resources and the potential for technological progress in discovery and production, OPEC members still hold more than one-half of all the conventional oil that remains (Fig. 3). The willingness of OPEC members to use their position of market dominance has enabled them to raise oil prices at the expense of oil-producing nations and has contributed to international conflict.

Though estimates vary, it appears that human beings have consumed approximately one-third of all the conventional petroleum that exists. Because consumption has been steadily increasing, it will take no more than a few decades to reach the point at which 50% of the earth's ultimately recoverable conventional petroleum resources have been consumed. If that point is reached, transportation may have to begin a transition to alternative sources of energy if world mobility is to continue to increase. One option is to make conventional fuels out of other fossil carbon resources. There are vast deposits of unconventional oil in the form of heavy oil in Venezuela and oil sands in Canada that are beginning to be developed to supply petroleum fuels at competitive prices. In addition, excellent conventional transportation fuels can be made at a higher cost from natural gas or coal via Fischer–Tropsch or similar conversion processes. The United States also contains enormous reserves of oil shale, which could be developed at much greater expense and with increased environmental impacts. On the other hand, given the right technological advances, the energy for 21st century transportation systems could be

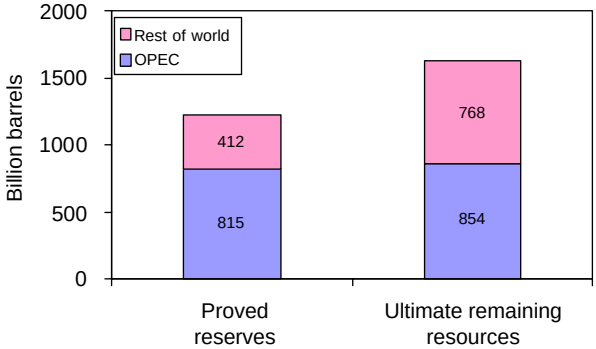

FIGURE 3 Estimated quantity and distribution of world's remaining oil resources.

supplied by very different fuels, such as hydrogen to power fuel cell vehicles or electricity for high-speed railways.

3. HISTORY OF PROPULSION TECHNOLOGY AND ENERGY

The history of transportation and energy is one of finding ways to apply greater power and to reduce the forces opposing motion, so that ever larger payloads could be moved at greater speeds. Defined as the tools devised by human beings to accomplish the transportation of persons and goods, vehicles could include everything from domesticated animals to jet aircraft. At a minimum, a vehicle consists of a structure for supporting a payload and a means of using energy to create motion. A wide variety of forms of energy have been applied to make vehicles go. The goals of increasing speed and payload have driven transportation vehicles not only to use more energy, but to use it more effectively by increasing the efficiency with which energy is converted to propulsion and by minimizing the forces of inertia and friction.

From the earliest times, human beings sought to augment the mobility that their legs provided by domesticating animals and harnessing their power. Horses, camels, oxen, donkeys, and even elephants and dogs have been employed by humans to pull or carry. Animals could be ridden or laden, but generally this did not take full advantage of their power. Larger amounts could be transported by harnessing animals to a sled or by harnessing them to two poles and dragging a load suspended between them. The Native Americans of the northern plains used such vehicles (with pointed pole ends to reduce friction) until the 19th century. The high friction produced by dragging across the ground was dramatically reduced by the invention of the wheel. Wheeled vehicles in the form of carts and chariots have been in existence since at least the second millennium BC. For the next 3000 years, animal power provided the energy for ground transportation vehicles and technological advances focused on reducing friction through the invention of rounder, lighter spoked wheels and turnable front axles and through the improvement of road surfaces and reduction of grades.

Waterborne vessels are known to have been used for transporting people and goods as long ago as 4000 BC. Motive power was provided by rowers, by the wind, and on rivers by downstream currents. To make oared boats larger and faster, two and three banks of oars were used. At the same time, hull designs were elongated and streamlined to reduce hydraulic drag. From a single square or triangular sail on a mast, more sails and more masts were added to increase the amount of wind energy that could be used. Sails were made maneuverable to allow headway to be made under a greater range of wind directions and to increase speed. Larger and faster sailing ships allowed humans to travel around the earth for the first time in the 15th century. On inland waterways, the construction of canals with towpaths allowed mules or oxen to take over from human power as a source of propulsion.

In the latter half of the 18th century, the invention of the (external combustion) steam engine began a revolution in ground and water transportation. For the first time, a vehicle's source of energy, generally coal, could be carried on board. The first steam engines were large and, because they operated at low pressures, provided relatively little power for their weight and size. Because of their low power density, the first use of steam engines in transportation was on ships. Early paddle-wheel-driven steamboats were no faster than sailing ships but had the advantages of more reliable propulsion and the ability to travel in any direction regardless of which way the wind blew. In the 19th century, improvements such as higher pressure engines using double and triple expansion to maximize the work derived from steam, the screw propeller, and steel hulls that could withstand the greater forces produced by the more powerful engines allowed the steamship to flourish. Just before the turn of the century, steam turbine engines were installed on ocean liners and proved to be somewhat faster than the reciprocating piston steam engines.

On land, early steam engines were installed on vehicles that operated on roadways and on fixed guideways. Operation on steel rails proved the most effective because of the low friction between wheel and rail. With only 1 atm of pressure, the earliest steam engines had too little power for their size to be effective propulsion systems for land transport. By the beginning of the 19th century, however, steam engines with 10 times the pressure of the early engines had been invented and the age of rail began. Rail's dominance of land transport lasted a full century until a new engine emerged with much higher power density, its energy supplied by liquid fuel.

The invention of the internal combustion engine has proven to be the single most important event in

the history of transportation. Almost immediately after the first successful internal combustion engines were developed in the 1870s, they were installed on tricycles, bicycles, and carriages; after only slightly more than 10 years, the first automobiles appeared on the roads of Europe and North America. In 1901, 425 automobiles were sold in the United States. They were chiefly toys, affordable only by the wealthiest Americans. The introduction of the Model T by Henry Ford in 1908 changed that forever. By 1929, 27 million automobiles traveled a largely inadequate U.S. road system.

New forms of propulsion that could displace the internal combustion engine in the 21st century are on the horizon. Fuel cells powering electric motors have made enormous progress as a potential propulsion system for automobiles. Fuel cells produce electricity by a chemical reaction between hydrogen (the fuel) and oxygen (usually supplied from the air). Unlike a battery, the fuel cell can supply electricity indefinitely as long as new fuel and oxygen are provided to the cell. Whereas modern gasoline internal combustion engines can achieve efficiencies of up to 30%, fuel cells coupled with electric motors can convert up to 55% of the energy in fuel to useful work. The hydrogen fuel cell is an inherently clean technology; the only product of its chemical reaction is water. In addition, hydrogen can be produced from a number of energy sources including natural gas, coal, biomass, or, via electrolysis, any source of electricity, including nuclear, wind, or solar power.

Magnetic levitation could someday revolutionize fixed guideway transportation. Magnetic forces can levitate a train above its guideway for noncontact, almost frictionless suspension, guidance, and propulsion at speeds up to 500 km/h. Successful technical demonstrations of maglev trains have been made in Japan, Europe, and the United States.

For aircraft to fly at speeds greater than mach 5 (hypersonic speed, greater than 1.6 km/s), they will need new propulsion systems and new fuels. Aerospace researchers are developing ramjet/scramjet engines to achieve these hypersonic flight speeds. Unlike conventional jet engines, which mechanically compress air prior to combustion, ramjets use the speed of the aircraft itself to compress the air that travels through the jet engine at subsonic speeds. In the scramjet, the air travels through the engine at supersonic speeds. This requires a fuel with an extremely fast rate of combustion. Petroleum-based fuels combust too slowly, so a new fuel, such as liquid hydrogen, will be needed.

4. PATTERNS AND TRENDS IN TRANSPORTATION ENERGY USE

By far, highway vehicles consume more energy than any other mode of transport. In both the developed economies belonging to the Organization for Economic Cooperation and Development and developing economies, road vehicles account for 80% or more of total transportation energy use (Fig. 4). In the Unites States, light-duty vehicles (passenger cars and light trucks) alone account for more than one-half of the transportation sector's total energy use. Air travel is the second largest and fastest growing energy user. Between the two, they consume more than 90% of transportation energy use. Other modes, rail, pipeline, and water, account for approximately 1–2% each.

Despite the oil price shocks of the 1970s and 1980s, world transportation energy use more than doubled from 1970 to 2000 (Fig. 5). Energy use in developing economies grew faster (3.5% per annum) than energy use in the developed economies (2.2% per year). If the growth in transportation activity continues at this pace, and if significant improvements in energy efficiency are not made, the world will soon be searching for alternative sources of energy to fuel the growth of its transportation systems.

5. ENERGY EFFICIENCY AND ENERGY CONSUMPTION

Increasing the energy efficiency of transportation vehicles has always been a key motivation for

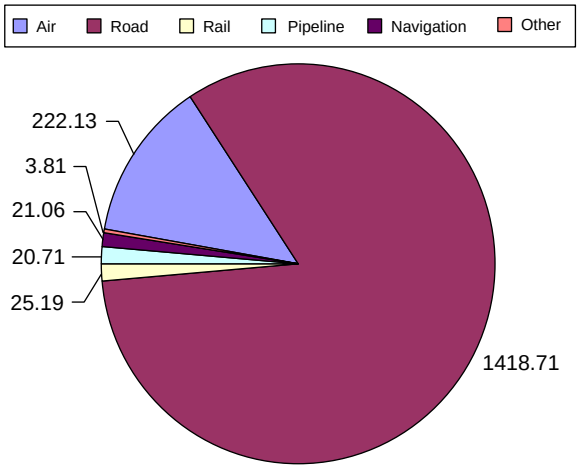

FIGURE 4 World transportation energy use by mode, in the year 2000 (million metric tons of oil equivalent).

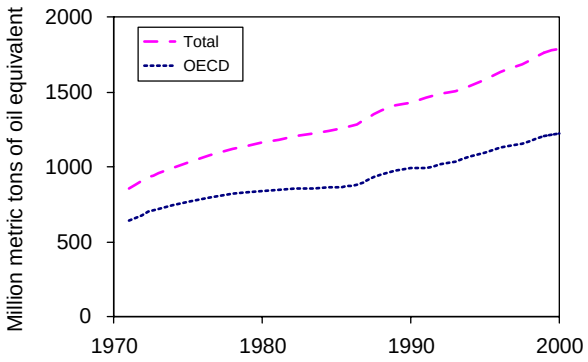

FIGURE 5 World transportation energy use. OECD, Organization for Economic Cooperation and Development.

TABLE I

Typical Engine and Transmission Efficiencies

Technology	Urban driving	Highway driving
Gasoline engine	10–15%	25%
Diesel engine	15–22%	35%
Automatic transmission	70–80%	85%
Manual transmission	85–90%	90–95%

advances in energy technology. It is useful to distinguish between propulsion efficiency (the efficiency with which energy delivered to a vehicle is converted into useful work) and vehicle efficiency (the energy required from a vehicle's propulsion system relative to the transportation services it delivers). In some circumstances (such as comparing the environmental impacts of alternative technologies and fuels), it is important to consider the life cycle or "well-to-wheels" energy efficiency of a complete fuel and vehicle system.

Propulsion efficiency is the ratio of the output of an engine in useful work to the energy content of the fuel used. The second law of thermodynamics requires that this ratio be less than 1 because in any reaction entropy must increase. Many other factors prevent engines from reaching thermodynamic efficiency limits, including internal friction, limits on temperatures and pressures, and energy requirements of auxiliary systems. All of these areas constitute possibilities for technological advances to increase efficiency. The spark-ignited, gasoline, internal combustion engine of a modern automobile, in typical urban driving, converts less than 20% of the energy in gasoline into useful work at its crankshaft (see Table I). Various engine losses (especially heat rejected to the engine's cooling system and exhaust) account for more than 60% of the energy in the fuel; fuel consumed during idling, braking, and coasting accounts for almost 20%. Although idling and braking losses are not a function of the conversion efficiency of the engine, they are an important component of the overall efficiency of the propulsion system. It is possible to recapture much of a vehicle's kinetic energy normally dissipated as waste heat during braking. Hybrid propulsion systems that combine an internal combustion engine and an electric motor minimize these losses by (1) shutting off the internal combustion engine during idling, coasting, or braking and restarting it quickly with the electric motor when needed and (2) using the electric motor as a generator during braking to convert kinetic energy into electricity, which is then stored in a battery for future use by the electric motor.

For any given driving cycle (a driving cycle is typically defined by a schedule of velocity versus time at a given load and under ambient conditions), the energy required to propel a vehicle is determined by the forces that oppose its motion. The amount of inertial energy is determined by the mass of the vehicle, since for the same rate of acceleration proportionately increased force must be applied as mass increases (Force = Mass × Acceleration). To a lesser degree, this also applies to the moving parts of an engine, which must also be accelerated to increase engine speed. Reducing the mass of these moving parts reduces friction and the inertial work internal to the engine. Force to overcome inertia must also be applied when vehicles change direction.

The remaining forces opposing motion are frictional. All vehicles moving within the earth's atmosphere must overcome aerodynamic drag. Aerodynamic drag becomes increasingly important as vehicle speed increases because drag grows with the square of speed. As a result, the energy required per unit of distance to overcome aerodynamic drag increases in proportion to vehicle speed. At any given speed, drag can be reduced by means of slipperier vehicle designs with lower drag coefficients. A bluff design with its full frontal area perpendicular to the direction of motion would have a drag coefficient of 1.0. Modern passenger cars have drag coefficients on the order of 0.3, whereas large truck drag coefficients are often 0.7 or higher. Advanced passenger car designs have achieved drag coefficients of 0.15. For motor vehicles, the other

major frictional force, rolling resistance, is caused by friction in wheels, axles, transmission, brakes, and the contact between wheels or tires and roads or tracks. Rolling resistance increases directly with speed so that per unit of distance traveled it is approximately constant. In a modern automobile, most rolling resistance is due to the deformation of tires as they meet the pavement.

Losses in the transmission and other driveline components of an automobile use slightly more than 5% of the total energy in fuel. Of the 12–13% of the original energy in fuel that reaches the wheels, approximately 6% goes to overcoming inertia, 3% to overcoming aerodynamic drag, and 4% to rolling resistance. In highway driving, the distribution is quite different, reflecting the greater importance of frictional forces at highway speeds: 2% to overcoming inertia, 7% to rolling resistance, and 11% to overcoming aerodynamic drag.

Commercial aircraft have settled on the gas turbine engine fueled by kerosene as the propulsion system of choice. Unlike the engines used in automobiles that employ reciprocating pistons to compress air prior to combustion, turbines use fan blades rotating about an axis to achieve compression. Turbine engines are more efficient for the constant speed operating conditions typical of most air travel. The overall efficiency of gas turbine propulsion is determined by its thermodynamic efficiency (which increases as the temperatures and pressures that can be achieved within the engine increase) and propulsion efficiency. Early turbojets achieved thrust solely by accelerating the air that passed through the engine's combustor. By accelerating air out the back of the jet engine, an equal and opposite force that accelerates the aircraft forward is created. The turbofan engine greatly increased propulsion efficiency by also producing thrust by means of fan blades driven by the turbojet engine to accelerate air passing around the engine. By 1990, turbofans employed bypass ratios of 5–6; in 2003, high-bypass engines have ratios of 8–10. It may be possible to increase ratios to 15–20 with further gains in propulsion efficiency. The overall energy efficiency of aircraft propulsion has improved dramatically over the past 50 years. In 2003, energy use per unit of thrust produced is less than two-thirds of what was required in 1960.

Aircraft must continuously overcome the force of gravity, which is proportional to their mass. They do so by using an airfoil to create lift. The airfoil also creates a frictional force (aerodynamic drag) that opposes the forward motion of the aircraft. The ratio of the force of lift to that of drag (L/D) is the key measure of the aerodynamic efficiency of aircraft. Early jet aircraft had L/D ratios of approximately 16. Today, long-range aircraft achieve L/D ratios of 20 and short- to medium-range aircraft have ratios of approximately 18.

The overall energy efficiency of air travel has also benefited from increased aircraft size (seats per aircraft) and higher load factors (average occupancy per seat). In 1970, airlines used 6.5 MJ per passenger-kilometer of service. In 2000, only 2.5 MJ was needed to produce 1 passenger-kilometer of service, approximately the same as the average energy efficiency of travel by passenger car.

Transportation modes differ in energy efficiency, but perhaps not as much as might be expected. Measuring efficiency for modal comparisons is made difficult by differences in the services that modes provide. The private passenger car provides the ultimate in personal convenience, offering privacy, point-to-point transport, and a completely flexible schedule. However, passenger cars cannot yet cruise at 800 km/h the way jet aircraft can. Also, although railroads consume far less energy per ton of freight carried, they cannot match trucks for point-to-point service and flexibility in scheduling. Nor can either alone guarantee overnight transcontinental delivery as can aircraft combined with trucks. Such differences in service are not reflected in readily measured energy efficiency indicators, such as energy use per passenger-kilometer or ton-kilometer. Bearing these limitations in mind, data for the United States indicate that energy intensities of passenger modes have tended to decline over time and suggest a degree of convergence across modes (Fig. 6). Air travel, the newest mode in terms of technological maturity, achieved the greatest reduction, most of it prior to 1980. Passenger car and light truck energy intensities declined through 1990, whereas most other modes' energy intensities remained the same or even increased.

For freight modes, data are inadequate to calculate energy intensities for truck and waterborne freight. Energy use per ton-kilometer transported by rail in the United States was cut by one-half between 1970 and 2000. These aggregated comparisons obscure significant variations from place to place and across types of service within modes.

6. ENERGY SOURCES

Early transportation vehicles relied on animal power, wind, flowing water, and gravity. With the motorization of transportation vehicles, combustible

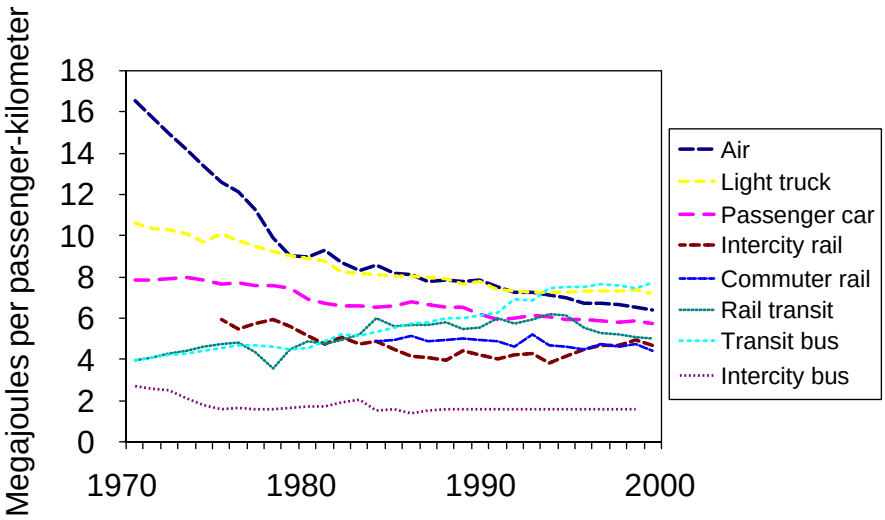

FIGURE 6 Energy intensities of passenger modes in the United States.

fuels and electricity became important sources of energy. External combustion engines, such as the steam engine (piston and turbine), played an important role in water and rail transport during much of the 19th century and early part of the 20th century. Solid fuels, such as coal and wood, are suitable for external combustion because the speed and completeness of combustion are not of great importance. The low cost and abundance of coal made it the fuel of choice for steam engines. The combination of the development of the internal combustion engine and discovery of vast resources of petroleum led to petroleum displacing nearly every other form of energy as the predominant energy source for transportation. Internal combustion engines favor volatile liquid and gaseous fuels because combustion must take place rapidly in a confined space (favoring fuels that vaporize easily or are already gaseous) and combustion products must be fully expelled in a gaseous medium.

The first electric automobile was a tricycle powered by lead–acid batteries, introduced to the world in 1881. An 1882 version is known to have carried 68 kg of batteries with an energy storage of 1.5 kWh, enough for a range of 15–40 km traveling at approximately 15 km/h. One and one-half kilowatt-hours is equivalent in energy to approximately one-sixth of a liter of gasoline. In 1900, electric automobiles had a tremendous advantage in energy efficiency over their competitors. Steam-powered automobiles were getting approximately 2.5 km/liter, gasoline-engine vehicles were getting approximately 5 km/liter, whereas electric cars could travel up to 75 km per energy equivalent of 1 liter of gasoline. Unfortunately, electric vehicles could store only approximately 30 kWh of energy on board (equivalent to approximately 3 gal of gasoline) and took hours to refuel.

The electric vehicle arrived first and, initially, competed well against the noisy and frequently unreliable gasoline-engine automobiles. But by 1912, there were 33,000 electric vehicles in use in the United States and over half a million gasoline-powered vehicles. Electric vehicles had distinct advantages in quietness, cleanness, and reliability, but gasoline vehicles had the decisive advantage: energy storage. The costs of electricity and gasoline were relatively minor factors. By either weight or volume, more than 100 times as much energy could be stored on board a vehicle in the form of gasoline versus electricity stored in batteries. In addition, batteries were, and still are, expensive storage devices in comparison to a gasoline tank. Primarily due to the cost of batteries, electric vehicles in 1913 cost $2000 to $3000, whereas gasoline-engine automobiles could be purchased for less than $1000.

Energy density remains a problem for alternative fuels. The energy densities of gaseous and liquid fuels are compared in Fig. 7. Diesel fuel has 11% more energy per volume than gasoline and thus requires only 90% of the volume to store the same amount of energy. Two alcohols that have been widely used as motor fuels, ethanol and methanol, require 50 and 100% greater volumes, respectively, to store the same amount of energy. Compressed natural gas (methane) needs 4 liters of storage space to equal the energy in a single liter of gasoline and liquefied hydrogen requires almost the same volume. Compressed hydrogen at 5000 psi needs 16 times the

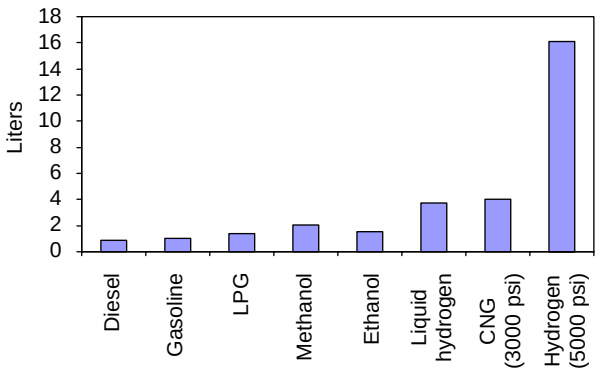

FIGURE 7 Volume required to store the energy equivalent of 1 liter of gasoline. CNG, compressed natural gas; LPG, liquefied petroleum gas.

volume. Batteries have even lower energy densities but are more often limited by weight than by volume. Three hundred kilograms of nickel metal hydride (NiMH) batteries (the kind used in hybrid vehicles today) are required to store the energy in 1 kg of gasoline. The most advanced NiMH batteries available could store that much energy in 170 kg of batteries.

Another problem faced by alternative fuels is the difficulty of displacing a fuel with an enormous, efficient infrastructure. The phrase "chicken or egg" dilemma has been used to describe the reluctance of energy companies to invest in fuel supply infrastructure when there are no vehicles that use the fuel and the reluctance of vehicle purchasers to buy, and automobile companies to manufacture, alternative fuel vehicles when there is no fuel supply infrastructure to support them. The economic barriers to displacing an established technology are real and substantial. In addition to the chicken or egg dilemma, initial problems include the lack of diversity of choice for novel technologies and large economies of scale in automobile production.

Alternative fuels without a decisive advantage over petroleum are not likely to succeed. Petroleum fuels and internal combustion engines have proven to be resilient and adaptable. In the 1980s, demands for cleaner cars seemed to favor inherently cleaner burning fuels, such as natural gas and alcohols. But the petroleum and motor vehicle industries responded by developing advanced emissions controls and a new reformulated gasoline, whose chemistry had been tailored to meet the emissions goals established by alternative fuels.

After nearly a quarter century of efforts to promote alternative fuels in the United States, there were only 456,000 alternative fuel vehicles in use out of 213 million (0.2%) in total and alternative fuels constituted only 0.2% of total fuel consumption by highway vehicles (1.3 billion out of 680 billion liters). Nonpetroleum energy has had greater success in blends with gasoline. In the United States in 2000, 11 billion gasoline energy equivalent liters of methyl tertiary butyl ether (made primarily from natural gas and butane) and 4 billion gasoline energy equivalent liters of ethanol (made from corn) were blended with gasoline.

7. TRANSPORTATION ENERGY IN THE FUTURE

What will transportation's energy future look like? Will demand for mobility continue to grow indefinitely or will a saturation point be reached and growth slow to a halt? Clearly, there are no certain answers to such questions. Yet transportation research has developed some useful principles that can help one peer into the future. Future world transportation energy use may well be determined more by what happens in the world's developing economies than by the evolution of developed economies. Not only is it likely that population growth and economic growth will be most rapid in the developing world over the next 50 years, but economic growth is likely to have the greatest impact on mobility in the developing world through its impact on the motorization of transport.

The average human being spends 1.1 h per day traveling. In addition, households not owning a personal car devote, on average, 3–5% of their expenditures to transportation. Typical car-owning households spend 10–15%. As income grows, the average time spent traveling remains approximately constant, but money expenditures grow. The increased expenditures go to faster (and more convenient) motorized modes of transport.

Whereas motorized transport is predominant in developed economies, walking, cycling, and mass transport are still the most commonly used modes in the developing economies. The average resident of Africa or China spends on the order of 10 min/day or less in a motorized form of transport. The average North American spends more than 1 h/day. The potential for growth is enormous and so are the rates of growth. In the developing world, automobile ownership rates are low: less than 50 vehicles per 1000 persons in China and Africa, 100 vehicles per 1000 persons in Latin America, and less than 150 vehicles per 1000 persons in the nations of the

former Soviet Union. By contrast, ownership rates exceed 500 vehicles per 1000 persons in Europe, are over 600 vehicles per 1000 persons in Japan, and top out at 800 vehicles per 1000 persons in the United States. In terms of motorization, China and Africa are approximately where the United States was in 1915 in terms of automobile ownership. In the developed world, travelers are switching from cars to airplanes to obtain more mobility out of their 1.1 h (average) of daily travel time. In the developing world, travelers are switching from animal and human power to motor vehicles. The impact on transportation energy use is likely to be enormous.

What energy sources will fuel the future growth of mobility? The world's fossil resources, especially coal and oil shale, are more than adequate to supply synthetic petroleum fuels for expanding mobility well beyond the end of this century. But will the world choose that path? It is also possible to manufacture hydrogen or electricity from those same fossil fuels or from almost any other source of energy. But will the technological challenges of fuel cells and hydrogen storage be solved? Will passengers and freight soon speed along at 500 km/h in magnetically levitated trains driven by linear electric motors? Or will unimagined technologies provide the increased speed, capacity, comfort, and convenience that human societies have sought ever since the first draft animals were domesticated? Regardless, an increasingly mobile world will demand more transportation, and transportation will require energy.

Glossary

ASIF matrix Basic structure of travel, providing a system for analysis; travel energy use is a function of the ASIF components: activity, structure, intensity, and fuel type.

fuel economy Fuel consumption per kilometer of vehicle travel (more commonly used in North America than elsewhere).

fuel efficiency The efficiency with which vehicles convert energy into movement—not necessarily the same as fuel economy; for example, one vehicle might have better technology and be more fuel efficient than another, but if it is larger and heavier than the other vehicle, it might still have worse fuel economy.

fuel intensity Similar to fuel economy, but where the term often describes the average fuel use per kilometer of the vehicle stock rather than of an individual vehicle.

light-duty vehicles A general term to describe cars, vans, sport utility vehicles, and even small trucks commonly used for personal transport; in the United States, more than 50% of new vehicle sales to households are no longer cars but rather other types of light-duty vehicles.

"on road" or "in use" fuel economy The fuel economy or fuel intensity of vehicles in actual use; this is typically anywhere between 10 and 25% worse than the "rated" fuel economy of vehicles, measured on test equipment using a fixed-duty cycle.

Organization for Economic Cooperation and Development (OECD) Organization that serves primarily industrialized, more developed countries, including North America, Western Europe, Japan, Korea, Australia, and New Zealand; OECD countries have become synonymous with the developed world, and non-OECD countries have become synonymous with the developing world.

transportation The movement of people and goods, providing mobility and access to desired destinations.

"well-to-wheels" greenhouse gas (or CO_2) emissions Emissions that occur not just from the vehicle but during the entire process of producing fuel and bringing it to the vehicle; this term may also include emissions during vehicle production and disposal.

Like all human activities, transportation, the movement of people and goods, is made possible by the use of energy. Current transport systems around the world rely nearly completely on a single form of energy—petroleum. As demand for petroleum fuels continues to increase, the unsustainability of this reliance has become an increasing concern. Not only is petroleum nonrenewable, but its use produces side effects such as air pollution and greenhouse gas emissions that could contribute to climate change. However, there is a range of available technologies and other options for reducing petroleum consumption in transport, mostly involving either switching to new fuels or cutting fuel use by improving transport efficiency. Significant changes in travel patterns are also possible. This article reviews current trends and outlines the options available for changing their direction so as to put transport on a more sustainable path.

1. RECENT TRENDS AND A FORECAST FOR THE NEXT 30 YEARS

In nearly every region of the world, transport energy use is increasing rapidly (Fig. 1) and is fueled nearly entirely by petroleum—more than 97% of transport fuel use worldwide. Because emissions of carbon dioxide (CO_2) are closely linked with consumption of petroleum (and other fossil fuels), these emissions have risen—and will continue to rise—in lock-step with the increases in petroleum use. Gasoline and diesel vehicles emit a variety of air pollutants, although

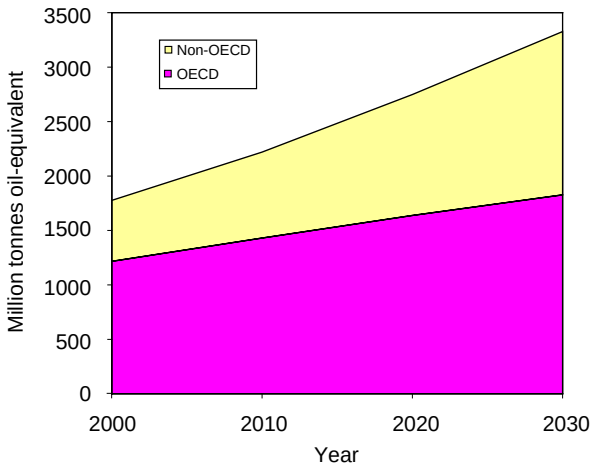

FIGURE 1 IEA forecast of transportation energy use through 2030: OECD and developing world.

tightened emissions control requirements have cut these emissions substantially during recent years, particularly in "developed" (i.e., Organization for Economic Cooperation and Development [OECD]) countries. Concerns regarding energy security, particularly "oil dependence," have become focused mainly on transport because most of the increase in global oil use over the past 30 years has been for the transport sector. In the developed world, oil use in other energy end use sectors, such as buildings and industry, has actually declined over this period.

Recent forecasts, such as the *World Energy Outlook 2002* of the International Energy Agency (IEA), suggest that most of the current trends are not likely to change over the next 30 years or so unless strong new policies and measures are adopted by governments. The IEA forecasts that between 2000 and 2030, global transport energy use (and associated CO_2 emissions) will nearly double (Fig. 1). Energy use will grow much more quickly in the developing (non-OECD) parts of the world, where it is expected to nearly triple; in OECD countries, the growth is expected to be "only" 50%. Even by 2010, global transport sector energy use and CO_2 emissions are forecast to increase by nearly 50% in the developing world, and only 15% in OECD countries, compared to 2000.

2. LOOKING BEHIND THE ENERGY TRENDS

Why is energy use continuing to increase in transport? It is helpful to consider the basic components of transport energy demand. These can be thought of in terms of the "ASIF" equation:

$$A * S_i * I_{ij} = F_{ij},$$

where A is total travel activity, often measured as person-kilometers of travel and freight ton-kilometers of travel; S_i relates to the structure of travel in terms of the types of travel modes i used and how they are used, often measured as vehicle-kilometers of travel for each mode per unit passenger-kilometer or freight ton-kilometer of travel; and I_{ij} is the energy intensity of mode i operating on fuel type j, often measured as energy use per vehicle-kilometer of travel. For any given mode i and fuel type j, this equation is an identity that determines F, that is, fuel use. Emissions of CO_2 can also be calculated with this equation simply by adding the appropriate coefficient of carbon per unit fuel use, generally fixed for any particular fuel type (although "well-to-wheel" emissions can vary considerably, as discussed later).

As this equation suggests, to affect transport energy use, either travel activity, structure, or energy intensity must be changed. This corresponds roughly to how much travel occurs, how it occurs, and how energy intensive it is. These represent the three main areas for potential policy intervention. It is also worth noting that the first of these represents largely a behavioral issue, the second is a combination of behavior and more technical issues, and the third—modal energy intensity—is largely (but not completely) a technical issue.

Travel activity is influenced by a number of factors. Most important is wealth; as incomes rise, so does travel activity, at least in terms of the average distance each person travels and the types of modes he or she chooses. The amount of time spent traveling is remarkably consistent across incomes as well as across regions, cultures, and even history (humans have been traveling roughly an hour each day, on average, throughout much of their history). But increasing wealth, along with improved technology, enables access to faster modes of travel, allowing humans to cover greater distances with the hour or so they spend traveling each day. One of the principal challenges in slowing—and perhaps eventually reversing—travel growth is encouraging people in an increasingly wealthy world to reorganize their lives so as to be closer to their destinations of choice (e.g., home, work, shopping, recreation) despite their increasing ability and apparent inclination to arrange these activities farther and farther apart. Increasing the cost of

travel is one way in which to do this; but stronger rules governing the way in which cities and regions are spatially developed is perhaps the best long-term solution.

The potential for travel growth around the world is staggering. This becomes clear when observing the current differences in travel per capita around the world, both in terms of amount and in terms of modes used (Fig. 2). Most of the world still travels far less than people do in OECD countries. But as incomes increase and people gain access to faster modes of transport, such as motorcycles and cars, their travel will increase. If the entire world traveled as much, and in the same modes, as North Americans do now, total world travel would increase by more than fivefold, and fuel use would increase by more than that (because travel would shift to more energy-intensive modes).

Travel structure, or the manner in which people travel in terms of the modes they use and the extent to which they travel together or alone, is also largely a behavioral issue. Automobiles have become the dominant mode of travel, not because they are technologically superior to buses or trains but rather because they provide a travel structure that most people prefer—flexibility in when and where travel occurs, comfort, convenience, and perhaps a benefit in terms of social status. Whether the strong trends toward car ownership and travel around the world can be reversed is unclear, but such a reversal will certainly require strong disincentives to car use, such as high fuel taxes, and significant improvements in other alternatives, such as bus and rail transit, to attract travelers back to these modes.

The energy intensity of vehicles and modes is a function of several factors. These include the technical efficiency of propulsion systems, vehicle characteristics such as weight and aerodynamic design, and the manner in which vehicles are used and maintained. For light-duty passenger vehicles (e.g., cars, minivans, sport utility vehicles [SUVs]), the actual "in use" energy intensity of vehicles can be up to 25% higher, on average, than their rated efficiency under test conditions. Human behavior enters this picture not only in terms of the manner in which people drive (which can have a significant impact on efficiency) but also in terms of the types of vehicles they choose to buy. Beyond the obvious differences between larger and smaller vehicles, even vehicles of a similar size can have quite different energy efficiencies due to differences in the factors mentioned.

There are strong differences in the energy intensities of different modes (Fig. 3). Until recently, aircraft were the most energy intensive per passenger-kilometer, but they have improved dramatically over the past 30 years or so due to strong, steady efficiency improvements in aircraft and aircraft engines as well as a steady trend toward larger and fuller aircraft that can carry many more passengers per unit fuel use. Today, light trucks (i.e., light-duty vehicles such as vans and SUVs but not cars) are the most energy-intensive vehicles. Passenger rail is by far the most efficient mode per passenger-kilometer. For freight, trucks are far more energy intensive than other modes; rail and waterborne transport are very energy efficient. Clearly, shifting some travel to more efficient modes could reduce overall transport energy use considerably.

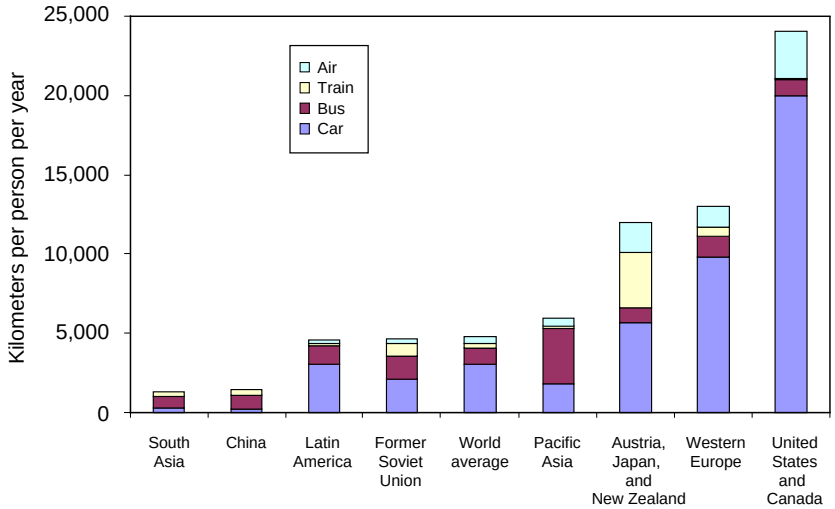

FIGURE 2 Travel by mode and region, 2000. Reprinted from World Business Council for Sustainable Development (2001).

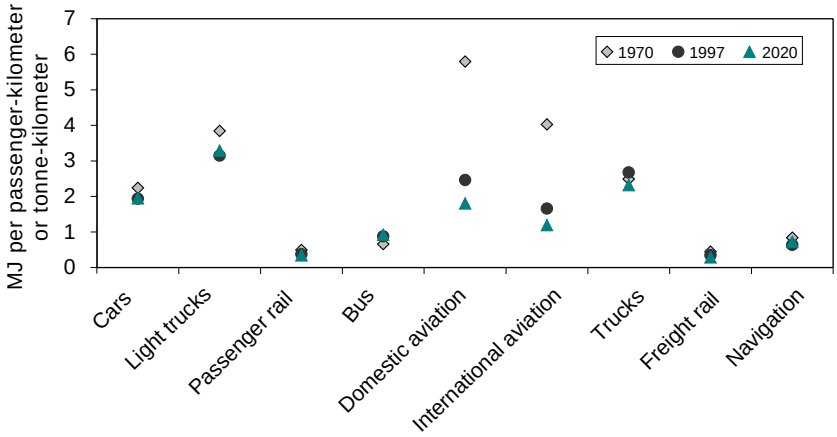

FIGURE 3 Energy intensities of various modes over time (OECD averages). From International Energy Agency (2002b).

What are the current trends regarding each of these factors? The following highlights the key trends identified in the IEA's forecast:

- In OECD countries, travel activity growth is slowing somewhat—most in OECD Pacific, less in OECD Europe, least in North America, and less for freight than for passenger travel. Europe's road freight travel is still growing significantly. Travel activity in most non-OECD regions is expected to maintain recent high growth rates for many years to come.
- Substantial fuel economy improvements will likely occur only in the European Union (EU) and Japan. These are the only world regions with aggressive policies to improve fuel economy. In other regions, improvements in vehicle technology will occur but are unlikely to translate into better new vehicle fuel economy and lower fuel intensity of the vehicle stock as consumers continue to opt for larger and faster vehicles rather than for more fuel-efficient ones. Even in Europe and Japan, improvements in fuel economy probably will not be enough to offset the expected growth in travel activity.
- In freight, rapid increases in truck travel will continue to raise average fuel use per ton-kilometer. Road freight and, increasingly, aviation freight are expected to gain shares in most regions. Small commercial trucks and vans are among the fastest growing vehicles and the most energy intensive.
- Growth in air travel is expected to account for nearly a quarter of the projected increase in fuel demand to 2030. Despite strong past improvements in fuel efficiency of aircraft, future reductions in fuel intensity are expected to offset only one-quarter of increases from expanding activity.
- Alternative fuels will continue to play a small role. Although significant increases may occur in the use of biofuels (e.g., ethanol) and, in a few places, in the use of gaseous fuels, the net effect is likely to be small without strong new policy interventions. The oil share of energy in transport is expected to remain at approximately 97%.
- CO_2 emissions from transportation will continue to grow significantly—by about the same rate as fuel demand. Globally, these will nearly double from 2000 to 2030.

Thus, the overall picture provided by the IEA forecast is one of continued strong growth in both oil consumption and CO_2 emissions from transport. The key drivers are travel demand growth and the shift from mass transit modes to personal vehicles.

3. CONCERNS FOR TRANSPORT ENERGY SUSTAINABILITY

One of the biggest long-term concerns for transport is its near total dependence on petroleum fuels. As petroleum supplies dwindle and become increasingly concentrated in the Middle East, the risk of supply disruptions and price shocks will likely increase. Management of these risks, such as through diversification of energy sources, represents a critical aspect of long-term transport energy sustainability.

A second major risk to long-term transport sustainability is its impact on climate change. CO_2 and other greenhouse gases (GHGs), including CO, N_2O, CH_4, and certain fluorocarbons, are emitted from all transportation modes and all types of vehicles to varying degrees. For alternative fuels,

such as natural gas, propane, and even renewable fuels (e.g., the heavily processed corn-derived ethanol in the United States), a well-to-wheels analysis of GHG emissions, including feedstock production, conversion, fuel distribution, and vehicle refueling, must be made to ascertain the full emissions impacts of these fuels, not just emissions occurring during driving. Recent studies show that most alternatives to gasoline and diesel have higher energy losses and GHG emissions during fuel production and transport to refueling stations. But several have lower vehicle emissions, and a few (e.g., pure hydrogen) produce no vehicle GHG emissions. For these fuels, the challenge is to produce and transport them with low GHG emissions, and this might not be simple or cheap. As discussed later, few alternatives appear to provide dramatic overall reductions. Those that do include hydrogen or electricity derived from renewable (or nuclear) sources and some types of biofuels such as biodiesel from oil crops and ethanol from cellulosic biomass.

Transport is currently running a "collision course" with a world increasingly convinced of the need to take major steps to dramatically reduce its CO_2 emissions over the next 10 years and beyond. The Kyoto accord, signed in 1997, targets a reduction in overall CO_2 emissions from annex I countries (mostly the developed countries, although not all have ratified the treaty) so that by 2010 they are returned to their previous 1990 levels on average. It may be possible to meet the Kyoto commitments without outright reductions in transport CO_2 emissions over the next 10 years or so (by more than offsetting transport increases with reductions in other sectors). But a major risk for transport is that the longer countries wait before beginning a shift toward significant decarbonization of this sector, the more difficult this shift may be. On the other hand, by waiting, it may be possible to develop and implement less expensive technologies to achieve sustainable levels of GHG emissions (which will eventually need to be far below 1990 levels).

Not all choices for our future transport systems will affect all aspects of sustainability equally or even in the same direction. Although the dominant (direct) environmental impact of energy use in transport is CO_2 emissions, the types and amount of energy used also affect emissions of other pollutants such as NO_x and particulate matter. The decisions that are made to reduce CO_2 emissions could, in some instances, increase the emissions of some other pollutants. Similarly, although energy use does not directly affect transport's impacts on the natural environment (e.g., ecosystems), humankind's willingness to allocate ever greater levels of energy to the transport system serves as an enabling force for an ever expanding transport system, encouraging sprawling urban development. This pattern might not itself be sustainable.

Another important determinant of global transport sustainability is the manner in which transport growth is handled in developing countries. Although it is only fair that all countries should eventually achieve the same level of mobility currently enjoyed by the wealthiest countries, the implications of a world with average travel and energy use levels as OECD countries not only is probably unsustainable but might also be very difficult to achieve, at least with the current mix of fuels. However, changing the direction of transport growth in developing countries may in some ways be easier than doing so in OECD countries because there is typically less of an existing entrenched transport system that must be changed. On the other hand, the amount of investment and policy effort that must be devoted to directing transport growth toward sustainable pathways in developing countries, relative to what is occurring today, may represent an even bigger shift than what will be required in IEA countries.

Transport's central economic role and its strong influence on daily life have made rapid changes in this sector difficult to achieve. Its relatively weak responsiveness to energy price movements and the slow turnover of its infrastructure render it both crucial and difficult for governments to implement strong measures to improve sustainability. In particular, twin challenges of reducing oil dependence and emissions of GHGs suggest that there are several key types of action needed:

- Improving vehicle and system energy efficiency
- Increasing the use of renewable and other low-carbon energy sources
- Expanding access around the world to clean and efficient transport energy technologies and developing and deploying advanced technologies more rapidly
- Developing politically acceptable, but aggressive, policies to shift the direction of transport toward a more sustainable path

4. IS AN ALTERNATIVE FUTURE POSSIBLE?

Having outlined one possible scenario for achieving a sustainable pathway in transport, the question arises

as to whether such a scenario can be realized. The answer depends on the following:

- What policy options are available to bend the curves of transport energy use and CO_2 emissions?
- What can specific policies accomplish in terms of oil and CO_2 reductions?
- What is the feasibility of implementing a package of policies strong enough to put transport on a new pathway?

Most countries that have tackled energy use and CO_2 emissions from transport have linked these issues directly to comprehensive transport policy reform, with an emphasis on improving transport efficiency and "getting the prices right." Other measures have focused on reducing the growth rate (or outright levels) of personal vehicle travel and improving traffic conditions. These policies typically are driven more by transport issues—congestion, safety, noise, and nuisance concerns—than by energy or CO_2 reduction concerns. It is primarily in the area of vehicle fuel efficiency and promotion of alternative fuels that transport energy policy has been the dominant driver.

Probably the most important technology-oriented policy measure now in place is the voluntary agreement for emissions reductions in new cars between the EU and the European Association of Car Manufacturers (ACEA). This EU–ACEA agreement will account for the bulk of reductions from baseline that are expected for the European countries that were studied. If successful, this measure alone could reduce emissions from cars by 15 to 20% below trend by 2010, with even greater reductions after 2010 when the more efficient new cars will have fully penetrated the vehicle stock.

Some measures to encourage modal shifts and nonmotorized transport modes, as well as measures to encourage less travel, are part of all the European programs, but it is difficult to judge what savings they have realized or will realize on their own. Improved transport services are expected from the privatization of railways, but the ultimate effect is unclear. Land use planning forms will complement transport policy reforms, but it is also difficult to predict how much this will reduce travel or induce modal shifting. In the European countries studied, infrastructure expansion and investment are increasingly tilting toward nonroad or intermodal facilities. Such efforts should at least slow the erosion of the share of low-CO_2 modes.

The following subsections provide a brief outline of potential measures for reducing travel, improving vehicle efficiency, encouraging fuel switching, and improving freight system efficiency. A listing (by no means exhaustive) of potential measures is provided in Table I.

TABLE I

Potential Measures to Reduce Transport Energy Use

Passenger travel: Measures to reduce private vehicle travel
Improving transit systems
Fuel and vehicle taxes
Travel pricing mechanisms (e.g., electronic road pricing)
Parking-related measures
Promotion of nonmotorized modes (e.g., biking, walking)
Stronger land use planning
Promoting telematics and telecommuting (substitution of communications for travel)
Measures to improve light-duty vehicle test and on-road efficiency
New vehicle fuel economy improvement
Improved vehicle maintenance
Vehicle on-board fuel use information and driver training
Speed limit reductions and increased enforcement
Roadway traffic flow improvement and capacity expansion
Vehicle scrappage programs
Alternative fuels
Incentives for marketing and purchase of advanced vehicle technologies
Incentives for and direct investment in refueling infrastructure
Removal of market barriers such as restrictions on use of specific vehicle types
Highway and surface freight movement
Technical efficiency improvement and alternative fuels in new trucks
Trucking system and operational efficiency improvements
Mode switching (e.g., from truck to rail and water)
Changes in freight demand patterns through spatial adjustments

4.1 Reductions in Growth of Motor Vehicle Travel

Measures that aim to restrain passenger travel in light-duty vehicles (among the most energy-intensive modes) and shift it to more efficient modes have begun to play an increasingly important role in the policy plans of many OECD governments. Other sustainability concerns, such as traffic congestion, urban sprawl, and "quality of life," often provide the key motivations to implement such measures. However, one problem with demand restraint policies for national governments is that many of these policies are implemented on regional or local levels.

Demand-oriented policies can encompass pricing of different transport activities and modes, investments in mass transport infrastructure and rolling stock, regulation and restriction of traffic, and urban and land use planning.
