When an events chart is constructed for a complementary prospect, it becomes a risk chart. The risk chart is derived from the petroleum-system events chart which, in turn, is derived from the summation of the events chart for each oil and gas field in the petroleum system. These oil or gas fields are successful prospects. Unsuccessful prospects are dry holes. For example, if a risk chart for a prospect is similar to the petroleum-system events chart, then it can be concluded that this prospect is more likely to contain petroleum than one that has a dissimilar risk chart. Conversely, if an events chart is constructed for each dry hole within a petroleum system, they should be dissimilar from producing fields. This dissimilarity indicates where the greater uncertainty lies. Used this way, the events chart is a useful analytical tool to deal with uncertainty or risk.

One important issue this simple bar graph addresses is as follows: For an evolving petroleum system to effectively trap migrating hydrocarbon fluids, the trap forming process must occur before or during the generation-migration-accumulation process in order for petroleum to accumulate.

When constructing an events chart, these rules should be followed. First, there is only one pod of active source rock for each petroleum system. Second, every effective reservoir rock needs a seal, no matter how thin. Third, show only reservoir rocks

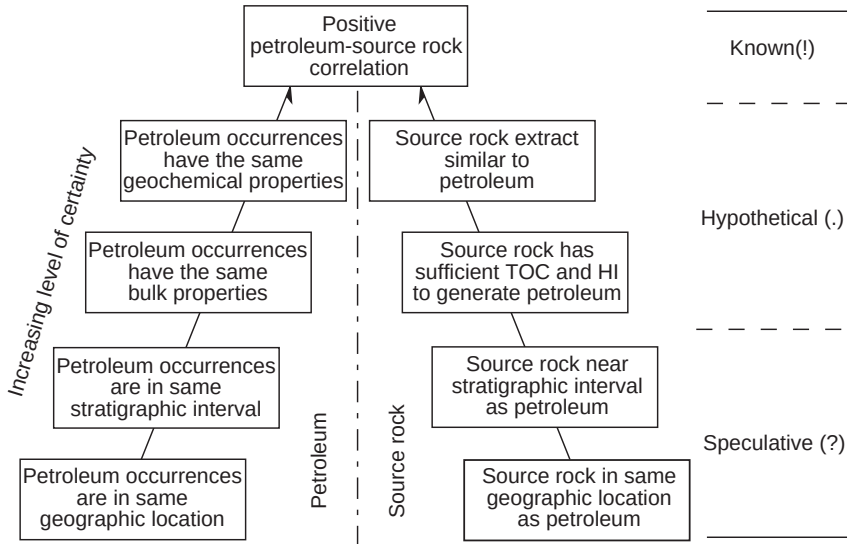

FIGURE 4 The logic sequence used for the levels of certainty from guessing to knowing. From Magoon, L. B., and Dow, W. G. (2000). that contain petroleum accumulations, shows, or seeps. Fourth, show eroded overburden rock with hatcher lines so that it can be incorporated in the modeling exercise. Fifth, the best information for timing of trap formation comes from oil and gas fields. Sixth, the best information for generation-migration-accumulation comes from geological and geochemical information about the source rock that are then incorporated into the burial modeling and kinetics. This information indicates the onset, peak, and end of generation-migration-accumulation or when the active source rock is depleted (spent) or uplifted (inactive source rock). This process takes place over a relatively short period of time. Seventh, preservation time, by definition, starts when generation-migration-accumulation ends and continues to the present. Some petroleum systems have no preservation time. Last, when the critical moment occurs is, as discussed earlier, in the judgment of investigator, but modeling software packages are useful tools as they show the time over which expulsion from the pod of active source rock occurs.

4. THE PETROLEUM SYSTEM AS A WORKING HYPOTHESIS

A petroleum system investigation starts with a working hypothesis for generation, migration, and entrapment of petroleum in a province, based on available geological and geochemical data, which evolves as more data becomes available (Fig. 2A, B). The investigator starts with an oil and gas field map and related field data for the petroleum province of interest. The geographic location of the accumulations is important because accumulations located close together are more likely to have originated from the same pod of active source rock (Fig. 4). Accumulations that occur in the same or nearly the same stratigraphic interval are also likely to be from the same active source rock. In contrast, accumulations separated by barren rock sections are presumed to have originated from different pods of active source rock. Accumulations of widely differing bulk properties, such as gas versus oil, API oil gravity, gas-to-oil ratios, and sulfur contents, may also be presumed to originate from different pods of active source rock. Detailed geochemical data on oil and gas samples provide the next level of evidence for determining whether a series of hydrocarbon accumulations originated from one or more pods of active source rock. Last, comparing the geochemistry of oils and gases to possible source rocks provides the highest level of certainty as to which active source rock generated which oil or gas type.

By acquiring and organizing information that addresses these issues of location, stratigraphic position, and geochemistry, an investigator can take a working hypothesis of how a particular petroleum system formed to increasing levels of certainty (Fig. 2; Table I). The investigator organizes the

information on the oil and gas accumulations into groups of like petroleum types on the oil and gas field map, cross section and table (Figs. 2A, 2B, and 2C).

With this step completed, the investigator then locates all surface seeps on the oil and gas field map, which now becomes the petroleum system map. The seeps with the same geochemical composition as the subsurface accumulation provides geographic evidence for the end point of a migration path. The stratigraphic unit from which the fluid emanates can be compared to the stratigraphic unit in which oil and gas accumulations are found to determine the complexity of their migration paths. If the stratigraphic units are the same, then the migration paths are simple. If they are different, migration may be more complex. Geochemical information from seeps can be compared with that of discovered accumulations in order to link the seep fluid to the proper petroleum system.

Oil and gas shows in exploratory wells are added to the petroleum system map and cross section to better define the migration paths. As this map and cross section evolve, the investigator is encouraged to anticipate how the final map will look based on the framework geology and petroleum fluid information. Intuitively, exploration risk is high if the petroleum system is complicated and hence less predictable; risk is lower if the petroleum system is simple and thus more predictable.

After similar hydrocarbon fluids in the petroleum system have been mapped individual oil and gas accumulations are tabulated to better understand the size (by volume) and complexity of the petroleum system. The petroleum system table is organized by stratigraphic interval in each field (Fig. 2C). These stratigraphic intervals are zones, members, and formations that produce or contain measurable amounts of oil and gas. The table should include age of the stratigraphic interval, API gravity and sulfur content of the oil, gas-to-oil ratio (GOR), cumulative amount of oil and gas produced, and the remaining amount of oil and gas that can be produced. Other information the investigator may chose to include are lithology, gross and net thickness, porosity and permeability of the reservoir rock, geometry, closure, and area of the trap, and detailed geochemistry of the oil and gas. The information included in the table will depend on what is available and the objectives of the investigation. The required information is used to determine the size (by volume) of the petroleum system, which reservoir rock name is to be used in the name of the petroleum system, and to evaluate the complexity of the migration path.

Now the provenance or origin of the petroleum is mapped as the pod of active source rock. Only one pod of active source rock occurs in each petroleum system. A pod is a contiguous body of source rock that has or is expelling oil and gas. Because this pod has thickness and area, it can be mapped using well, outcrop, or geophysical data. When an organic-rich rock is in close, or reasonably close, proximity, both stratigraphically and geographically, to oil and gas accumulations, shows, or seeps, it is tentatively correlated with those fluids. Based on seismic, well, or outcrop data, the likelihood of correlation increases when the source rock's burial depth is known to reach 3 km, which in the experience of the authors is a reasonable minimum burial depth for thermal maturity or when burial depth modeling indicates a source rock is in of below the oil window. The correlation gains certainty if the source rock, by vitrinite reflectance or some other analytical technique, is established as being thermally mature. If the kerogen type of the source rock is consistent with that of the oil and gas, then confidence increases that the source rock is correctly correlated. If the geochemical composition of the organic matter in the source rock compares favorably with the migrated petroleum, the oil-source rock correlation is considered a match. Using seismic, well, and outcrop data, the suspected or confirmed active source rock is mapped as a contiguous, three-dimensional body, or pod, on the petroleum system map and cross section.

In this manner, the petroleum system map and cross section evolve, as the working hypothesis is taken to successive level of certainty. To further refine this work, a burial history chart and events chart are constructed and the petroleum system is named. This article discussed each of these petroleum system components in sequence, but they are frequently developed in parallel, and their relationship to each other is considered so that the petroleum system can be properly mapped. To organize these components, the petroleum system folio sheet is used.

Glossary

energy/environmental nexus The fact that the world's energy problems cause the majority of the world's environmental problems.
foundation A philanthropic organization; assets remain tax free as long as 5% of those assets are given for charitable and educational purposes each year.
leverage The ratio of philanthropic investment and the quantifiable change that results.
philanthropy (1) A desire to improve the material, social, and spiritual welfare of humanity; (2) a term applied to institutions that disperse wealth in pursuit of these goals.
sustainable energy The energy that is produced and used in ways that support long-term human development in all its social, economic, and environmental dimensions.
Tax Reform Act of 1969 A reform of U.S. tax code, codifying the rules under which U.S. foundations operate.

Smart philanthropy can play a productive role in U.S. and global energy policy. It can help spur markets for the next generation of clean energy technologies that address the energy/environment nexus, especially global warming pollution. This article offers some principles for focused philanthropy in energy, discusses the merits of energy as a philanthropic endeavor, and outlines the recent history of energy and philanthropy in the United States.

1. INTRODUCTION TO ENERGY AND PHILANTHROPY

The best philanthropy involves the search for cause, an attempt to cure evils at their source.

—John D. Rockefeller, Sr.

Philanthropy's impact on society is both underappreciated and misunderstood. At their worst, the individual foundations that comprise the world's philanthropic sector are opaque institutions with vague goals; their funds disappear with no apparent trace. At their best, they are strategically driven, staffed by experts in the field, and can claim major contributions to the fields of human health and medicine, agricultural science, social policy, education, art, and, more recently, energy and the environment.

In essence, foundations are nonprofit institutions that disperse accumulated wealth. John D. Rockefeller and Andrew Carnegie, who built institutions to give away their considerable wealth at the end of the 19th century, are credited with birthing the modern grant-making foundation. The Tax Reform Act of 1969 codified their favorable tax treatment in the United States. In short, assets converted to foundation status are not taxed as long as 5% of those assets are given out each year for "charitable and educational purposes." Coupled with the growth in wealth in the last half of the 20th century, these rules spurred rapid growth of the foundation sector. Since 1975, the number of foundations has more than doubled and total giving (in constant dollars) has more than tripled. According to a report published by the American Association of Fundraising Counsel (AAFRC) Trust for Philanthropy, *Giving USA 2002*, over 56,000 registered foundations in the United States collectively gave out $27.6 billion in funding. Figure 1 shows their investments. Of the total, only 7% was for environmental purposes, and

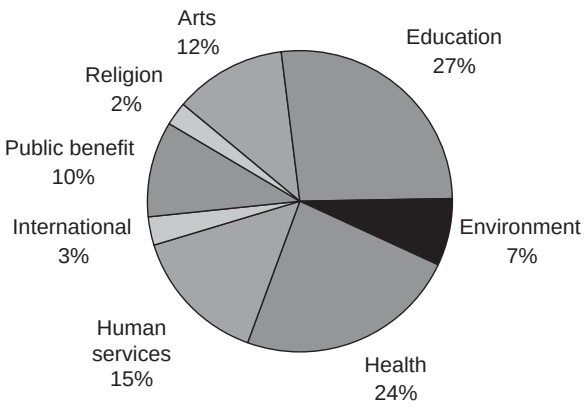

FIGURE 1 Philanthropic investment by field.

a fraction of that focused on energy. This investment pales in comparison to the nation's $700 billion annual energy bill, raising the question, "What is the role for philanthropy in energy?" Some answers are proposed here, first by offering some characteristics of good philanthropy, followed by looking at the merits of energy as a philanthropic investment strategy, including some recent results, then concluding with some thoughts on the future role for philanthropy in energy.

2. QUALITIES OF EFFECTIVE PHILANTHROPY

Foundations do not have the resources to fund directly solutions to the world's energy challenges, whether that means transitioning to a clean energy future or simply providing basic energy services in developing countries. Focusing on the United States, where the challenge is to transition to a clean and low-carbon energy system, total foundation investments in energy pale in comparison to the nation's energy research and development budget of $1.3 billion, which in turn is dwarfed by our annual energy bill. Given the scale of the investment flows compared to the size of the philanthropic resources, the theory of change adopted by all serious philanthropy work in energy is simple: public policy will change investment patterns, public or private, which will drive change (the U.S. experience is the focus here, but the same theory holds for international energy grant making). Since the 1970's, smart philanthropy has proved this approach, affecting policies that in turn change investment streams, often with a billion-to-one dollar or more leverage. Of course, it is impossible in a scientific way to attribute these changes solely to foundation investments; political change is too complex. But careful students of the best philanthropy find remarkable returns, as is discussed in Section 4. So the question looms, "what makes good philanthropy?" Borrowing liberally from the writings of Hal Harvey, Director of the Hewlett Foundation's Environment Program, and Dr. Kenneth Prewitt, former Vice President of the Rockefeller Foundation, the following list of answers is offered:

1. Target root causes: To begin, it is essential, as John D. Rockefeller, Sr. advised, to target root causes. Alleviating symptoms will never change the underlying dynamic that created them; it may bring solace, but it will not speed change. This is why energy makes such an interesting philanthropic topic: it is the root cause of many environmental, economic, health, and international security problems facing the world.
2. Be focused: The biggest mistake many philanthropies make is to dabble in many areas instead of going deep in one area. This advice holds with respect to the choice of topics (e.g., marine conservation, forest preservation, energy) and choice of philanthropic means (e.g., research and analysis, policy development, policy advocacy, grassroots advocacy, or media work). It is very difficult to understand the political dynamics of any given sector. Deep insight is required to understand capital flows, to learn who the "brain trust" for a specific field is, and to learn the inclinations of the key decision makers. To do this in many fields at once is difficult. With respect to means, learning to fund the best research demands different skills, then choosing an effective grassroots advocate or trying to influence the media. The best philanthropies—those with a track record of measurable change—focus narrowly on a few topics and specialize in a few means.
3. Hire professional staff: To see the best prospect for change requires expertise equivalent to the best businesses or advocates in the field. The myth that giving away money is easy and thus any generalist can take up the task is one of the most harmful approaches to quality philanthropy.
4. Be strategy driven: Thinking through, writing down, and peer reviewing an explicit strategy of change is essential to good philanthropy. There are many paths to change. Philanthropies should know precisely what path they seek and what series of steps has to happen to affect change. Foundations should expose the premise of their strategy for debate and adjust their strategies, refining them to adapt to changing conditions as needed.

5. Scale to the problem: Solving large, complex problems, such as the nexus of energy/environment problems, begs for large philanthropic investments. Though the scale of philanthropic investments pales in comparison to the $700 billion per year energy business, by focusing resources on key venues such as public utilities commission hearings or, in the transportation sector, air pollution authorities, foundation dollars can have a large impact.

6. Think long term: No serious energy or environmental problem can be solved overnight. Changing investment patterns, technologies, or consumer choices is a slow process, sometimes frustratingly so. Foundations, unlike most of the for-profit world, do not have next quarter's bottom line to define today's agenda. The best philanthropy takes the long view, investing for decades, not years.

3. THE MERITS OF ENERGY AS A PHILANTHROPIC ENDEAVOR

3.1 Energy as an Environmental and International Security Nexus

The goal of most philanthropy is to make the world better, whether improving conditions of the poor, stamping out disease, protecting endangered habitats, or increasing international security. Energy is interesting for philanthropy because it is simultaneously a key driver of economic growth and is at the center of Earth's most pressing environmental and security problems.

3.1.1 Environment

Fossil energy—coal and oil—has fueled tremendous economic growth over the past century, but at substantial, and growing, environmental cost. The U.S. Environmental Protection Agency (EPA) and Department of Energy (DOE) statistics show energy use is the leading cause of greenhouse gas emissions, smog, acid rain, air toxics, oil spills, and nuclear waste (Fig. 2). None of these problems can be solved without new energy trajectories. If the United States and the rest of world ramp up fossil fuel consumption to fuel further economic growth, there will be potentially catastrophic global environmental consequences. China, for example, is expected to surpass Western Europe's carbon emissions before 2010 and will surpass the United States to become the world's largest carbon emitter by about 2030. The Energy Information Administration (EIA) *International Energy Outlook 2003* report shows that Brazil and India are on similar trajectories for rapid fossil energy growth (Fig. 3).

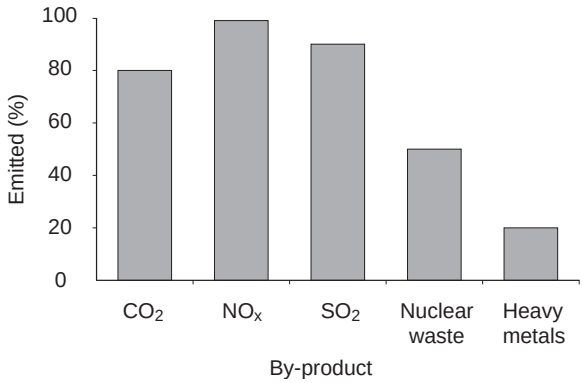

FIGURE 2 Percentage of emissions into the environment from energy use by-products.

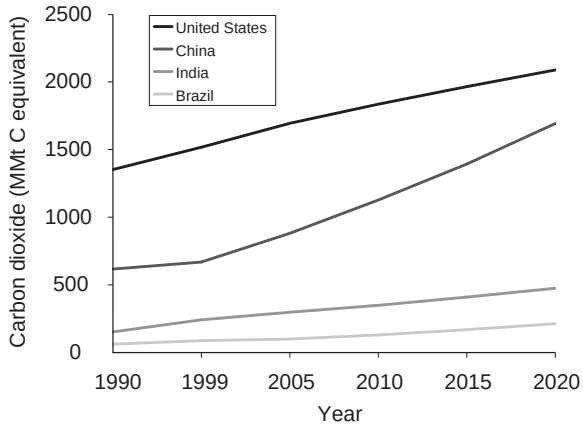

FIGURE 3 Projected carbon dioxide emissions. MMt C, million metric tons of carbon.

The energy crises of the 1970s inspired great concern about running out of fossil fuels. Geology and technology have since revealed that there are vast reserves of coal, and large reserves of natural gas and oil. A major crisis in energy, instead, turns out to be that the capacity of the environment—our atmosphere, forests, soils, rivers, and oceans—to absorb the wastes of our energy-intensive society is threatened and will suffer long before energy supplies will be exhausted. *Laissez-faire* economics, wherein prices rise due to supply scarcity and so drive investment in new energy options, will not solve this dilemma. Sensible policy is needed to move developed and developing nations to a sustainable energy path. Foundations can help create and advance new policies.

3.1.2 International Security

The 2003 war in Iraq, a country situated on the world's second largest remaining oil reserves, brings

home the international security implications of the U.S. economy's dependence on imported oil. The world's largest remaining oil supplies and, even more important in the short term, the swing production that most influences world market price, are in the politically volatile Middle East. We import more oil today than at any time in U.S. history. Worse, the latest government forecast by the Energy Information Administration, *Annual Energy Outlook 2003,* projects a 60% increase in domestic oil use over the next 25 years, with imports rising to 67.8%. And some developing countries are on even faster oil consumption growth trajectories. China's automobile market, for example, is growing at almost 35% per year. In the International Energy Agency report, *China's Worldwide Quest for Energy Security*, projections show oil imports increasing to 8 million barrels per day (mbd) by 2020 (from 0 mbd in 1993), further increasing competitive pressures on diminishing world oil supplies.

3.2 Promising Technology Solutions

The compelling question is whether it is possible to build a benign energy system given a large and still-growing world population and universal aspirations for higher income. The answer to that question must be found in technology transformation. Our society needs to invent a low-carbon, low-pollution affluence. The energy field is replete with examples of how this might be done and, over the past several decades, examples of how philanthropy can help accelerate change. It is clear that technologies are available to reduce drastically pollution and carbon from buildings, industry, and transportation. Recent philanthropic efforts focus on catalyzing this technology transformation in the building sector, transportation field, and power sectors. There are promising trends in each sector.

3.2.1 Buildings

The case for technology transformation is perhaps easiest to make in the buildings sector. It is neither difficult nor costly to design a building that uses only nominal energy for heating and cooling and that requires only a quarter of the electricity of a conventional building. In the mid-1980s, California revamped its building codes toward this end. Title 24, as the resulting codes were named, reduces energy use in newly constructed buildings by some 75% compared to precode buildings. Appliance standards are another example of the transformative power of new technologies. Refrigerators sold today are larger and have more features, yet use one-third the energy compared to 20 years ago. State appliance standards, eventually adopted by the federal government, drove these savings, with billion dollar savings for consumers. The American Council for an Energy Efficient Economy estimates that existing standards—for refrigerators, air conditioners, lights, washings machines, etc.—will save the equivalent of the energy generated by 400 large power plants, at net consumer savings of $160 billion by 2020. Standards being contemplated for adoption by the federal government today could save consumers another $75 billion dollars by 2020. Foundations have been the largest nongovernmental supporters of advancing such standards.

3.2.2 Transforming the Automobile

Transportation has the highest potential for technological advancement. The automobile is on the verge of a technological revolution. Today's automobiles are between 15 and 20% efficient; the lion's share of each gallon of gasoline goes directly out the exhaust pipe. Existing new technologies can double the efficiency of the engine, and double again the efficiency of the driveline, resulting in cars that exceed 100 miles per gallon with only modest air pollution (Fig. 4). High-efficiency tires, drivelines, and aerodynamic shells can reduce power requirements by a factor of two to four. Hybrid drives, which couple the efficiency of electric drives with the range and power output of liquid or gaseous fuels, can double engine/driveline efficiency. And fuel cells, which convert gas or liquid hydrogen directly into electricity at high efficiency with no moving parts and virtually no pollution, offer a very clean transportation future.

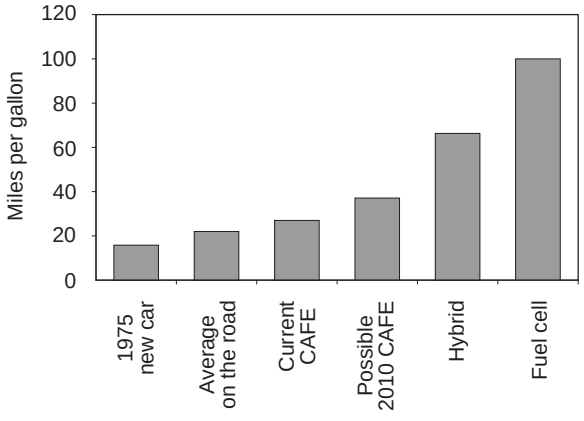

FIGURE 4 Automobile fuel efficiency. CAFE, Corporate average fuel economy (standards imposed under the Energy Policy and Conservation Act of 1975).

Toyota's Prius offers a hybrid drivetrain, including regenerative braking. The Prius gets almost 50 miles per gallon, but otherwise has features and performance similar to those of a Toyota Corolla. The Prius is exceeding all sales predictions, and Toyota recently doubled production volume. Honda has come out with a hybrid version of its popular Civic model, which gets 45 miles per gallon. Ford expects to introduce a sport utility vehicle (SUV) hybrid that is projected to obtain 40 miles per gallon, more than double today's average SUV mileage. Toyota is expected to offer an SUV on its Lexus 330 platform as well. GM has also announced hybrid versions. Foundations have a role in making the analytic case for these technologies and in spurring the policies that spur their commercialization.

3.2.3 Cleaner Power

Renewable energy technologies have enjoyed dramatic price reductions over the past two decades. Wind power has dropped from 25¢/kilowatt-hour to less than 3¢/kWh today. The central region of the United States is known as the "Saudi Arabia of wind energy." The 11 contiguous states from the Dakotas to Texas have the wind energy potential to supply more than the total current electricity consumption of the entire United States (the states are Montana, Wyoming, North Dakota, South Dakota, Minnesota, Iowa, Nebraska, Kansas, Colorado, Oklahoma, and Texas). Driven largely by state policies spurring wind investments—which foundation-supported advocates championed in many states—wind is the fastest growing source of generation in the United States. California, the world's fifth largest economy, has adopted a goal of 20% renewable power generation by 2015. This policy will spur nearly $10 billion in new wind investments. New York has announced a goal of 25% renewable energy by 2010, and 12 other states have similar renewable energy goals, which are driving new markets for renewable energy developers (Fig. 5).

4. RECENT HISTORY: ENERGY AND PHILANTHROPY

4.1 The Ford Foundation Energy Policy Project

Major foundation investments in energy began in the 1970s, driven partly by the emerging environmental movement and more directly by the Organization of Petroleum Exporting Countries (OPEC) oil crisis. Under McGeorge Bundy, former National Security Advisor to Presidents Kennedy and Johnson, The Ford Foundation launched The Energy Policy Project in 1971, ultimately spending $4 million on a series of energy studies. The most influential study, published in 1974, was *A Time to Choose*, by S. David Freeman. It was pathbreaking in two respects. First, it argued that economic growth and energy demands need not grow in lockstep—conservation and efficiency could decouple them. Second, it laid out the policies—from auto fuel efficiency regulations, to appliance efficiency standards, to federal energy efficiency research and development—that continue to be the mainstays of the U.S. energy efficiency policy today.

The Ford Foundation followed *Time to Choose* with two other major studies. In early 1979, they released *Nuclear Power Issues and Choices*, which concluded that, despite its many problems, nuclear energy should be a major power source in the future. Most important today, it argued that plutonium processing in breeder reactors was both uneconomic and created too great a danger of plutonium prolifera-

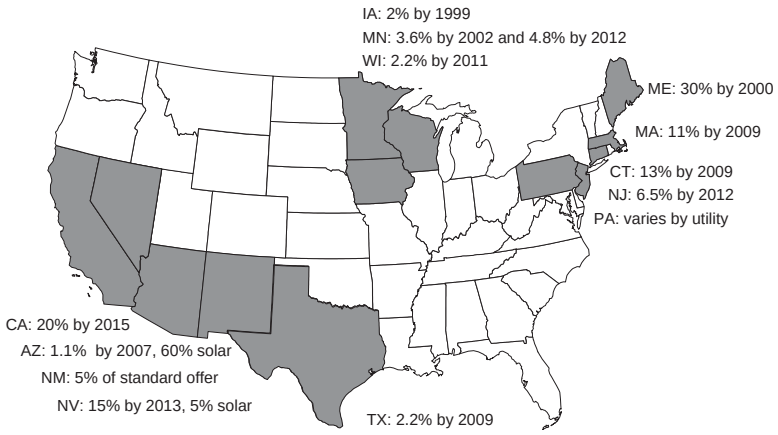

FIGURE 5 State renewable energy policies.

tion. One of the lead authors of the study, Dr. Spurgeon Keeny, Jr., argues that the study was a major factor in President Jimmy Carter's decision to defer commercial reprocessing of plutonium indefinitely. A third Ford Foundation study, released in 1979, *Energy, the Next Twenty Years*, was the least influential of the three studies; it concluded that the energy problem was essentially economic in nature. The U.S. would not run out of energy (given coal and oil shale reserves) any time soon, but prices would inevitably rise. Its main conclusion, that society would benefit from having the price of energy reflect its true value, continues to be the holy grail of energy economists today.

4.2 The Next Wave: From Studies to Advocacy

The premise of The Ford Foundation's investments in the 1970s was that serious new policy studies—the equivalent of investing $14 million today—would capture high-level decision-maker attention and move the country along a more "intelligent" energy path. As the decade progressed, and as the environmental movement matured, a handful of foundations began to invest based on a different premise—namely, that direct advocacy was needed to change policies, which, in turn, would shape energy investments for the country. The crucible in which these early advocacy efforts were born was the nuclear power debate. Small, environmentally focused foundations such as the Mertz Gilmore Foundation, Levinson Foundation, Nathan Cummings Foundation, New-Land Foundation, List Foundation, J. M. Kaplan Fund, Compton Foundation, and the Rockefeller Family & Associates supported technical advocacy in state regulatory proceedings to (1) attack nuclear industry cost and safety claims and (2) make the case for cheaper and cleaner alternatives, particularly natural gas power plants and energy efficiency. Historians attribute the decline of the nuclear industry to many factors, including cost overruns, the public movement against nuclear power, and the fear of accidents such as the 1979 Three Mile Island incident. The early foundation-funded advocacy efforts deserve some of the credit as well. They also spawned a new approach to foundation-supported advocacy that continues to this day. The leaders in the energy policy advocacy work included the Mertz Gilmore Foundation, an early supporter of global warming policy work and one of the first foundations to offer grants in support of renewable energy. Other foundations taking on energy issues at this time were the Jessie Smith Noyes Foundation, the Evergreen Fund, the Changing Horizons Charitable Trust, the Conservation and Research Foundation, and the Aria Foundation.

Following on the heels of Earth Day 1990 and the Gulf War in 1990/1991, which put global warming and oil dependency in the public eye, the presidents of the John D. and Catherine T. MacArthur Foundation, the Rockefeller Foundation, and the Pew Charitable Trusts launched a special-purpose foundation focused entirely on the energy/environmental nexus. Opening its doors in January 1991, the Energy Foundation received a $100 million commitment for its first decade. Focused entirely on advancing energy efficiency and renewable energy, the Energy Foundation's first decade concentrated primarily on advancing state policies to spur commercialization of clean energy technologies. In the utility sector, for example, foundation-supported advocates in a dozen states advanced policies to make energy efficiency investments for utilities as profitable as building power plants. By 1994, U.S. utility investments in energy efficiency nearly tripled to $2.7 billion per year, halving growth in electric demand. Even after a major restructuring of the utility industry, which slashed all capital investments by utilities, spending on energy efficiency by utilities today exceeds $1 billion per year.

The Energy Foundation also invested heavily in state efforts to advance the cleanest and most efficient cars. Beginning in California in the early 1990s, and moving to New York, Massachusetts, Maine, and Vermont, scientists, energy experts, and grassroots groups worked in state air regulatory proceedings, arguing that only the most advanced vehicle technologies would clean the air adequately to meet public demands for healthy air. Because California, New York, Massachusetts, Maine, and Vermont represent 20% of the U.S. automobile and light-truck market, new tailpipe requirements captured the attention of the automobile industry. California's low-emission vehicle and zero-emission vehicle standards, and the subsequent adoption of the standards by New York and Massachusetts, are credited by many experts as the primary drivers spurring new investments in hybrid technology and fuel cell vehicles. Today, the Toyota Prius and Honda Civic hybrids are five-passenger production cars that are superclean and get nearly 50 mpg in real-world driving. Toyota's goal is to sell 300,000 hybrids annually worldwide by the end of this decade. GM, Ford, and Chrysler have all announced plans for hybrid vehicles as well. The newly revised California Air Resources Board rules, released April 2002, called for minimum annual sales of 110,000 hybrids by 2009.

These two examples—working toward reduction of electric demand and advocating for fuel efficiency—are indicative of Energy Foundation work. The foundation continues to invest in the power sector to advance efficiency and renewable energy, to promote superefficient building technologies, and to spur commercialization of advanced-technology vehicles. The Energy Foundation has evolved into a project of major foundations advancing clean energy technologies. In 1996, the Mertz Gilmore Foundation joined, and in 1998, the McKnight Foundation joined. The David and Lucile Packard Foundation joined in 1999, launching the China Sustainable Energy Program, which helps China promote energy efficiency and renewable energy technologies and employs nine Chinese nationals in a Beijing office. The William and Flora Hewlett Foundation joined in 2002, supporting advanced vehicle technology work in China and the United States as well as work to advance clean energy in the western United States. The Energy Foundation annual budget is now around $20 million per year.

The Energy Foundation is the only special-purpose energy philanthropy in the United States, but it is by no means alone in supporting energy work. Under its Environment Program, the Pew Charitable Trusts has been a major investor making the case for action on global warming emissions. At the federal level, this includes the Pew Center on Global Climate Change (www.pewclimate.org), which built a coalition of major businesses that endorse action on climate and which has been a player in international deliberations and U.S. policy debates. The Pew Charitable Trusts, independent of the Energy Foundation, also built a state network of advocates focused on the health and environmental damages from the many Eisenhower-era coal power plants that still generate a significant share of U.S electric power. Many of these power plants—in Texas, Ohio, Minnesota, and North Carolina—have been cleaned up or shut down as a result, and the federal debate to cap power sector emissions and, possibly, control carbon emissions from power plants is active. The William and Flora Hewlett Foundation is also a major new investor in energy work, beyond its investment in the Energy Foundation. Hewlett is focused on advanced vehicle technology in Mexico and Brazil, as well as on energy production on western U.S. lands. The Turner Foundation has also made energy investments, as have the Rockefeller Brothers' Fund and the W. Alton Jones Foundation. Major regional funders have also invested in energy, especially the Joyce Foundation in the midwestern United States, the John Merck Fund in New England, and the Bullitt Foundation in the Pacific northwest, among others. This author estimates that annual philanthropic support for energy (broadly defined to include global warming work) in the United States is about $40 million per year in 2003.

5. CONCLUSIONS: THE FUTURE ROLE FOR FOUNDATIONS IN ENERGY

Foundations have made good progress on the energy front, but huge gaps remain. Promising technologies in use and production today prove that the prospects for an affluent but low-carbon society are good. But the U.S. and the world economies continue to run primarily on oil and coal. As the largest consumer and producer of energy in the world, the United States has the responsibility to lead the transition to cleaner technologies. Philanthropy can play a role in this transition by spurring policies that commercialize the best technologies.

But U.S. leadership is not enough. Rapidly developing economies, such as those of China, India, and Brazil, cannot afford to follow our path of energy consumption—they need opportunities to leapfrog to advanced technologies that offer higher standards of living but with radically reduced energy use. Here, too, philanthropic opportunities in energy abound, with potential billion-to-one payoffs. In essence, we are confronted with the ultimate "diffusion of innovations" challenge. Technology learning curves—for clean technologies such as wind power, photovoltaics, or superefficient gas turbines—tell us that each cumulative doubling of production can reduce prices by 20–30%. In turn, lower prices speed the penetration of these new energy technologies into U.S. and world markets. The history of the past three decades suggests energy policy, in the absence of higher price signals driven by energy scarcity, will be the major factor in how fast we move down these clean technology cost curves and toward a transformed energy economy. They also suggest that smart philanthropy can play a productive role.

Glossary

adenosine triphosphate (ATP) Energy-bearing molecule formed during the light reactions through the phosphorylation of adenosine diphosphate. The energy bound in ATP is used as the primary energy source for most biological reactions.

C_4 photosynthesis In order to reduce the amount of carbon lost during photorespiration, some plant have developed C_4 photosynthesis. These plants initially carboxylate the acceptor molecule phosphoenolpyruvate to form four-carbon organic acids (hence the term C_4 photosynthesis). These molecules are transported internally to specialized bundle sheathe cells. There, the plant enzymatically breaks down the acid and releases CO_2. The CO_2 is then fixed again using the normal enzymes of the dark reactions. As a result, the concentration of CO_2 at the point of the dark reactions is much higher than that of the surrounding atmosphere and effectively eliminates photorespiration.

chemoautotrophs Organisms that use CO_2 as a source of carbon, but rather than using light energy they obtain reducing power and energy from the oxidation of inorganic compounds.

dark reactions The process of using the reducing power and energy produced during the light reactions to fix inorganic material into high-energy organic molecules.

light reactions The process of coupling light energy to the creation of chemical reducing power and energy. This process occurs in the thylakoid membrane in higher plants.

nicotinamide adenine dinucleotide phosphate (NADPH) Reducing molecule formed during the light reactions. Reducing energy of NADPH is used to reduce (i.e., store energy) inorganic material making organic high-energy molecules.

oxidation–reduction reaction Chemical reaction involving the transfer of electrons. Reduction is the transfer of an electron from a donor molecule to an acceptor molecule. During the reaction, the donor is said to become oxidized and the acceptor reduced.

photorespiration The RuBP carboxylase–oxygenase enzyme also exhibits oxygenase activity (i.e., it will catalyze the reaction of O_2 with RuBP). This leads to the loss of a CO_2 molecule previously fixed and decreases the efficiency of photosynthetic carbon assimilation.

photosynthesis The process of converting light energy to organic chemical energy.

RuBP carboxylase oxidase Arguably one of the most important enzymes on Earth. RuBP carboxylase oxidase (or Rubisco) catalyzes the reaction of CO_2 and an acceptor molecule, ribulose bisphosphate (RuBP), to form 3-phosphoglyceric acid (3-PGA). This is the initial carboxylation step of the dark reactions of photosynthesis.

Photosynthesis and the resultant autotrophic energy flow is a multistep pathway that is arguably the most important set of chemical reactions on earth. The reduction of compounds (i.e., the storing of energy in chemical bonds) is the foundation of all biological metabolism. Photosynthesis and, to a lesser extent, chemoautotrophy are the processes of this reduction. The capture of light energy or the oxidation of inorganic material produces energy and reducing power to form high-energy molecules necessary for life. This article gives a general introduction and overview of photo- and chemoautotrophic reactions and the organisms who perform these reactions, and

it briefly outlines the recent human impact on photosynthetic processes and global carbon cycling.

1. INTRODUCTION

Photosynthesis or photoautotrophism is the mechanism of converting light energy to organic chemical energy performed by certain bacteria, algae, and plants. The photosynthetic process consists of both physical and chemical reactions enabling organisms to exploit an energy resource external to the Earth's system: the sun. The organic molecules produced by these organisms provide the energy powering nearly all living organisms. In short, photosynthetic reactions directly or indirectly provide energy for most biological reactions and may be expressed as:

$$\text{Inorganic molecule} + \text{light energy} \rightarrow \text{high-energy organic molecule}$$

According to the laws of thermodynamics, complex systems will tend to move from a state of organization (i.e., high energy) to a random state (i.e., low energy) through time until equilibrium is reached. In the case of living organisms, equilibrium between the organism and the environment is the death and decomposition of the organism. Therefore, to stay alive an organism must consume energy to reverse the thermodynamic direction. Living organisms are not in balance in terms of thermodynamics and require energy to maintain structure, accumulate matter, conduct metabolism, grow, and, eventually, reproduce.

All nonphotosynthetic organisms, such as animals, fungi, and bacteria, are dependent on organic materials originally generated through photosynthetic (or chemosynthetic) reactions. Without this supply of high-energy molecules, organisms would not survive. Only those organisms able to utilize the supply of energy from the sun increase the total free energy of the earth and increase the energy available to organisms unable to use either chemical or solar energy sources, including humans.

The photosynthetic process is found in some bacteria, cyanobacteria (often referred to as the blue-green algae), algae, and higher plants. Given a supply of sunlight, photosynthetic organisms can survive, grow, and reproduce using only inorganic forms of matter. Molecules, known as pigments, that absorb light and convert physical energy to chemical energy have allowed the evolution and proliferation of complex multicellular organisms, dependent on light as their ultimate energy source.

2. THE PHOTOSYNTHETIC PROCESS

In simple terms, photosynthesis is the process by which light energy is used to convert chemical substances to a more energy-filled state. In all photosynthetic organisms, it involves the capture of the energy of a photon of light by a pigment molecule, the formation of an excited electron, and the use of the excited electron to reduce an acceptor substance and to form reduced or energy-rich molecules (Fig. 1). Photosynthesis is often thought of as a two-stage process. The first stage, the light reactions, is the process of coupling light energy to the creation of chemical reducing power and energy. The second stage, the dark reactions, is the process of using the reducing power and energy produced during the light reactions to fix inorganic molecules into organic molecules. This two-stage process is outlined in detail in the following sections.

2.1 Oxidation–Reduction Reactions

The foundations of photosynthesis are a series of oxidation and reduction reactions. Very simply defined, reduction is the transfer of an electron (e^-) from a donor (M_d) molecule to an acceptor molecule

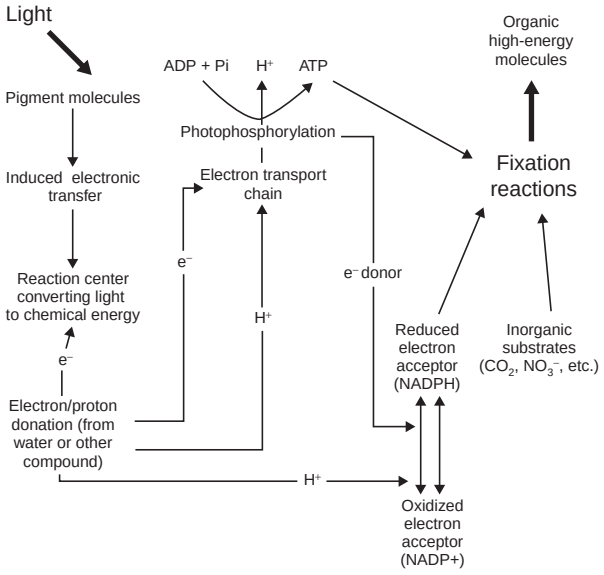

FIGURE 1 The basic reactions found in most photosynthetic organisms.

(M_a). During the reaction, the donor is oxidized and the acceptor is reduced. An electrically neutral compound becomes negatively charged and will extract a proton from water to restore electrical neutrality:

$$M_d + M_a \rightarrow = M_d^+ + M_a^-;\ M_a^- + H^+ \rightarrow M_aH;\quad M_d^+ + e^- \rightarrow M_d.$$

Reduction and oxidation reactions are fundamental to the photosynthetic process. The primary reaction of photosynthesis is the linking of light energy to a biochemical process. This is accomplished by the transfer of electrons from a light-excited chlorophyll pigment to an acceptor molecule. The acceptor molecule (in higher plants, a quinone) is reduced and the chlorophyll oxidized. Electrons are then donated from various sources (water in the case of higher plants) to the oxidized chlorophyll, reducing it and allowing the process to repeat.

The separation of the photosynthetic process into the light and dark reactions is primarily a historical artifact and has led to confusion regarding the use of terms. The generation of both the reducing [nicotinamide adenine dinucleotide phosphate (NADPH)] and the energy-containing molecules [adenosine triphosphate (ATP)] requires light energy, and these are logically referred to as the light reactions. The NADPH and ATP molecules are subsequently used to reduce other inorganic substances and convert them to organic molecules. With an adequate supply of NADPH and ATP, the chemical reactions of photosynthesis will proceed irrespective of light. The dark reactions of photosynthesis can and do occur in the light and darkness.

2.2 Capture of Light Energy and Electron Donation: The Light Reactions

Pigment molecules of various kinds allow photosynthetic organisms to both capture light and convert the captured light energy into chemical energy. Light-harvesting pigments (primarily the chlorophylls) capture light from the sun and form excited pigments. The combined excitation energy of multiple pigment molecules is focused in a single pigment molecule known as the reaction center (RC) and used to reduce acceptor molecules. The light-harvesting apparatus (the RC plus multiple accessory pigments) or antenna pigments absorb light and excitation energy is produced. This excitation energy moves through the antenna molecules to the RC where an electron is excited and lost. The electron that is lost from the pigment is then replaced by an electron from another source in the environment. In photosynthetic bacteria, a wide variety of compounds may donate electrons to the oxidized pigment. In cyanobacteria, algae, bryophytes, ferns, and higher plants water is used as the source of electrons and diatomic oxygen (O_2) is released:

$$2\,H_2O + \text{light energy} + \text{photosynthetic pigments} \rightarrow O_2 + 4H^+ + 4e^-.$$

The most common pigment molecule in higher plants is chlorophyll, but there are many other pigments involved in photosynthesis across different organisms, including phycocyanin, phycocoerythrin, and allophycocyanin in blue-green and red algae and carotenoids and xanthophylls in most higher plants and some algae and bacteria.

In both bacteria and higher photosynthetic organisms the excited electrons are used to form reducing molecules, either nicotinamide adenine dinucleotide (NADH) or, more commonly in photosynthetic organisms, NADPH. Simultaneously, through electron transport, protons accumulate on one side of a cellular membrane, forming a proton concentration gradient, the energy of which is used to produce ATP through the phosphorylation of adenosine diphosphate. ATP and NADPH provide reducing power and energy to nearly all biological energy and matter transformation reactions.

2.3 Reduction of Inorganic Material: The Dark Reactions

All organic biomass created by photosynthetic organisms is generated using reductant (NADPH) and energy (ATP) from the light reactions. This energy (i.e., ATP and NADPH) of photosynthesis may eventually be used to reduce a range of organic substances. The most common compound reduced is carbon dioxide (CO_2), leading to the synthesis of common sugars (CH_2O) and other organic molecules based on carbon. The fixation of carbon is the focus of this section. However, ATP and NADPH from the light reactions are also used to assimilate other inorganic compounds. Nitrate ions (NO_3^-) are reduced to ammonia, which is synthesized to amino acids and, eventually, proteins:

$$NO_3^- + 9\,H^+ + 8\,e^- \xrightarrow{\text{nitrate and nitrate reductase enzymes}} NH_3 + 3\,H_2O.$$

Sulfate ions must also be reduced before entering biological metabolism:

$$SO_4^{2-} + 9\,H^+ + 8\,e^- \xrightarrow{\text{enzymes}} HS^- + 4\,H_2O.$$

Photosynthesis, although almost always associated with the fixation of carbon, is a process with many possible products and it participates in many facets of metabolism.

The dark reactions of photosynthesis in higher plants occur within the chloroplast. The rate of CO_2 fixation is determined by the enzyme activity, the supply of CO_2, and the conditions within the chloroplast. The assimilation of carbon dioxide is a cyclical process. The assimilation (i.e., fixation or reduction) of CO_2 can be simply described as

$$\begin{aligned} &3\,CO_2 + 9\,ATP + 6\,NADPH + 5\,H^+ \\ &\quad \rightarrow C_3H_5O_3P\ (\text{simple sugar}) + 9\,ADP \\ &\quad + 8\,P_i + 6\,NADP^+ + 3\,H_2O + \text{energy}. \end{aligned}$$

This scheme is a simplification listing only the substrates and energy inputs. The process includes 11 enzymes catalyzing a 13-step carboxylation cycle. In the initial carboxylation reaction, the enzyme ribulose bisphosphate (RuBP) carboxylase catalyzes the reaction of CO_2 and an acceptor molecule, RuBP, to form 3-phosphoglyceric acid (3-PGA). RuBP is then regenerated from 3-PGA in reactions consuming NADPH and ATP. For each CO_2 assimilated, a minimum of three ATP and two NADPH are needed from the light reactions. The roles of the dark reactions are therefore to regenerate RuBP for additional CO_2 assimilation and to produce simple sugars.

Interestingly, the enzyme RuBP carboxylase exhibits dual activity. RuBP carboxylase will catalyze CO_2 assimilation as described previously or the assimilation of O_2—oxygenation. Because of this dual functionality, the enzyme is often referred to as RuBP carboxylase oxygenase or Rubisco. The ability of Rubisco to catalyze oxygenation reactions has implications for photosynthetic energy flows and will be considered later.

2.4 Variations in Photosynthesis among Biological Organisms

The most primitive type of photosynthesis is thought to be that exhibited in the halophilic bacterium, *Halobacterium halobium*. These organisms have patches of the pigment bacteriorhodopsin on their outer membrane. This pigment captures light and transports H^+ from inside the cell to the outside. This process forms a pH/electrical gradient that the organism then uses to synthesize ATP when the H^+ diffuses back into the cell. This is the simplest form of photosynthetic reaction and is not associated with more complex electron transport systems found in other photosynthetic organisms.

Most photosynthetic bacteria exhibit a slightly more complex photosynthetic system in which electron transport is used to form a pH gradient for ATP synthesis. An electron transport chain greatly increases the efficiency of ATP synthesis and allows for the generation of NADPH. To facilitate an electron transport chain, the outer cell membrane of most photosynthetic bacteria is folded, creating an enclosed space where a chemical gradient can be generated between the pocket and the interior of the cell. Within these pockets, bacterial chlorophyll and associated pigments bound in the membrane capture light and form a reduced acceptor. Simultaneously, the transported electrons reduce quinone compounds within the membrane that transport H^+ from the interior of the cell to the pockets. A pH gradient is created and the diffusion of H^+ back into the cell drives the synthesis of ATP. In contrast to *Halobacterium*, these more complex photosynthetic bacteria utilize electron transport and produce NADH in addition to ATP.

The prokaryotic cyanobacteria (blue-green algae) produce oxygen during photosynthesis similar to higher plants and have a membrane structure similar to that of the complex bacteria: extensive membranes arranged around the exterior of the cell in sheets. The red algae are also similar to the complex bacteria. The membranes have regularly arranged patches of pigment called phycobilisomes. The phycobilisomes contain a grouping of pigments linked to a single reaction center. There are two types of complexes in the membranes, one associated with electron transport (photosystem I) and the other associated with water oxidation and electron further transport (photosystem II). As in the bacteria, transport of electrons leads to the synthesis of reductant (NADPH) and the formation of a pH gradient, which drives the synthesis of ATP.

In higher algae, bryophytes, ferns, and higher plants, the photosynthetic membranes (thylakoids) are enclosed within a double-membraned organelle known as a chloroplast. Multiple chloroplasts can be found within a single plant cell. The inside of the thylakoid membrane is called the lumen and is chemically equivalent to the outside of the cell. There are two photosystems, as in the cyanobacteria, but the higher photosynthetic organisms use some form of chlorophyll as the primary pigment and a variety of secondary pigments. Also, as in the cyanobacteria, electron transport leads to the reduction of an acceptor, the formation of a pH gradient, and the synthesis of ATP.

3. CHEMOAUTOTROPHY

Not all organisms require light to reduce inorganic molecules. These organisms are referred to as chemoautotrophs and are found entirely within the bacteria. Chemoautotrophy has received considerable attention since the discovery of several deep-sea vent communities in the Galapagos rift in 1977. The areas surrounding these sea vents contain entire communities based on energy from chemoautotrophic bacteria; primarily sulfur oxidizers. These bacteria use CO_2 as a source of carbon and obtain reducing power and energy from the oxidation of elemental sulfur, hydrogen sulfide, or thiosulfite. The submarine volcanic vents with which these organisms are associated discharge large quantities of sulfide-rich warm water. Although unique in the sense of an entire community based on chemoautotrophically derived energy, deep-sea vent communities are not the only environments to support chemoautotrophic bacteria. Other sulfur-oxidizing bacteria are known in deep freshwater lakes, in surface springs, and in caves. In addition, other chemosynthetic bacteria are known to oxidize ammonium (NH_4^+), nitrite (NO_2^-), iron (Fe^{2+}), hydrogen (H_2), or carbon monoxide (CO). Of these, the nitrifying bacteria, which oxidize ammonium to nitrite and nitrite to nitrate, are among the most ecologically important organisms on Earth due to their role in the cycling of global nitrogen between organic and inorganic pools. Without them, much of the nitrogen necessary for plant growth would be unavailable.

4. PHOTORESPIRATION

The oxygenase activity of the RuBP carboxylase–oxygenase enzyme is significant because it leads to the loss of a CO_2 molecule previously fixed and decreases the efficiency of photosynthetic carbon assimilation. When RuBP catalyzes an oxygenase reaction, it produces a phosphoglycolate (PG) and 3-PGA. The PG then moves out of the chloroplast and is metabolized by the glycolate pathway and leads to the eventual release of CO_2. This is a form of respiration to the plant and offsets the amount of carbon fixed during assimilation. This process occurs during the light and is directly associated with photosynthesis; it is therefore referred to as photorespiration. The amount of photorespiration (i.e., the affinity of Rubisco for oxygen as a substrate) is dependent on temperature and the ratio of O_2 to CO_2 in the chloroplast. Early in Earth's history when the photosynthetic reactions were thought to have evolved, the ratio of O_2 to CO_2 concentration was relatively low compared to today. Under these conditions, photorespiration is negligible. However, in the current atmosphere, in which the partial pressure of O_2 is 1000 times higher than that of CO_2, 20–30% of the fixed carbon may be lost to photorespiration. Some plants have developed mechanisms that elevate the concentration of CO_2 inside the leaves, thereby decreasing or eliminating photorespiration. These specialized mechanisms are discussed in the following section.

5. PHOTOSYNTHETIC PATHWAY VARIATION

To minimize the effects of photorespiration, some plants have developed anatomical and biochemical characteristics allowing them to concentrate CO_2 at the site of Rubisco activity. The traditional photosynthetic dark reactions are often referred to as C_3 photosynthesis because the initial product of carboxylation is the three-carbon compound, 3-PGA. Some plants in hot and dry environments, in which photorespiratory loss of carbon is very high, have developed an alternative pathway, the C_4 pathway, to minimize carbon loss. The internal leaf anatomy and biochemistry of a C_4 plant is significantly different than that of a C_3 plant (Fig. 2). C_3 plants have vascular bundles surrounded by a layer or sheathe of large colorless cells. Other cells, known as palisade cells, contain chlorophyll and are arranged against the

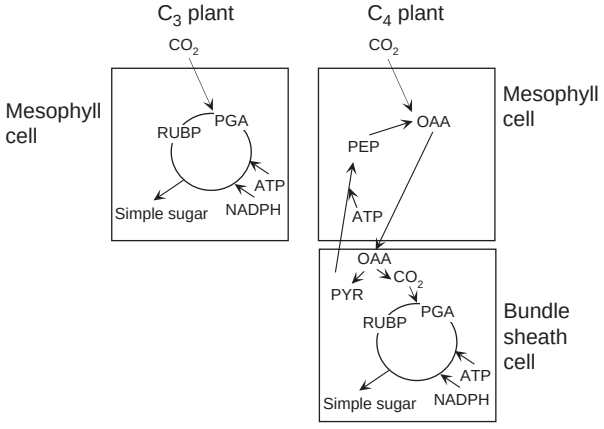

FIGURE 2 The leaf anatomy and biochemistry of a typical C_3 plant compared to a typical C_4 plant. The specialized structure and biochemistry allow C_4 plants to concentrate CO_2 inside the leaf and avoid losing carbon through photorespiration.

upper edge of the leaf surface. In contrast, plants utilizing the C_4 pathway have vascular bundles surrounded by a sheathe of cells rich in chlorophyll. C_4 plants initially carboxylate the acceptor molecule phosphoenolpyruvate (PEP) using the enzyme PEP carboxylase to form oxaloacetate, which is then converted to one of two four-carbon organic acids, malic or aspartic acid (hence the term C_4 photosynthesis). These molecules are transported internally to the specialized bundle sheathe cells. There, the plant enzymatically breaks down the malic and aspartic acid to release the fixed CO_2. The CO_2 is then fixed again using the normal enzymes of C_3 photosynthesis to form three-carbon molecules. C_4 plants do not replace the C_3 cycle; the PEP in conjunction with the bundle sheathe anatomy acts as a CO_2 pump to concentrate CO_2 at the site of Rubisco fixation in the bundle sheathe cells. As a result, the concentration of CO_2 within the bundle sheathe cells is much higher than that in the surrounding atmosphere and effectively eliminates photorespiration.

Under scarce water conditions, a third photosynthetic pathway has developed: crassulacean acid metabolism (CAM). These plants tend to be succulents and members of the plant families Cactaceae, Euphorbiaceae, and Crassulaceae. The CAM pathway is similar to the C_4 pathway in that CO_2 is first fixed into a four-carbon acid, malate, using the enzyme PEP carboxylase. The malate is then enzymatically cleaved, yielding a CO_2 molecule, which then participates in the traditional dark reactions of C_3 photosynthesis. Unlike C_4 plants, in which these two steps are physically separated in the mesophyll and bundle sheath cells, in CAM plants both steps occur in the mesophyll cells but at different times. The CAM plant opens its stomata at night, taking up CO_2 and fixing it to malate using PEP carboxylase. During the day, the plant closes its stomata and converts the malate into CO_2, which is then fixed using the normal C_3 dark reactions. By only opening stomata at night when the temperature is lowest and relative humidity highest, CAM plants conserve water. Although CAM plants use water very efficiently, the pathway is energetically expensive and is not usually observed except in very dry environments.

6. GLOBAL CARBON CYCLING: PHOTOSYNTHETIC CONSIDERATIONS

The global cycling of carbon involves both biological and physical processes. Only the biological components are discussed here. Plants and other photosynthetic organisms assimilate CO_2 and eventually convert the CO_2 to simple sugars. From simple sugars, plants synthesize a variety of compounds and store them in the form of plant tissue. When herbivores consume plant material, simple sugars are synthesized and transformed to other carbon-based compounds. Predators feeding on the herbivores redigest and again transform the carbon. At each step, some of the carbon returns to the atmosphere in the form of CO_2 as a by-product of respiration. The remainder is incorporated and temporarily stored in living biomass. Carbon contained in living organisms is eventually released through decomposition. The rate of release is highly variable and depends on both environmental and biological conditions. In tropical forests, most of the carbon in detritus is rapidly recycled. In drier, cooler regions considerable quantities of carbon are stored in the soil for long periods of time.

Similar cycling takes place in aquatic environments. Phytoplankton assimilate carbon dioxide that has diffused into the upper layers of water and dissolved carbonate and bicarbonate ions and convert it to organic sugars. The carbohydrate produced eventually passes through the aquatic food web. Significant portions of carbon, bound as carbonate in shells and exoskeletons of organisms, settle to the lake or ocean floor. This carbon is largely isolated from biotic activity and becomes incorporated into bottom sediments. It may then enter a long-term pool and may not recycle to the atmosphere again until it resurfaces as limestone through geological time.

The total global carbon pool involved in global carbon cycling is estimated to be approximately 55,000 Gt (1 Gt = 1 billion metric tons). Fossil fuels, the result of ancient photosynthesis, account for approximately 10,000 Gt. The ocean contains approximately 35,000 Gt, primarily as bicarbonate (HCO_3^-) and carbonate ions (CO_3^-). Dead organic matter in the ocean contains 1650 Gt of carbon. Living biomass in the ocean, primarily phytoplankton, is 3 Gt. Terrestrial ecosystems contain approximately 1200 Gt as dead organic matter and 550 Gt as living matter. The atmosphere holds approximately 740 Gt of carbon.

Although global carbon cycling is a combination of both physical and biological processes, photosynthesis is obviously a central controlling factor. In order to understand the global carbon cycle, we must understand how photosynthetic reactions occur over broad temporal and spatial scales.

Human activities have severely altered the global carbon cycle during the past century, with unknown future consequences.

7. GLOBAL CLIMATE IMPLICATIONS

The flux of carbon among terrestrial, aquatic, and atmospheric pools is at least partially controlled by photosynthetic processes. The relative carbon pool sizes have major effects on global climate. The CO_2 flux among land, sea, and atmosphere has, since the industrial revolution, been disturbed by a rapid injection of carbon dioxide to the atmosphere from the burning of fossil fuels and from the clearing of forests. Both the fossil fuel and biomass carbon are relatively long-lived pools with long residence times. However, human activity has volatilized this carbon originally fixed by photosynthesis into the atmosphere. At the beginning of the industrial revolution, atmospheric CO_2 was approximately 260 ppmv. Since then, input of CO_2 has increased this concentration to approximately 372 ppmv in 2002.

Only approximately 40–50% of the total CO_2 injected into the atmosphere remains there. What happens to the rest is a subject of current research and not completely understood. Most likely, the ocean is a large sink for this excess carbon. The other potential major sink is the terrestrial biota. Terrestrial ecosystems, especially forests, do have the ability to store some carbon through the photosynthetic production of biomass. However, whether this storage is greater than the contribution of carbon through respiration is not clear in many terrestrial systems. A complete mechanistic understanding of the global carbon cycle has yet to be achieved, and this will be an area of active scientific endeavor for many years. However, there is very little disagreement that atmospheric CO_2 has increased dramatically during the past century and that if atmospheric CO_2 concentrations continue to increase at the present rate, it will exceed 400 ppmv by 2030. In view of our dependence on fossil fuels and the growing body of evidence linking atmospheric CO_2 and climate, understanding the fate of excess atmospheric carbon is one of the most pressing scientific research needs.

In addition to potentially changing the earth's climate system, rising atmospheric CO_2 concentrations directly impact the photosynthetic process and may increase the primary production of photosynthetic organisms in some systems. Satellite imagery and remote-sensing information for the past two decades indicate as much as a 6% increase in total production of terrestrial systems, primarily in the tropics. Smaller scale manipulative experiments, such as free air CO_2 enrichment (FACE) studies, have yielded more complex results. Most FACE studies have observed an initial increase in productivity but then a stabilization in productivity over time. The mechanisms behind these observations are not clear, but it seems likely that some other limitation besides CO_2 is eventually expressed in most terrestrial systems. The processes and feedbacks of carbon cycling, of which photosynthesis is a major component, are very active areas of research.

8. CONCLUSION

The photosynthetic process is literally the most important energy transfer on Earth. The fixation of carbon by photosynthetic organisms provides the high-energy molecules needed to sustain nearly all organisms on Earth. Photosynthesis is a two-stage process: (i) harnessing of light energy to produce reducing power (NADPH) and energy (ATP) and (ii) use of the reducing energy to fix organic molecules. We usually associate photosynthesis with the reduction of atmospheric CO_2 to organic sugars. However, the energy generated during the light reactions of photosynthesis can be used to reduce other compounds (e.g., nitrogen and sulfur). Photosynthetic reactions have, in part, controlled the relative carbon pool sizes on Earth. Human activities, especially fossil fuel consumption and biomass burning, have led to an injection of carbon as CO_2 into the atmosphere. This rapid increase in carbon in the atmosphere has the potential to dramatically alter future Earth systems function and climate. A complete mechanistic understanding of global carbon cycling including photosynthetic processes is imperative.

Glossary

G0005 **anode** The electrode in an electrochemical cell that supplies electrons into the external circuit. This electrode results in removal of electrons from the electrolyte at the electrode/electrolyte interface.

G0010 **cathode** The electrode in an electrochemical cell that injects electrons into the electrolyte.

G0015 **electrochemical cell** A complete electrical circuit, consisting of two electrodes, the anode and the cathode, an electrolyte in contact with the electrodes, and a redox species that can carry electrical charge in the electrolyte solution.

G0020 **electrolyte** A liquid containing an ionic salt that allows electrical conduction in the liquid.

G0025 **photoelectrode** A material that absorbs incident light and produces current through an external circuit.

G0030 **photoelectrolysis of water** A specific photoelectrochemical cell in which water is oxidized, forming oxygen gas, at the anode, and water is reduced, forming hydrogen gas, at the cathode.

G0035 **redox couple** A pair of chemical species that is involved with donating and/or accepting electrons from electrodes in an electrochemical cell. The redox couple consists of a chemically reduced species that can donate electrons to an electrode, thereby forming the chemically oxidized form of the redox couple. The oxidized species of the redox couple can accept electrons from an electrode, forming the chemically reduced form of the redox couple.

P0005 The global primary energy consumption from all sources in 1998 was approximately 400×10^{18} J, which equates to a mean energy consumption rate of 12.8×10^{12} W or 12.8 terawatts (TW). By comparison, the net solar power striking the surface of the earth is approximately 1.2×10^{5} TW. A diurnally averaged 20 TW of power could be obtained if approximately 0.16% of the land on Earth were devoted to energy farms that converted solar energy at 10% net conversion efficiency. Biomass farms generally display net solar energy conversion efficiencies of 0.1–0.5%. In contrast, the theoretical maximum energy conversion efficiency for a simple light-absorbing solar energy conversion device is more than 30%, and photovoltaic cells that produce electricity from sunlight have demonstrated efficiencies in the field in excess of 20%. Numerous laboratories throughout the world are therefore building artificial photosynthetic systems with the hope of understanding, and ultimately improving on, the energy conversion properties of the natural photosynthetic process.

1. TYPES OF ARTIFICIAL PHOTOSYNTHETIC DEVICES S0005

P0010 Several molecular systems have been constructed that mimic various aspects of photosynthesis. Two of these utilize molecular systems that are derived from natural photosynthesis but that incorporate chemically based modifications to produce artificial photosynthetic devices. These devices use artificial photosynthetic pigments to drive chemical reactions across lipid bilayers or use noble metal catalysts to change the function of the photosynthetic process to produce hydrogen and oxygen instead of sugars and oxygen. Neither of these systems are sufficiently robust to be operated for extended periods of time as energy conversion devices, but they have shown that it is possible to produce artificial photosynthetic assemblies that function well in a laboratory setting.

P0015 The third system, semiconductor photoelectrochemistry, utilizes a nonbiological approach to produce fuels in an entirely artificial photosynthetic system. Photoelectrochemical systems use sunlight to supply part or all of the energy required to generate the storable chemical fuels (Fig. 1). Photoelectrochemical

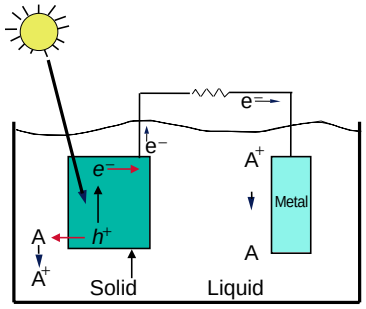
F005 ***FIGURE 1*** Known methods for transforming solar energy into chemical fuels or electrical energy. Photosynthesis stores approximately 3% of the incident solar energy in the form of chemical fuels for use by the plant. Photovoltaics produce electrical energy with up to 25% efficiency. Wet solar cells based on semiconductor/liquid junctions produce either storable chemical fuels or electrical energy, depending on their mode of operation. Efficiencies of these artificial photosynthetic systems can be greater than 15%.

systems can also be utilized to provide electrical energy. Photoelectrochemical energy conversion systems, although a relatively new technology, have demonstrated laboratory solar energy conversion efficiencies of $>16\%$ for electricity formation and $>10\%$ for fuel formation during the sunlight-assisted splitting of water into $H_2(g)$ and $O_2(g)$. In this respect, they represent a promising method for obtaining renewable, storable energy from the sun.

P0020 A photoelectrochemical cell is closely related to a battery, fuel cell, or other type of electrochemical system in that it is composed of two electrodes and an electrolyte. Unlike batteries or fuel cells, in which the energy is initially stored in the reactants and is then released through the electrical discharge circuit during the formation of chemical reaction products, photoelectrochemical cells utilize the input optical energy to drive electrochemical reactions (Fig. 1). To construct a photoelectrochemical cell, one of the metal electrodes of a conventional electrochemical cell is replaced by a semiconductor electrode. Light absorbed by the semiconductor electrode produces a current through the cell, which results in the production of chemical fuels and/or electrical energy by the device.

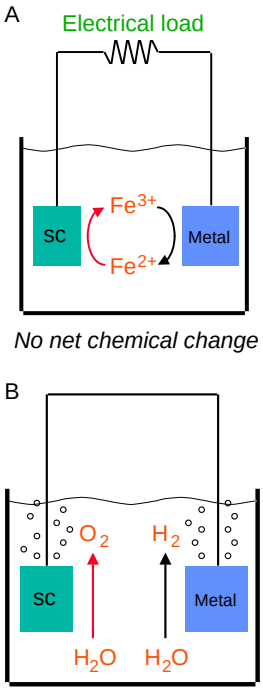
S0010 2. *BASIC PROCESSES OF A PHOTOELECTROCHEMICAL ENERGY CONVERSION DEVICE*

P0025 The basic processes that occur in such a system are well understood. The semiconductor electrode efficiently absorbs light, producing an excited electronic state. In this excited state, the electron and the electron vacancy (the "hole") are both more energetic than they were in their respective ground states. The photoexcited electrons and holes are generally not tightly bound to an individual atom or set of atoms in the solid. These delocalized charge carriers readily move through the semiconductor and are therefore available to perform chemical reactions at the solid/liquid interface (Fig. 2). When the photogenerated electrons and holes drive chemical reactions at the electrodes in the cell, energy from sunlight is stored in the system.



F0010 ***FIGURE 2*** Basic operation of a photoelectrochemical cell. The semiconducting electrode absorbs energy from sunlight and produces a current through the electrochemical cell. The current produces electrical and/or chemical energy in the system.

P0030 If the chemical reaction at one electrode is exactly the opposite of the reaction at the other electrode, no net chemical change will occur in the electrolyte. The overall process is then conversion of light into



F0015 ***FIGURE 3*** Two modes of operation for wet solar cells based on photoactive semiconductor materials. In both possibilities shown, the semiconductor (sc) absorbs the light and produces energetic electrons that can flow through the circuit. The differences between the cells result from the types of chemical reactions that occur in the liquid as a result of this electron flow. (A) A wet solar cell that produces electrical power from incident sunlight. The semiconductor produces excited electrons that flow through the circuit, doing work on an electrical load. This load could be a light bulb, battery, or other type of electrical machinery. The electrons are then injected into the solution at the metal electrode and produce a chemical reaction in the liquid. In this example, the injected electrons convert one form of iron (Fe^{3+}, with three ionized electrons) to another (Fe^{2+}, with only two ionized electrons). The Fe^{2+} then moves to the semiconductor electrode, carrying with it the injected electron. To complete the circuit, the Fe^{2+} then donates this electron to the semiconductor electrode. This regenerates the Fe^{3+} state in the solution. Thus, no net chemical change occurs in the liquid, but the light has produced a current through the electrical device in the circuit. (B) A wet solar cell that produces both electrical power and chemical fuels from incident sunlight. The processes of light harvesting and current flow through the circuit are very similar to those in A, but the chemical reactions are different at the two electrodes. In this example, the injected electrons react with the water to produce gaseous hydrogen (H_2), which bubbles out of the solution. To complete the electrical circuit, the semiconductor electrode must be provided with electrons. Here, they come from the water. Removal of electrons from the water produces oxygen gas (O_2), which also bubbles out of the solution. Thus, illumination of this cell with light produces both current flow and gaseous chemical fuels. The gases could be collected and stored for later use, with the stored energy being recovered either in a fuel cell or by burning the hydrogen and oxygen in an engine to regenerate the water.

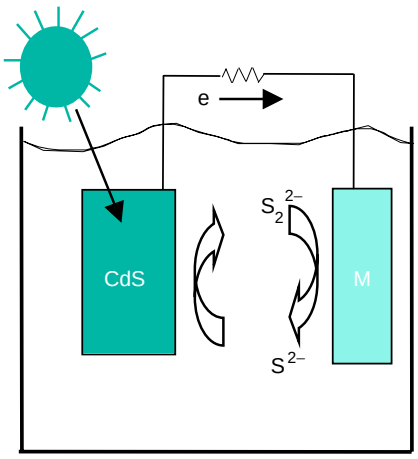
electricity. This mode of photoelectrochemical cell operation resembles that of a photovoltaic device and is designated as a regenerative photoelectrochemical cell. Alternatively, if the chemical reactions are different at each electrode, chemical fuels will be produced by the light-induced current flow. This type of system is designated as a fuel-forming photoelectrochemical cell. Both regenerative and fuel-forming photoelectrochemical cells have been demonstrated in the laboratory. A particularly appealing situation is depicted in Fig. 3, in which water is the liquid and current flow through the circuit simultaneously produces electricity, hydrogen gas, and oxygen gas.

P0035 Closer consideration of a photoelectrochemical cell makes it clear that efficient light absorption alone is not sufficient to obtain efficient device operation. If the charged carriers created by optical excitation of the semiconductor had no preference regarding their direction of motion, equal numbers of excited electrons would travel in clockwise and counterclockwise directions through the circuit in the cell. The equal magnitudes, but opposite signs, of the currents would lead to a net cancellation of current in the wire, and no net energy output would be obtained from such a cell.

P0040 Charge separation, however, is very efficiently effected in a well-designed photoelectrochemical cell. The key to directing the charge carriers preferentially through the circuit lies in the formation of a strong electric field at the semiconductor/liquid interface (Fig. 4). This electric field either attracts or repels electrons from the interface, depending on the polarity of the field. Fortunately, maintaining the field does not require a constant energy input from an external source: This electric field occurs spontaneously whenever two phases with different chemical properties are brought into contact. In semiconductor/liquid junctions, the interfacial fields are generally so strong that any photogenerated electrons and holes are rapidly driven in opposite directions, and charge carrier recombination is thereby suppressed.

S0015 *3. PHOTOELECTROLYSIS USING METAL OXIDES AND OTHER SEMICONDUCTORS*

P0045 Certain materials, generally metal oxides, can sustain the unassisted photoelectrolysis of water into H_2 and O_2 (see Fig. 3). The energy contained in the photons that are absorbed by these materials can in many cases be efficiently converted into energy stored into



F0020 ***FIGURE 4*** Schematic of a wet semiconductor/liquid-based solar cell with a stabilizing agent in the solution. The light is absorbed by the semiconductor and produces excited electrons. Although CdS is shown, the semiconducting material could be silicon, gallium arsenide, titanium dioxide, or other suitable samples. The excited electrons are directed into the wire by the electric field because the negatively charged electrons are repelled by the negative charges that reside on the liquid side of the semiconductor/liquid boundary. The electrons then flow clockwise through the circuit, performing work through a load. They then reach the metal electrode and are forced to undergo a chemical reaction with the liquid in order to continue the circuit. The chemical produced from this reaction then moves through the liquid and reacts with the semiconductor electrode. This restores the electron to its original position and completes the current loop. The stabilizer is needed to accept and donate electrons at the two electrode/electrolyte interfaces to prevent corrosion or passivation of the two active electrodes in the cell.

the chemical fuels produced by the photoelectrolysis system. However, these materials have optical absorption thresholds (band gaps) that are too large to permit effective absorption of the visible and infrared portions of the solar spectrum, thereby wasting a large fraction of the incident solar energy and yielding overall energy conversion efficiencies of $<1\%$. Modification of metal oxide materials has been claimed to be much more promising, with a modified TiO_2 photoanode yielding 8% efficiency in the photoassisted splitting of water into H_2 and O_2.

P0050 Metal chalcogenides have been investigated as photoanodes because the lattice S, Se, or Te atoms are weaker oxidants than lattice oxygen atoms and thus would enable more efficient utilization of the incident solar energy. Photoelectrochemical studies of metal chalcogenide electrodes, however, have revealed materials that are better absorbers than TiO_2 and therefore can provide more desirable semiconductor electrodes in photoelectrolysis systems. However, these materials are unstable in contact with water. There is no fundamental thermodynamic reason that this should be the case; rather, it is a limitation of the known materials systems in photoelectrochemistry.

4. APPROACHES TO CONSTRUCTING STABLE, EFFICIENT PHOTOELECTROCHEMICAL CELLS

S0020

4.1 Regenerative Cells in Aqueous Solution

S0025

P0055 Several approaches are being pursued to circumvent the problems described previously with the direct, efficient photoelectrochemical splitting of water. An alternative approach to minimize aqueous-based corrosion of semiconductor electrodes has been to search for water-soluble molecules that exchange electrons with the photoelectrode much more readily than does water. Such molecules, if present in the liquid in sufficient concentration, could prevent electrode corrosion by reacting with the photogenerated holes in the electrode before the holes can participate in the corrosion process. If the oxidized form of these corrosion-inhibiting reagents also provides a useful fuel, the system is even more desirable.

P0060 This approach has been successfully implemented for the II–IV semiconductors, such as CdS, CdSe, and CdTe. These materials can be stabilized in aqueous solutions through addition of sulfide to the solution to provide another source of reduced sulfide to compete with electrode corrosion (Fig. 4). In this manner, a stable regenerative photoelectrochemical cell can be constructed from an otherwise unstable semiconductor electrode. Long-term stability for several years has been demonstrated for such systems. The use of the stabilizing agent eliminates the possibility of production of desirable chemical fuels from the photoelectrochemical process but in return provides a stable photoelectrochemical cell for the conversion of light into electrical power. For example, stable, 16% efficient cells have been obtained using gallium arsenide in contact with an aqueous medium containing high concentrations of selenide ions.

P0065 $CuInSe_2$ photoanodes have yielded $>10\%$ efficiency for the production of I_2 from aqueous iodide ions. The production of I_2 is more desirable than the formation of Se (as in the GaAs system) because the I_2 could provide a useful fuel to charge an *in situ* storage battery. If properly coupled with a metal electrode, this $CuInSe_2$ cell could produce H_2 and I_2

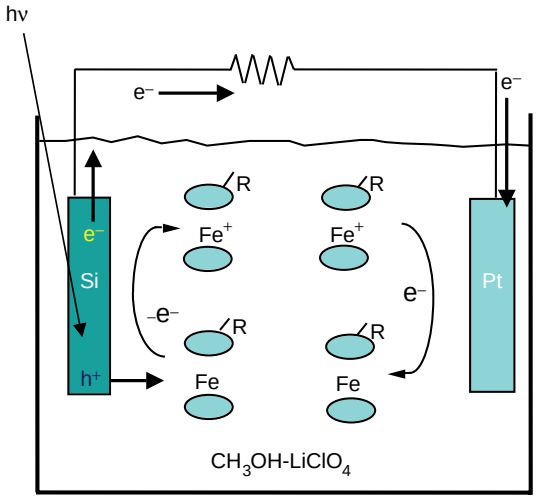
from aqueous HI. The stored chemical energy in the H_2 and I_2 would then be recovered at a later time, much as would be done if H_2 and O_2 gases had been obtained from a water-splitting process. Similar results for I_2 production have been obtained for $MoSe_2$ electrodes and for *in situ* electrical storage using the alloy material $CdSe_{0.65}Te_{0.35}$. Si electrodes have been covered with small metal islands to produce Br_2 from aqueous HBr with high efficiency, and $>10\%$ solar energy conversion efficiencies have been demonstrated for the formation of $H_2(g)$ from water at p-type InP electrodes. The key to making these fuel-forming systems more practical is the efficient coupling to the other, nonsemiconducting electrode: If this can be done without significant additional electrical energy input, fuel production could be sustained in a very efficient manner.

S0030 ## 4.2 Regenerative Cells in Nonaqueous Solvents

P0070 For some materials, such as CdS, several stabilizer/electrolyte combinations have been identified that are stable on the months/years timescale, whereas for others, such as Si photoanodes, no reagent has been discovered that provides stable operation even on the timescale of minutes in aqueous solution. A general approach to circumvent the instability of electrode materials such as Si and GaAs in aqueous solutions is simply to eliminate the corrosive liquid, water, from the environment of the photoelectrochemical cell. If the water in the cell is replaced by alcohol or another organic liquid, stable photoelectrode operation can readily be obtained, provided that the organic solvent also does not effect corrosion of the solid. Using this approach, stable photoelectrochemical cells have been obtained with Si, GaAs, InP, and other semiconductors whose optical properties are well matched to the solar spectrum.

P0075 In a nonaqueous photoelectrochemical cell, photogenerated charge carriers in the semiconductor are not scavenged by reaction with the solvent but are transferred to a chemical reagent that has been deliberately added to the electrolyte solution. This chemical stabilizing agent accepts an electron (is reduced) at one electrode and donates that electron (becomes oxidized) at the other electrode. The stabilizing agent carries the electrical charge between the plates of the electrochemical cell but undergoes no net overall chemical change during extended cell operation. Stabilizers should ideally be species that rapidly exchange electrons with both the semiconductor and the metal electrodes in the cell. Rapid reaction with the semiconductor is required to compete effectively with corrosion reactions that will arise from the inevitable presence of trace quantities of water in the cell, whereas rapid electrochemical reaction with the metal electrode will minimize resistive losses from the charge transfer step. Nonaqueous semiconductor/liquid junctions are almost universally restricted to operating as regenerative photoelectrochemical cells because the reduced and/or oxidized forms of the stabilizers are rarely useful fuels. The stabilizing reagents are therefore most effectively utilized when they are added to the cell only once to facilitate the sustained stable production of electrical energy from an otherwise unstable semiconductor electrode.

P0080 An advantage of nonaqueous photoelectrochemical cells is that they allow utilization of many semiconductors that are not stable in any known aqueous electrolyte. An example is provided by the properties of Si photoanodes, which are readily stabilized for months when the solvent is methanol or ethanol in the presence of organometallic stabilizing agents (Fig. 5). Another advantage of using nonaqueous solvents is the ability to use a variety of stabilizing agents and to vary their chemical properties widely while still obtaining stable



F0025 ***FIGURE 5*** Stabilization of semiconductor electrodes in nonaqueous solvents. Although unstable in aqueous solutions, many semiconductors can be stabilized in nonaqueous electrolytes. In this example, the Si electrode is in contact with a nonaqueous liquid that contains a high-boiling solvent (propylene carbonate), salt to provide electrical conductivity (lithium perchlorate), and redox ions to carry the electrical charges through the liquid (ferrocene, which is an organometallic complex of Fe^{2+} that is soluble in organic solvents). The cell is 14% efficient in converting incident solar energy into electrical energy.

electrical currents from the photoelectrochemical device. This can be extremely useful in optimizing the energy conversion efficiency parameters of a photoelectrochemical system. For example, in the water splitting systems discussed previously, significant energy is wasted when there is a large energy difference between the levels of electrons or holes in the photoelectrode and the oxidation/reduction potentials for the water splitting reaction. Such energy differences can be minimized, for example, using Si/alcohol contacts because the energy level of the stabilizer can be changed until it closely matches the desired energy level of the semiconductor. This allows optimization of the cell efficiency through simultaneous chemical design of the electrolyte, photoelectrode material, and stabilizing agent.

P0085 These nonaqueous photoelectrochemical devices can yield relatively high solar energy conversion efficiencies: 12–14% efficiency has been obtained in unoptimized photoelectrochemical cells compared to the 15–20% efficiency that is obtained for production-line solid-state Si and GaAs photovoltaics. The nonaqueous photoelectrochemical cells also offer an opportunity to readily change the chemistry at the solid/liquid interface and to investigate the effect of these changes on the electron yield of the system. Although much remains to be learned about the principles that govern the behavior of these cells, many of them can properly be denoted as technical successes because they are efficient and stable in sunlight.

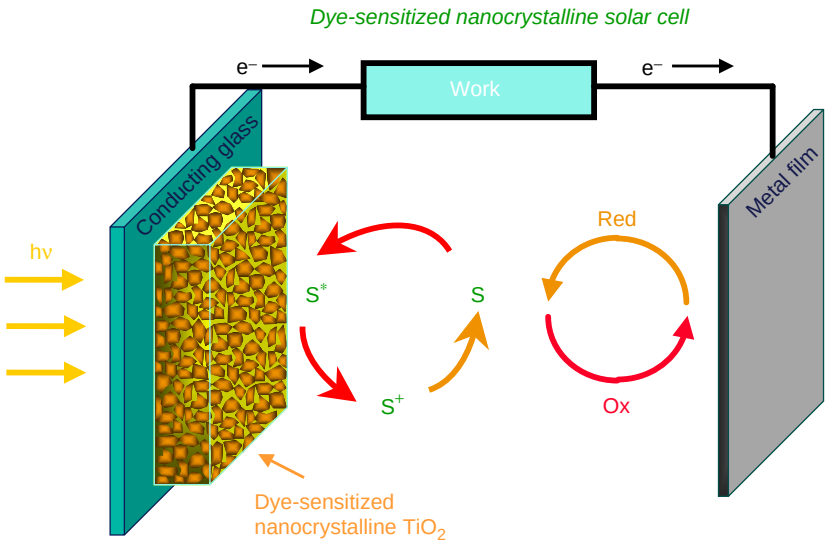
S0035 ## 4.3 Dye Sensitization of Stable Electrode Materials

P0090 Another approach to artificial photosynthesis using semiconductor photoelectrochemistry is to extend the optical response of photoelectrode materials that are known to be stable in water, such as TiO_2. When a highly colored dye is coated on the surface of a semiconductor, the absorption of a white (i.e., high band gap) material such as TiO_2 can be extended into the visible region of the spectrum. This type of dye sensitization is analogous to the chemistry that forms the basis of the modern color photographic process, with the solid being semiconducting AgBr and with various dyes providing the color response of the AgBr film emulsion.

P0095 Most dye-coated, single-crystal semiconductor electrodes exhibit solar energy conversion efficiencies of less than 0.1%. Even with the most highly colored molecules (i.e., dye molecules having very large optical absorption coefficients), several layers of dye are required to absorb all the incident light. However, only the dye layer closest to the electrode surface is generally effective in injecting an excited electron to the electrode. Since only a monolayer of dye is effectively useful for light absorption, most of the photons incident onto the cell are either transmitted through the device or absorbed by dye molecules that do not contribute to photocurrent flow.

P0100 To deal with this issue, very rough, high-surface-area, dye-coated titanium dioxide electrodes are used. In this system, the TiO_2 consists of crystallites with a diameter of approximately 10 nm. A sintered film of these nanocrystals, although relatively transparent, possesses such a high surface area that only a monolayer of adsorbed dye molecules can absorb $>90\%$ of the photons incident onto the sample. The excited state of the adsorbed dye is sufficiently reducing that it will donate an electron to the conduction band of the TiO_2. The presence of the TiO_2, or similar semiconducting material, is crucial because the TiO_2 accepts the photogenerated electrons from the excited state of the dye and directs the injected electron toward the electrical contact, preventing recombination with the oxidized form of the dye or with the species in the electrolyte solution. The dyes investigated to date, including Ru(polypyridyl) complexes and chlorophylls, have extended the absorption range of TiO_2 into the visible region of the spectrum and have provided much better overlap of the electrode response with that of the solar spectrum. Furthermore, the excited states of these adsorbed dye molecules have yielded very effective charge separation, producing photocurrent in the TiO_2 with near unity quantum yield. The efficiency of the system is thus not limited by the charge collection and electron injection process but by the voltage that can be obtained from the specific system of concern.

P0105 This system resembles the molecular photosynthetic process in that the photochemical reactions in the cell are completely dictated by the reactivity of the adsorbed dye molecules. The solid induces the charge separation and dictates the directionality of current flow, but the adsorbed dye molecules determine the course of the remaining steps in the energy conversion cycle. After injection of an electron into the solid, the oxidized dye molecule receives an electron from a soluble electron donor, regenerating the original form of the dye. The electrical circuit is then completed by injection of the electron into the solution at the other electrode in the system (Fig. 6).



F0030 ***FIGURE 6*** A wet solar cell made from a dye-sensitized semiconductor. A colored dye is used to allow normally transparent semiconductors to absorb sunlight in the visible region of the electromagnetic spectrum. The high surface area of the mesoporous solid allows nearly complete absorption of the incident light by a monolayer of dye adsorbed onto the surface of the semiconducting solid. The excited electrons produced from absorption by the dye are injected into the semiconductor and then make their way through the circuit as in a conventional wet cell. The dye is a ruthenium-based metal complex, and the support is a high-surface-area TiO_2 material, related to the inexpensive pigment commonly used in white paint. Solar energy conversion efficiencies as high as 10% have been reported in test devices of this type of potentially inexpensive solid/liquid junction.

P0110 Some of the Ru(polypyridyl) dyes investigated have oxidation potentials that are very close to those required to form $O_2(g)$ from water. Thus, the problems encountered in the photoelectrochemistry of metal oxide electrodes, involving severe energy loss between the level of the photogenerated holes and potential for the oxidation of water to $O_2(g)$, can be avoided, in principle, in the dye-sensitized system. The electronic energy levels of the adsorbed dye molecules are simply tuned chemically until they are close to that of the desired chemical reaction in the cell. Unfortunately, oxidation of water to oxygen gas is a multielectron process and is generally very difficult to accomplish at a rapid rate. To quickly regenerate the original dye molecule for reuse in another photochemical cycle, another molecule, called a supersensitizer, must be added to the dye-sensitized photoelectrochemical cell. The supersensitizer donates an electron to the oxidized form of the dye, regenerating the original form of the dye and producing the oxidized supersensitizer. The oxidized supersensitizer is then reduced at the second electrode, yielding a regenerative photoelectrochemical cell for the entire photoelectrochemical cycle.

P0115 The TiO_2 dye-sensitized photoelectrochemical cell has been modified and improved by using nonaqueous solvents. Nonaqueous solvents allow greater stability of the system and also a wider choice of supersensitizers. This system is essentially an extension of the strategy for producing stable photoelectrochemical cells involving the use of redox stabilizers in nonaqueous electrolytes, but in which relatively expensive single-crystal semiconductors have been replaced by less expensive, dye-sensitized nanocrystalline photoanode materials. Using this approach, solar energy conversion efficiencies of up to 10% have been reported. Relative to conventional photovoltaic cells, it has been claimed that this type of photoelectrochemical system has cost advantages, including the use of inexpensive raw materials, the lack of difficult fabrication steps or expensive crystal purification processes, and the ability to implement the design simply over large areas. The system indeed appears promising for electrical energy generation, provided that efficiencies can be improved and that light-induced degradation of the dye and the other constituents in the cell can be kept to levels required for long-term, maintenance-free operation of the system.

P0120 As can be seen, there are many possibilities for improving these photoelectrochemical cells, and no one strategy has emerged as the clear choice. We know a great deal about the fundamental operating

principles of each component of these artificial photosynthetic systems. Advances have also been made in practical efforts to improve their energy conversion efficiencies and to increase their production rates of chemically desirable fuels. In some cases, the systems show promise in the laboratory as highly efficient energy conversion devices. Even for these systems, choices must still be made to obtain the correct combination of materials that might comprise a complete artificial photosynthetic system. Siting considerations indicate that at 10% overall conversion efficiency, a relatively small fraction of the suitable land area available globally would be required to produce significant amounts of power relative to current global fossil energy consumption. Artificial photosynthetic systems, however, are in their infancy, and the resultant energy costs that might be realized from a fully developed artificial photosynthetic technology are difficult to estimate. Possible advantages of the approach relative to photovoltaics for production of electricity are the ability to directly form fuels from an inherently intermittent energy source as well as the ability to use inexpensive raw materials as the light absorbers without suffering large decreases in energy conversion efficiency of the resulting photoelectrochemical energy conversion devices. The environmental impacts of these systems would be relatively benign provided that inert raw materials, such as Si and TiO_2, were used as the basic photoelectrode materials. The actual decision to construct a commercial system will also require input regarding a number of market-related factors, including the price of alternative energy sources, the value of the fuels produced by the photoelectrochemical cells, and the cost in both dollars and energy of fabrication and maintenance of the system. There are similar constraints for all alternative energy sources, but the promise and demonstrated efficiency of these devices is too great to rule out these interesting artificial photosynthetic devices as energy options for the future.

Glossary

air mass zero (AMO) Location outside Earth's atmosphere.
antireflecting coating Dielectric layers deposited on solar cells to reduce reflection of incident sunlight.
back surface field (BSF) Electric field at the back surface of a solar cell.
back surface reflector (BSR) Mirror formed at the back surface of solar cells to increase reflection of unabsorbed sunlight from the back surface.
beginning of life (BOL) Period immediately after spacecraft is launched.
conversion efficiency Fraction of the power output of a solar cell to the incident power from the sun, expressed as a percentage.
coverglass Transparent cover bonded to the front surface of solar cells.
end of life (EOL) Period after solar cells have withstood defined operating conditions in space, mostly exposure to radiation.
epitaxial layers Layers grown to replicate the crystal lattice properties of a substrate material.
metal organic chemical vapor deposition (MOCVD) Deposition of epitaxial layers using gaseous elements, obtained mainly from compounds consisting of organic chemical groups (e.g., methyl and CH_3) and a metal.
organometallic vapor phase epitaxy (OMVPE) Similar to MOCVD.
PN junction Voltage barrier formed in a semiconductor, providing the conversion of optical (photonic) energy into electrical energy.
P/N solar cell The illuminated surface is a P-type emitter layer formed over an N-type base. N/P solar cells have opposite layer polarity.
substrate The starting material for forming solar cells; also refers to the material to which solar cells are bonded to form panels (or arrays).

Photovoltaic arrays on satellites and spacecraft provide electric power for on-board equipment and communication with control centers on Earth. Before 1957, when the first satellite, Sputnik I, was launched, there was much debate about the best way to generate electric power on satellites. Most conventional fuels do not function well in the vacuum of space, and even if usable, they cannot operate for extended periods without exceeding the weight limits set by the propulsion rockets and posing serious safety concerns. Sunlight is the obvious power source in space, removing the need to launch fuel with the spacecraft. In 1954, Bell Telephone Laboratories (BTL) announced that it had made a significant increase in the output from silicon solar cells. Four years later, commercial versions of BTL cells were successfully used on the second U.S. satellite Vanguard I to provide power for a radio-tracking signal that lasted for several years. Following this successful demonstration, space photovoltaic (PV) power was rapidly accepted and used widely. For more than 40 years, arrays of solar cells have delivered power flawlessly for long periods. PV power is one of the major reasons for the successful performance of thousands of satellite. Satellite applications have become familiar, including worldwide telecommunications, sensing of weather and other Earth surface geographic conditions, and navigation using the constellation of global positioning satellites (GPS). Satellites have also performed many scientific missions, carrying astronomical telescopes and exploring around or on the moon

and Mars and diverse locations toward or away from the sun. Military satellites have collected large amounts of data for surveillance or information gathering. Space PV continues to be an active niche market, supplied by organizations throughout the world. The high visibility of space programs has publicized the many advantages of PV-generated power.

1. SPECIAL FEATURES OF SPACE PHOTOVOLTAICS

Space photovoltaic (PV) differs from terrestrial PV in several ways.

1.1 Components of a Space Solar Power System

Space solar power systems comprise the following components:

- *Solar cells*: The most important components are the solar cells, which are connected together in series-parallel circuits to supply the required voltages and currents.
- *Coverglasses*: Thin transparent covers of glass or quartz are adhesively bonded to the cells to reduce their temperature by increasing the reradiation of infrared wavelengths into space. Covers also protect the cell from damage caused by low-energy protons and have an optical coating to reject ultraviolet (UV) wavelengths to prevent UV darkening of the adhesive.
- *Metal interconnectors*: Thin metal foils, 100–150 μm thick, are soldered or welded to electrically connect the contact pads on the cells. Placing all the contact pads on the back surface of the cells facilitates automated bonding. The metal-to-cell bonds must be robust for high reliability.
- *Array substrates*: Interconnected cells are bonded to lightweight substrates to form a panel or array. Aluminum honeycomb and graphite-epoxy composites are used most. Kapton has been used on fold-out arrays to reduce weight.
- *Deployment and tracking mechanisms*: In some cases, cells are attached to the outer surface of the satellite (body mounted), but they are usually mounted on wings or paddles. Wings are folded during launch and deployed by releasing spring clamps, or by folding out or rolling out, with means to lock the array in position. Sun tracking mechanisms keep the solar arrays facing the sun.
- *Power storage*: Chemical batteries store PV-generated energy and stabilize the electric power fed to the satellite circuitry. Many charge–discharge cycles can occur, and to operate in the vacuum, custom-manufactured sealed batteries are used with nickel–cadmium or lithium electrodes.
- *Electric power distribution*: Autonomous power conditioning equipment controls the battery charge conditions and allocates power to the circuits in the satellite.

1.2 Variety of Locations

Locations where spacecraft must operate are classified into four broad categories:

- *Near-Earth*: In the vicinity of the earth, there are five types of satellite orbits:
  1. Low earth orbit (LEO), altitude 150–1000 miles.
  2. Medium earth orbit (MEO), altitude 1000–22,000 miles.
  3. Geosynchronous earth orbit (GEO), altitude approximately 23,000 miles. Worldwide communications requires 3 satellites in GEO, 15–20 satellites in MEO, and 50 or more satellites in LEO.
  4. Orbital transfer missions (e.g., LEO to GEO).
  5. Cislunar to near the moon, 23,000–250,000 miles distant.
- *Near-Sun*: These include missions toward Venus, Mercury, or even closer to the sun.
- *Far-Sun*: Missions beyond the earth's orbit, including those to Mars, the asteroid belt, Jupiter, and Saturn.
- *Landers*: These are bases on the moon or Mars or for landing on comets or asteroids. Manned bases require a large amount of power.

1.3 The Space Environment

Space contains only minute amounts of gases. In this ultrahigh vacuum, heat cannot be removed from the spacecraft by conduction or convection but only by radiation. The power received from the sun and the solar array temperatures at any location depend on the distance from the sun. In the vicinity of the earth, outside the gaseous atmosphere, the incident solar output as a function of wavelength is shown as solar extraterrestrial in Fig. 1. This solar spectrum is called air mass zero (AMO), and the power density is approximately 1365 watts per square meter (Wm^{-2}).

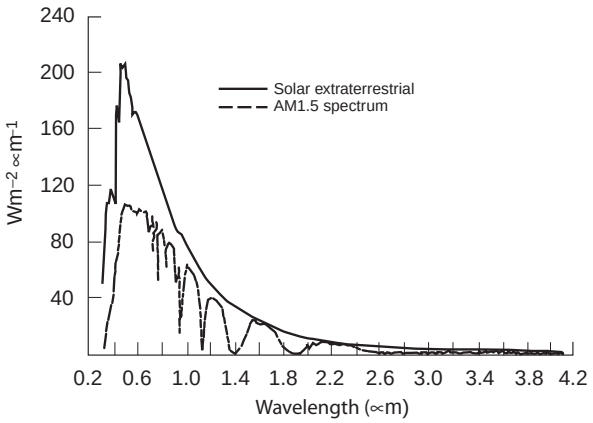

FIGURE 1 Solar spectrum incident on the earth. Solar extraterrestrial, outside gaseous atmosphere; AM1.5 spectrum, at the earth's surface.

Figure 1 also shows the spectrum received at the earth's surface (AM1.5), with the losses in the atmosphere reducing the power density to 800–1000 Wm^{-2}. All solar cell conversion efficiencies given in this article are AMO efficiencies, given by the percentage ratio of the electric power output of the cell, held at a test temperature of 30°C, to the incident power, 1365 Wm^{-2}, from a light source that simulates the AMO spectrum.

1.3.1 Charged Particles

Exposure to charged atomic particles emitted from the sun is not a problem, except during short periods of solar flares or when satellites move through the Van Allen Belts (VABs), in which the particles have been trapped by the earth's magnetic field. A series of satellites measured the energies and concentrations of charged particles in the belts. The outer VAB, at an altitude of approximately 14,000 miles, is more intense than the inner VAB, which has an altitude of approximately 3000 miles. The relative exposures to radiation in LEO, MEO, and GEO are low, high, and moderate, respectively. To estimate the power lost by solar cells from particle bombardment during a mission, the accumulated dosage for the specific mission orbit is calculated and used in ground radiation tests of cells to estimate the end of life output.

1.3.2 Solar Storms

It is recognized that very intense emissions from active regions on the sun can cause serious problems for both terrestrial and satellite power systems. The emissions include X-rays, bubbles of plasma ejected from the sun's corona (coronal mass ejection), and high-energy charged particles, mostly protons and electrons. The plasma generates shock waves that accelerate atomic particles, including those trapped in the VAB, and it also depresses the earth's magnetic field to altitudes at which it affects satellites in GEO orbits. The charged particles cause electrostatic charging problems in solar arrays and in semiconductor circuitry. Failures in satellite attitude controls, especially if they are based on magnetometers, lead to loss of power when the solar arrays are not facing the sun and to reduced communication with the satellite antennas. The large increase in charged particles causes significant power loss from radiation damage in the solar panels.

These solar storm activities have occurred mostly during solar maxima, but problems are observed during quieter periods. Following disruption of several communications satellites, with worldwide impact, additional satellites have been deployed to monitor the sun's activity to provide early warning, allowing some preventive measures to be taken.

1.3.3 Other Orbital Effects

Satellites in low LEOs experience atmospheric drag, causing the satellites to move to lower orbits and eventually fall to the earth. To reduce the amount of booster rocket fuel needed to offset drag effects, the area of the solar arrays must be as small as possible.

For orbits below GEO, satellites pass into the shadow of the earth for part of the orbit. For LEO, shadowing for 30 min during each 90-min orbit causes temperature swings from 60 to −150°C. In 1 year, satellites in LEO can experience 9000 of these temperature cycles. For reliable operation during these cycles, qualified robust procedures must be used to deposit and bond the metallic contacts.

Solar arrays may experience impact damage from many thousands of pieces of space debris left by earlier satellites. The debris must be monitored, shielded, or avoided, especially for manned satellites.

1.4 Remote Operation with High Reliability

The PV power system must be highly reliable because its performance is essential to the success of the satellite mission. PV arrays usually operate unattended, although there have been a few cases of repair or replacement. The solar cells and the rest of the array are manufactured to comprehensive specifications, controlled jointly by the manufacturers and the users. The successful record of space PV arrays is

attributed to this tight process control and detailed documentation.

2. EVOLUTION OF SPACE SOLAR CELLS

Solar cells, which convert sunlight to electrical energy, are the most important component in space PV power systems. High beginning-of-life (BOL) efficiencies are needed because a limited area is available for mounting cells and arrays on satellites. High end-of-life (EOL) efficiencies and very high reliability when operating in space are also required.

2.1 Silicon Space Solar Cells

Silicon (Si) has a band gap (1.15 eV) slightly below the optimum value (1.35 eV) that gives highest PV efficiency. For many years, Si cells had the highest efficiency because of the high-quality, single-crystalline Si developed by the semiconductor industry. The efficiency of the P/N Si space cells derived from the Bell Telephone Laboratory cells was improved from 7 to 10%, and they were used until the early 1960s. After the discovery of the VABs, ground-based particle accelerator tests showed that N/P Si cells had superior resistance to radiation damage. N/P Si cells were quickly adopted and were steadily improved to become the workhorse solar cells used in space.

2.1.1 Choice of Silicon

After extensive testing, simple crystals of Si grown by the Czochralski method (Cz-Si) were found to give cells with the best combined BOL and EOL performance. Two Si resistivity levels were used most, 2 and 10 ohm-cm, containing boron (the P-type impurity), at concentrations of approximately 150 and 30 parts per billion, respectively.

2.1.2 Silicon Cell Improvements

Improved performance was obtained from cells that were manufactured under space-qualified manufacturing methods and that were also compatible with the design and assembly of space solar arrays. One improvement formed shallower PN junctions with reduced concentrations of impurity (phosphorus) in the N-layer. Back surface fields (BSFs) were incorporated to reduce loss of charge carriers by recombination at the back surface. Reflection of incident sunlight was reduced by depositing multilayer antireflection layers, or by texturing the front surface by preferential etching, to form many small random pyramids. Cell temperatures in space were reduced by increasing the reflectivity of the back surface (BSR). Optimized gridline contacts were evaporated on the front surface, and the adhesion of the metal-to-Si contacts was increased.

For some special array designs, or to facilitate automated bonding procedures, pad contacts to the N and P regions were both located on the back surface of the cell. If the back contact was also formed in a grid pattern, the cells were bifacial, generating power when illuminated from the front and back. Bifacial cells can generate additional power in space, converting albedo reflection from clouds or the oceans. Thin Si cells (down to 70 μm) were manufactured. Table I shows production median BOL and EOL efficiencies for the three N/P Si cell designs used most until the 1980s and that are still used when they meet all mission goals. The EOL conditions specified in Table I are also used for EOL efficiencies mentioned in the following sections for other types of cells.

2.1.3 Advanced Silicon Cells

Research centers, principally the University of New South Wales and Stanford University, made significant increases in the efficiency of Si cells (to 19–20% AMO) by using high-quality float-zone refined Si (Fz-Si), by forming regular patterns of pyramids on the front surface, and by "passivating" the front and back surfaces to reduce recombination of charge carriers. Very clean processing conditions were maintained throughout processing to preserve the high quality of the Si. When advanced cells were adapted for space use, improved Cz-Si was used, with slightly lower BOL efficiency (17–18%). EOL efficiency was 12%,

TABLE I

Performance of Most-Used Silicon Space Cells[a]

Cell structure	BOL efficiency (%)[b]	EOL efficiency (%)[c]
2 ohm-cm, BSR	13.5	10.0
10 ohm-cm, BSF, BSR	14.8	9.6
10 ohm-cm, BSR	12.5	10.1

[a] Abbreviations used: BOL, beginning of life; EOL, end of life; BSR, back surface reflector; BSF, back surface field; AMO, air mass zero.

[b] AMO illumination; cell temperature, 30°C.

[c] AMO illumination; cell temperature, 30°C; after exposure to IE15 1 MeV electrons/cm^2.

higher than that of standard Si cells, but the large excess BOL efficiency resulted in problems in the power conditioning equipment. Figure 2 shows the structure of an advanced space Si cell. These cells have been used in applications when radiation exposures were moderate, but they were largely superseded by III–V cells.

2.2 III–V Space Cells

Compounds with elements in group III and group V in the periodic table are semiconductors, like the group IV elements Si and Ge, and have a wide range of properties.

2.2.1 Gallium Arsenide Solar Cells

Gallium arsenide (GaAs) has a band gap of 1.42 eV, close to the value giving peak solar cell efficiency. High-efficiency GaAs cells had been demonstrated, but the space cell community made significant improvements in forming large-area, high-efficiency GaAs cells. The important advance was the ability to grow the GaAs layers by organometallic vapor phase epitaxy (OMVPE) in large production-scale reactors that accommodated an area of 1500 cm^2 of GaAs substrates per run and gave very uniform layers over large areas. In a further advance, the GaAs substrates were replaced by Ge substrates, which have atomic lattice spacing very similar to that of GaAs, leading to growth of high-quality epitaxial GaAs layers. Ge substrates cost less and are stronger mechanically, allowing fabrication of GaAs/Ge large-area, thin GaAs cells. GaAs/Ge cells with an area of more than 36 cm^2 with median BOL efficiencies of 18 to 19% were developed, with superior radiation resistance (EOL efficiency, 14%) and less fall-off in output when operated at elevated temperatures. The improved performance resulted in significant reduction of area and weight of the solar array, making GaAs/Ge cells cost-effective for the PV system, even though they may cost 5–10 times as much as Si cells. These system advantages resulted in rapid acceptance, especially for commercial communications satellites and defense satellites.

2.2.2 Multijunction Solar Cells

Tandem cells made by stacking cells with appropriate band gaps have higher efficiency. After groups at the National Renewable Energy Laboratory successfully grew gallium-indium-phosphide ($GaInP_2$) cells over GaAs cells, on the same GaAs substrate, these $GaInP_2$/GaAs cells were adapted by the space cell community using Ge substrates and production-level OMVPE growth. These dual-junction (DJ) cells eventually attained BOL efficiencies as high as 25.5% and EOL efficiencies of approximately 20%. Additional research led to formation of a PN junction in the Ge substrate during growth of the DJ cell. The resulting triple-junction (TJ) cells have median efficiencies of approximately 27.5% and have been modified to have superior radiation resistance, with EOL efficiencies of approximately

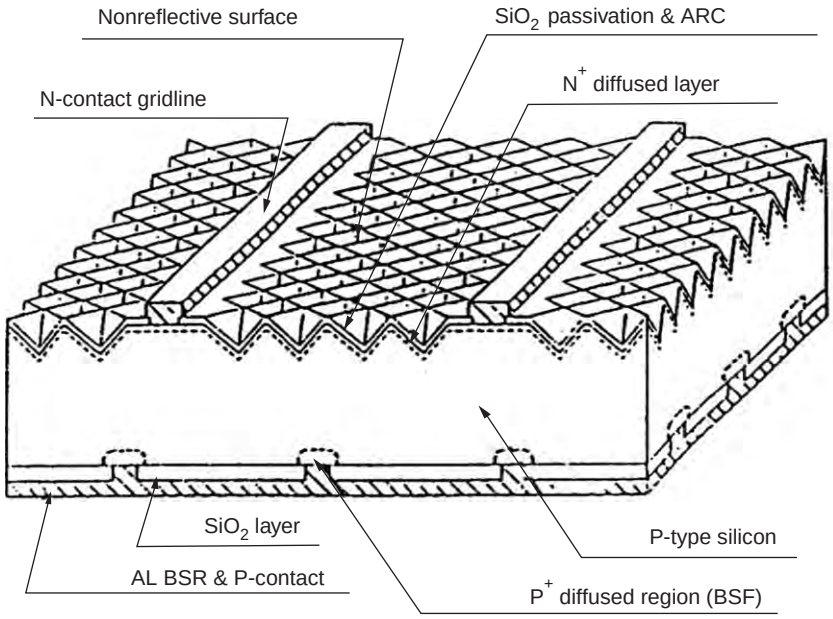

FIGURE 2 Structure of advanced space silicon cell.

23%. Figure 3 shows the cross section of a TJ cell. In addition to the three PN junctions, there were many other layers for passivating interfaces and surfaces and for effectively conducting current through the cell. The growth and properties of all these layers were systematically optimized and controlled by computerized growth programs. Consistency of performance was checked by advanced characterization procedures after each reactor run. The costs resulting from the higher complexity were slightly higher than for GaAs/Ge cells but were offset by the superior performance.

Testing showed that when some multijunction cells in a series string were shadowed, they often degraded. To prevent this shading loss, each MJ cell required its own bypass diode. At first, discrete diodes were used, but now each TJ cell includes a bypass diode formed during OMVPE growth of the cell.

Development of four-junction cells promises efficiencies of 33–35%, but to date efficient four-junction cells have had severe material problems.

2.2.3 Indium Phosphide-Based Cells

Cells containing indium and phosphorus (InP and $GaInP_2$) have high radiation resistance and show recovery of output after radiation. These cells, especially InP grown on Si substrates, are candidates for orbits with very high radiation levels, including MEO or near to Jupiter.

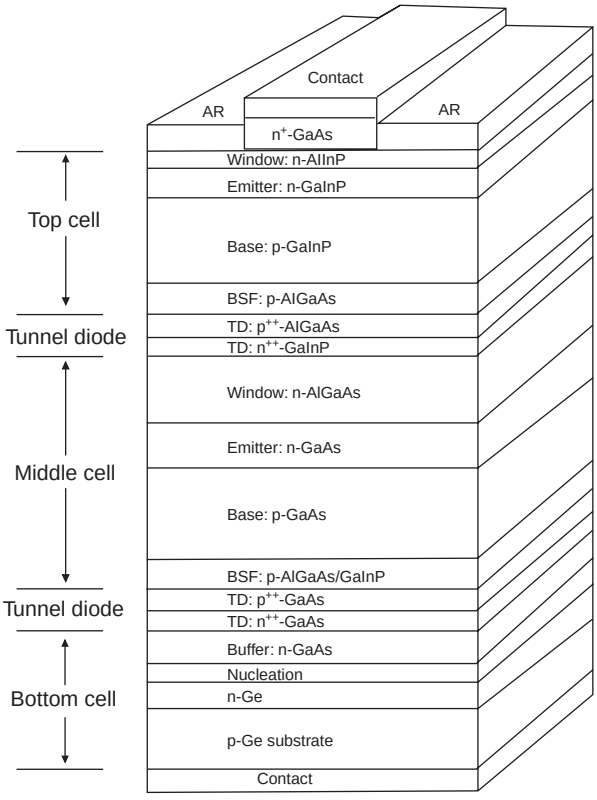

FIGURE 3 Cross section of triple-junction solar cell.

2.3 Thin Film Cells

Thin film (TF) cells, such as amorphous Si or copper-indium-diselenide ($CuInSe_2$), have advantages of low mass, easy deployment, and low cost. However, TF cells with efficiencies of 8–10% AMO have required the use of heavy substrates, which offsets their advantages. TF cells may find use for Mars bases or orbital transfer.

2.4 Solar Cells with Concentrators

With slight redesign, mostly of the front contact gridlines, all solar cells have higher efficiency when incident sunlight is concentrated by lenses or mirrors. Near-Earth operation is limited to low concentrations (five suns) because of the difficulty in removing excess heat from the arrays. However, for far-Sun missions, lightweight concentrators have been used successfully to increase the low intensity and low temperatures leading to higher solar array output.

2.5 Adapting to a Variety of Missions

All solar cells can be modified to perform a wide range of different space missions, but the TJ cells have proved to be most effective. Triple junction cells are versatile, being effective for far-Sun journeys and on the Martian surface. They also perform well in near-Sun operation. Closer to the sun, array temperatures are reduced by tilting arrays away from direct sunlight. At temperatures of approximately 120°C, Ge cells become inoperative and TJ cells become DJ cells, still with high efficiency and sufficient output at the increased intensities.

3. PROGRESS IN PHOTOVOLTAICS

3.1 Power Needs

Photovoltaic power systems have evolved to meet the increasing demands for electric power on a wide range of spacecraft. Cell efficiencies, array designs, and reliability have steadily improved (Table II). Until the 1980s, Si solar cells were used most, and since then GaAs/Ge or multijunction (MJ) cells have been used to meet the specified power needs. Most

TABLE II

satellites have performed successfully with PV power levels of a few kilowatts or less. To handle increased data requirements, communications satellites must deliver power levels up to 15 kW, using MJ cells and sometimes low-concentration mirrors. Even higher power levels are needed for constellations of communications satellites. An example is Iridium, comprising 66 satellites, each delivering approximately 4 kW for a total of approximately 250 kW.

Manned space stations require high power. The International Space Station uses large-area, coplanar back contact Si cells specially designed for deployment of large-area, lightweight arrays. Two wings, each approximately 100 ft long and 40 ft wide, deliver approximately 150 kW, and plans call for adding further wings to produce more than 400 kW. This is approximately 10,000 times the average power available on satellites in the early 1960s. The estimated working life of these cells is 10–20 years.

Some well-publicized spacecraft provide good examples of adapting PV technology to suit the mission. The Mars Pathfinder lander derived approximately 200 W from the unfolded panels and 16 W from the Sojourner robotic rover. GaAs/Ge cells were used, and the output of one cell was monitored to measure the gradual loss of power as Martian atmospheric dust settled on the cell.

Other satellites have approached or landed on comets or asteroids. Deep Space I traveled approximately 100 million miles into the asteroid belt. Its PV arrays consisted of MJ cells with lightweight Fresnel lens concentrators, giving approximately 30-times concentration. In addition to operating on-board equipment, the PV arrays powered an ion engine that propelled the satellite on its journey. This solar electric propulsion technology is promising for travel within the inner Solar System.

3.2 Interaction with Mainstream Photovoltaics

There has always been close cooperation between groups developing space cells and those developing terrestrial cells. For many years, Si space cells had the highest efficiency, but terrestrial Si cells were developed with significantly increased output. Space PV has been a highly visible showcase for high-efficiency cells. The process procedures for Si space cells were the most consistent available for objective evaluation of the terrestrial solar cell potential of many forms of solar-grade Si. High-efficiency MJ cells designed and operated under incident sunlight concentrated 500–1000 times have promise for large-scale terrestrial PV applications. III–V semiconductor optoelectronic technology has benefited from PV experience with large-scale OMVPE reactors.

4. FUTURE TRENDS IN SPACE PHOTOVOLTAICS

4.1 To 2012

In the next decade, there will be continued and increased demand for PV power on a wide range of missions. Higher power levels will be required, especially for communications satellites and manned stations. Plans call for exploration of Mars or the

moon to prepare for later manned bases. Development of very small satellites used for smart sensing will begin.

Advanced array designs will be developed, and solar electric propulsion will be used for travel to distant destinations. Some satellites will have to operate in high-radiation fields, including ME orbits. For these missions, solar cells with very high radiation resistance will be needed, probably InP or $GaInP_2$ cells, which have high tolerance to radiation damage as well as the ability to recover later while illuminated by the sun.

Thermophotovoltaic cells developed from III–V solar cell technology may be used to convert heat generated by radioactive isotopes to provide electric power for satellites journeying to distant planets such as Pluto or beyond.

Space-qualified four-junction cells with efficiencies in the mid-30% range will continue to be developed, with effort directed to resolve the severe materials problems involved. The need for higher efficiencies may be relaxed somewhat if transponders can be built to use less power or if electronic circuit designs can further compress the data handled on the satellite.

Current solar cells and arrays and their manufacturing base can probably meet all space power needs in the next decade.

4.1.1 Unmanned Aerial Vehicles

Several applications currently provided by satellites are being planned for unmanned aerial vehicles (UAVs), which include high-flying unmanned airplanes, airships (blimps), or balloons. PV arrays provide propulsion power for the airplanes and airships and power the electronic equipment on the UAVs. UAVs operate at altitudes as high as 100,000 ft for periods of months, and they can be used for surveillance, crop monitoring, or as communications links. The solar arrays on UAVs must be highly efficient and lightweight, and current space-use solar cells are best suited to this application. Current UAV plans call for 50 kW per vehicle, in the next decade increasing to several hundred kilowatts of PV power for constellations of UAVs.

4.2 After 2012

In this period, other power generators, possibly nuclear, will be developed and become available for use in space. It is difficult to predict the needs for space PV beyond 2012, but PV will continue to play a major role. There will be continued extension of most of the previous missions. Manned bases on Mars or the moon will require large amounts of PV power, and it is an advantage that PV systems are modular, allowing large power stations to be assembled during a series of flights.

The problems in manufacturing four-junction cells will be resolved, providing cells with efficiencies of approximately 35%. Long term, there are exciting possibilities to increase efficiencies perhaps as high as 60–90%. These cells, called "third generation" by Martin Green, will require advanced control over semiconductor material properties and possibly application of nanotechnology. Resolution of these material problems and validation for space use are not anticipated until well after 2012.

After 2012, significant advances will be made in the use of small satellites (called microsats or nanosats). These nanosats will act as smart sensors, operating in autonomous clusters or "swarms."

In the future, there may be some very large-scale applications of PV power in space. These projects will require significant advances in solar cell and array technology and use of very sophisticated manufacturing methods. Some of these applications may involve assembly in space, and in the distant future solar cells may be manufactured using lunar materials. The following sections discuss some of these large-scale applications.

4.2.1 Space Power Satellites

Peter Glaser proposed placing large satellites in geosynchronous orbits to provide terrestrial power. The satellites would carry very large-area solar arrays, generating many megawatts (or even gigawatts) of electric power. This power would be converted to microwave power, to be beamed to Earth, and converted back to electric power. In principle, the satellites receive full AMO sunlight for almost 24 h per day. However, this advantage is offset by the conversion losses incurred in beaming the power to Earth. Power satellites are more attractive for regions that have low sunlight levels or restricted areas for deploying PV arrays. There are many problems to be resolved, including the cost and complexity of building and maintaining large arrays in space and in controlling and beaming large amounts of power. Also, at this future time, improved terrestrial PV power generators will be widely available at reduced costs, requiring assessment of whether the many problems with space power satellites justify their use to meet terrestrial needs.

Even more ambitious long-term proposals call for installing several bases containing PV solar arrays on the moon. The electricity would be carried by buried

lines to microwave generators beaming power to the earth.

4.2.2 Space Colonies

Colonies living in satellites located at stable positions in space, between the earth and the moon, will require large amounts of power to sustain life and operate equipment. Preliminary plans call for PV power combined with solar–thermal converters.

4.2.3 Space Cities

Arthur Clarke's concept of cities located at GEO altitudes uses space elevators to transport materials and electric power to orbit. This is a very speculative project, requiring materials that can support structures 23,000 miles long. If successful, it would require removing most of the LEO and GEO satellites operating at that time.

5. CONCLUSION

For almost all of the space age, PV has been a prominent and essential key to successful operation of thousands of satellites performing a wide variety of activities. This continuing niche market has shown great resilience, sustained by the manufacturing of space solar cells with significantly increased efficiency and high reliability. Steady improvement in space cells has served as a focus for general research on high-efficiency cells. The programs to develop III–V-based cells demonstrated that large-area, good-quality crystalline layers could be grown in large-capacity OMVPE reactors. Pioneering work led to the use of Ge substrates for these cells. Some of the experience gained with space cells designed to operate at high concentrations has led to possible terrestrial applications. The unique need to deal with the degrading effects of charged particle radiation on space cells has added considerable understanding of the effect of radiation on semiconductor properties. Current manufacturing technology for space cells and arrays can deliver power for most satellites planned for the next decade and probably beyond. Based on the good record to date, PV power will continue to make major contributions to many exciting space projects.

Glossary

autonomous electricity supply system Any electricity supply system that operates independently from the grid, be it in remote locations, mobile, or grid-independent applications for which a grid is nearby.

backup generator Controllable source of electricity in photovoltaic hybrid systems (e.g., based on a piston-type engine).

charge controller Electronic device to control the charging and discharging of batteries and thus protect the batteries.

grid-connected photovoltaic system A photovoltaic system that feeds power into the electricity grid using an inverter.

hybrid system Autonomous electricity supply system based on at least two sources of electricity, such as photovoltaic, wind, or diesel generator, always including a battery storage.

inverter Power electronic device to convert direct current (DC) to alternating current (AC).

maximum power point (MPP) The point of operation at which a photovoltaic module provides the maximum power output.

minigrid An AC electricity grid that forms an island and is not or not always part of the regular grid. Minigrids can be used to power small regions or villages or to maintain the power supply in a region when the main grid fails.

solar home system (SHS) Autonomous DC power supply system for light, radio, or TV used for rural electrification of single houses.

stand-alone PV system Autonomous electricity supply system based on photovoltaics as the power source.

Power supplies based on photovoltaics (PV) were first used commercially for space applications and small appliances, such as pocket calculators and watches. Because of lower prices of PV modules and growing experience in PV system design, higher power ranges have become technically and economically viable.

1. APPLICATIONS OF PHOTOVOLTAIC SYSTEMS AND MARKETS

There are a vast number of applications for photovoltaic (PV) technology, covering all kinds of autonomous systems as well as grid connection (Fig. 1). The power range is extremely wide due to the modularity of PV power, from milliwatts to megawatts. To improve the economics or to use the variety of available energy sources, in a power range of kilowatts and higher so-called hybrid systems are often used. They combine two or more power generators, such as PV, wind turbines, diesel generators, or microhydro generators.

Driven by large market introduction programs, an increasing share of PV capacity has been installed in grid-connected applications. In 2000, these exceeded 50% of the market of the 20 International Energy Agency member countries for the first time (Fig. 2). Due to strong interest in PV technology, further growth of grid-connected systems is expected. However, in the long term the larger economic potential lies in off-grid power supplies. It is estimated that approximately 2 billion people live without electricity from the grid. Autonomous power supplies based on PV or PV hybrid systems are cheaper than diesel systems or grid connection in many of these cases. Socioeconomic and sociotechnical issues are the main barriers to large-scale market takeoff.

2. SYSTEM CONCEPTS AND SPECIAL ASPECTS

2.1 Autonomous Systems

2.1.1 PV Products and Applications Based on PV Only

Simple autonomous power supplies consist of a PV generator, a charge controller, and a storage unit. However, since batteries have a complex behavior with respect to aging, state of charge, temperature dependencies, etc., the charge controller can have a simple voltage-dependent charge/discharge control or complex algorithms.

Figure 3 shows a solar home system (SHS) as an example of an autonomous power supply system

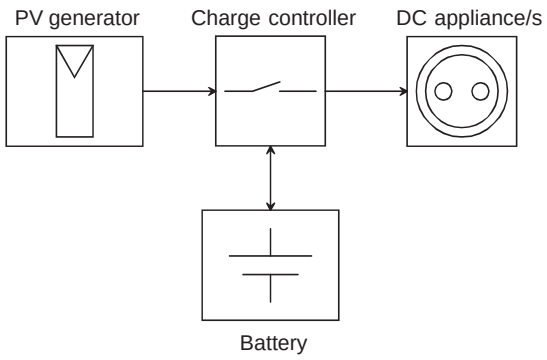

FIGURE 3 Typical configuration of a solar home system.

based on PV only. Typical component sizes are 50 W for the PV module and a 12-V, 70- to 120-Ah lead acid battery; direct current (DC) appliances for this system are compact fluorescent lamps, a radio, and a black-and-white TV set. Typical electricity consumption of such systems is up to 250 Wh per day. In some electrification programs, alternating current (AC) appliances are used in SHSs instead of DC appliances. This requires an additional inverter with a peak power in the range of 150–500 W.

2.1.2 DC-Coupled PV Hybrid Systems

If larger power or energy demand is to be satisfied, additional generators must be introduced into the system. This particularly applies if solar irradiation varies widely throughout the year. To guarantee a reliable power supply during wintertime, large PV generators and storage units are required in these cases. Wind, hydro, or diesel generators are also typically used (Figs 4–6).

Introducing additional components can lower overall electricity cost but also increase the need for energy management and maintenance. Energy management considers the profile of electricity generation from PV or other renewable energy sources, the battery characteristics, and the energy demand of the appliances. To economically optimize energy and battery management, predicting the fluctuating sources (PV, wind, and hydro) can be helpful. The appliances can be either DC or AC. In the latter case, an inverter is used to provide AC electricity. Additionally, an AC bypass from the diesel generator can be used as backup for AC appliances.

2.1.3 AC-Coupled PV Hybrid Systems

Instead of coupling generators and battery storage via a DC bus, hybrid systems can also be AC coupled. The extend to which DC busses are avoided can vary. Fig. 7 shows a system layout in which the

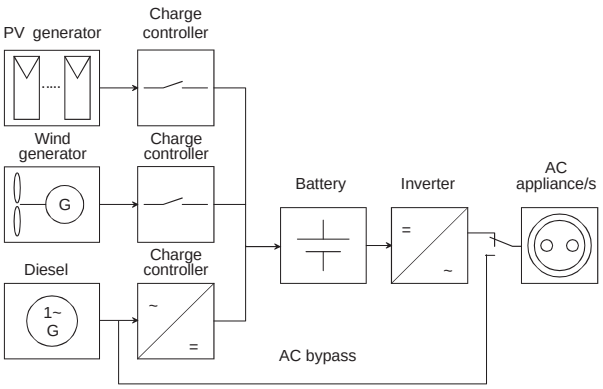

FIGURE 4 Typical layout of a DC-coupled hybrid system.

FIGURE 5 The Rotwand house in the German Alps. Electricity is provided with a PV, wind, and diesel hybrid system in operation since 1992.

PV generator and battery are connected via a DC bus and additional generators are AC coupled to the system. Using the concept of modular system technology, DC coupling is completely avoided and the battery is equipped with extra power electronics (Fig. 8). Modularity adds to the cost of additional equipment and power conversion losses.

In AC-coupled hybrid systems, an island grid is built. There are different ways to achieve this, particularly concerning stability and fast voltage control. In the most common design, one component

FIGURE 6 A telecommunication repeater station powered by a PV hybrid system.

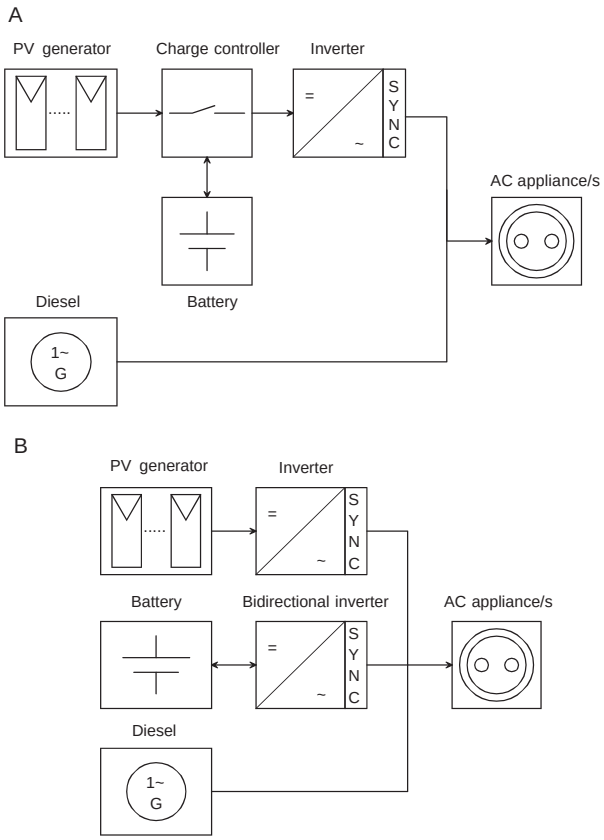

FIGURE 7 Typical layouts of AC-coupled systems (A) with PV generator and battery coupled via a DC bus and (B) following the modular system technology concept.

acts as the voltage source and constitutes the grid, setting voltage and frequency (e.g., 230 V and 50 Hz). The other AC generators then feed in their power, acting as current sources. Reactive power demand (either capacitive or inductive) is provided by the generator acting as a voltage source. The advantage

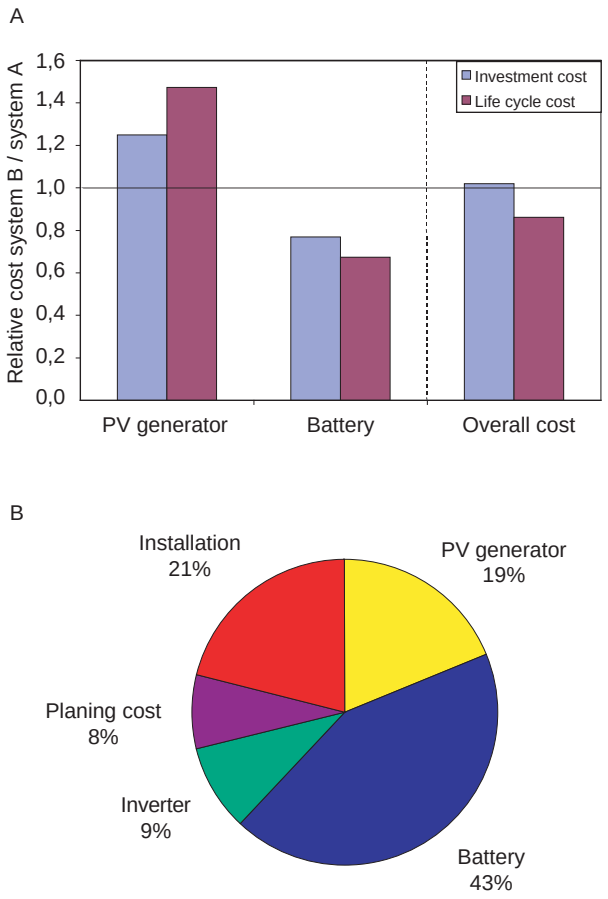

FIGURE 8 (A) Comparison of calculated costs for two systems in Mexico. The systems will provide 1500 kWh per year for 20 years. The interest rate is 6%. System A is optimized toward minimum investment cost and system B toward minimum life cycle cost. In system B, costs are shifted toward the PV generator to reduce the battery stress. Although both systems have approximately the same investment cost, system B has 14% less life cycle cost. The more complex hybrid systems are, the more benefit such economic optimization can yield. (B) Shares of life cycle cost for system A. The battery accounts for more than 40% of overall life cycle cost.

is a relatively easy control structure. However, overall system efficiency may be negatively affected, for example, if a diesel generator is used in building the grid and is mainly running idle just to maintain the grid voltage. Furthermore, if fast load or generation changes occur, the constituting component (diesel or inverter) has to cope with them solely and provide all extra power.

As for large electricity networks, new control concepts distribute this burden to several or all generators, which also build the grid (i.e., constitute the AC voltage). Using droop characteristics for frequency and voltage control is one approach to synchronize the voltage control without the need for very fast and excessive communication between components. The first systems of this type have recently been introduced into the market.

Independent of how fast voltage control is achieved, in DC hybrid systems and AC-coupled systems an overall energy management system determines which components operate and at which power level, thus optimizing energy and battery management.

2.1.4 Main Design Criteria for Hybrid Systems and Advantages and Disadvantages of Different System Concepts

As the number of different types of generators bound together increases, so does the complexity of the system. This also applies if several generators of one type are introduced into the system (e.g., in the case of expansion). Thus, depending on the type of application and the prospect for changing needs in power supply following installation, a number of criteria must be considered during the concept design phase. Some of these are contradicting, so trade-offs must be made.

One of the most expensive components of such systems, the PV generator, has a long lifetime of approximately 20 years. Thus, in order to fully make use of this investment, many systems are designed for such long lifetimes, with the following specifications:

- Lowest possible life cycle cost: The cost structure of autonomous power supply systems is often complex and strongly dependent on operation schemes and depreciation times (e.g., 20 years).
- Stability against load and generation variations: Daily, monthly, and yearly profiles of the load as well as generation by renewable generation vary widely over time. Furthermore, over the years, the amount of energy needed changes in most applications. For example, additional loads might be connected over the years. In applications such as lighting systems in bus stations, rare blackouts are acceptable. In many others, they are not. The system design must be stable against such variations and have a minimum of costly overcapacity (e.g., during summer).
- Modularity and flexibility: If load or generation change too much, the system hardware needs to be changed. Usually, this implies an expansion due to increased energy demand. It must be possible to adapt the system with minimal engineering effort regarding the hardware and the energy management algorithm.
- Maintenance and repair: Over the course of many years of operation, maintenance is crucial. The

system must be as easy to maintain as possible. Also, the availability of spare parts may be crucial.

- Voltage stability and quality of power supply: Quality of power supply does not only include the availability of power and energy but also the quality and stability of the voltage. Especially in AC-coupled systems, this implies strong demand for fast current and voltage control.
- Socioeconomics: In most applications, users interact with autonomous power supplies. Be it in remote houses, village power systems, or for SHSs, without taking sociotechnical and socioeconomic factors into account, the system will fail over the long or short term. This is of particular importance for rural electrification.
- In certain applications such as telematics and signaling, in which blackouts can lead to accidents, the reliability and safety of power supply are of utmost importance.

Many of these demands are contradictory, making optimization complex and susceptible to changed boundary conditions. Thus, new system designs have been developed to more easily and flexibly optimize systems during the planning phase as well as during operation. The designs for energy management constitutes the most important system characteristics and are thus described in more detail.

2.1.5 Energy Management in Off-Grid Systems

Energy management is usually achieved by one central intelligence. All system parameters, such as generator and storage sizes, storage characteristics and charging/discharging strategies, weather forecast (e.g., for PV and wind), and user profiles are fed into the system before operation. Using these parameters and actual measured values of voltages, currents, temperature, PV generation, etc., the system operation is optimized. In addition to standard software, fuzzy logic and artificial neural networks are also used. However, expansion or changes to the system require changes to these system parameters. Furthermore, the system operator requires data that are often not well specified on data sheets, particularly for the battery and the backup generators. Thus, determining a proper operating strategy is difficult.

Alternative methods from automation and control in industrial applications or from management of distributed generation try to decentralize as much intelligence as possible, combining a central control unit with one decentralized control unit per generator, storage, or load. Corresponding software concepts can vary from hierarchically controlled communication and interaction to software agents. In all these cases, component information is stored in a device preferably provided by the component manufacturer. Using measured values, this device is also able to compute cost functions and the availability of the generator or storage (e.g., using the filling state of the diesel tank and maintenance intervals). For these calculations, some information may be provided by the central control unit, such as weather forecasts or the cost for maintenance personnel to visit the site of operation. All cost functions and limiting conditions from the components are then used to optimize the system operation (e.g., using virtual trading schemes). Thus, there is no need to change the energy management parameters when changing the system design. New components are registered and removed components are deregistered automatically and provide data and cost functions in a generic format. The virtual stock market takes into account all registered players at a certain time. Such flexible systems are currently under development and not available on the market.

2.1.6 Cost Structure of Autonomous Power Supply Systems

Autonomous power supply systems often have long lifetimes or depreciation times of up to 20 years. Thus, to develop a mature system design, life cycle cost needs to be considered rather than investment cost. The following are especially important to consider: the complex dependency of aging of the battery on the operating conditions (batteries need to be replaced every 4–8 years), repair or replacement of electronic components, costly maintenance in remote locations, and the cost of financing and penalties for electricity demand that may not be met (if allowable). Because weather profiles differ from year to year, the technical optimization should be based on long time series of 20 years. The difference between systems optimized toward investment cost and those optimized toward life cycle cost is shown in Fig. 8. The main difference between system designs is that, if optimized toward minimum life cycle cost, the battery costs are reduced by appropriate design and operation strategies and by the expanded lifetime or more efficient use of the battery. It is important to note that in autonomous systems the PV generator is not the largest cost factor and that the overall life cycle cost of the system is typically approximately three times more than the pure investment cost (considering interest payments, replacement of components, maintenance and repair, fuels, etc.). When designing an autonomous power

supply, the choice of power generators and their sizes should be determined only with respect to overall lifetime costs. All options should be considered. Nevertheless, in many cases PV or PV hybrid systems are the most cost-effective solution.

2.1.7 Socioeconomic Aspects of Autonomous Systems and Rural Electrification

Autonomous power supplies are the most promising technology for the 2 billion people living without electricity today. During the past few decades, in all regions of the world many projects have demonstrated the technology and its viability. However, a large number of these projects were not sustainable due to equipment failure after a few years, payments not being made by the rural customers, or electrification programs not being accepted by the population as a viable alternative to grid connection. From such projects, many lessons have been learned providing valuable feedback for the design of components and systems as well as business models, infrastructure programs, and policy.

In rural electrification, it is of utmost importance to include cultural aspects in technology and business model design. Sustainable projects and thus sustainable business require not only a screening phase of the respective region and a planning and implementation phase, but also sociotechnical monitoring during operation and ongoing analyses to adapt the strategy. Companies and staff have to learn the specifics of rural electrification and the sociocultural backgrounds of the people, and they must understand that rural electrification is a process. The following issues are crucial:

- There is often a gap between the energy demand and the supply by the PV or PV hybrid system after a short period of time. Once electricity is available, people buy new appliances and consume more energy than expected. This particularly applies if there is little "ownership" for the system (e.g., if a village power supply is used by many users). In this case, the cause (too high energy consumption) and the effect (blackout) are not easily linked to the individual user. In any case, if demand is too high and cannot be met, dissatisfaction is created, possibly leading to stoppage of payments, etc. Although difficult, the future electricity consumption needs to be evaluated before the system is installed.
- Due to erroneous handling of components and systems, these systems degrade or break more quickly.
- Replacement of components is time-consuming and expensive. It is vital to develop a minimum density of systems within a certain area and to install an adequate infrastructure. This includes measures for capacity building, such as training of technical staff and users.
- Lack of financing, especially after several years of service, is often experienced. There might be clear reasons, such as dissatisfaction of customers, but even if the systems run properly, payments tend to decline significantly after several years. Financing schemes and business models need to take this into account.

2.2 Grid-Connected Systems

Grid-connected systems constitute the largest market share for photovoltaics. Major driving forces are market introduction programs in Japan, Germany, and the United States. These systems are targeted at households. Typical system sizes range from 1 to 5 kW. However, there are commercial actors and many systems more than 10 kW and up to several megawatts have been built (e.g., utility owned or joint ownership). The power of inverters that is required to feed the PV electricity into the grid ranges from 100 W to more than 100 kW.

The smallest inverters are module integrated ones, with each single PV module having its own inverter. Main advantages are lower losses at partial shading and lower mismatch losses between modules due to individual maximum power point (MPP) tracking and less demanding cabling because standard AC cables can be used. DC cabling and switches are more expensive because in the case of faults arcs can cause fire. On the other hand, maintenance and repair of many small inverters are more difficult and communication between inverters (e.g., to determine the overall output) requires higher effort. Cost benefits have not yet been realized. It has also been reported that large numbers of module integrated inverters influence each other through increased harmonics on the AC line. Today, few systems are built with module integrated inverters.

The most common system is shown in Fig. 9. A number of PV modules are connected in series to form a string, typically with output voltages at the MPP of 700 V. One or more parallel strings are connected to one inverter to feed the power into the grid. Depending on regulations and inverter power, either one-phase or three-phase inverters are used. Often, large systems are built using many inverters in the range of a few kilowatts. Again, the modularity of PV electricity is apparent.

In addition to the modular concept shown in Fig. 9, for large PV systems, large inverters are used with up to 250 kW or even 1 MW per unit. Both designs, few large inverters or many medium-size inverters, are motivated by cost and neither is superior by principle. The first makes use of the economies of scale, and the latter makes use of the economies of quantities.

The generation profile of PV systems strongly depends on location. In the Northern Hemisphere, most of the energy of PV systems is yielded at partial load, as shown in Fig. 10. Thus, high inverter efficiency at partial load is mandatory. Furthermore, PV inverters with a nominal power rating between 10 and 20% below the peak power of the PV generator are typically used. The inverter is able to handle short periods of overload situations and the energy loss is small compared to the cost reduction due to the smaller inverter.

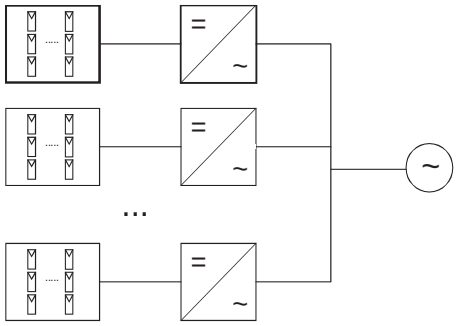

FIGURE 9 Configuration of a grid-connected PV system consisting of several strings.

The performance ratio is used as a measure of the quality of PV systems that is site independent with respect to insolation. The performance ratio is defined as the annual AC energy output of a PV system divided by the annual global insolation in the module plane weighted with the nominal PV module efficiency. Good systems achieve a performance ratio of approximately 0.75. For larger commercial power plants, values of approximately 0.80 should be obtained. The performance ratio aggregates most component and system characteristics: mismatch losses between modules and strings, real module efficiency compared to nominal efficiency, inverter efficiency, and quality of MPP tracking.

2.2.1 Safety

Technical standards, and thus system layouts and inverter concepts, differ from country to country.

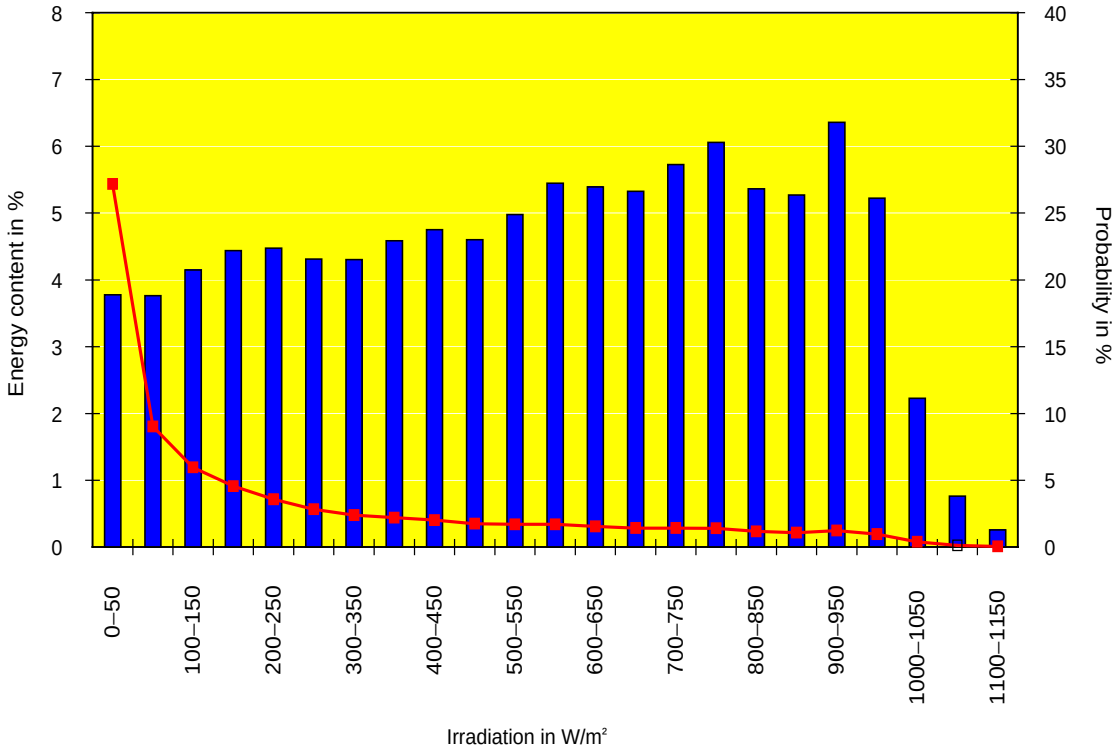

FIGURE 10 Distribution of the energy yield of a PV system in southern Germany. The bars show the energy content for each class of irradiation, and the line shows the probability of the occurrence of this class with respect to time. Most of the electricity is generated at partial load.

Whereas in the United States earthing of the generator is mandatory, in European countries the use of isolated modules (safety class II) is standard. This also allows different inverter designs, particularly transformerless inverters, which have been increasingly used due to their lower weight and higher efficiency.

In addition to earthing, protection against islanding as well as fault current detection in systems with transformerless inverters are necessary, and these are treated rather differently. Islanding is a phenomenon in which during a blackout distributed power sources such as PV systems keep a grid segment—an island—live. This could pose a danger to users, maintenance personnel, and equipment. However, the prerequisite for islanding is that active and reactive power supply by the distributed sources and the active and reactive power demand in the segment be very close. Thus, to prevent islanding it is sufficient to measure voltage levels and frequency and automatically disconnect the inverter if the standard margins are left. If the maintenance personnel follow the safety rules, PV systems do not pose any danger. However, often much more complex methods are used to prevent islanding. With standardization of PV system technology, this might change.

2.2.2 Metering and Cost

To meter the electricity generated, either an extra meter is installed or the electricity is fed, for example, into the house wiring that supplies existing loads (net metering). In the latter case, if PV generation exceeds the actual load, either the meter runs backwards or an extra meter measures the excess electricity.

The generation cost of PV electricity in grid-connected systems varies between approximately 30 €c in sunny regions and 60 €c in northern Europe if good practice is assumed. Unlike in autonomous systems, the PV modules contribute the largest share of life cycle cost. Further cost reduction, however, is achievable using inverter technology and better installation practices.

2.2.3 Building Integration Aspects

Solar energy by nature is a distributed energy source. In order to optimally use existing infrastructure and not unnecessarily seal additional areas, building integration is the best option for grid-connected PV. The PV modules can also provide the following:

- Weather protection (wind and water)
- Sun protection (glare and heating of buildings)
- Use of daylight
- Noise protection
- Act as a blind
- Shielding of electromagnetic fields
- Aesthetics

As such, there are a large number of PV module technologies involving isolating and nonisolating modules, different mounting principles, different module and cell colors, etc.

The cost of integrating PV in rooftops and facades and that of the required standard material can be regarded as a credit. Particularly for facade integration, for which costly material such as marble or metal constructions are often replaced, this can compensate a large share of the overall system costs. This remains true even though facade-integrated PV modules have a significantly lower energy yield due to the nonoptimal tilt angle. In northern Europe, the energy yield is reduced by approximately 30–40% (Fig. 11).

For roof and facade integration, shading of PV modules and operation temperature are of special importance. If one module of a string of modules is shaded, the output of the whole string can be dramatically reduced, depending on the connection scheme and the use of bypass diodes. Thus, particularly for PV facades, which often experience complex shading situations from neighboring buildings or trees, the system must be designed carefully. System parts that are shaded during certain times should have a separate inverter and should be made less susceptible through the use of additional bypass diodes.

Because temperature affects the performance of PV modules, rear ventilation by natural convection is

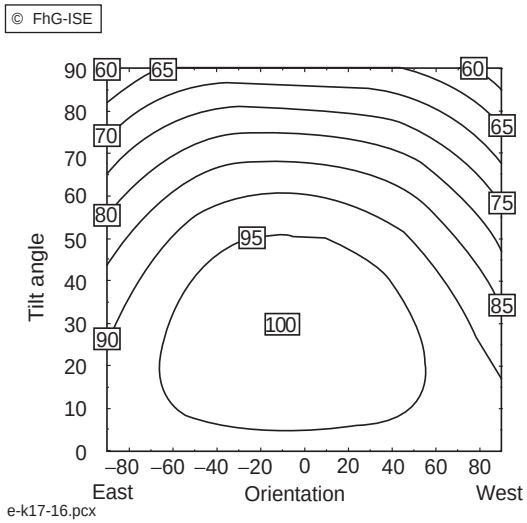

FIGURE 11 Maximum annual PV module yield as a function of orientation and tilt angle in Freiburg, Germany (48°N, 7.8°E).

another issue to consider for building integrated systems. The lower the temperature, the higher the yield. The difference in performance between PV modules with good ventilation and those with bad ventilation can be up to 10%.

2.2.4 Distributed Generation Aspects

Building integration of PV modules can provide significant additional value, as described previously. Another dimension of added value can be tapped if the service provided to the grid is considered. However, improperly integrated PV can also pose additional burden to the grid and thus cause additional cost. Possible factors are as follows:

- Correlation of PV generation and load (reduced peak load in distribution grids)
- Increased security of supply in weak grids (continued operation during blackouts in remote areas)
- Reduced distribution losses in cables and transformers
- Reduced load of transformers, cables, switches, etc. leading to reduced aging
- Deferral of investments for capacity expansion of existing grids
- Active compensation of reactive power or harmonics
- Reduced risk due to short lead times for planning and modularity of PV technology

The actual added or reduced value of grid-connected systems has not been studied. However, several case studies show that at least part of this potential can be tapped.

3. COMPONENTS OF PV SYSTEMS

3.1 PV Modules

Crystalline silicon solar cells comprise approximately 90% of the market share of PV modules. These PV modules typically consist of 36 cells, but other configurations can be bought off the shelf. The current-voltage curve of a 36-cell module fits very well to 12-V lead acid batteries, so simple autonomous power supplies can be built. However, the exact number of 36 cells is more historically motivated. With improved cell technology, even at higher ambient temperatures the module voltage would still be high enough to fully charge a lead acid battery if 32 cells were connected in series. Depending on climatic conditions, even less cells could be used.

The yield of a PV system is usually measured in kilowatt-hours per kilowatt peak (kWh/kW_p) and depends on several factors:

- Cell and module technology used
- Location/climatic conditions
- Tilt angle and orientation
- Mechanical installation (facade or roof integration, freely ventilated modules etc., influencing module temperature)
- Efficiency of system components (MPP tracking and conversion efficiency)
- Type of system

The area needed for 1 kW of PV power mainly depends on the cell and module technology used. Module efficiencies vary from several percent (for some thin-film modules) to approximately 16 or 17% for monocrystalline silicon solar cells. Typical module sizes for grid connected systems range from 50 to more than 300 W. Especially for solar lanterns and lighting, modules in the range of 10–20 W_p are available. Because 36 cells per module are standard, smaller modules are made from cells that are cut into half or quarter cells. Thus, small PV modules with crystalline silicon solar cells are more expensive. This does not apply to thin-film modules.

The performance of PV modules depends on their operation temperature. Depending on the technology used, the temperature coefficient is between -0.2 and -0.5%/K. Thus, the type of installation and degree of rear ventilation are important.

PV modules are rated in watt peak under standard test conditions (STCs). The STCs are defined as 1000 W/m^2 insolation with a AM solar spectrum of 1.5 and 25°C module temperature. However, these conditions rarely occur in real systems. Thus, PV generators can actually yield significantly less or more energy than rated, depending on the location, climatic conditions, etc. However, there is no widely accepted alternative rating model that takes into account more realistic reporting conditions. Furthermore, there is relatively large uncertainty of the measurements at the manufacturing plant and on site. Spectral mismatch, temperature distribution, etc. comprise approximately 3–5% of uncertainty. Overall deviations in systems measurement can be 5–10%.

Whereas in grid-connected systems usually all energy can be fed into the grid, in autonomous systems part of the energy yield in summer cannot be used due to limited storage capacity. Thus, the tilt angle of PV modules in autonomous systems is usually optimized for large energy yield during winter. The overall yearly energy yield is reduced.

Fig. 11 shows the maximum energy yield of PV modules as a function of orientation and tilt angle for the Northern Hemisphere (48°N, 7.8°E).

3.2 Batteries

Batteries are a central component in autonomous power supply systems based on PV or PV hybrids. As discussed previously, batteries contribute the largest share of cost of autonomous systems if life cycle cost is considered. Thus, except for small, portable systems, lead acid batteries are the most common technology used. They are the most cost-effective and have good electrical characteristics (e.g., energy efficiency in PV systems can be as high as 85–90%). Several different technologies for electrodes and electrolytes are available. Thus, for all applications suitable products can be chosen with a wide range of electrical and lifetime characteristics.

For reliable and economic operation of autonomous systems, the charging/discharging principle and system operation strategies are highly relevant in order to make full use of the installed capacity and reduce aging of the battery. In particular, most IV (current phase, voltage phase) charging strategies in autonomous systems rarely fully charge a battery if non-optimal conditions are assumed (e.g., during periods of reduced PV generation). Deep discharge in winter or during longer periods with little generation from PV or wind generators accelerate aging processes.

Depending on the application, different classes of systems can be defined that determine how the battery is stressed (Fig. 12). In addition to the dimensions of the system, the choice of battery type and operation strategy is strongly influenced by these classes.

3.3 Charge Controllers

Charge controllers ensure that the battery in autonomous systems is treated as well as possible, particularly that deep discharge and overcharging are avoided. Furthermore, some devices provide information about the battery state of charge. Modern charge controllers use charging and discharging procedures that take into account the battery temperature and the charging and discharging currents over time. Today, IV charging is state of the art, but new charging strategies are being developed [e.g., IVI (current phase, voltage phase, current phase) charging].

There are two basic designs for charge controllers in PV applications: series or parallel regulators. A series regulator adds a voltage drop between the PV module and battery, whereas a parallel regulator draws current from the PV module bypassing the battery (Fig. 13). Hybrid configurations have also been developed. In all cases, voltage regulation can be performed statically or can be achieved as an average by pulse width modulation. The advantage of the latter is reduced power losses in the

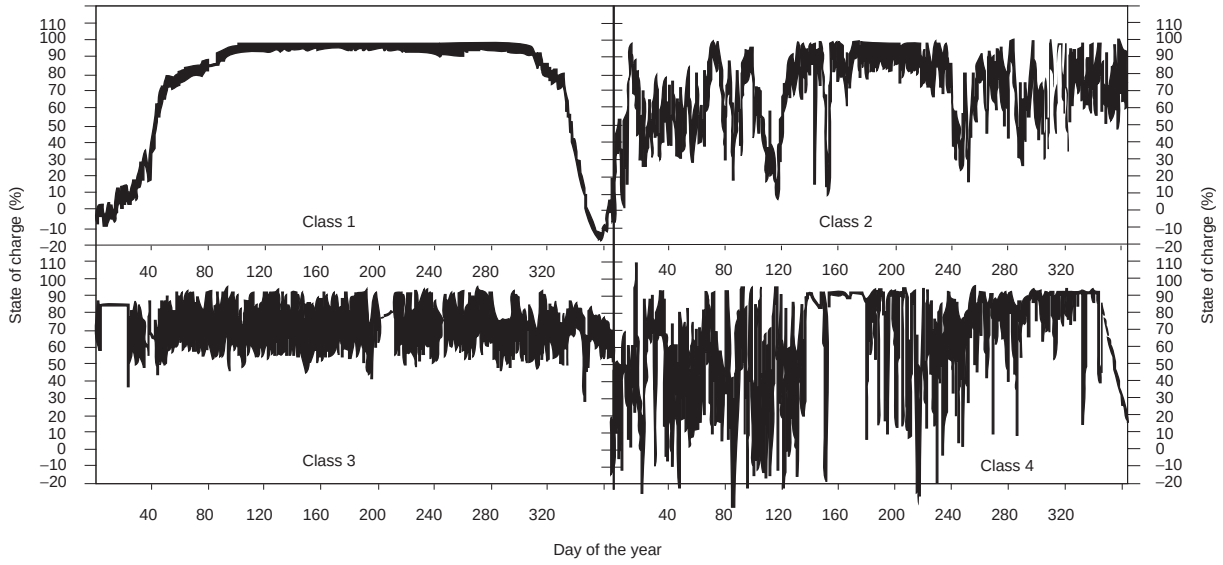

FIGURE 12 State of charge of the battery during a year for four typical operating conditions. The annual energy turnover ranges from approximately 20 times the nominal capacity in class 1 to 180 times in class 4. This demonstrates the different requirements for the batteries under different system designs.

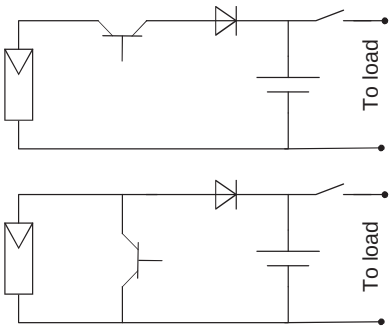

FIGURE 13 Basic principles of charge controllers: series (top) or parallel (bottom) regulator. To avoid deep discharge, the load can be disconnected. A series diode prevents reverse power flow through the PV generator.

semiconductor switch for the microcycles in the battery current and electromagnetic interference (EMI).

The most important functions of charge controllers are to

- Avoid high voltages during charging of the battery (temperature compensates cutoff voltage by −4 to −6 mV/K per battery cell)
- Avoid deep discharging of the battery
- Avoid extended periods without full charging of the battery
- Slightly overcharge once a month to ensure that the battery is fully charged and to promote gassing if applicable

Since some of these aims are contradictory, suitable compromises must be found (e.g., between avoiding high voltages to reduce corrosion and occasionally overcharging the battery to reduce sulfation).

Charge controllers should have a low internal consumption, high efficiency (96–98%), and make reverse poling impossible. They should withstand overvoltages (at least twice the open circuit voltage of the solar generator) and ambient temperatures of 0–50°C. Some charge controllers use DC/DC converters to adapt PV module and battery voltage. They can also perform active MPP tracking, whereas with most charge regulators the PV module is operated at the level of the actual battery voltage.

Additional functions, such as starting backup generators and stirring the electrolyte, might be added for systems of higher complexity. In any case, providing information about the state of charge or even state of health of the battery is crucial in order to enable the user to learn how to operate the system effectively, to establish optimal energy management, and to avoid detrimental deep discharging of the batteries.

3.4 Inverters

Inverters are used to convert the DC output of PV or a battery to AC electricity, either to be fed into the grid or to form an island system. There are many different types of power electronic topologies used in the market. Early PV systems were equipped with thyristor inverters, which were commutated by the grid. Due to their poor voltage and current quality (such inverters have very large harmonics), they have been replaced by self-commutating inverters (with IGBT or MOSFET as semiconductor switches). Only in the 100-kW power range are thyristor inverters still used. The first self-commutating inverters performed sine modulation of the output current on the primary side and had a 50-Hz transformer to adapt the voltage level to grid voltage. Such inverters still comprise a significant market share. Some manufacturers offer devices with high-frequency transformers instead, thus reducing the efficiency and the cost. In countries in which earthing of the PV generator is not mandatory, transformerless inverters are increasingly used. They are lighter and more efficient, but particular care must be taken with regard to EMI and fault current detection.

Whereas the first PV inverters were often adaptations of existing inverters for electrical drives, today's devices are manufactured taking into account the complexity and demands of specific PV applications. Inverter efficiency is generally important in PV applications but of particular significance at partial load because the bulk of the energy is yielded at partial load. Furthermore, with a large-area PV generator coupled to the DC side of the inverter and the public grid on the AC side, stricter standards have to be met with regard to harmonics and EMI.

Design criteria and functions of PV inverters are as follows:

- Efficiency: well above 90% efficiency at 5% of nominal load
- Cost
- Weight and size: inverters with a 50-Hz transformer typically weigh more than 10 kg/kW, sometimes causing a problem with handling
- Voltage and current quality: harmonics and EMI
- Overload capability: approximately 20–30% for grid-connected inverters and up to 200% for short-term overload for island inverters

- Precise and robust MPP tracking (reliably finding the overall MPP in partial shading situations)
- Supervision of the grid, safety/ENS (Einrichtung zur Netzüberwachung)
- Data acquisition and monitoring

To optimize inverters following these partially contradictory aims, the design of the power stages and control algorithms are increasingly more integrated. To implement suitable control schemes, digital signal processors are increasingly used.

To account for the fact that PV electricity is yielded following a typical distribution, in Europe a weighted efficiency measure is used to aggregate the efficiency curve of inverters—the European efficiency. Good inverters in the kilowatt power range have a European efficiency of 92–96% and up to 97% for large central inverters.

Inverters also perform MPP tracking in order to optimally operate the PV generator. Many different algorithms are used for MPP tracking for the following:

- Precision: high precision of MPP tracking requires high-precision measurement components
- Finding the global maximum power output in the case of partial shading, when a local maximum can occur
- Quickly adapting the MPP to changes in insolation (e.g., if clouds pass by).

3.4.1 Inverters for Island Systems and Minigrids

Inverters for island systems and minigrids are very similar to inverters for grid connection with regard to the power stages. Most inverter topologies are suitable for island operation as well. The major prerequisite is the capability to provide reactive power. The actual design of the power stages still differs significantly because in island systems the inverter requires a much higher overload capability. Furthermore, fast voltage and current control and higher dynamics of load profiles require appropriately dimensioned power stages.

Thus, there are major differences concerning control algorithms for voltage and current control. Particularly when several inverters are to be connected in parallel in island systems or when inverters are to be combined with other AC generators, achieving voltage stability is a complex task.

3.5 Backup Generators

In PV hybrid systems, backup generators are used to provide additional electricity in times of low insolation, to increase system availability, and to reduce overall electricity cost. In most medium or large power applications, diesel generators are the cheapest backup solution (backup capacity of 5 kW or more). In many countries, subsidized prices for diesel contribute significantly. However, the major disadvantages of piston-type backup generators are their need for maintenance every few hundred hours of operation and bad efficiency during operation at partial load, which is the common operation mode. In remote areas, access to the systems is often difficult or time-consuming, thus imposing extra cost for maintenance and fuel transport. The availability of spare parts and competent maintenance staff can be a major problem in developing countries in which diesel or PV–diesel hybrid systems are used for electrification of villages.

A major problem regarding relatively small hybrid power systems is the lack of suitable backup generators in the power range of 1 kW or less. Thus, oversized piston-type generators are sometimes used for applications in which 1-kW backup capacity would be sufficient. Due to the poor efficiency of diesel and Otto engines under partial load conditions, the overall system efficiency of such systems is not satisfactory.

In small hybrid systems, thermoelectric converters with a backup capacity of 10 to hundreds of watts are also used. In the medium term, fuel cells are an interesting alternative to small diesel or thermoelectric units because they promise high efficiency and low maintenance cost. However, the problem of hydrogen supply needs to be resolved.

Glossary

amorphous silicon An amorphous semiconductor that has allowed fabrication of moderately high-efficiency thin-film solar cells using a deposited layer of silicon–hydrogen alloy. It lacks crystallinity or the exact periodical arrangement of atoms.

buffer layer A thin layer inserted near the junction of a solar cell to enhance its performance, mostly by enhancing the voltage of a solar cell.

cadmium telluride A thin-film semiconductor that has allowed fabrication of high-efficiency thin-film solar cells.

copper indium diselenide A chalcopyrite semiconductor that has allowed fabrication of very high-efficiency thin-film solar cells.

diode A rectifying semiconductor junction. If designed appropriately, it will deliver electric power upon illumination and function as a solar cell.

silicon The most common material used to build semiconductor devices and solar cells.

solar cell A solid-state semiconductor device used for the direct conversion of light into electric power (i.e., photovoltaic energy conversion).

At the beginning of the 21st century, the direct conversion of sunlight into electricity (solar electricity) via semiconductor devices called solar cells or photovoltaic modules was commercially established. The total number of photovoltaic modules produced worldwide (approximately 500 MW in 2002) was much too small to be considered energy significant. However, energy significance can be expected between 2010 and 2015, when annual production levels of several 1000 MW per year are reached, based on expected annual growth of 20–30%. Assuming a conversion efficiency of 10%, 1000 MW of photovoltaic module power will cover an area of 10 km^2 or approximately 4 square miles. In a sunny location, an area of approximately 160 × 160 km (approximately 25,000 km^2 or 10,000 square miles) would be required to generate from solar power all the electricity currently consumed by the United States. Therefore, a tremendous industrial scale-up must occur to accomplish these goals. The material candidates likely to be used for achieving such commercial potential and the associated physics that relates to solar cell performance and performance limitations are discussed in this article.

1. SOLAR CELL OPERATION

1.1 Construction of the Solar Cell Device

A solar cell is a device that allows the collection of excess electric carriers, called electrons and holes, because of a built-in potential. When semiconductors are used to build such a device, the operation is determined by the bandgap [E_g, usually given in units of electron volts (eV), or voltage multiplied by the charge of the electron e] or energetic separation of the conduction and valence bands. Light is absorbed when the quantum energy of the light (the photon energy) is greater than the bandgap. Under the influence of the built-in potential and, to a lesser degree, gradients in the carrier concentration, carriers will flow from one side of the cell to the other. Electrons will move along the conduction band edge, and holes will move along the valence band edge. Figure 1 represents a solar cell in its most generic form. The schematic depicts the physical composition of layers, using terminology that typically describes

 © 2004 Elsevier Inc. All rights reserved.

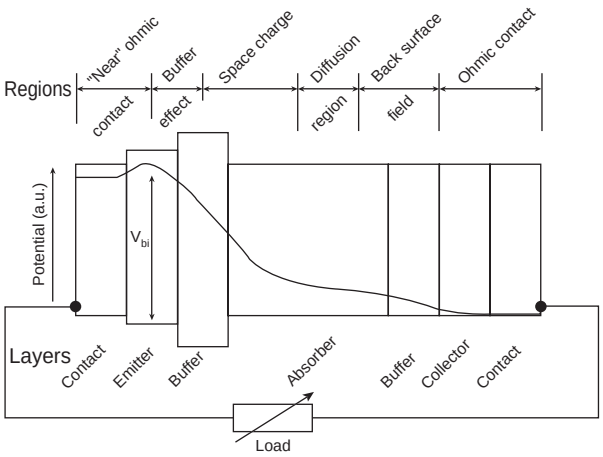

FIGURE 1 Schematic of a p-i-n diode. The potential is shown for no-lead (i.e., open-circuit) conditions.

thin-film solar cells. The terms along the top of the schematic indicate the electronic regions of the cell. The built-in potential, V_{bi}, will determine the maximum voltage that the cell could theoretically deliver. For a homojunction cell such as a crystalline silicon cell, the emitter and collector are usually formed by heavily doping the silicon p-type and n-type (as shown for the right-hand collector in the schematic). However, in heterojunction cells, the bandgaps of the materials making up the junction may vary (as shown for the left-hand side, i.e., the emitter in the schematic). For a homojunction cell, the maximum value of V_{bi} is approximately, but less than, E_g/e. In heterojunction solar cells the determination of V_{bi} is less straightforward because the bandgaps of the emitter, buffer, and absorber layers are different. In this instance, in addition to the value of E_g of each layer, the relative alignment of the conduction or valence band edges depends on the "affinity" or work function of each layer. However, in all cells, the potential profile is a smooth continuous curve passing through the device. Emitter and collector layers with low conductivities may not have enough lateral conductivity to collect the currents at a metal gridline. In these instances, the insertion of a transparent conductive layer is required. SnO_2, ZnO, or indium tin oxide layers are used as transparent conductors. Often, this layer has a double function, acting as an antireflection coating in addition to providing the electrical contact.

The potential profile through the cell will also be determined by the load. Figure 1 depicts the device near open-circuit conditions. When one device contact is shorted to the other one, they have to come to the same potential, forcing a lowering of the electrical potential on the left-hand side down and/or rising on the right-hand side. Traditionally, much analysis went into identifying collection losses within a specific layer or region of a cell. Regions are often characterized by the material properties of the layer making up most of it. It is important to realize, however, that the distinction of such regions in terms of layers alone is somewhat arbitrary. Manipulation of the physical construction of one region of a solar cell or merely a change in the operating condition of the solar cell device will affect what occurs in adjacent regions.

1.2 Solar Cell Operation

The device shown in Fig. 1 is basically a p-i-n diode, where the emitter and collector doping define the junctions. The cell absorber layer can be lightly doped, undoped (i = intrinsic), or, in some instances, show a naturally prevailing doping that cannot be easily controlled by adding chemical dopants. If a bias is applied to such a diode in the dark (replacing the "load" in Fig. 1 with a power source), the current flow is blocked for one polarity of the applied voltage (reverse direction) and increases exponentially for the opposite polarity. Such "forward" current flow can be approximated by the diode equation:

$$I(V) = I_o[\exp(V/nk_BT) - 1], \qquad (1)$$

where I and V are the currents and voltages, respectively; n is the diode quality factor (a fitting parameter); k_B is the Boltzmann constant; and T is the temperature in Kelvin. The diode quality factor is often interpreted to account for "losses" or nonideal diode behavior. Some theories predict that the factor should fall between 1 and 2 depending on the recombination loss mechanism encountered. In practice, there is little correlation between solar cell performance and the actual n values used in fitting experimentally observed I–V characteristics. For moderately high-efficient cells, unpredicted values of $n > 2$ have been observed. The I_o factor depends on the height of the barrier, which in a homojunction cell is given by

$$I_o = I_{oo} * \exp(-E_g/mk_BT), \qquad (2)$$

where m is a fitting parameter and I_{oo} a constant. Very often, the sum of two superimposed exponential curves is used to fit experimental $I(V)$ data. Theories have been developed to relate the magnitude of the fitting parameters to material properties, most commonly those of the absorber layer, which is often

assumed to be the most important factor controlling the performance of a solar cell.

When the diode is illuminated, a current flows in the reverse direction under the influence of the built-in field. If the device is short-circuited, the current density measured (per unit area of the cell surface) is called the short-circuit current density (J_{SC}). When the device is not connected to a load, the open-circuit voltage (V_{OC}) is measured. When the device is connected to a load, an *I–V* curve, as shown in Fig. 2 for a $CuInGaSe_2$-based solar cell, is obtained. Following the curve, a value for J and V can be found where the power output $J_{mp}V_{mp}$ is maximized (mp = maximum power). The ratio of $J_{mp}V_{mp}/V_{OC}J_{SC}$ is called the cell fill factor (FF). The power P generated by a solar cell is $P = FF \times V_{OC} \times J_{SC}$. The cell efficiency, η, relates the fraction of the total power of the incident sunlight (the solar constant, $S = 1\,kW/m^2$) to the electrical power generated by the cell (strictly speaking, under normal incidence and for a cell operating at a temperature of 20°C). Efficiency $\eta = P$ (kW/m^2)/S (kW/m^2) and is usually reported as a percentage. It is important to note that there can be a difference in the current–voltage behavior of the dark and the light current, commonly causing a "crossover" of the measured curves. Such observations clearly complicate the way in which solar cell efficiency can be related to the material properties used in a solar cell.

Another important property frequently measured is the solar cell collection efficiency and its spectral dependency. This is important because sunlight has a wide energetic distribution of photon energies. In the ideal case, all photons with energies larger than the bandgap E_g of the absorber generate one electron-hole pair, and ideally these can be separated and collected. Photons with energies $< E_g$ are not absorbed, thereby not creating carriers. Photons with energies much larger than E_g still only generate one electron-hole pair, and the excess energy is lost through thermalization because the carriers can be transported and collected only at the band edges. This fundamental limitation to solar cell efficiency is referred to as the Shockley–Queisser (SQ) limit after the authors who first considered this effect. Because of the SQ limitation, there is an optimum bandgap for the cell absorber; such an optimum is found by trading off the inability to absorb the low-energy solar photons in larger E_g absorbers and the need to increase the E_g and built-in potential (and thus voltage) of the cell. The optimum bandgap for a single absorber is approximately 1.4 eV. However, for E_g values between 1.0 and 1.8 eV, the dependency of the cell efficiency on the bandgap is not very strong, making all materials within this bandgap range candidates for solar cell absorbers. Because the electronic properties of a semiconductor may change as the bandgap is altered (e.g., by alloying), absorbers used in high-efficiency cells are often selected by making a compromise between bandgap and electronic performance.

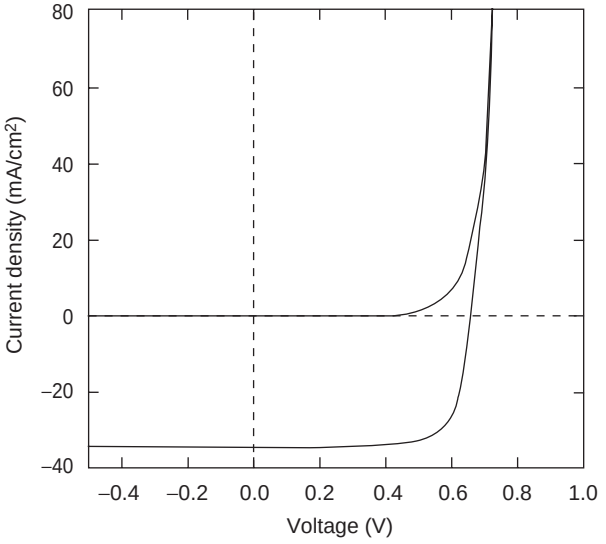

FIGURE 2 I–V curves under light and in the dark for a $CuInGaSe_2$ solar cell. Parameters are as follows: $V_{OC} = 0.66$ V; $J_{SC} = 34.3\,mA/cm^2$; FF = 77%; eff. = 17.4%.

A demonstrated way to overcome the SQ limitation is to stack two (or more) cells with different absorber bandgaps on top of each other. Thereby, the higher energy photons are absorbed in a higher bandgap top cell(s) (delivering higher voltage), whereas the low-energy photons pass through the top cell(s) and are converted in the lower E_g bottom cell(s).

Figure 3 shows the quantum efficiency (QE) of the cell from Fig. 2. The cell response is determined for light of single wavelength (or a narrow band of wavelengths), measuring the relative response with monochromatic or narrow-bandwidth light. Ideally, this curve would be almost a rectangle. In practice, optical and electrical collection losses determine the shape. There are also reflection, shadowing, and sometimes absorption losses as light enters the cell. It is often straightforward to account for such optical losses. It is more difficult to analyze the losses to the QE response that result from incomplete carrier collection. These losses may depend on the light penetration into the absorber—that is, how far away from the emitter (or collector, if the cell has a back-surface

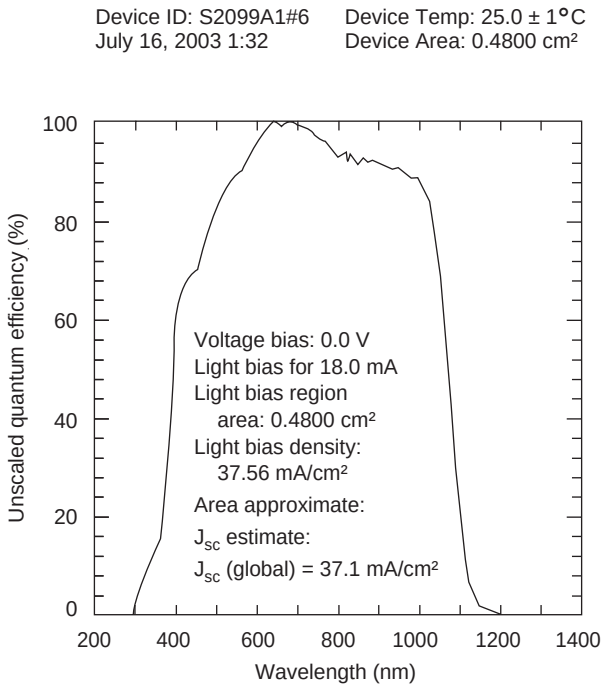

FIGURE 3 Spectral response for the cell shown in Fig. 2. The curve shows the relative response at each wavelength relative to the strongest response that defines the 100% value.

field) the carriers were generated. Except for amorphous and nanocrystalline thin-film silicon, organic, and dye-sensitized TiO_2 (Grätzel) solar cells, usually the absorber layers are thick enough to absorb most of the incident sunlight with photon energies $> E_g$. To first order, the shape of the long-wavelength fall-off of the QE is determined by the absorption edge of the absorber material. More detailed analyses reveal that the response depends on the details of cell design and the experimental conditions used, such as probe and bias light intensities, bias light wavelength, and electrical bias. For example, in crystalline Si solar cells, the edge of the long-wavelength QE response is determined by the doping of the wafer "base" (absorber). The base doping (at the levels typically used) does not change the optical properties of the Si wafer, but the response changes as if E_g were increased.

1.3 The Role of Buffer Layers

Solar cells are made from a wide variety of materials, and traditionally, less-than-ideal performance was attributed to very specific imperfections and defects found in the materials used to build the cells. It is also of interest to identify and characterize mechanisms and observations applicable to cells made from different materials. For many cell technologies, it has been a challenge for the experimental device fabricator to obtain cells with high V_{OC}. The opposite problem typically exists when a device structure is run in a computer model. The most important factor determining V_{OC} is the bandgap of the layers involved, so the initial modeling calculations often predict V_{OC} values greater than those observed experimentally. Although modeling may introduce ad hoc thin defective layers at the interface to match calculated and experimentally observed V_{OC} values, researchers usually maximize V_{OC} by employing grading schemes for the electronic and optical properties of the layers used near the junction. In thin-film solar cells, these schemes are typically referred to as buffer layers. In crystalline Si- and GaAs-based solar cells, these schemes are often referred to as contact passivation. It can be argued that a unique voltage-enhancing mechanism is operational in all solar cells built from different semiconductor materials.

Figure 4 presents a unifying buffer layer concept that can explain how buffer layers enhance solar cell voltages. Traditionally, it is assumed that the recombination loss current j_j would be determined by recombination through surface or interface defect states near the junction. Figure 4 suggests that, instead, the transport properties or carrier mobilities of the materials used to build the junction should be reduced (e.g., by using materials with potential fluctuations of the band edges that have significantly reduced carrier mobilities). This configuration reduces access of carriers to such voltage-reducing loss pathways. Solar cell fabrication depends on robust, repeatable, and scalable processes for creating an optimum or near-optimum grading of the transport properties in the materials used to build the junction regions of the cell. Ideally, the carrier-transport mobilities should be sufficient to allow carrier collection in the direction of the applied field but no larger. The principle can be best understood by comparing a Schottky barrier (SB; metal/semiconductor) crystalline Si junction and a metal/insulator/semiconductor (MIS) junction. Although working SB solar cells can be fabricated, they suffer from low cell voltage. On the other hand, MIS devices can attain voltages comparable to the best achievable by other junction-formation techniques. Although it is sometimes argued that the oxides provide passivation of the interface, it is well-known that for crystalline Si one or two atomic layers of thermally grown oxide provide excellent surface passivation. However, for

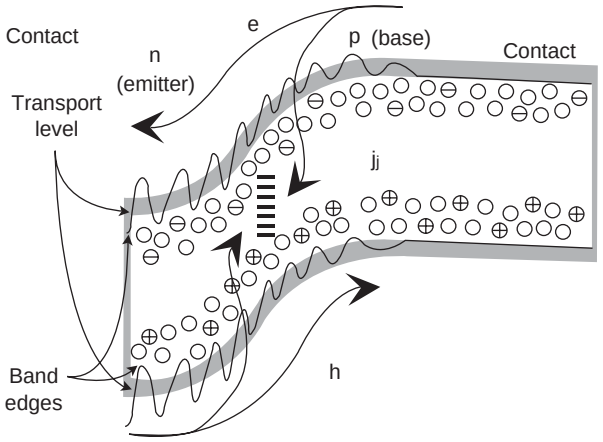

FIGURE 4 A unifying buffer-layer concept that can explain how buffer layers enhance solar cell voltages.

an MIS structure to exhibit much larger V_{OC} and device efficiency than the equivalent SB structure, the oxide buffer layer must be approximately 1.5 nm thick, nearly preventing carrier transport through this thin insulating layer. In a diffused crystalline Si p-n junction, the existence of a specific buffer layer is not generally acknowledged; however, a low-mobility buffer is likely present (i.e., a compensated layer as the phosphorus emitter diffuses into the boron-doped base). A buffer layer concept helps explain the trade-off between cell current and voltage that is often observed in the experimental research on optimizing solar cells. Because of its resistive nature, the buffer will cause a larger drop in the electric field near the junction, thereby reducing the extension of the space charge region in the absorber layer. Traditional cell analyses account for the measured device behavior in terms of surface and absorber recombination losses but cannot provide an explanation for the commonly occurring current-for-voltage trade-off observed in the optimization of experimental and commercial solar cells. It is important to realize that adding too much of a buffer layer can have disastrous consequences and ruin the solar cell performance. For industrial purposes, the thickness and electrical properties of the buffer layers must be uniformly and repeatedly obtained over large areas to achieve a consistent product.

2. *CRYSTALLINE SILICON*

2.1 Workhorse of the Industry

Most photovoltaic modules are made from crystalline silicon cells. Each cell is made from wafers produced either from Czochralski single crystals or from large-grain polycrystalline ingots. Many photovoltaic manufacturers produce their own wafers in order to have tight control over manufacturing cost and wafer quality. In fact, in the early stages of technology development, inventions focused on deriving economical and performance advantages predominantly from the wafer-preparation process. The crystal growth processes appear to have become less critical in recent years because the structural perfection may be a lesser factor for cell performance than initially thought. Instead, much manufacturing cost reduction was derived from changing the wafering technology by switching from inner-diameter saws cutting one wafer at a time to wire saws slicing several feet of ingot in one cut. This has resulted in an increase in the number of usable wafers obtained per centimeter of ingot from 8–12 to 16–22, with typical wafer thicknesses at or slightly less than 300 μm and a further decreasing trend. In principle, wire sawing allows the cutting of much thinner wafers. However, it remains a challenge to process these thinner wafers and avoid excessive breakage during cell processing and module assembly.

Smaller, but not insignificant, portions of crystalline Si cells are based on wafers grown as silicon ribbon or as thick silicon films deposited on conducting ceramic substrates. These technologies avoid the wafering steps, and the performance of Si ribbon cells has reached levels comparable to those of wafer Si-based technologies. Of interest is that these various approaches still continue to be developed and used in parallel. Approximately 15 years ago, when today's manufacturers or their predecessors began to develop the different processes, each had hoped that their preferred method of making the Si substrate would result in a unique cost/performance advantage. It has not become evident which of these approaches is the most cost-effective. The reason for this may lie in the fact that the quality of the wafer plays a lesser role than originally thought. Instead, it became much more important to learn how to process each wafer into a high-efficiency solar cell.

2.2 Silicon Solar Cell Operation

For a crystalline Si solar cell, the complicated structure of Fig. 1 is often approximated in terms of a bulk (wafer) lifetime and a surface recombination velocity. Another frequently used parameter is the (zero-field) diffusion length as a measure for collecting carriers generated in the diffusion region of the absorber. Such characterization omits a crucial parameter: the cell voltage. For diffusion-processed cells,

V_{OC} depends critically on the boron doping level of the wafer base. Typical doping levels for optimum cell performance are 0.2–2 Ωcm. It is typically found that higher doping levels of the wafer or absorber increase V_{OC}, whereas they decrease J_{SC}. For the highest efficiencies, a compromise must be made.

Although most commercial cells are manufactured by diffusing emitters and collectors, higher performing champion Si solar cells often have a different cell structure. Point-contact or buried laser grooved-contact cells (referred to as passivated emitter, rear locally diffused cells) have reached efficiency levels of 24%. Because the localized contacts require large diffusion lengths to collect carriers over even greater distances, these high-efficiency cells can only be made with single-crystal "float zone" or Czochralski wafers. Many analyses have correlated V_{OC} values with the hole density in the absorber and have ascribed lower than optimum V_{OC} values to recombination losses in the absorber. With the realization of the so-called HIT (heterojunctions with intrinsic thin layers) solar cell developed by Sanyo Corporation, this interpretation becomes challenging. The HIT cell, a heterojunction Si cell, uses amorphous silicon emitter, collector, and buffer layers and n-type Czochralski wafers as the absorber. One practical advantage of this cell type is a temperature coefficient approximately half that in typical diffused cells, giving these cells an advantage at typical operating temperatures under full sunlight. The latter observations suggest that cell voltages and their temperature coefficients are predominantly determined by the details of junction formation and not by losses in the wafer or absorber.

The use of buffer layers in crystalline Si HIT cells supports the universality of a voltage-enhancing buffer layer concept. In diffusion-processed and screen-printed cells, fire-through nitride passivation layers are used. A nitride layer between the emitter and the metal grid contacts, frequently referred to as a passivation layer because of the high hydrogen contents of the nitride layers, can also be seen as a buffer concept. Finally, the sensitivity of V_{OC} to the boron base doping level in diffusion-processed cells can also be understood in terms of a buffer layer (in this instance, a low-mobility compensated layer that must be formed while the phosphorus emitter is diffused into the boron-doped p-type base).

2.3 Defect Engineering

Most crystalline Si cell manufacturers produce their cells by phosphorus diffusion for the emitter and use aluminum alloy for the collector. It has become well accepted that the Si material can be upgraded during the cell-processing step. Figure 5 shows a pyramid schematic of how fundamental starting-material properties, substrate preparation, and processing during solar cell fabrication all strongly affect the resulting solar cell efficiency. Upgrading during cell processing often occurs automatically as the cell emitter, collector, and passivation and antireflection layers are formed, and it is usually referred to as phosphorous and/or aluminum gettering. Optimizing these gettering processes was critical in achieving today's high commercial cell efficiency levels (typically 12 to >15%). Some manufacturers use additional process steps such as hydrogenation treatments for defect passivation. Such upgrades are commonly believed to lower the defect densities or the effectiveness of defects.

It is difficult *a priori* to distinguish whether the cell processes only affected the defect properties in the wafer (absorber region) or whether manipulation of the junction and buffer regions affected the space-charge region of the cell, improving the carrier collection from an unaltered absorber. The interactive nature of defects and impurities is well accepted among researchers. The lifetimes or diffusion lengths not only depend on the impurity levels (e.g., the concentration of a lifetime-killing metal impurity) but also depend, in a complicated way, on the presence of other inactive impurities, such as oxygen or carbon. Impurities interact with point or extended defects such as dislocations and structural defects in polycrystalline materials. The effectiveness of impurities in promoting recombination losses is strongly determined by

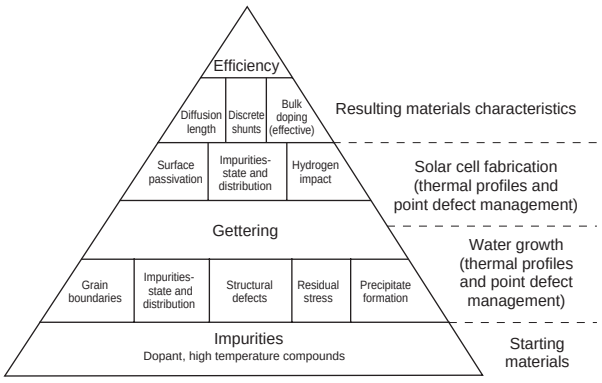

FIGURE 5 Pyramid schematic of how fundamental starting-material properties, substrate preparation, and processing during solar cell fabrication all strongly and interactively affect the resulting solar cell efficiency. Reproduced with permission from Rand *et al.* (2002).

gettering and passivation effects. In summary, it is difficult to describe solar cell performance simply in terms of defect and impurity concentrations in the Si wafer or sheet material alone.

3. THIN-FILM SILICON

3.1 Amorphous Silicon

Amorphous silicon solar cells are commercially available and can be produced on a variety of substrates ranging from glass to flexible thin foils. Cells are built in p-i-n or n-i-p configurations, where p and n represent thin doped (amorphous or nanocrystalline) layers, and the absorber layer is an intrinsic undoped layer. Cells are deliberately made thin (<300 nm thick) such that the space-charge region extends through the entire absorber (i-layer). The very small thickness is possible because amorphous silicon has stronger light absorption than crystalline Si (a direct bandgap) and light-trapping schemes have been developed to enhance the optical absorption.

The semiconducting properties of this material were discovered when films were prepared by plasma-enhanced vapor deposition of silane (SiH_4) gas. It was established that the optical and electrical properties are dominated by approximately 10 atomic-% (at.%) hydrogen in the film. It was also discovered that the material could be doped n-type (usually with phosphorus) and p-type (usually with boron), making this material much like a crystalline semiconductor. Until then, there was debate about whether amorphous semiconductors could, in principle, be doped. Some argued that the flexibility of the amorphous network would prevent three-valent acceptor or five-valent donor atoms from being incorporated into the four-valent Si network, which is necessary to produce additional conduction electrons or holes. Doping changes the resistivity of amorphous silicon by more than seven and six orders of magnitude for n- and p-type doping, respectively.

Unhydrogenated amorphous silicon films can also be prepared, for example, by evaporating silicon onto a substrate below 400°C. However, such films are very defective and show high conductivity. It is generally accepted that the quality of such films is low because the very high density ($>10^{20}/cm^3$) of silicon "dangling bonds" acts as a defect. With hydrogenation, their density is orders of magnitude lower (10^{15}–$10^{17}\,cm^{-3}$). Device-grade intrinsic hydrogenated amorphous silicon (a-Si:H) has the following properties: bandgap, 1.6–1.8 eV; dark conductivity, 10^{-9}–$10^{-12}\,\Omega$cm; and photoconductivity under 1 sun intensity light of 10^{-5}–$10^{-6}\,\Omega$cm. The conductivity activation energy ranges from 0.65 to 0.9 eV.

Amorphous silicon degrades under illumination. In a solar cell, all three parameters—V_{OC}, FF, and J_{SC}—can be affected and usually decrease upon illumination. In intrinsic layers, the degradation affects the photoconductivity (which decreases), and the midgap density D_o, which increases. The properties of the light-induced D_o defect (e.g., its paramagnetic spin resonance signal) are virtually indistinguishable from those of the native D_o defect found in the annealed state in much lower concentrations. Fortunately, the degradation appears to be self-limiting and stabilizes. The exact rates of degradation depend on the material properties and the conditions (temperature and light intensity) used for light soaking. Annealing (for 5–150 min at 150–180°C) essentially restores the light-soaked material (or cell) to its original state. With 1 sun intense light, most of the degradation will occur within several tens to hundreds of hours. This effect is referred to as the Staebler–Wronski mechanism.

It is clear that the effect, although influenced by the presence of impurities, is inherent to the amorphous silicon– (or germanium–) hydrogen alloy system. There is no sure mitigation scheme to avoid degradation in high-quality a-Si:H, but the details of materials preparation can noticeably influence the amount of material property or solar cell degradation observed. Because of the intrinsic nature of the effect, it is common to examine stabilized materials and solar cell performance or efficiency.

In the past, the near-midgap dangling bond defect was used as a strong quality indicator. Specifically, models were made that correlated such defect density with solar cell fill factors and the photoconductive properties of the layer. However, careful quantitative work later showed that the solar cell fill factor or the photoconductivity (PC) of the intrinsic layer are not controlled by a simple, single, straightforward mechanism. In the past, it was assumed to be the generation of D_o defects. It has been confirmed that the kinetics with which observables such as D_o, PC, or cell FF change upon light soaking or annealing show differences, and there is a lack of quantitative correlation between D_o generation and PC and FF losses but a better correlation between PC and FF. Such findings may explain why materials with lower stabilized D_o densities have not led to improved stabilized solar cell performance.

Also, degradation and annealing behavior in most instances can be classified into two mechanisms: fast (low-temperature annealable) and slow (below 80°C nonannealable) mechanisms. Any comprehensive Staebler–Wronski model must account for both mechanisms, which appear to be linked. The effects of the two mechanisms on degradation and annealing are large enough to affect the power output of a-Si:H-based modules by $\pm 10\%$. Interest in mitigating Staebler–Wronski degradation remains high because if it were possible to maintain today's solar cell performance in the higher annealed state, 16% efficient multijunction cells and 10% efficient commercial modules would likely be a reality. However, all data suggest that the degradation is intrinsic to a-Si:H and related alloys.

The prevailing mechanisms suggested in the literature implicate weak Si–Si bonds and weakly bonded hydrogen in the material as the cause for the instability. Experimentally, the instability appears not to depend systematically on hydrogen content of the material or on how tightly hydrogen is bonded. In fact, some of the more stable (deuterated and high hydrogen dilution, lower substrate temperature) solar cell recipes were achieved using materials that contain larger amounts of loosely bonded hydrogen.

Amorphous silicon solar cell technology has realized the first low-cost multijunction bandgap commercial solar cells. To make the cells more sensitive to red light, a-Si:H is alloyed with germanium (Ge). Especially for Ge contents >50 at.% (corresponding to a bandgap of <1.45 eV), the solar cell performance decreases significantly. A plausible explanation for this phenomenon is the decreased carrier collection due to lower carrier mobilities or higher recombination losses. This decreased carrier collection is mitigated by making the narrow bandgap cells very thin (150 nm or less) and by grading the Ge content in the intrinsic layers, such that the highest Ge content is found near the p-i interface of the junction. Use of Ge alloying for multi-bandgap cells has increased the stabilized device performance (e.g., on the order of 1 absolute efficiency point when an a-Si:H/a-Si:H cell and a-Si:H/a-$Si_{0.5}Ge_{0.5}$:H cell are compared). However, Ge alloying has enhanced the cell performance less than expected from the reduction in bandgap because of deterioration of the electronic properties with Ge alloying and significant light-induced degradation in such alloys, which can be offset only by using a very thin, Ge-graded, narrow bandgap cell structure. Attempts were made to use carbon alloys (a-SiC:H) to widen the bandgap of the top cell of a triple-junction device to increase the voltage of this component cell. Such efforts have been abandoned because a-SiC:H cells showed aggravated light-induced degradation, and it was not possible to increase the voltage of these cells beyond the best values achievable with optimized a-Si:H intrinsic layers (1.0 V). There is no consensus as to which microscopic mechanisms cause the electronic deterioration upon alloying with Ge, C, or, even more significant, other elements.

3.2 Crystalline Silicon Films

There are two approaches for using thin silicon films for photovoltaic applications. When amorphous silicon deposition techniques are used with excessive hydrogen dilution, the resulting films become nanocrystalline (nc-Si). The term microcrystalline has also been used for such films; however, grain sizes are always $\ll 1\,\mu$m. Typical crystallite sizes are on the order of tens of nanometers, and to have reasonable electronic properties, a few atomic percent of hydrogen must be incorporated in such films. Solar cells with efficiencies of approximately 7% have been demonstrated using low-temperature deposition approaches.

Conventional thinking caused researchers to search for higher solar cell efficiency using Si films with much larger grain sizes. However, experimental work established a lack of improvement of cell efficiency with grain size in the range of 100 nm to 1 mm. To achieve grain sizes >1 mm, either high-temperature recrystallization (remelting) or epitaxial growth on a larger grain silicon substrate are required. Such methods require a substrate that can withstand the high temperatures involved and that is chemically inert so as not to release impurities into the silicon film. Such requirements may eliminate commercial glasses as a substrate. In the laboratory, graphite and ceramic substrates have been used with some success.

First, the low-temperature approaches are discussed. The solar cell efficiencies achieved appear too low to justify the development of a single-junction nanocrystalline solar cell technology. The main application is replacing the bottom cell in a-Si multijunction cells. To function as a bottom cell, the nc-Si cell must generate $>24\,\text{mA/cm}^2$ and have a sufficiently high red response to generate $>8\,\text{mA/cm}^2$ in a triple-junction stack cell or $>12\,\text{mA/cm}^2$ for a double-junction device. With a high-quality back reflector for optical enhancements, current densities

of approximately 24 mA/cm^2 were demonstrated with nc-Si absorbers $\leq 2\,\mu$m thick.

How nanocrystalline cells operate is very poorly understood. Preparation of nc-Si films and cells is extremely sensitive to deposition conditions. Physical properties that may change are the crystalline orientation, luminescence properties, and conductivity of the films. When such changes occur, solar cell properties also change, often dramatically. However, it is difficult to pinpoint how the properties of the films determine cell performance. Rather, whenever the absorber properties change, it is necessary to readjust the junctions (p, n, and buffer layers) used in the cell. It appears from the optimization of nc-Si cells that a regime is often encountered in which higher J_{SC} values are obtained by sacrificing V_{OC} or vice versa. Such a trade-off between voltage and current is not uncommon for both thin-film and wafer-based crystalline silicon. The highest voltages for the nc-Si cell, in conjunction with the required high J_{SC} values, remain to be determined. Better optimization and better understanding of the mechanism leading to such a trade-off are both required.

Cells spanning the amorphous to nanocrystalline transition (adding a gradually increasing nanocrystalline phase to the intrinsic layer) have been prepared. Cells with a large fraction of amorphous phase in their i-layer show large voltages but also light-induced degradation. Light soaking actually enhances V_{OC} but decreases FF. With such unstable i-layers, the high J_{SC} values required for multijunctions could not be demonstrated. It is important to note that even the stable cell recipe with the largest grain size and best-ordered i-layers did not result in the highest efficiency.

Two additional universal findings about nc-Si cells should be mentioned. First, as for a-Si:H alloys, the best cell results are obtained when the i-layer deposition rate is slow (<0.5 nm/s). However, some deposition methods [such as hot-wire chemical vapor deposition (CVD)] have shown that different film structures and modest cell efficiencies (routinely, approximately 5%) can be obtained at higher deposition rates (1–2 nm/s). Second, it has been observed that some nc-Si films are porous and therefore subject to postdeposition oxidation. After oxidation, solar cell performance degrades severely. Such films must be avoided because it has been reported that oxidation occurs even when such devices are capped, for example, by a p-layer in a solar cell.

Of concern with regard to nc-Si is that in recent years cell efficiency records have been somewhat stagnant (approximately 10%). Given the current performance, it appears that there is opportunity to incrementally improve a-Si:H-based multijunctions by using the nc-Si cell as a bottom cell. Given the large variety of nc-Si films that can be produced, it may well be possible that cell recipes, at greater deposition rates, can be found that result in a breakthrough for even higher cell efficiency.

Next, the higher temperature, large-grain crystalline Si films are discussed. Two approaches have resulted in larger grain sizes. One approach to thin-film solar cells relies on melt recrystallizing a CVD-deposited, $\sim$100-μm-thick growth layer on a ceramic or other substrate. Then, active solar cell layers are deposited epitaxially by CVD. The active Si layers used are a 5-μm-thick back-surface field and contact layer (boron-doped, $\sim 0.1\,\Omega$ cm) and a very lightly boron-doped, 30- to 35-μm-thick absorber layer. The cell emitter is formed by a P-diffusion process, resulting in a cell with the following parameters: $\eta = 9.1\%$, $V_{OC} = 0.54$ V, FF $= 0.73$, and $J_{SC} = 23.1$ mA/cm^2. Because the ceramic substrate is insulating, monolithic interconnection of cells can be accomplished and has been demonstrated. Interestingly, the current generated and collected in these absorbers is similar to the current densities measured in the 1.5- to 2-μm-thick nc-Si absorbers. This may be because in thin, optically enhanced Si film cells, carrier collection is quite efficient, whereas in thicker films carrier collection remains a challenge for carriers generated some distance (more than a few micrometers) from the junction.

Other deposition approaches, such as using an iodine vapor transport reaction, provide a process for growing large-grain films in the 750–950°C substrate temperature range. Cell efficiencies of these larger grain silicon films have not met expectations. One reason may be that grain size is not as much a driver of material quality and cell performance as has been hitherto assumed. The behavior of the nanocrystalline cells (in which smaller grain size leads to higher cell performance) suggests that there may be a genuinely beneficial aspect of polycrystallinity. For intermediate grain size silicon films, it may be that this effect is lost, and the carrier collection is still too impeded compared to that of single- or large-grain (>1 mm) crystalline Si wafers.

4. POLYCRYSTALLINE THIN FILMS

Since approximately 1990, solar cell efficiencies of $>13\%$ have been obtained with copper indium diselenide ($CuInSe_2$ or CIS) and cadmium telluride

(CdTe) polycrystalline thin-film semiconductors. These materials have few other applications. They are attractive as solar cell absorbers because they perform well. Cell efficiencies on the order of 19% for CIS and 16% for CdTe have been demonstrated. These materials were mostly developed using heuristic solar cell optimization schemes, with a lagging understanding of the fundamental physical properties of the materials and cells.

4.1 Copper Indium Diselenide

CIS was developed after it was realized that CdS/CuS solar cells developed earlier, despite promising cell efficiency (10% demonstrated), were not viable because of their propensity to become shunted while operating. This shunting was related to copper migration. On the other hand, the ternary $CuInSe_2$ and quaternary $CuIn_{1-x}Ga_xSe_2$ compounds (x is typically 0.2–0.3 for high-efficiency cells) do not suffer from such intrinsic degradation. Early on, it was realized that to obtain high solar cell performance, the films had to be nonstoichiometric. Specifically, for good cell performance, the Cu/(In + Ga) atomic ratio must be between 0.86 and 0.96. The Se content of the film must be slightly higher than 2. Films for solar cells are deposited by a variety of methods, including coevaporation from metal or metal–selenide precursors. It is beneficial to have some excess selenium available during deposition. However, it is also possible to react mixed-phase metal or metal–selenide precursors into a single-phase (or seemingly single-phase) $CuInGaSe_2$ layer in a selenization reaction in the presence of Se vapor or H_2Se gas. Another approach is to produce absorbers from nanoparticle precursors. Many deposition recipes for high-efficiency cells call for ramping both the substrate temperature and the ratios of the metal or metal–selenide precursors during film growth such that the Cu deficiency is greatest near the surface of the film. The addition of Ga has made it easier to achieve higher efficiency cells, both because the bandgap of the absorber increases from approximately 1.0 to 1.15 eV and because Ga affects the electronic properties in a way that is favorable to cell performance, especially the V_{OC} parameter. For the best cell results, Ga incorporation in the absorber should be uniform or in a "notch" distribution (higher concentrations near the front and back of the absorber). The best solar cell results are obtained for films deposited or selenized at temperatures higher than 500°C. Unfortunately, some deposition approaches lead to an undesirable high accumulation of Ga mostly near the back surface of the absorber. In these instances, sulfur has been used to form $Cu(In,Ga)Se_{2-x}S_x$ pentenary compounds to achieve the bandgap widening and desirable electronic modification near the front surface of the absorber. However, experimental results suggest that S alloying leads to somewhat inferior cell performance compared to optimized Ga alloying.

CIS solar cells are built up on a molybdenum (Mo)-coated soda-lime glass substrate. The use of Mo metallization is important to achieve high cell performance, but the reason for this is poorly understood. It is well established that the addition of some sodium during film growth is quite beneficial; Na had been incorporated inadvertently when soda-lime glass substrates were used. Sodium can be added during absorber growth to achieve high performance on Na-free glasses or on Mo-coated metal or high-temperature resistant plastic foils.

CIS devices use a ZnO/CdS heterojunction emitter layer. The best and most consistent solar cell results are obtained when a thin CdS layer is deposited using a wet chemical bath deposition (CBD) process. The reason for this is debated in the literature, and no consensus has been reached. Alternatives to CdS (such as resistive oxides or ZnS) have been explored with some success but have not achieved the same champion cell efficiencies or processing robustness as CBD CdS. The ZnO contact is often prepared in the form of a graded layer or bilayer, where the part of the film in contact with the CdS is deliberately made more resistive. It can be argued that in a CIS solar cell the optimum junction profile is affected by the resistive ZnO layer, the CdS or alternative buffer layer, and the surface portion of the $Cu(In,Ga)Se_2$ absorber. This makes the cell optimization process very interdependent; that is, if one of the layers in the cell is altered, all other layers (their properties and thicknesses) must be reoptimized. In other words, there is no unique optimum for the properties of each layer. Conventionally, it is assumed that cells fabricated from more perfect layers result in higher cell efficiency. For CIS and CdTe solar cells, cells deposited as multicrystalline thin-film layers on low-cost substrates have achieved greater device performance than solar cells made on (bulk or epitaxial) single-crystal versions of these materials.

4.2 CdTe Solar Cells

CdTe was developed after it was realized that a number of deposition approaches, such as

evaporation, sublimation, sputtering, or electrodeposition, resulted in promising devices (10% demonstrated). Early on, researchers realized that to obtain high solar cell performance, the films had to be heat treated after exposing them to a $CdCl_2$ solution or vapor. Initially, growth of the crystallite grain size and Cl incorporation into the film were observed. However, it was later found that the $CdCl_2$ heat treatment is also essential for cells with CdTe absorber layers grown at high temperature having even larger grain sizes. Treatments are carried out in the range of 360–500°C. CdTe always grows as a stoichiometric compound that is much less toxic than Cd metal. There is debate as to whether oxygen incorporation (doping) of the CdTe layer is necessary or beneficial.

CdTe cells usually use a SnO_2/buffer/CdS heterojunction emitter layer. It is important to keep the thickness of the CdS as thin as possible to avoid optical absorption losses from this layer. However, reducing the thickness too much often leads to reduced V_{OC} and FF. The buffer layers are often undoped SnO_2 layers. Some alternative buffer layers, such as zinc stannate or CdS:O (the latter prepared as an amorphous layer that crystallizes during the cell anneal step), may ultimately lead to higher cell performance. It is generally accepted that some intermixing of the CdS and CdTe takes place and that such intermixing may positively affect cell performance.

The rear-contact preparation for CdTe is more an art than a science. Unsuitable contacts result in very poor device performance. At first, for laboratory cells, a bilayer of copper and gold was used with good success. All contact applications generally benefit from acid etching the CdTe device. This has been shown to leave a Te-enriched surface. The Cu/Au contacts, in general, show poor long-term stability and are not suitable for commercial product. Graphite pastes were found to be another good contacting scheme; graphite paste ("dac") that is typically doped with Cu has been applied to the etched surface. Usually, conductive silver ink is applied as a secondary contact to the graphite layer. This type of contact performs well but is less desirable as a contacting scheme for large-area commercial modules. Because contact formation was difficult due to the nearly intrinsic nature of the CdTe layer, Cu-doped ZnTe layers have also been successfully developed as a back contact. Although they are thought of as completing the junction, it has been reported that the choice of metal used to contact this ZnTe layer can affect the solar cell properties. Commercial manufacturers have developed proprietary thin-film contacting schemes.

It is remarkable that the performance of a CdTe solar cell is very strongly affected and can be dominated by either junction (i.e., the emitter or the collector). Early commercial CdTe modules have shown some change (sometimes an initial improvement, but also degradation) in performance. Laboratory cells are typically stressed at 60–90°C and show some loss of power (0–30%) after such stressing, unless the cells are processed in a very narrow, empirically established process window. The stability is affected by the details of both the front and back contact as well as by the $CdCl_2$ anneal treatment of the CdTe. The rapid degradation of cells using Cu/Au contacts suggests Cu diffusion or migration as a major cause. Further studies have revealed, however, that although too much Cu applied with the back contact leads to degradation, variations for modest amounts of Cu (e.g., in Cu-doped graphite or Cu-doped ZnTe contacts) can increase or decrease cell stability. Cells made without any Cu deliberately added were also found to degrade. Thus, minimizing or eliminating the Cu doping of the back contact is not a sure way to eliminate the degradation. It appears that cells and modules with sufficient commercial stability ($<$10–20% degradation over 20 years of operation) can be manufactured, but each manufacturing process must be tested to eliminate processes that result in too much degradation.

5. CONCENTRATOR SCHEMES AND III–V SOLAR CELLS

For large centralized photovoltaic arrays, it has been proposed to minimize the use of semiconductor material by focusing the sunlight through lens or mirror systems onto a solar cell mounted at the focal point of the concentrator. Such systems must be "tracked" (i.e., rotated around two axes to remain in focus with the sun). This approach opens up the possibility of using very high-efficiency solar cells that would be too costly to incorporate into flat-plate arrays for terrestrial power production. Because of the complexity and maintenance requirements of mechanical trackers, this approach is only viable for large systems in which hundreds of kilowatts or perhaps megawatts of power are required. An advantage of this scheme is that the efficiency of high-efficiency solar cells increases further under concentrated sunlight. A drawback is that such

systems have some optical and system losses and produce power only from direct sunlight (i.e., when the sun is directly visible), whereas flat-plate systems still convert the 5–50% of sunlight available during cloudy conditions when the sun is partially or totally obscured.

The solar cells for such concentrator systems are either high-efficiency single-crystal silicon solar cells (20–27% conversion efficiency under concentration) or GaAs-based multijunction solar cells that have demonstrated efficiencies well above 30% under concentration. Champion Si cells and GaAs cells have attained close to theoretically possible efficiency values, and the challenge is to incorporate such cells into even higher efficiency multijunction solar cells.

The GaAs or III–V semiconductor community has developed near-ideal high-efficiency multijunction solar cells. Typically, these cells are built as homojunctions. For high performance, combinations of a lower doped n-type homoemitter and a higher doped (AlGaAs) heteropassivation layer are used. Without concentration, these high-efficiency cells are also used commercially for space cells, for which their high efficiency and radiation resistance outweigh their much higher cost. The cells are grown in thin-film form using heteroepitaxy on a Ge substrate. A popular cell structure is the GaInP/GaAs/Ge triple-junction cell, providing the appropriate lattice-constant match to Ge and GaAs for successful heteroepitaxy growth. In principle, although for the III–V semiconductors there are a wide variety of compounds providing a very large range of E_g (while still being lattice matched to Ge and GaAs), some materials clearly work better than others for solar cells. There has been no success in achieving high cell performance for a 1-eV bandgap cell using lattice-matched $Ga_{1-x}In_xAs_{1-y}N_y$ alloys. Even for this near-ideal and well-characterized semiconductor system, it is unknown which physical/chemical absorber properties determine high and low solar cell performance.

6. EMERGING SCHEMES

6.1 Dye-Sensitized

A solar cell efficiency greater than 10% has been reported by Michael Grätzel *et al.*, who invented and optimized a dye-sensitized solar cell at the Swiss Federal Institute of Technology. The dye-sensitized cell is an electrochemical cell in which an electrolyte, rather than a conductor or semiconductor, is used to make one of the junctions of a solar cell. The absorber layer consists of a deliberately porous SnO_2/titanium dioxide (TiO_2) coating, for which the surface of the TiO_2 is on the order of 1000-fold enhanced over the surface of a smooth film. This $\sim$100-nm-thick TiO_2 is coated with a very thin ($\sim$1-nm-thick) dye. The best performance has been achieved with ruthenium (Ru)-containing dyes, such as Ru bipyridyl or Ru terpyridine complexes that absorb near-infrared light. The contact is made with an iodine redox electrolyte and a second piece of SnO_2-coated glass as the electrical contact. Note that this type of cell is not actually wet. The electrolyte simply has to wet the dye, requiring only drops of electrolyte per 100-cm^2 device area. Nevertheless, when multiple cells are made on one substrate with monolithic interconnection, this device must be tightly sealed not only around the perimeter but also between adjacent cells. In an attempt to simplify fabrication, solid or gel electrolytes have been investigated but have resulted in inferior cell performance compared to cells with liquid electrolytes.

The prevailing physical description of cell operation assumes that in this device the photogenerated electrons and holes are already separated upon generation in the physical phase boundary of the dye. This creates a photo-induced potential gradient that drives electrons and holes in opposite directions.

6.2 Other Schemes

Although semiconducting organic polymers have been known for some time, only recently has there been a focus on using these materials for preparing solar cells. Their physics and limitations are poorly understood. The junction is made from an electron conductor (e.g., perylene benzimidazole) and a hole conductor (e.g., poly-3-hexylthiophene). It is generally believed that in these materials the absorbed light creates excitons that are transported to the planar interface at which the carriers are separated. The efficiency levels achieved (up to 4% in a few instances but typically lower) suggest that further development is required before these will become candidates for terrestrial power application. Interest is high because in recent years there have been significant advances with regard to organic light-emitting diodes in terms of luminosity.

6.3 Theoretical Concepts

Several schemes have been proposed to overcome the SQ limit discussed previously. Aside from multijunction solar cells, which have been produced and

allowed moderate efficiency gains, schemes have also been proposed in which suitable arrangements in single-junction devices may lead to cell efficiencies exceeding 80%. One proposal suggests that sub-bandgap light can be absorbed via defect states (impurity solar cells). Other schemes propose using the energy that is greater than the corresponding bandgap of the absorber to create additional electron hole pairs (hot carrier cells). These schemes rely on separating the generation and collection processes of carriers, and they assume lossless carrier collection. Experimentally, attempts to realize such schemes have been unable to verify the expected significant enhancement of the short-circuit current density or spectral response.

7. FUTURE POTENTIAL (PHYSICAL LIMITATIONS OF MATERIALS)

There is good empirical knowledge that some materials work better than others for solar cells. In the search for new materials, materials with the desired bandgap, electronic properties allowing carrier separation and collection, and electronic properties that allow robust junction-fabrication schemes must be found. Researchers with a background in GaAs-based semiconductors have also stressed the importance of matching the lattice constants to achieve perfect epitaxial growth.

Achieving the desired bandgap (e.g., by alloying different materials) is possible most of the time. Cell efficiencies hinge on the electronic properties, which are often not conducive for achieving high cell performance. Often, it is difficult to determine what causes low cell efficiency. Structural perfection and lattice matching are requirements for GaAs-based solar cells. However, in other materials systems disordered polycrystalline semiconductor films lead to solar cell performance equal to or exceeding that which can be achieved from single crystalline versions of these materials.

Robust junction-formation processes remain a challenge, although nature has provided some schemes for either homo- or heterojunctions that are quite reproducible, controllable, and manufacturable. It is becoming increasingly accepted that solar cell optimization is a very interdependent process; that is, if one layer of the cell is altered, leading to lower solar cell performance, this can be fixed by reoptimizing the processing of other layers in the cell. In other words, cell optimization cannot rely on combining individually optimized layers to achieve high performance. Rather, the correct combination of absorber, junction, and contacting layers is required to achieve high solar cell performance.

Glossary

emergency response planning guideline-2 (ERPG-2) The concentration of a hazardous material below which nearly all people could be exposed for up to 1 h without irreversible or other serious health effects or symptoms that would impair their ability to take protective action.

immediately dangerous to life or health concentration (IDLH) The maximum concentration of a hazardous material from which one could escape within 30 min without any symptoms impairing escape or any irreversible health effects.

threshold limit value—ceiling The concentration of a hazardous material that should not be exceeded during any part of the working exposure.

threshold limit value, short-term exposure level (STEL) The maximum concentration of a hazardous material to which workers can be exposed for up to 15 min, provided not more than four excursions per day are permitted with at least 60 min between exposures, and provided that the daily permissible exposure limit is also not exceeded.

threshold limit value, time-weighted average (TLV-TWA) The time-weighted average threshold concentration of a hazardous material above which workers must not be exposed during work shifts (8 h/day, 40 h/week).

Photovoltaic (PV) technologies have distinct environmental advantages for generating electricity over conventional power technologies. The operation of PV systems does not produce any noise, toxic emissions, or greenhouse gases; regardless of the composition or technology used, PV generation of electricity is a zero-emissions process. Photovoltaic modules are durable and do not produce emissions even during extreme conditions (accelerated aging with low Earth orbit radiation and thermal cycles from 80 to -80°C). Photovoltaic energy can help meet the growing worldwide demand for electricity and can do so without incurring the high economic and environmental costs of burning fossil fuels and installing power lines. Compared to burning coal, every gigawatt-hour of electricity generated by PVs would prevent the release of approximately 1000 tons of carbon dioxide, 10 tons of sulfur dioxide, 6 tons of nitrogen oxides, and 0.4 tons of particulates.

However, as is the case with any energy source or product, there are also environmental, health, and safety (EHS) hazards associated with the manufacture of solar cells. The PV industry uses toxic and flammable substances, although in smaller quantities than do most other industries, and using hazardous chemicals can entail occupational and environmental hazards. Addressing EHS concerns is the focus of numerous studies of the National Photovoltaic EHS Assistance Center at Brookhaven National Laboratory, which operates under the auspices of the U.S. Department of Energy. These studies are proactive and ongoing as new technologies, materials, processes,

 © 2004 Elsevier Inc. All rights reserved.

and increased production levels are encountered. The activities of the center are coordinated with the U.S. PV industry, which is very sensitive and responsive to EHS issues. This article provides a concise summary of EHS issues pertaining to the manufacture of crystalline silicon, amorphous silicon, copper indium diselenide, copper indium gallium diselenide, gallium arsenide, and cadmium telluride solar cells, all of which are commercially available.

1. OVERVIEW OF HAZARDS IN PHOTOVOLTAIC MANUFACTURE

A variety of materials are used in manufacturing photovoltaic (PV) cells, including materials widely used in commercial applications (e.g., aluminum and glass), chemicals that have seen extensive use in the semiconductor industry (e.g., silane and hydrofluoric acid), and some chemicals that are unique to the PV industry [e.g., copper indium selenide (CIS) and cadmium telluride (CdTe)]. For such new materials, the U.S. Department of Energy has collaborated with the National Institutes of Health to study their potential health hazards. Table I presents the main hazards associated with specific technologies, and Table II shows that these hazards differ for different technologies and deposition processes. Potential risks are related to the materials' toxicity, corrosivity, flammability, and explosiveness.

2. CRYSTALLINE SILICON SOLAR CELLS

2.1 Occupational Health Issues

In manufacturing wafer-based crystalline silicon (*x*-Si) solar cells, there are some occupational health issues, including potential chemical burns and inhalation of fumes from the hydrofluoric acid, nitric acid (e.g., HNO_3), and alkalis (e.g., NaOH) that are used for cleaning the wafers, removing dopant oxides, and cleaning the reactor. Dopant gases and vapors [e.g., phosphorus oxychloride ($POCl_3$) and diborane B_2H_6] are also hazardous if inhaled. $POCl_3$ is a liquid, but in a deposition chamber it can generate toxic P_2O_5 and Cl_2 gaseous effluents. Inhalation hazards are controlled with properly designed ventilation systems in the process stations. Other occupational hazards are related to the flammability of silane (SiH_4) and its by-products used in silicon nitride deposition.

TABLE I

Major Hazards in PV Manufacturing

Module type	Potential hazards
x-Si	HF acid burns, SiH_4 fires/explosions, Pb solder/module disposal
a-Si	SiH_4 fires/explosions
CdTe	Cd toxicity, carcinogenicity, module disposal
CIS, CGS	H_2Se toxicity, module disposal
GaAs	AsH_3 toxicity, As carcinogenicity, H_2 flammability, module disposal

2.2 Public Health and Environmental Issues

No public health issues were readily identifiable with this technology. The environmental issues are related to generating liquid and solid wastes during the slicing, cleaning, and etching of wafers and during the processing and assembling of solar cells.

The *x*-Si PV industry has initiated programs of waste minimization and hence studies environmentally friendlier alternatives for solders, slurries, and solvents. Success was reported at both laboratory and manufacturing scales in reducing the caustic waste generated by etching. Other efforts for waste minimization include recycling stainless-steel cutting wires, recovering the SiC in the slurry, and in-house neutralization of acid and alkali solutions.

Finally, the content of Pb in solder in many of today's modules creates concerns about the disposal of modules at decommissioning. One U.S. company is using Pb-free soldering and has offered assistance to the rest of the industry for adopting this option. It is likely that the *x*-Si industry will gradually move away from Pb–Sn solder.

3. AMORPHOUS SILICON SOLAR CELLS

Amorphous silicon (a-Si), CdTe, CIS, and gallium arsenide (GaAs) are thin-film technologies that use approximately 1/100 of the costly PV material used on *x*-Si.

3.1 Occupational Safety Issues

The principal safety hazard of this technology involves the use of SiH_4 gas, which is extremely pyrophoric. The lower limit for its spontaneous

TABLE II

Hazardous Materials Used in PV Manufacturing[a]

Material	Source	TLV-TWA[b]	STEL[c]	IDLH[d]	ERPG-2[e]	Critical effects
Arsine	GaAs CVD	0.05 ppm	—	3 ppm	0.5 ppm	Blood, kidney
Arsenic compounds	GaAs	0.01 mg/m^3	—	—	—	Cancer, lung
Cadmium compounds	CdTe and CdS deposition $CdCl_2$ treatment	0.01 mg/				m^3 (dust) 0.002 mg/ m^3 (fumes)
—	—	NA	Cancer, kidney			
Carbon tetrachloride	Etchant	5 ppm	10 ppm		100 ppm	Liver, cancer, greenhouse gas
Chlorosilanes	a-Si and *x*-Si deposition	5 ppm	—	800 ppm	—	Irritant
Copper	CIS deposition	1 mg/				m^3 (dust) 0.2 mg/ m^3 (fumes)
—	100 mg/m^3	—				
Diborane	a-Si dopant	0.1 ppm	—	40 ppm	1 ppm	CNS, pulmonary
Germane	a-Si dopant	0.2 ppm	—	—	—	Blood, CNS, kidney
Hydrogen	a-Si deposition	—	—	—	—	Fire hazard
Hydrogen fluoride	Etchant	—	C[f], 3 ppm	30 ppm	20 ppm	Irritant, burns, bone, teeth
Hydrogen selenide	CIS sputtering	0.05 ppm	—	1 ppm	—	Irritant, GI, flammable
Hydrogen sulfide	CIS sputtering	10 ppm	15 ppm	100 ppm	30 ppm	Irritant, CNS, flammable
Indium compounds	CIS deposition	0.1 mg/m^3	—	—	—	Pulmonary, bone, GI
Lead	Soldering	0.05 mg/m^3	—	—	—	CNS, GI, blood, kidney, reproductive
Nitric acid	Wafer cleaning	2 ppm	4 ppm	25 ppm	—	Irritant, corrosive
Phosphine	a-Si dopant	0.3 ppm	1 ppm	50 ppm	0.5 ppm	Irritant, CNS, GI, flammable
Phosphorous oxychloride	*x*-Si dopant	0.1 ppm				Irritant, kidney
Selenium compounds	CIS deposition	0.2 mg/m^3		1 mg/m^3		Irritant
Sodium hydroxide	Wafer cleaning		C[f], 2 mg/m^3	10 mg/m^3	5 mg/m^3	Irritant
Silane	a-Si deposition	5 ppm	—	—	—	Irritant, fire and explosion hazard
Silicon tetrafluoride	a-Si deposition	—				
Tellurium compounds	CIS deposition	0.1 mg/m^3				CNS, cyanosis, liver

[a] Abbreviations used: CVD, chemical vapor deposit; NA, not available; CNS, central nervous system; GI, gastrointestinal tract.

[b] The threshold limit value, time-weighted average (TLV-TWA) is defined by the American Conference of Governmental Industrial Hygienists (ACGIH) as the time-weighted average threshold concentration above which workers must not be exposed during work shifts (8 h/day, 40 h/week).

[c] The threshold limit value, short-term exposure level (STEL) is defined by the ACGIH as the maximum concentration to which workers can be exposed for up to 15 min, provided not more than four excursions per day are permitted with at least 60 min between exposures, and provided that the daily permissible exposure limit is also not exceeded.

[d] The immediately dangerous to life or health concentration (IDLH) is defined by the National Institute for Occupational Safety and Health (NIOSH) as the maximum concentration from which one could escape within 30 min without any symptoms impairing escape or any irreversible health effects.

[e] The emergency response planning guideline-2 (ERPG-2) is defined by the American Industrial Hygiene Association as the concentration below which nearly all people could be exposed for up to 1 h without irreversible or other serious health effects or symptoms that would impair their ability to take protective action.

[f] The threshold limit value—ceiling (C) is defined by the ACGIH and the NIOSH as the concentration that should not be exceeded during any part of the working exposure.

ignition in air is 2 or 3%, depending on the carrier gas. If mixing is incomplete, a pyrophoric concentration of SiH_4 may exist locally, even if its concentration in the carrier gas is less than 2%. At silane concentrations $\geq$4.5%, the mixtures were found to be metastable and ignited after a certain delay. In an accident, this occurrence could be extremely destructive because the protection provided by venting would be ineffective. In addition to SiH_4, hydrogen used in a-Si manufacturing is flammable and explosive. Most PV manufacturers use sophisticated gas-handling systems with sufficient safety features to minimize the risks of fire and explosion. Some facilities store silane and hydrogen in bulk from tube trailers to avoid the need to frequently change gas cylinders. A bulk module typically contains eight cylindrical tubes that are mounted onto a trailer suitable for short- and long-range transport. These modules carry up to 3000 kg of silane. Another option utilizes a single, 450-liter cylinder mounted on a skid, which contains up to 150 kg of silane (minibulk). For additional safety, these storage systems are equipped with isolation and flow-restricting valves.

Bulk storage decreases the probability of an accident since changing the trailer is an infrequent event that is executed in a precise, well-controlled manner under the supervision of the plant's management, safety officials, the gas supplier, and local fire department officials. On the other hand, if an accident does occur, the consequences can be much greater compared to those involving gas cylinders. Silane is used mainly in glow discharge deposition at very low utilization rates (e.g., 10%). To the extent that this rate increases in the future, the potential worst consequences of an accident will be reduced.

Toxic doping gases (e.g., AsH_3, PH_3, and GeH_4) are used in quantities too small to pose any significant hazards to public health or to the environment. However, leakage of these gases can cause significant occupational risks, and management must provide continuous vigilance to safeguard personnel.

3.2 Public Health and Environmental Issues

Silane, used in bulk quantities in a-Si facilities, may pose hazards to the surrounding community if separation zones are inadequate. In the United States, the guidelines of the Compressed Gas Association specify minimum distances from places of public assembly that range from 80 to 450 ft, depending on the quantity and pressure of silane in the containers used. The corresponding minimum distances to the plant's property lines are 50–300 ft. These prescribed separation distances are considered sufficient to protect the public under worst-condition accidents. No environmental issues have been identified with this technology.

4. CADMIUM TELLURIDE SOLAR CELLS

4.1 Occupational Health Issues

In CdTe manufacturing, the principal concerns are related to the toxicity of the feedstock materials (e.g., CdTe, CdS, and $CdCl_2$). The occupational health hazards presented by Cd and Te compounds in various processing steps vary as a function of their specific toxicity, physical state, and the mode of exposure. No clinical data are available on the human health effects of exposure to CdTe. The National Institute of Environmental Sciences conducted a limited number of laboratory tests comparing the acute toxicity of CdTe, CIS, and copper indium gallium diselenide (CGS). These tests showed that of the three compounds, CdTe has the highest toxicity and CGS has the lowest. No comparisons were made with the parent Cd and Te substances. Cadmium, one of the CdTe precursors, is an extremely hazardous material. The acute health effects from inhaling it include pneumonitis, pulmonary edema, and death. However, CdTe is insoluble to water; as such, it may be less toxic than cadmium. This issue needs further investigation.

In solar cell manufacturing facilities, workers may be exposed to Cd compounds through inhalation of contaminated air and by ingestion from hand-to-mouth contact. Inhalation is probably the most important pathway because of the greater potential for exposure and the higher efficiency of absorption of Cd compounds through the lung than through the gastrointestinal tract. The physical state in which the Cd compound is used and/or released to the environment is another determinant of risk. Processes in which Cd compounds are used or produced in the form of fine fumes or respirable particulates present larger health risks than when they are in liquid or solid forms. Similarly, operations involving volatile or soluble Cd compounds (e.g., $CdCl_2$) must be more closely scrutinized. Hazards to workers may arise from preparing feedstock, fume/vapor leaks, etching of excess materials from panels, maintenance

operations (e.g., scraping and cleaning), and handling of waste. Caution must be exercised when working with this material, and several layers of control must be implemented to prevent employees from being exposed. In general, the hierarchy includes engineering controls, personal protective equipment, and work practices. Area and personal monitoring would provide information on the type and extent of workers' exposure, assist in identifying potential sources of exposure, and provide data on the effectiveness of the controls. The U.S. industry is vigilant in preventing health risks and has established proactive programs in industrial hygiene and environmental control. Workers' exposure to Cd in PV manufacturing facilities is controlled by rigorous industrial hygiene practices and is continuously monitored by medical tests, thus minimizing potential health risks.

4.2 Public Health and Environmental Issues

No public health issues have been identified for this technology. Environmental issues are related to the disposal of manufacturing waste and end-of-life modules; these are discussed in Section 8.

5. COPPER INDIUM DISELENIDE SOLAR CELLS

5.1 Occupational Health and Safety

The most common processes for forming CIS solar cells are the coevaporation of Cu, In, and Se and the selenization of Cu and In layers in an H_2Se atmosphere. The toxicity of Cu, In, and Se is considered mild. There is little information on the toxicity of CIS. Laboratory animal studies have shown CIS to have mild to moderate toxicity in the respiratory track; in comparing CIS, CGS, and CdTe, CIS was found to be less toxic than CdTe and somewhat more toxic than CGS.

The selenium threshold level [threshold limit value, time-weighted average (TLV-TWA)] of $0.2\,mg/m^3$ was set to prevent systemic toxicity and to minimize the potential for irritation of the eyes and upper respiratory tract. Interestingly, selenium is an essential element in the human diet and in small doses has exhibited cancer-preventive properties.

Although elemental selenium is only mildly toxic, hydrogen selenide is highly toxic. It has an immediately dangerous to life and health (IDLH) concentration of only 1 part per million (ppm). Hydrogen selenide resembles arsine physiologically; however, its vapor pressure is lower than that of arsine and it is oxidized to the less toxic selenium on the mucous membranes of the respiratory track. Hydrogen selenide has a TLV-TWA of 0.05 ppm to prevent irritation and the onset of chronic hydrogen selenide-related disease. To mitigate hazards from H_2Se, the CIS deposition system should be enclosed under negative pressure and be exhausted through an emergency control scrubber. The same applies to the gas cabinets containing H_2Se cylinders in use.

The options for substitution, isolation, work practices, and personnel monitoring discussed for CdTe are also applicable to CIS manufacturing. In addition, the presence of hydrogen selenide in some CIS fabrication processes requires pertinent engineering and administrative controls to safeguard workers and the public against exposure to this highly toxic gas.

5.2 Public Health and Environmental Issues

Potential public health issues are related to using hydrogen selenide in facilities that employ it as a major feedstock material. The hazards can be minimized by using safer alternatives, limiting inventories, using flow-restricting valves, and employing other safety options. Emissions of hydrogen selenide from process tools are controlled with either wet or dry scrubbing. Also, some facilities have scrubbers that can control accidental releases of this gas. Environmental issues are related to the disposal of manufacturing waste and end-of-life modules; these are discussed in Section 8.

6. GALLIUM ARSENIDE HIGH-EFFICIENCY SOLAR CELLS

6.1 Occupational Health and Safety

Metal organic chemical vapor deposition (MOCVD) is the most common process for fabricating III/V high-efficiency PV cells. It employs as feedstock arsine and phosphine, which are highly toxic hydride gases. Similar to the handling of silane and hydrogen selenide, the safe use of these hydrides requires several layers of engineering and administrative controls to safeguard workers and the public against accidental exposure. Such requirements pose financial demands and risks that could hinder scaling up of the

technology to multi-megawatt levels. Part of the problem is that use of the hydrides in MOCVD is highly ineffective. Only approximately 2–10% are deposited on the PV panels because a 10–50 times excess of V to III (As to Ga) is required. Metal organic compounds are used more effectively, with their material utilization ranging from 20 to 50%. In scaling up to 10 MW/year production using MOCVD, the current designs of flat-plate III–V modules require several tons of arsine and hydrogen. These quantities can be effectively delivered only with tube trailers, each carrying 2 or 3 tons of gases. The potential consequences of a worst-case failure in one of them could be catastrophic. However, it is more likely that terrestrial systems will be concentrators, not flat plates, because the former would be less expensive to manufacture. PV cells concentrate light between 100 and 2000 times. Therefore, a possible practical strength is 500 times concentrators; the material requirements for producing such concentrators are 600 times less than those needed for flat plates, and worst consequences are equally reduced.

The best way to minimize both the risks associated with certain chemicals and the costs of managing risk is to assess all alternatives during the first steps of developing the technology and designing the facility. Studies by Komeno and coworkers have shown that these hydrides may be replaced in the future by using tertiary butyl arsine (TBAs) and tertiary butyl phosphine (TBP). There appear to be no intrinsic technical barriers to growing PV-quality GaAs with TBAs and GaAsP or $GaInP_2$ with TBP. However, until substitutes are tested and implemented, it is prudent to use arsine and phosphine from commercial, reduced-pressure containers. Research efforts are under way in Europe to replace hydrogen by inert nitrogen. Apparently, there is no inherent reason to prohibit such a substitution. However, since molecular hydrogen decomposes to some extent, and atoms participate in the gas-phase chemistry, the PV research community is challenged with learning how to optimize III–V growth conditions with nitrogen.

7. OPERATION OF PV MODULES

The operation of PV systems does not produce any emissions. Although some toxic materials are imbedded in PV modules, these are used in extremely small quantities (e.g., 5–10 g/m^2) and they are safely encapsulated within sheets of glass or plastic. Toxic compounds cannot cause any adverse health effects unless they enter the human body in harmful doses. The only pathways by which one might be exposed to any materials from a PV module are by accidentally ingesting flakes or dust particles or inhaling dust and fumes. The PV material layers are stable and solid, and they are encapsulated between thick layers of glass or plastic. Unless the module is finely ground, dust particles cannot be generated. All the PV materials discussed herein have a zero vapor pressure at ambient conditions. Therefore, it is impossible for any vapors or dust to be generated during normal use of PV modules.

The potential exists for exposure to toxic vapors via inhalation if the modules are consumed in a residential fire and people inhale the smoke from the fire. However, common residential fires in the United States are not likely to vaporize CdTe and GaAs layers; flame temperatures in roof fires are in the 800–900°C range. The melting point of CdTe is 1041°C, and evaporation occurs at 1050°C in open air and at approximately 900°C under nonoxidizing conditions. The melting point of CdS is 1750°C and that of GaAs is 1238°C. CIS starts evaporating at 600°C, but only a 20% weight loss was measured at 1000°C. Experiments at Brookhaven National Laboratory showed that CdTe modules with both back and front glass effectively encapsulate Cd when heated up to 1100°C.

8. DECOMMISSIONING PV MODULES

Photovoltaic modules may contain small amounts of regulated materials, which vary from one type to another. Environmental regulations can determine the cost and complexity of dealing with end-of-life PV modules. If they are classified as hazardous according to federal or state criteria, then special requirements for material handling, disposal, record keeping, and reporting increase the cost of decommissioning the modules. In doing so, the principal concern regards the presence of Cd in CdTe and CdS solar films and of Pb in *x*-Si modules if they contain Pb-based solder. Should these modules end in a municipal waste incinerator (MWI), the heavy metals could gasify and a fraction of the gases will be released into the atmosphere. If the MWI is equipped with an electrostatic precipitator (ESP), this fraction can be as small as 0.5%, with the balance of the heavy metals remaining in the ash. The ash must be disposed of in controlled landfills.

Should the modules end up in municipal landfills, there is the potential for the heavy metals to leach

out into the soil. The leachability of metals in landfills is characterized by two elution tests: the U.S. Environmental Protection Agency Toxicity Characterization Leachate Profile (TCLP) and the German DEV S4 (Deutsches Einheitsverfahren). Both tests assume a worst-case scenario for such potential leaching. In these tests, small pieces ($<1\,cm^2$) of broken modules are suspended and rotated in an eluent for 24 h. The metals present in the eluent are then measured and compared with limits prescribed by each testing protocol. If the metals' concentration exceeds the limits, the modules are demonstrating the metals' leachability and may need to be recycled or disposed of in a hazardous waste landfill. If the metals are not leaching in excessive quantities, the modules can be disposed of in a commercial landfill. Early CdTe modules failed the TCLP and the DEV tests, while Apollo modules produced by BP Solar have been reported to pass the TCLP. In exploratory tests with a few commercial *x*-Si modules, some failed the TCLP limit for Pb by approximately 30%. No data were found on TCLP testing of currently produced *x*-Si modules. CIS modules passed the test for Se in a first set of experiments. No data were found for GaAs modules. The a-Si modules contain very little hazardous material and easily pass the test. The TCLP test is a conservative one that requires breaking up the whole module into very small pieces, whereas under normal conditions the PV layer is sandwiched between two layers of glass and reasonably isolated from the environment.

The ultimate solution to PV waste and end-of-life management is recycling the useful materials. Studies at Brookhaven National Laboratory and Solar Cells, Incorporated showed that recycling is technologically and economically feasible based on the current collection/recycling infrastructure and on emerging recycling technologies. Metals from used solar panels in large centralized applications can be reclaimed in metal smelting/refining facilities that use the glass as a fluxing agent and recover most of the metals by incorporating them in their product streams. In dispersed operations, small quantities and the high costs of transportation make this option relatively expensive. Research supported by the U.S. Department of Energy Small Business Research Initiative (SBRI) program aims the development of technologies for hydrometallurgical separation that may be used for both small-scale (in-house) and large-scale recycling. The PV industry is investigating these options as part of its proactive long-term environmental strategy to preserve the environmental friendliness of solar cells. Although the PV industry will not face this problem on a large scale before 2020, today's choices of materials and module designs may very well set a precedent for the future. The PV industry may choose to recycle spent modules, even if there are no regulatory issues related to their disposal, because recycling may improve market penetration.

9. ENVIRONMENTAL BENEFITS OF PHOTOVOLTAICS OPERATION

Carbon dioxide emissions are zero during the operation of PV systems because they require little or no maintenance or oversight. Some CO_2 emissions can be attributed to manufacturing because it takes energy to make a module. Thus, PV systems require some input energy, which they pay back early in their lifetime. This energy payback (EPB) was the focus of studies by Alsema, Frankl, Kato, and others. In the past, PV manufacture had a high EPB because the technology was immature and burdened by energy-intensive processing. Existing PV systems have an EPB of 3–10 years; future technological options likely will reduce the system's EPB to 1–3 years. In this range, the amount of CO_2 displaced by PV during a 30-year lifetime outdoors is 90–97% compared to the CO_2 of the energy it offsets. For example, assuming that U.S. energy generation causes 160 g carbon equivalent of CO_2 per kilowatt-hour of electricity, then a 1-kW PV array in an average U.S. location would produce approximately 1600 kWh each year and 48,000 kWh in 30 years. This array would avoid approximately $(48{,}000 \times 0.95) \times 160$ g/kWh, or approximately 7 metric tons of carbon equivalent during its useful life. Building integrated photovoltaics may further shorten the period of EPB by avoiding the energy required for structural supports. Exact predictions require a knowledge of the mix of energies with which PV will be manufactured and the mix that it will displace (which will vary with location, application, and date). The U.S. Photovoltaic Industry Roadmap projected that by 2020 the domestic PV industry could provide up to 3.2 GW of new peak electricity, increasing to approximately 25 GW by 2030. These projections correspond to an average growth in PV capacity of 25% per year. The estimated mixture of applications is one-half AC distributed generation, one-sixth AC wholesale grid generation, and one-third DC and AC value applications.

Fthenakis and Morris used the MARKAL MACRO model to test these projections. MARKAL is a multiperiod, linear programming model that

captures the complex interrelationships of energy systems and their environmental emissions across the spectrum from energy resources to energy services. The model minimizes the total cost of the energy system over a multiyear period, subject to constraints, such as limitations on pollution emissions or on the growth rates of technologies. The analysis includes the entire energy system: extracting the resources; processing operations (such as refineries); electric, gas, and oil transmission and distribution operations; and end-use technologies, such as lighting, industrial heat production, and transportation technologies (from automobiles to ships and airplanes).

All energy resources on both the supply and demand sides, as well as energy efficiency and conservation technologies, compete in an even-handed manner. The model and its associated database are continually upgraded. Current projections are based on the 2001 MARKAL database, designed to closely match the U.S. Energy Information Administration's "Annual Energy Outlook 2001" except for the PV and wind data, which were obtained from the Department of Energy (DOE) and the Electric Power Research Institute (EPRI). There are 922 technologies in the MARKAL database, including demand devices such as residential heating, commercial refrigeration, and lighting. The database includes 52 electricity-generating technologies. MARKAL also projects pollution emissions based on the characteristics of the individual technologies in the energy mixture.

Table III shows the PV input data for the model. This information derives from the PV Roadmap for 2000–2020 and from the DOE/EPRI for 2025 and 2030 (the Roadmap stops at 2020). We assumed that the peak electricity demand largely overlapped the peak power demand. The only constraint on the model was the upper bound on growth of 25% per year. An average U.S. insolation of 1800 kW/h/m^2 was assumed; the PV penetration in regions of high solar insolation could be much greater than the average (Table IV).

Carbon and other gas emissions are an important part of the model's output. PV technology under the predicted rates of implementation in the United States would accelerate a steadily increasing displacement of carbon emissions. In 2030, this displacement is projected to be 17 million tons/year, and during the entire 30-year period PV would displace a total of 128 million metric tons of carbon (Table V).

In addition, in 2030 alone, PV would displace 169,000 tons of SO_2, 103,000 ton/year of NO_x, and 6200 tons of particulates (Table VI).

TABLE III

Cost Assumptions for PV ($/Wp) Input Values in MARKAL

	2000	2005	2010	2015	2020	2025	2030
$/Wp	6.1	4.3	3.0	2.1	1.5	1.0	0.9

TABLE IV

Total U.S. Capacity and % PV for the MARKAL Roadmap Case

	2000	2005	2010	2015	2020	2025	2030
Total capacity (kW/h/m^2)	768	821	895	972	1033	1129	1252
PV capacity (kW/h/m^2)	0.08	0.32	1.19	3.84	11.93	36.6	111.9
% PV	0.01	0.04	0.13	0.40	1.15	3.24	8.94

TABLE V

Displacement of Carbon Emissions by PV (Million Metric Tons/Year)

	2000	2005	2010	2015	2020	2025	2030
Carbon displaced	0.02	0.06	0.21	0.64	1.98	5.80	17.02

TABLE VI

Displacement of Other Emissions by PV (Thousands of Tons/Year)

	2000	2005	2010	2015	2020	2025	2030
NO_x	0.17	0.70	2.23	5.92	15.60	39.8	103
PM10	0.005	0.02	0.08	0.22	0.89	2.10	6.22
SO_2	0.23	0.82	2.62	7.45	21.3	59.4	169

This analysis addresses only the grid-connected portion of the Roadmap in the highly competitive U.S. market; it does not examine the PV prospects of the promising markets of the developing world.

10. CONCLUSION

The manufacture of PV modules uses some hazardous materials, which can present health and safety risks if adequate precautions are not taken. Routine conditions in manufacturing facilities should not pose any threat to health and the environment.

Hazardous materials could adversely affect occupational health and, in some instances, public health during accidents. Such hazards arise primarily from the toxicity and explosiveness of specific gases. Accidental releases of hazardous gases and vapors can be prevented by using safer technologies, processes, and materials, better material utilization, and enhancing employee training and safety procedures. As the PV industry vigilantly and systematically approaches these issues and mitigation strategies, the risk to the industry, the workers, and the public is continually minimized.

Photovoltaics in the energy market will replace fossil fuel combustion technologies and will subsequently reduce the discharges of carbon dioxide, sulfur dioxide, nitrogen oxide, and particulates throughout the region where they are installed. Based on energy–environmental–economic analysis, we predict that with the current price projections for the energy technologies in the U.S. energy mixture, photovoltaics could reach a capacity of 12 GW by 2020 and 112 GW by 2030, eliminating a significant amount of pollutants from the U.S. energy cycle.

Glossary

entropy A measure of the disorder or unavailability of energy within a closed system. More entropy means less energy is available for doing work.

First Law of Thermodynamics The internal energy in a system isolated from other systems remains constant (energy is conserved).

Law of Conservation of Matter During an ordinary chemical change, there is no detectable increase or decrease in the quantity of matter.

Second Law of Thermodynamics The principle that the disorder of an isolated system (entropy) increases to a maximum.

1. INTRODUCTION

The use of energy in human society is a many-faceted subject. Many fields of knowledge are involved in the understanding of this subject. Energy is a fundamental concept in physics. When dealing with energy in society, a certain usefulness is assumed, a set of qualities of energy forms that are also possible to describe in physical terms. Energy is procured from natural systems and given back to natural systems after transformations in the society. These processes are economic and biological as well as technical in nature and they are often regulated by society. The technical processes can be designed or analyzed on the basis of the physical sciences. Exchanges and regulations can be analyzed in terms of values and costs/risks. Here, environmental and health aspects become intertwined with technical, economic, and judicial aspects. On a fundamental level, there are the value aspects, in particular, ethical aspects.

One must keep in mind that all these aspects are relevant. In science, one often must simplify, and there are often temptations for scientists to adopt one aspect as being supreme and to let it dominate the description or analysis. Simplified pictures of this kind can be very pedagogical, but they may also lead to misconceptions that can be very harmful. One way to check one's understanding is to ask what the system/process or the problem in question looks like on another level. Traditionally, in science, analyzing in terms of subsystems or subprocesses has been a very successful approach. It has become increasingly clear that it may also be necessary to analyze a certain system or process in relation to the larger context, sometimes several larger contexts, in which it is embedded.

In the case of energy in society, from looking mainly at technical systems for providing primary energy, one has been forced to ask whether the whole societal energy system can be sustainably embedded in the ecosphere. For nuclear energy, one has been forced to ask whether the bulk handling of radioactive material can be performed safely in the present and future world with its conflicting interests and unforeseeable risks. The time scale involved in considering the handling of nuclear waste is long not only compared to lead times in energy technology but even compared to the know human history.

One system boundary that must be broken immediately is the one between energy and matter. First, most of the crucial problems of the energy system are material-related. In the case of energy and climate, it is the transition of carbon from its original

 © 2004 Elsevier Inc. All rights reserved.

state in fossil coal, oil, or gas to atmospheric carbon dioxide that is crucial. Second, a very large part of the energy use in society is related to material transformations or transports of materials. Energy use in the aluminum and cement industries are two examples of this.

Physical processes of conversions of energy and materials are fundamental for the metabolism of living organisms and for the metabolism of human society. Different forms of energy and matter have different physical (thermodynamic) values and also different degrees of usefulness and economic value.

Sections 2 and 3 deal with basic concepts and principles related to the physical aspects of energy. Section 4 deals with the use of energy in society and the interface between physics and economics. Section 5 discusses energy in connection to values and economic principles. The two aspects are brought together in Section 6, where the evolutionary perspective on the use of energy and matter meets the human responsibility of today's resource handling on Earth.

2. PHYSICAL ASPECTS OF ENERGY

The scientific field that deals with transformations of energy and materials is thermodynamics, which describes macroscopic quantities of energy and matter. The theoretical way to understand this is statistical; the underlying theory is statistical mechanics, which analyzes populations of many particles and their motions and interactions.

In the late 1950s, E. T. Jaynes showed how statistical mechanics can be interpreted in terms of another relatively new theory, C. E. Shannon's theory of information, basically a theory of signals. It deals with probability distributions, conjectured or observed. Information theory is of fundamental interest for describing an important use of energy in nature and society, the build up of structures.

In information theory, an answer, "yes" or "no," or, equivalently, a binary figure, 0 or 1, carries one bit of information, against a background of total uncertainty with *a priori* probability $\frac{1}{2}$ for 0 or 1. The information carried by a certain symbol having a priori probability p is (in bits)

$$^2\log\frac{1}{p}.$$

Clearly, when $p = \frac{1}{2}$, the result is unity.

In a text, the different letters appear with different probabilities (different frequencies), and hence they carry different amounts of information. In an n-letter alphabet, the letters can be denoted by $i\,(i = 1, 2, \ldots, n)$. Let p_i be the probability that, in a randomly chosen space, the letter that one finds there is i. Weighing the information gain in finding the letter i, $^2\log\frac{1}{p_i}$ with the probability p_i for its appearance, and summing over all letters, one obtains the expected information gain, i.e., the present information deficit,

$$S(p) = \sum_{i=1}^{n} p_i \, ^2\log\frac{1}{p_i}.$$

This is the entropy of the probability distribution $p = \{p_i\}$.

From looking just at single letters in a text, one can continue and look at pairs of neighboring letters or, more generally, at strings, i.e., sequences, of increasing length. In a text in a certain language, there are correlations between neighboring letters; i.e., certain letter combinations occur more frequently than others.

If there are two probability assignments, $p^{(0)} = \{p_i^{(0)}\}$ and $p = \{p_i\}$, and the latter is based on more knowledge than the former, then the information gain in going from the former to the latter is

$$K(p^{(0)}; p) = \sum_{i=1}^{n} p_i \left[-\left(^2\log\frac{1}{p_i} - ^2\log\frac{1}{p_i^{(0)}} \right) \right]$$
$$= \sum_{i=1}^{n} p_i \, ^2\log\frac{p_i}{p_i^{(0)}}.$$

(The information difference is minus the information deficit difference; moreover, the best probability assignment $p = \{p_i\}$ must be used to give the weights.)

Here, $K(p^{(0)}; p)$ is the relative entropy (or Kullback information) of the probability distribution p with respect to the reference distribution $p^{(0)} = \{p_i^{(0)}\}$. The Kullback information has the property that it is never negative and it is zero only when the probability distributions coincide.

These two concepts, entropy and relative entropy, are the basic concepts of information theory. They are very flexible and can be readily used in information theory, statistics, linguistics, and physics, as well as in other sciences.

As already mentioned, one may generalize from a string of discrete letters, i.e., a text, to a lattice in two or more dimensions. An important example of a two-dimensional lattice is a picture image, consisting of pixels, in black/white or color. Generalizing to continuous systems in any number of dimensions is also possible. In classical physics, one has vectors in the so-called phase space of positions and momenta of many particles, and the resulting theory is, as

mentioned already, statistical mechanics. Here, probability assignments represent macroscopic physical states. Extension into quantum mechanics is quite straightforward but is not discussed here. It should be mentioned, though, that this extension is essential for several important energy technologies.

Entropy is thus a fundamental quantity not only in information theory but also in statistical mechanics and thermodynamics. The two entropies are identical for a physical system except for a constant factor,

$$S_{\text{thermodyn}} = (k\ln 2)S_{\text{info}},$$

where k is Boltzmann's constant, and

$$k\ln 2 = 1.0 \times 10^{-23}\,\text{JK}^{-1}\,\text{bit}^{-1}.$$

Energy is a fundamental physical quantity. It is closely related to time and momentum is closely related to space. In fact, the quantity representing energy in quantum mechanics also has the function of generating displacement in time and momentum generates spatial displacement. Conservation of energy, the first law of thermodynamics, is related to the fact that the laws of nature are invariant under time displacements. Similarly, conservation of momentum (the law of inertia) and conservation of angular momentum follow from the universality of physical laws in space.

Matter, under the conditions of the universe of today, is made up of nucleons (neutrons and protons, the constituents of atomic nuclei) and electrons. Three quarks constitute a nucleon. The mass of an electron is approximately 1/200 of the mass of a nucleon. In particle physics, as studied at accelerator laboratories, a large variety of particles made up of quarks and anti-quarks are created and investigated. This includes the formation of matter and antimatter. Also leptons, the particle family to which the electron belongs, can be similarly produced and studied.

Electric charge is conserved. The same is true for lepton number and quark number with extremely good accuracy (except possibly for extreme situations, such as in the very early universe). Since accelerator laboratory reactions are rare, this means that for all practical purposes, one can regard the number of nucleons as constant and consider this the law of conservation of matter.

The state of a system of many particles is usually not exactly known. Even if the laws of motion were exactly known, the uncertainty would still grow in time due to delicate dependence on unknown parameters of the initial state. Hence, for any system left by itself, the entropy increases. This is the second law of thermodynamics.

When the entropy of a closed system has reached its maximum value, the system will remain in this state; i.e., it is in its equilibrium state. Hence, the deviation of entropy from its maximum value is a measure of the degree of nonequilibrium.

Another useful measure related to this is the Kullback information or relative entropy, defined above. Where there is disequilibrium, there is, at least in principle, the possibility of extracting work. Consider an ideal process, i.e., a reversible and entropy non-producing process, to extract mechanical work (which is of zero entropy) from a system, while it approaches equilibrium. Then, the amount of extractable work from the system, called the exergy E of the system, is proportional to the Kullback information,

$$E = (k\ln 2)T_0K(p^{(0)};p).$$

Here, p is the original state of the system, and $p^{(0)}$ is the equilibrium state of temperature, T_0, reached reversibly under the extraction of the amount E of mechanical work.

This may all seem very theoretical, but it is applicable to all sorts of disequilibria, such as differences in temperature or in pressure or chemical disequilibria. It is thus generally applicable to physical and technical systems and processes for energy and material transfers and conversions.

Earth is situated in a radiation flow from the Sun and it radiates this energy as heat into the interstellar space. The geophysical systems and life on Earth's surface convert radiated energy coming from the Sun at an average temperature of 5800 K. Approximately 30% is reflected. After conversions, involving the water cycle and the carbon cycle, the absorbed energy leaves Earth as radiation at an average temperature of 255 K (−18°C). This can be viewed as a huge heat engine with an available exergy power of 115,000 TW. Of this, the global society uses less than 0.01%.

In terms of information inflow or, rather, flow of information capacity, the radiation exchange of Earth amounts to 4×10^{37} bits per second. Of the huge inflow of information, some has been coded into the structure of life and the complex molecular interplays within the cell, also into the regulatory mechanisms within organisms, between individuals of a population, and between species of an ecosystem. Life has interacted with and changed the geophysical systems in a mutually adaptive evolution. Earth has a large system of biogeochemical

cycles on which life depends. Except for the influence of actions of the human society, in particular the industrial society, this system would be relatively stationary.

There are many examples of structure formation in systems with a through-flow of energy (Fig. 1). The whole living world contains an enormous richness of such phenomena on various scales. There are also many non-living examples, such as cloud formation and the formation of snowflakes.

A classroom experiment of self-organization, easy to repeat, is the set of reactions in a solution of chemicals, devised by Belousov and Zhabotinsky. The solution contains an energy-rich substance and substances that become involved in nonlinear reaction kinetics and diffusion. Small thermal fluctuations in concentrations are sufficient to trigger the system to form visible geometrical structures that are slowly changing and eventually decaying.

Figure 2 shows a diagram of exergy (information capacity) flows in such a self-organizing system. The same principle applies also to spontaneous structuring on various levels in cosmic, stellar, and biological evolution. A through-flow of energy can give a net inflow of exergy. In a self-organizing system, there are flows driven by gradients, differences in concentration, pressure, or temperature. Such motions are irreversible processes involving entropy production.

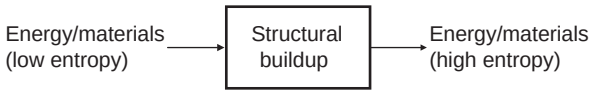

FIGURE 1 Diagram of structure formation of a system in a flow of energy or of energy with matter. Due to differences in entropy between the flows, there is a net inflow of exergy or information capacity. There is also entropy production (dissipation) within the system.

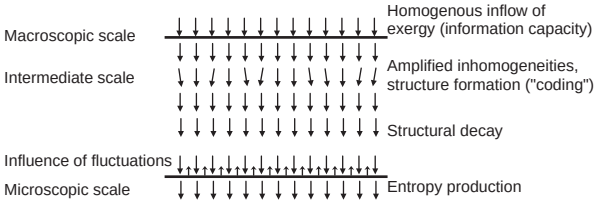

FIGURE 2 Diagram indicating flow of information from the macroscopic scale to the microscopic scale via an intermediate scale with structure formation triggered by fluctuations. Structure formation can take place on different scales. Structure formation and decay are both present in the flow from macro to micro.

In practice, of course, no process is totally ideal/reversible; there is always production of entropy. Therefore, not all of the exergy present in a system can be extracted as work. The exergy loss in a conversion process is proportional to the entropy produced in the process,

$$W = E - T_0 \Delta S.$$

(Here, E the original exergy, W is the extracted work, ΔS is the entropy production, and T_0 is a reference temperature, usually the ambient temperature or the equilibrium temperature.)

Thus, exergy can be lost but not created. It is something valuable, also economically. Therefore, it is useful as a physical resource measure. Expressed in thermodynamic quantities, the exergy is

$$E = U - T_0 S + p_0 V - \sum_i \mu_{i0} N_i,$$

where U is the internal energy, S is the entropy, V is the volume, and N_i are the amounts of different chemical components. Furthermore, T_0 is the reference temperature, p_0 is the reference pressure, and μ_{i0} are reference chemical potentials. The exergy is thus context-dependent through the choice of reference system.

Apart from nuclear reactions and decays, chemical elements are conserved. Thus, chemical elements, energy, and exergy can be subject to bookkeeping; i.e., balance accounts can be set up for inflows, outflows, and internal movements and conversions. Clearly, such bookkeeping can easily be generalized to include nuclear reactions and decays, for instance, in the nuclear industry. If the context dependence of exergy is to be avoided, entropy and entropy production can be taken into account instead. Physical bookkeeping can be done for natural systems, such as an ecosystem, a population, an individual organism, or a cell, but also for production/consumption units, such as a factory, a machine, a car, or a household.

The disequilibrium between the dense and hot Sun and the cold interstellar space functions like the poles of a large battery. Earth is situated in a radiation flow, an energy current from the hot pole to the cold pole of this battery. On Earth, this current charges secondary batteries and secondary currents: temperature and pessure differences, differences in gravitational potentials between high-altitude dams and the sea; the water cycle, incuding rivers and ocean currents, winds, and waves. Many of those secondary batteries and currents are used by the societal energy systems.

3. COSMIC ORIGIN OF EXERGY RESOURCES

It may be natural to ask for the origin of the Sun/space battery. How was it charged? The answer is that two disequilibria developed in the early universe, one nuclear and one gravitational. Both were related to the expansion of the universe and with this the changing equilibrium conditions (and with this the maximum possible entropy).

According to the standard theory of the early universe, nuclear matter existed as nucleons and was in thermal equilibrium 0.01 s after the Big Bang. The universe continued to expand and when the temperature passed below the dissociation temperatures for ordinary nuclei, the possible equilibrium state for nuclear matter became iron nuclei (^{56}Fe). At that time, approximately $\frac{1}{8}$ of the nucleons were neutrons; the rest were protons. Only the first steps of nuclear reactions could take place under the prevailing conditions. During the fourth minute, neutrons joined with protons to form helium (^{4}He). After this, almost all nuclear matter was in the form of helium $\left(\frac{1}{4}\right)$ and the remaining hydrogen, i.e., protons $\left(\frac{3}{4}\right)$. The conditions needed for continued nuclear reactions were not prevalent. The nuclear fuel of the early universe was thus saved for later burning in stars. During the first hours of the universe, through the cooling by cosmic expansion, the difference widened between the actual state of nuclear matter and the equilibrium state. The nuclear matter had become "supercooled" through cosmic expansion and nuclear exergy had been created.

In the early universe, matter was suspended in radiation. When the temperature dropped below the ionization temperature of helium and hydrogen a few hundred thousand years after the Big Bang, neutral atoms could form and radiation became more weakly coupled to matter. Then, gravitational clumping was possible and gravitational exergy was created. Matter could assemble on various levels to become galaxies or solar systems. Stars could start to form and in them, energy was converted into radiation through nuclear burning, which produced the various chemical elements. Matter thrown out from exploding stars was reassembled in later generations of stars, such as the Sun. What now remains of the original radiation is the 3 K cosmic background radiation.

With self-organizing systems, the old clockwork metaphor of physical science had to give way to a new view of dynamics, supported by a vastly increased capacity to study processes through computer simulations. The clockwork itself is a dissipative (entropy-producing) system: when it runs down, it converts mechanical energy into heat. Even if fundamental physical laws, as in quantum field theory, may be elegantly summarized in a principle of least action, actual physics is still indeterministic due to uncertainties in initial conditions and external influences. The old deterministic way of viewing physics may have had too strong an impact on other sciences, providing them with obsolete ideals.

4. ENERGY IN SOCIETY

It is of interest to consider the main uses of exergy in society. They can be summarized as follows:

1. to replace losses that occur through
   i. leakages (e.g., heat leaking in or out through roofs or walls),
   ii. friction (e.g., in machines or vehicles), and
   iii. material degradation and dispersion (through wearing and tearing and corrosion); and
2. to steer irreversible processes of flows from one state to another (e.g., matter moving from high to low pressure or thermal energy moving from hot to cold).

With this kind of description, the places to look for improved efficiency become more obvious.

Physical bookkeeping, as described above, is then of interest for analyzing the efficiency of a system or for studying a system as part of a larger system, such as a community as part of an ecosystem in which it is embedded. In the 1970s, Robert Ayres developed physics-based principles and schemes for book keeping of the turnover of energy and materials in society.

Human society is a major component in Earth's cycles of nitrogen and sulfur. Humans are systematically interfering with the carbon/oxygen flows by bringing fossil carbon into the atmosphere as CO_2. Thereby, the natural greenhouse effect that makes Earth inhabitable is enhanced, resulting in global warming and risks for major climatic changes.

Some material flows are crucial for the functioning of the ecosphere. Others are toxic or geophysically harmful and must be avoided. This means that, in material balance accounts, some flows must be more carefully guarded than others. There is no single quantity that can function as an overall index. Good overviews are needed, but the generalists cannot do away with the detailed knowledge provided by the specialists.

Robert Ayres also pointed out that energy and matter are never consumed; both remain after consumption. Even the matter of our bodies is continuously exchanged; it is a temporary loan to be ultimately paid back. Exergy, i.e., energy quality, is consumed, however, through entropy production.

What is useful is a flow of services that is enjoyed, directly or in the use of products. Thus, "product" is an intermediary concept; the concept of basic economic importance is "service." It is useful to think of temporary leasing of products (carrying energy and matter) as a kind of service being consumed.

Figure 3 shows a diagrammatic representation of one unit in societal resource use and service production. In Fig. 4, production of a displacement service (transport or storage) is similarly represented.

Strictly speaking, a production process is not completed until all the flows have been duly processed in society or nature. This means that in the case of fossil fuels, the relaxation mechanisms of the atmosphere and climatic systems are to be viewed as part of the process of producing energy services. This is anomalous in the sense that completion of the production process must continue long after the consumption of the energy services. The waste handling in the nuclear energy industry, as mentioned, is anomalous in the same way.

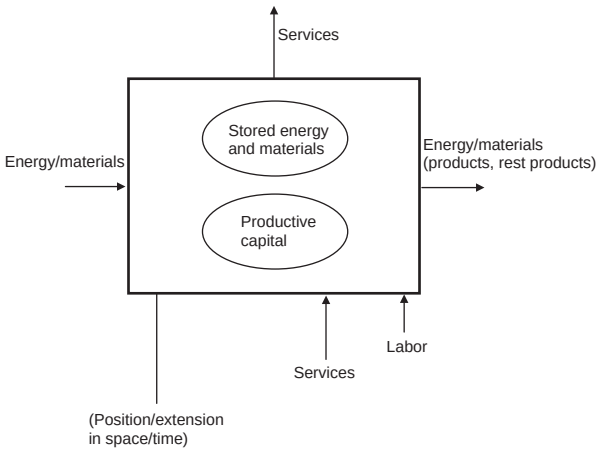

FIGURE 3 The metabolism of a society can be viewed as being built up of transformation activities like the one represented here. Physical flows are shown as horizontal arrows. Primary inflows come from natural systems and the final physical outflows also end up in natural systems. Only services are finally consumed. Products are viewed as intermediate entities. Leasing of a product over a time period is viewed as a service. Here labor is represented as nonphysical, since its human and economic aspects are more important than its physical aspects.

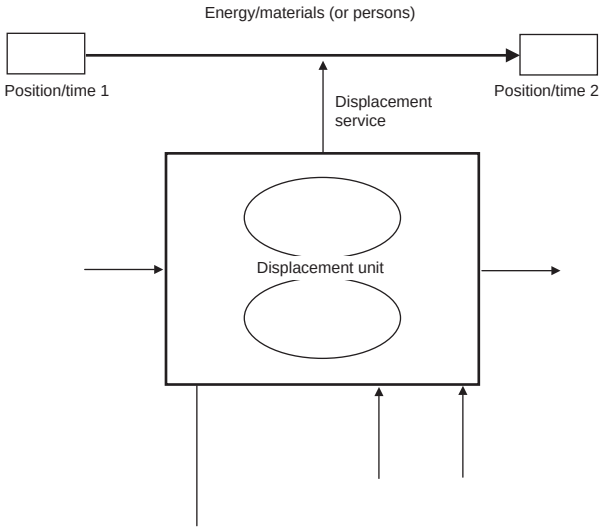

FIGURE 4 Diagram of a transport or storage (displacement) production unit, providing a transport or storage service.

Exergy was noted above as a resource measure. It is very general but still it cannot serve as a total resource measure, because it does not include all important aspects of the actual context. Exergy is needed to run everyday systems that make bodies, homes, and societies function. It is used (and most of it is consumed) for both maintenance and buildup.

Sadi Carnot's classical problem of maximizing the work output from heat can be viewed as an engineering problem with a physical solution but also as an economization problem. Thus, exergy expresses thermodynamic value but can also carry economic value.

To determine the space available for the totality of human activities (Daly's issue of scale, a reasonable size of one's ecological footprint or environmental space), one must analyze how the global society as a physical and ecological system can be sustainably embedded in the ecosphere. The global society is clearly far from static. A more just distribution of resources involves expansion, which must be compensated for by structural changes and increased efficiency ("factor 4" or "factor 10").

Very important discussions are going on in connection to the United Nations system, United Nations conferences and international negotiations, as well as in environmental science and in development research and in non-governmental organizations working with these issues. Consumers' responses to environmental and fair-trade rating of products have taken global issues into everyday life.

As mentioned above the exergy flow into Earth through its radiation exchange (Sun/space) is vast. There are large areas where solar energy could be efficiently harvested, in areas where people live as well as in uninhabited areas. Hydrogen can be expected to become a light and convenient energy carrier. The amount of exergy used in human society could be collected by photovoltaics in a rather limited desert area. The transition from fossil fuels to solar energy is at least physically feasible.

From the 2002 United Nations Conference on Environment and Development in Johannesburg, South Africa, the Swedish Ministry of Environment summarizes the discussion within the Forum on Science, Technology, and Innovation for Sustainable Development as follows (translation from Swedish by K.-E.E.):

> *From frontline research it is reported that it is possible to develop the technologies needed for the whole of humankind to enjoy a high standard of living. Access to clean water and good sanitation, clean energy, food and good health conditions for everybody is totally feasible. In this development, one must take as points of departure the ecological systems that form the basis for all this. Research and new investments will be needed. Sufficient amounts of capital and other resources are available but have to be redistributed—a massive resource mobilization is necessary from the public sphere as well as the private sphere.*
>
> *—Kjellén et al., 2002, Summary*

It would be good to have a clearer picture of a future sustainable resource use technology and the action space allowed for, say, an average family in a just global society.

The movement away from dumping CO_2 into the atmosphere may for some time involve sequestering of CO_2 into underground deposits, but in the long run, the necessary decarbonization must take place through abandoning of fossil carbon and a transition to renewable primary energy.

It is worth noting that, apart from biomass, renewable energy leads not only to decarbonization but also to dematerialization by largely removing material energy carriers. Wind energy and solar energy can be harvested without anything that corresponds to hydropower dams or nuclear reactors, and when a material energy carrier is needed, it can be hydrogen. More sophisticated material quality management can be achieved through repair, reuse, and recycling and through substitution of organic materials and light metals for heavier metals.

It is important to note that several materials that are candidates for energy converters and energy storage (photovoltaics, fuel cells, and batteries) are problematic. Some are quite rare in Earth's crust; some have toxic effects and should not be allowed into the ecosphere. Fortunately, silicon, still a top candidate for photovoltaics, is both abundant and nontoxic. Exactly which technological combinations will prove sustainable in the long term cannot be foreseen as yet.

One can ask what the resource system of a just global society would look like and how it could be organized administratively and economically to serve the average family mentioned above. It should be possible to use physical, technical, and ecological constraints as inputs in economic models and deduce relative prices, probably quite different from today's prices.

5. ENERGY, VALUES, AND ECONOMICS

We have seen that exergy is basic for life and activities in nature and society. Exergy is a measure of value in physical terms. However, the more complex a system or a process becomes, the less can be said by physics. Even the term "complexity" is problematic. There are several definitions of complexity as a quantitative concept in information theory. These definitions capture important aspects, but there is no mature theory of complexity. For the understanding of complex systems and processes, one needs the life sciences, social sciences, and humanities. What about economics, in particular, energy economics?

Some years ago, in a draft of the economics chapter for a report from the Intergovernmental Panel on Climate Change (IPCC), in an estimate of the costs of climate change, a statistical life in a poor country was valued as $\frac{1}{15}$ of a statistical life in a rich country. Willingness to pay for life insurance was part of the basis for this finding.

This led to very strong criticism by many scientists and finally the discussion convinced the authors that a change was necessary in the principles for making cost estimates in a global perspective. Willingness (or rather ability) to pay for life insurance could no longer be considered a reasonable basis for value. The presently dominant ideology that attributes a fundamental significance to market and money was shaken, at least temporarily. If the IPCC draft had taken into account that the marginal value of money is greater for a poor person than for a rich person, then a factor of approximately 15 would have appeared and canceled the factor $\frac{1}{15}$.

All this shows that moral values can be deeply involved in dealing with economic evaluations of energy systems.

If the idea that economic value is tied to human welfare is taken seriously, then this has very strong implications. The global welfare deficit can be computed for the current very unequal income distribution with a conventional welfare function. The deficit can then be expressed as a cost in money terms, using money value at the average income level. The cost turns out to be on the same order of magnitude as the total global income or larger. Thus, if inequality were included in measures of economic performance, economic descriptions would change drastically.

This discussion shows that it is important to test the validity limits of reasoning and concepts. It is especially so with economics, considering the dominant position of economic rationality for decision-making on almost all levels.

An important study in this context attempted to arrive at an economic value of nature. This work showed that large modifications are needed in economics in order to include the value of natural systems. It also showed that the uncertainties are large. Economics also has difficulties in handling not only natural capital, but also human capital and social and cultural capital and the value flows associated with these.

Either such value aspects should be included in economic considerations or those value aspects should define the boundaries within which economic considerations are to be made. As the above example from the IPCC draft shows, pure economic considerations, not governed by human value, can become immoral. The conclusion is that physical and economic aspects are both very important, but one should be well aware of their limitations.

Efficiency is a topic where physics and economics meet. Carnot's efficiency problem opened a new branch of physics: thermodynamics; at the same time, it was an economic problem. Thermodynamic efficiency can be economically visible through an exergy price.

There are also other links. Distributional inefficiency is related to technical (and thermodynamic) inefficiency: poor people may not afford investments to improve efficiency and rich people may not feel the fees introduced to discourage them from waste. Organizational efficiency and social efficiency are also relevant aspects to be included in an efficiency analysis.

Justice between generations can be seen as an intertemporal efficiency. If the time anomalies in production described above are to be taken seriously, then, for consistency, there should be no discounting of the future; the *a priori* discount must be zero.

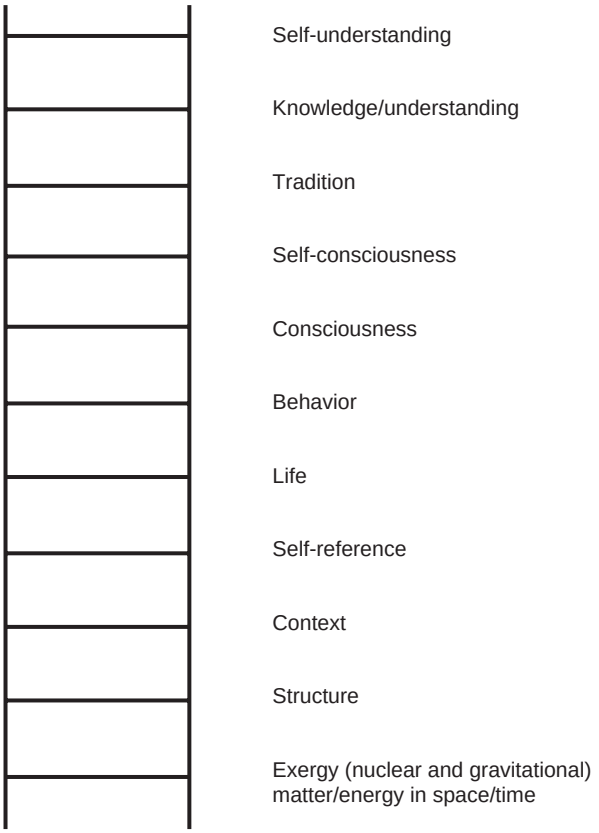

FIGURE 5 Diagram of an evolution ladder with emergent system characteristics.

6. THE EVOLUTIONARY PERSPECTIVE

Since the very early beginnings of the universe, transformations of energy and matter have involved the emergence of new systems and phenomena. The history of the universe is a history of creation. Structure was created or became manifest in early clouds on a different scale, to become solar systems or galaxies.

The surface of Earth developed conditions favorable for the richness of carbon chemistry, a wealth of possible forms and processes of varying permanence and flexibility. Self-organization also came to involve self-reference, i.e., systems carrying blueprints of themselves. Accidental changes in such blueprints sometimes led to more efficient modified systems. Reproduction, life, variation, selection, and

evolution became possible. Evolution is a process of accumulating information, selected on the basis of its functional advantages for reproduction. The story is as represented in Figs. 1 and 2, repeated on many levels and many scales. Information capacity (exergy) became coded into relatively stable information carrying a meaning.

The ladder in Fig. 5 is an attempt to identify steps in evolution, starting with the cosmic origin of the universe in the Big Bang. The steps may be quite ambiguous, but they are meant to convey the evolutionary perspective of modern science. We human beings may be seen as organs, through which the universe/cosmos can view itself and reflect over itself.

Not knowing of evolution in other parts of the universe, it is reasonable to ask what evolutionary step could or should be taken by humans on Earth. Information and communication technology reaches almost everywhere on Earth and is becoming global in character. Technically, humankind is one unit. Ecologically, we humans are strongly dependent on one another in the treatment of Earth. However, economically, politically, and ideologically, we are still divided. In the quoted summary from Johannesburg, adequate resources for a good life for everybody, including clean energy, is described as a realistic possibility. The next evolutionary step on the ladder would therefore be to unite, to develop and share a common self-understanding, and to act together and organize a good life on Earth.

Glossary

bio-based plastics Plastics that are fully or partially produced from biomass-derived feedstocks (renewable raw materials).
cradle-to-factory gate System covering all process steps from the extraction of resources to their transformation (e.g., in refineries) and the conversion to monomers and polymers.
cradle-to-grave Same as cradle-to-factory gate but including also all activities related to waste management (due to the diversity of application areas, the use phase is often excluded in comparisons for polymers).
finite energy Nonrenewable energy sources (i.e., mainly fossil and nuclear fuels).
petrochemical plastics Plastics that are produced from petrochemical feedstocks.
plastics Macromolecular materials produced from petrochemical feedstocks or renewable raw materials by means of polymerization.

Worldwide, the production of polymers totaled approximately 180 million tonnes in 2001. Of all man-made bulk materials, the total energy input for plastics production is estimated to be fifth after that for cement, steel, paper/board, and bricks/tiles. In the past few decades, plastics production outpaced that of all other bulk materials, with the average worldwide growth rate for plastics 5.8% per year between 1990 and 2000. During the same period, the growth rate of plastics production exceeded gross domestic product growth [3.6% per annum (PA)] by more than 2% PA. Plastics enjoy high growth rates both in low-income and high-income countries (e.g., approximately 40% PA in Western Europe versus approximately 300% PA in India between 1990 and 2000). Given the very low per capita consumption rates in developing countries (India, 3.5 kg/capita; China, 12 kg/capita; world, 24 kg/capita), plastics production can be expected to continue to grow considerably in the next decades.

1. INTRODUCTION

Among the bulk plastics, use of polyolefins has increased most in the past decade, with particularly high growth rates for polypropylene (PP) and linear low-density polyethylene (LLDPE). Polystyrene (PS) and polyvinyl chloride (PVC), on the other hand, have grown at a rate approximately the world average. Table I provides an overview of products that are typically manufactured from these and other types of polymers.

The overwhelming share of all plastics is produced from petrochemical feedstocks (more than 99.9%). This is the consequence of the growth of the petrochemical industry in the early 20th century, whereas the first man-made polymers were derived from biomass resources. However, since the 1980s and 1990s, increased use of bio-based polymers has been observed in certain application areas. In 1998, production of bio-based polymers in the European Union (EU) was approximately 25,000 tonnes. The total market is projected to grow autonomously to approximately 500,000 tonnes until 2010 [28% per annum (PA), 1.5% market share] and to approximately 1 million tonnes if supportive policies and measures are implemented (36% PA, 3% market share). So far, there are no policies and measures at the EU level, whereas national legislation provides advantages for bio-based polymers in certain areas (e.g., due to the packaging ordinance in Germany).

TABLE I

Overview of Typical Applications by Types of Polymers

Polymer	Applications
Epoxy resin	Industrial floorings, foams, fiber-reinforced plastics
High-density Polyethylene	Moulded products, heavy-duty films
Linear low-density polyethylene	Films (food packaging), rotational moulded products (e.g., tanks)
Low-density polyethylene	Food packaging
Melamine formaldehyde resin	Decorative laminates, lacquers
Phenol formaldehyde resin	Laminates for printed circuit boards
Polyacrylonitrile	Fibers
Polyamide (nylon)	Fibers, plastic gears, tire cord
Polycarbonate	Safety goggles, safety transparent shields, machinery housings
Polyethylene terephthalate	Blow-moulded bottles
Polypropylene	Injection-moulded products (e.g., technical parts for washing machine), films (e.g., for cigarette wrappers), monofilaments, ropes
Polystyrene	Moulded containers, lids, jars, bottles, foamed plastics
Polyurethane	Foams, coatings, adhesives and elastomers
Polyvinyl chloride	Extrusion products (wire and cable, conduits, profiles)
Unsaturated polyesteralkyd resin	Fibers, coatings, adhesive
Urea formaldehyde resin	Paper coating, adhesive

Most of the bio-based plastics that are currently on the market are biodegradable, but there are also increasingly more bio-based materials that are not biodegradable (e.g., composites of natural fibers and petrochemical polymers).

Starch polymers represent by far the largest group of commercially available bio-based plastics. Other prominent bio-based plastics are polylactic acid (PLA), polytrimethylene terephthalate, and polyhydroxyalkanoates (PHA).

Due their importance, starch polymers, PLA, PHA, and natural fiber composites, which are all manufactured at an industrial scale, are discussed in this article in addition to conventional petrochemical plastics. The first three materials are biodegradable; this is not the case for the natural fiber composites and the petrochemical plastics covered.

Given the dynamic developments discussed previously and the variety of plastics on the market, it is of great relevance to provide an overview of the energy use related to plastics. If the total life cycle of plastics is taken into account—comprising all process steps from the extraction of resources to polymer production and plastics processing and waste management—plastics account for approximately 4% of the total primary energy use in high-income countries (4.2–4.4% in Western Europe; data exclude the use phase). More than 90% of this is required for all processes related to plastics production, on which we will focus in this article (approximately 4.0% of total fossil fuel use in Western Europe). In the future, improved waste management, including recycling, reuse, and advanced energy recovery, may contribute substantially to materials and energy savings. These options and the attendant potential for energy saving are not discussed in this article.

2. METHOD AND SCOPE

This article is based on a review of energy analyses and life cycle studies on petrochemical and bio-based plastics. The studies reviewed basically follow the principles of life cycle assessment (LCA), which is a standardized method to quantify environmental impacts. In practically all LCA studies, energy use is included in the set of indicators, which typically also includes the release of greenhouse gases, the acidification and eutrophication potentials, waste generation, and other environmental impacts.

As in most LCA studies, we focus on the use of finite (i.e., nonrenewable) energy. This comprises fossil fuels and, to a lesser extent, nuclear fuels. Large amounts of renewable resources (especially biomass derivatives) are used for the production of bio-based plastics, but the quantities used are not discussed in this article. We focus on finite energy because of the limited resource perspective, the high dependence on foreign supplies, and the generally higher environmental impacts than in the case of renewable energy.

As indicated previously, we focus on energy use for plastics production, also referred to as cradle-to-factory gate analyses. This type of analysis includes all processes, including the extraction of energy resources, their transformation (mainly in refineries and power stations), the conversion of the feedstocks to monomers and polymers, and the manufacture of the required auxiliaries (Fig. 1, gray box). Processing of polymers to final products, their use phase, and

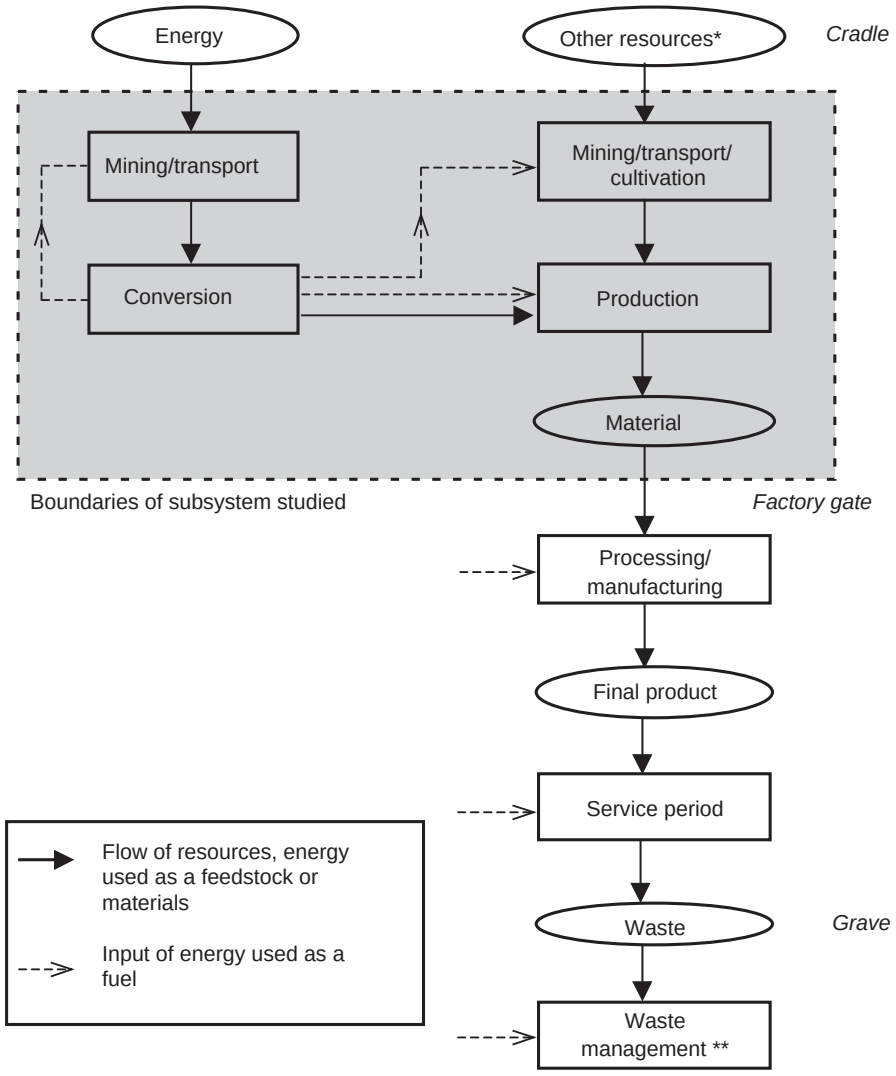

FIGURE 1 Overview of the entire system and the subsystem discussed in this article (gray box). *Energy analyses do not account for the consumption of resources other than energy, but they do include the energy requirements to process these "other resources." **Landfilling, incineration, and recycling (not shown).

the waste management stage are not included in the system boundaries (in contrast, studies that do include the latter are referred to as "cradle-to-grave analyses).

Fossil fuels are used both as a feedstock for chemical reactions and to cover the energy requirements of the production processes and transportation (Fig. 1). In the case of bio-based plastics, the biomass-derived inputs are almost exclusively used as a feedstock but efforts are being made to integrate waste and by-products in the energy supply.

As a basis for all comparisons, 1 tonne of plastics in the form of pellets (granules) has been chosen as the functional unit. This is a convenient basis since it allows the comparison across types of polymers, but it also has some drawbacks.

3. RESULTS

A distinction can be made between the use of energy resources as feedstocks and as process energy (in the form of electricity, steam, or direct fuel use). Reporting of feedstock energy is complicated by the fact that in some processes, part of the feedstock is used to fuel the process (e.g., in steam crackers for olefin production and in ammonia production). As a consequence, feedstock energy use should be

defined precisely in every study, but this is rarely done (if feedstock and process energy are distinguished at all). For this reason, we do not distinguish between these two types of energy use and exclusively report total energy use (cradle-to-factory gate energy).

However, there is a relatively safe way to address the issue by making use of information on the heating value of plastics. The heating value represents the amount of feedstock energy that is physically fixed in the plastics (Table II). Hence, the remainder (i.e., the difference between cradle-to-factory gate energy and the heating value) can be defined as the process energy consumed in the various production steps.

In the following sections, we discuss energy requirements for the production of petrochemical plastics and bio-based plastics.

3.1 Petrochemical Plastics

Table III provides an overview of cradle-to-factory gate energy requirements of 21 petrochemical primary plastics (pellets and granules; compare Table I for typical applications). The studies identified differ with regard to the geographic scope (only high-income countries are represented) and the reference year (the oldest source dates back to 1980). There is also a major difference concerning the coverage of types of plastics: Whereas some of the sources specifically focus on plastics production and/or recycling, others cover the most important building materials or even all major bulk materials.

A key source used frequently in Europe (also in LCA software tools) is the Eco-Profiles published by the Association of Plastics Manufacturers in Europe (APME). Table III shows two data sets from APME, one of which was published in 1999 and the other pre-1999. Other widely disseminated data sets are those released by the U.S. Office of Industrial Technology (OIT). It is interesting to note that substantial corrections have been made in the revised APME data set and that the values in the two data sets published by the OIT differ considerably (Table III). The difference in values across the other sources is even larger.

We calculated the standard deviation for those plastics for which at least 7 independent sources are available (polyethylene, polyvinyl chloride, polystyrene, polyethylene terephthalate, polyurethane, and nylon 6,6) and determined values ranging between 18 and 23% of the arithmetic mean. Assuming a normal distribution, the cradle-to-factory gate energy requirements have a probability of 68% within a range of $\pm 23\%$. For the remaining 14 plastics, there are less than 7 independent sources. The data from approximately half of these fall into the uncertainty range established for the 7 plastics, whereas the spread is larger for the others. Due to the low number of independent sources, quantification of the uncertainty range for the 14 plastics is hardly possible.

Especially for sources covering a larger number of materials, it is possible to make a statement about the relative position of the values: The data reported by APME (both data sets) are in the medium range, whereas the values published by Kindler and Nikles are partly in the medium range and partly on the higher side (PE is an exception since it is on the lower side). Data from studies by Alcorn and by Shutov are on the higher side, whereas those published by Patel and by the Plastic Waste Management Institute, Japan, are in most cases lower than those in the other sources (with the exception of nylon 6,6).

For the data published by the APME and by Patel, relatively detailed information is available about the assumptions and system boundaries that allow discussion of the reasons for the discrepancy. Except for ammonia, nylon-6,6, polyethylene, and polyvinyl chloride, the energy requirements determined for Germany are generally lower than those determined by the APME for Western Europe. The main reasons are as follows:

TABLE II

Heating Value of Bio-Based and Petrochemical Polymers[a]

Polymer	Lower heating value, GJ/tonne (dry matter)
Starch polymers	13.6
Polyhydroxybutyrate	22.0
Polyhydroxyvalerate	25.0
Polylactic acid	17.9
Lignin (picea abies)	24.2
China reed	18.0
Flax	16.3
Hemp	17.4
Kenaf	16.5
Polyethylene	43.3
Polystyrene	39.4
Polyethylene terephthalate	22.1
Polyvinyl chloride	17.9

[a]Heating values calculated according to Boie, compare Reimann and Hämmerli, 1995.

- The data for Germany refer to the net calorific value (NCV; lower heating value), whereas the APME publications use gross calorific values (GCVs; higher heating value). The difference is within 10%.
- The APME data are based on surveys for all of Western Europe. They may therefore include some smaller, older plants that are less efficient than the average of all units in Germany in the mid-1990s.
- The APME data accounts for the various shares of purchased versus autogenerated electricity, including the respective efficiencies for the sites and the public grids in the various countries covered. In contrast, exclusive autogeneration of power in efficient combined heat and power (CHP) plants has been assumed for plastics production in Germany.
- The efficiencies for steam generation assumed in the APME publications are smaller than the average assumed in the calculations for Germany.

There are also several aspects that have not been taken into account in the calculations for Germany but that are covered by the APME data:

- For specific processes, data were only available for the selectivities and not for the yields of the products. In these cases, the calculations are based on selectivities instead of yields, thus assuming a conversion of 100% (yield = selectivity × conver- × conversion). Consequently, material efficiency is slightly overestimated and therefore the results for the energy requirements in Germany are somewhat underestimated.
- The assumed losses in the steam system (7.5%) in plastics production in Germany may be too low, as indicated by the literature data on the losses related to degasification of the boiler feed water, elutriation of the boiler, and noncovered recycling of condensate indicate. On the other hand, the German Association of Chemical Industry estimates that the average steam losses are 2.5–4% (G. Thomas, personal communication, 1999).
- Facilities outside the battery limits (e.g., flue gas scrubbers and sewage treatment plants) are not included in the system boundaries and, consequently, they are not included in the data for Germany.
- Ancillary materials (e.g., packaging materials or lubricants), catalysts, and other materials used in small amounts have not been taken into account in the calculations for Germany.
- It is possible that the operating rates assumed in the calculations for Germany are higher than in reality. Moreover, the process data used for Germany refer to continuous operation with no maintenance intervals (i.e., they exclude energy-intensive reactor start-ups and shutdowns).
- Transport energy used in the extraction and supply of resources has been accounted for (Fig. 1). However, due to the lack of detailed data, transport between all the subsequent conversion steps was not included in the calculations for Germany. Since the majority of the products studied were transported in pipelines, which does not consume a large amount of energy, and since transport energy generally only represents a small share of the total energy consumption, the errors resulting from this procedure can be assumed to be negligible.

To summarize, it may well be that the data for Germany underestimate the real energy requirements. However, the different choices made regarding the aspects listed previously and the differences in the years and regions analyzed largely explain the difference compared to the APME data. The results for Germany are therefore considered to be representative estimates for this country in the mid-1990s.

Despite the ranges in values in Table III, most studies confirm that relatively little energy is required to manufacture the bulk plastics PE and PVC. In contrast, the energy required for the manufacture of engineering and other plastics can be more than twice as high.

3.2 Bio-Based Plastics

Contrary to petrochemical plastics, the feedstocks used to produce bio-based plastics are derived from agricultural crops (e.g., maize, wheat, or sugar beet) or from suitable waste streams (e.g., from the dairy industry). Regarding petrochemical plastics, processing, cultivation, and transportation almost exclusively rely on finite energy sources, particularly fossil fuels. For bio-based plastics, the cultivation of crops (or the supply of suitable waste streams) results in an energy demand that is absent in the case of petrochemical plastics. Moreover, feedstock preparation and product separation may be clearly higher in the case of bio-based plastics due to relatively low yields and high water content in the raw material and product streams. It is thus not obvious from the outset that cradle-to-factory gate energy requirements for bio-based plastics are lower compared to those for petrochemical plastics.

However, Table IV shows that this is the case for nearly all of the bio-based plastics studied: thermoplastic starch (TPS), starch copolymers [blends of TPS with polycaprolactone (PCL) or polyvinyl

[a] Cradle-to-factory gate nonrenewable energy including both feedstock energy and process energy. Complete bibliographic information on the references cited in this table can be found in Patel *et al.* (2003). Abbreviations used: TPS, thermoplastic starch; PVOH, polyvinyl alcohol; PCL, polycaprolactone; PLA, polylactides; PHA, polyhydroxyalkanoates; ABS, acrylonitrile, butadiene, styrene; HDPE, high-density polyethylene; LDPE, low-density polyethylene; LLDPE, linear low-density polyethylene; PET, polyethylene terephthalate; PS, polystyrene; APME, Association of Plastics Manufacturers in Europe.

[b] Total of process energy and feedstock energy. Finite (nonrenewable energy) only; i.e., total of fossil and nuclear energy. In the cradle-to factory gate concept, the downstream system boundary coincides with the output of the polymer or the end product. Hence, no credits are ascribed to potential benefits in the use phase to valuable by-products from waste management (steam, electricity, and secondary materials).

[c] Application studied: Interior side panel for passenger car; ABS stands for acrylonitrile-butadiene-styrene.

[d] Application studied: Transport pallet.

alcohol (PVOH), polylactides (PLA), and the natural fiber composites. For polyhydroxyalkanoates (PHA), the energy use strongly depends on the process and feedstocks used and ranges between values that are somewhat lower to those that are clearly higher than for petrochemical plastics. To facilitate direct comparison, Table IV also provides the energy requirements for the most important petrochemical polymers and for PCL and PVOH, which are both used as copolymers for starch plastics. Life cycle practitioners consider the data for PCL and PVOH to be subject to major uncertainties.

Most of the materials listed in Table IV can be produced according to the current state-of-the-art. Future options (e.g., the production of PHA in crops and the medium- and long-term production processes for PLAs) are not listed in Table IV. As an exception, technical problems still need to be resolved for pallets reinforced with china reed (material stiffness).

It can be concluded from Table IV that the cradle-to-factory gate energy requirements of pure TPS are 65–75% below those for PE. For starch polymers with high amounts of petrochemical polymers, the energy requirements are approximately 30% lower than those for polyolefins. However, the applications for pure starch polymers and blends with small amounts of petrochemical copolymers are limited due to inferior material properties (especially sensitivity to moisture). With larger amounts of petrochemical copolymers, polymers with wider application profiles can be produced. This allows to obtain higher energy savings in absolute terms while the marginal energy savings decrease with higher shares of petrochemical copolymers.

For PLA, data are only available from a source (Cargill Dow), according to which cradle-to-factory gate energy requirements are 20–30% less than those for PE.

The results reported for PHA vary greatly. Cradle-to-factory gate energy requirements in the best case (66.1 GJ/t) are 10–20% lower than those for PE. The upper range in Table IV refers to substrate supply from fossil-based feedstocks (e.g., methanol).

It can be concluded that of all bio-based plastics studied, starch polymers perform best in environmental terms under the current state-of-the-art, with some differences among the various types of starch polymers. Compared to starch polymers, the environmental benefits seem to be smaller for PLA. For PHA, the environmental advantage seems to be very small compared to that for conventional plastics in the best case; in the worst case, it can be substantially higher. For both PLA and PHA, the production method and the scale of production can influence decisively the cradle-to-factory gate energy requirements.

The extent to which natural fibers (e.g., hemp and flax) can replace fiberglass (which is heavy and energy intensive to produce) determines the net environmental benefits. Interesting possibilities are also available.

Since most of the data in Table IV refer to the current state-of-the-art, technological progress, improved process integration, and various other possibilities for optimization will likely provide more favorable results for bioplastics in the future.

4. DISCUSSION

In the preceding section, all data were compared on the basis of 1 tonne of plastics. Although this is a convenient choice, it suffers from the drawback of not taking differences in material properties and the resulting parameters at the end use level into account. For cradle-to-factory gate analyses, this mainly concerns (i) materials processing, in which the amount of material required to manufacture a certain end product and the energy use in the processing step may differ depending on the type of plastic (e.g., bio-based vs petrochemical plastics), and (ii) transportation energy, which can be substantial for end products with a low bulk density such as packaging chips (so-called loose fill).

On the other hand, these aspects can only be fully taken into account by analyses dedicated to specific end products (e.g., plastic bag), whereas the choice of one mass unit of polymers as a functional unit allows a preliminary conclusion about the advantages or disadvantages in terms of energy use. If, for example, the energy requirements for a given polymer are relatively high at the level of primary materials (pellets), there is a good chance that this will also be true at the end product level.

The studies reviewed in this article reflect the situation in different countries. The types of feedstocks used and the processes applied can vary from country to country or from continent to continent. For example, olefin production in steam crackers is mainly based on naphtha in Europe and Japan, whereas in the United States natural gas-based ethane crackers dominate. Differences in processes and feedstocks may result in different yields and energy efficiencies. Due to the competition in the sector, the differences in efficiencies of the production processes can be assumed to be relatively low across high-income countries. This may be less the case for power production: Here, the requirements of (finite) energy resources depend to a large extent on the type of fuel used (e.g., coal with relatively low efficiencies vs natural gas with high ones), the share of CHP, and the percentage of renewable energy (generally very low but high in Norway and Switzerland).

Direct comparison of energy data is complicated by the fact that both the NCV and the GCV are used in this type of analysis but that the choice is not always clearly reported. This also concerns the

inclusion or exclusion of ancillary materials, catalysts, and additional facilities such as sewage treatment plants that generally have a much lower impact on the results. This can also be assumed for different reference years as long as they do not differ by more than a decade. Larger discrepancies among the studies may accrue from different allocation procedures for processes with larger amounts of coproducts. Also in these cases, the concrete choices are hardly ever explained in detail.

An attempt should be made to consider these aspects when using cradle-to-factory gate energy data for further analysis and when interpreting the results and drawing conclusions. Moreover, whether the waste management system should also be included in the system boundaries (cradle-to-grave system) should be carefully considered.

5. CONCLUSION

By combining the cradle-to-factory gate energy data with current production data, the global primary energy use for the production of polymers is estimated to be approximately 15,000 PJ or 3.6% of the global primary energy use. Although the uncertainty of the production data is unknown, the specific energy requirements for industrialized countries have been estimated with a probability of 68% within a range of $\pm 23\%$. Since the energy efficiency in developing countries is generally lower, the global value can be considered a conservative estimate. In view of the high current and anticipated growth of plastics production, the attendant energy use is very likely to increase substantially. Basically, four strategies can be distinguished to minimize this growth:

1. Energy efficiency: The most straightforward strategy is increased energy efficiency in the petrochemical processes and in polymerization and increased use of production routes and intermediates with low overall energy requirements. For example, PVC, which was formerly manufactured from energy-intensive acetylene, is currently mainly being produced from ethylene. Research and development efforts are directed toward the use of ethane as a feedstock.
2. Material substitution: With advances in polymer science, it may become increasingly possible to replace energy-intensive engineering plastics (such as polyamides) with modified bulk polymers (e.g., polyolefins), which are more energy efficient to produce.
3. Waste management: Various types of recycling, the reuse of plastic components, and energy recovery can contribute to lower life cycle energy requirements and environmental impacts.
4. Bio-based plastics: As apparent from Section III, the substitution of bio-based raw materials for petrochemical feedstocks may provide an interesting potential for energy saving (Table IV).

Energy analysis can be a useful tool for establishing the relative benefits of specific measures of these strategies.

When conducting an energy analysis, the researcher is often confronted with the fact that different sources provide different values for a certain product and that the deviation between them can be substantial (Table III). This is generally due to different system boundaries (e.g., concerning the years and geographical regions studied and the technologies and processes covered). It is a prerequisite for a reliable analysis that the cradle-to-factory gate data used have been determined in a consistent manner. In contrast, comparative assessments that use energy data originating from various sources can easily result in distorted conclusions given the large data ranges shown in Table III (differences of a factor of two in extreme cases). These data ranges and the corrections made by the APME indicate that considerable uncertainties continue to exist despite the fact that petrochemical polymers are manufactured by use of mature technologies that are applied globally with only limited variations. On the other hand, there is good agreement concerning the relative position of the various plastics.

As a consequence, further analyses on cradle-to-factory energy requirements for plastics should be conducted. For the time being, it is suggested to use, wherever available, data sets that are valid for the country (e.g., Germany) or region (Western Europe) under investigation. In order to check the reliability of the results, it is recommended to conduct sensitivity analyses using other data sets that have been determined in a consistent manner for a different region than the one investigated. Alternatively, calculations on error propagation can be conducted.

Glossary

corridor Linear infrastructure (e.g., road, railway, and power line) that cuts across otherwise intact vegetation/soil cover, such as closed boreal forest or tundra.

cumulative impacts Responses to disturbance, often relatively indirect, that differ from simple direct and additive effects by accumulating in space and time, sometimes in unforeseen ways.

disturbance Any sudden deviation (e.g., a reduction in species richness or biomass) from a reference state, which need not be static. A disturbance regime has four basic dimensions: frequency, intensity, scale (extent), and timing (season).

permafrost Perennially frozen ground; a substrate that is in a state at or below 0°C (32°F) for 2 or more years. It can be composed of soil, bedrock, water/ice, or any combination of these. Moving generally from north to south, the Arctic can be divided into regions of continuous, discontinuous, and sporadic permafrost.

rehabilitation Used as a broader term than revegetation to denote the establishment of productive and functioning systems and may include revegetation, erosion control, or fish transplanting efforts.

restoration A more restrictive term referring to the long-term process of reestablishing the original composition, structure, and function to a disturbed site.

revegetation Refers to the establishment of vegetation, regardless of composition, on a disturbed area. Can be either natural (unassisted) or assisted.

succession Generally involves changes in vegetation species composition or in the relative numbers of individual plants through time at a given locale. It is often, but not always, precipitated by disturbance.

thermokarst The process by which characteristic landforms result from the melting of ice-rich permafrost.

tundra From the Finnish word *tunturi,* for sparse barrens near the timberline. Tundra is the Russian translation of this and refers more to the treeless zones beyond the latitudinal or arctic timberline as opposed to altitudinal timberline.

The polar regions hold enormous potential for the production of energy, mainly in the form of crude oil, natural gas and gas condensates, coal, and hydroelectric power. Some coal deposits in arctic Russia have been under industrial exploration and exploitation since the 1930s, and in other countries sources of hydropower and petroleum have also been under development for several decades. The Arctic contains by far the greater proportion of proven and economically viable deposits. In Antarctica, the Antarctic Treaty currently bans mining of any kind, although coal has been found in two regions and it has been suggested that rock formations there may well contain oil or gas. However, even if sizable reserves were discovered, and no exploratory drilling has been done, it is highly unlikely that the deposits could be recovered economically or safely. This article therefore focuses on the impacts of energy development in the Arctic, with special emphasis on oil and gas production, the main source of energy-derived revenue as well as a major cause of concern for environmental and sociocultural degradation. Examples are drawn from past and current energy developments from throughout the circumpolar North.

1. REGIONS OF IMPACT

The way we view energy development in the circumpolar North has partly to do with where we

 © 2004 Elsevier Inc. All rights reserved.

come from. Americans tend to think of Alaska as the Arctic. Because of the construction of the Trans Alaska Pipeline (TAPS) in the 1970s, the oil spill from the Exxon Valdez in Prince William Sound in 1989, and the bitter fight over opening the Arctic National Wildlife Refuge (ANWR) to oil development during the past decade, many Americans are familiar with the image of Alaska as an important oil-producing state. In neighboring Canada, increasingly more Canadians are probably aware of the rekindled prospects for a major gas pipeline from the Beaufort Sea south via the Mackenzie River valley to central Alberta. Talk to British or Scandinavian nationals about oil and one will hear about the declining production from the North Sea. Also, whereas most Russians know of the political power wielded by the former state monopoly, Gazprom, relatively few outside of international business/finance circles recognize this company's name.

The fact is that arctic energy development has become an increasingly multinational domain driven by a high-tech, expensive, and growing network of extraction and transport infrastructure that spans virtually the entire Northern Hemisphere. Drivers in Europe fill up their cars with gasoline refined from crude oil pumped from beneath reindeer pastures in western Siberia. Homes in Chicago are heated in winter with natural gas piped halfway across Canada from the mountains of northern British Columbia. Village power plants in central Russia burn coal mined at a former gulag camp in the open tundra well north of the Arctic Circle in the faraway Komi Republic. New England buys surplus electricity generated from huge artificial lakes in the James Bay region of northern Quebec. A hydropowered smelter under construction in the highlands of eastern Iceland will soon be providing aluminum to the world market. A fleet of icebreakers and ice-strengthened tankers is being constructed to carry oil via Russia's northern sea route (NSR) to markets in Europe and the United States. In other words, arctic energy exemplifies the process of globalization.

To understand the impacts of energy development in the Arctic we must consider first the geography, accessibility, and economics of energy reserves within the Arctic rim countries: Russia, Finland, Sweden, Norway, Iceland, Greenland, Canada, and the United States. Nonrenewable and renewable resources vary widely in quantity and quality across the circumpolar North, as do the financial and human resources available to exploit them, not to mention the prevailing environmental conditions. Some countries, such as Finland and Sweden, have little or no petroleum resources of their own and must import virtually all gasoline and fuel oils. They rely on nuclear plants, hydropower, coal, and even the burning of their plentiful woodchips to produce sufficient electricity for lighting and heating during the long, cold, and dark winters. Iceland has abundant geothermal energy available locally, but it also relies heavily on hydropower and imported petroleum to meet its energy needs. In contrast, Russia is considered the Saudi Arabia of natural gas and may one day be Europe's prime supplier.

2. GEOGRAPHY, ACCESSIBILITY, AND ECONOMICS OF ENERGY RESERVES

2.1 Alaska

Interest in petroleum development in Alaska dates to the early 20th century, when representatives of the U.S. Geological Survey sent to explore the North Slope provided reports about oil seeping out of the ground in places on the coastal tundra beyond the Brooks Range. In 1923, President Harding ordered that a 37,000 square mile area be set aside as National Petroleum Reserve No. 4. After the outbreak of World War II, the U.S government became concerned about the domestic supply of oil and began seismically exploring the huge area. During the period 1944–1953, dozens of test wells were drilled in the zone of continuous permafrost. At the time, the area was extremely remote, and with no roads most travel across the tundra was necessarily by helicopter and tank-like off-road vehicles with metal tracks instead of wheels. The oil fields found were disappointingly small, although six sizable gas fields were discovered. It was not until January 1968, after 10 years of exploration, that Atlantic Richfield Company (ARCO), Humble Oil, and, later, British Petroleum (BP) tapped into a field estimated to contain at least 5–10 billion barrels (bbl). The strike at Prudhoe Bay turned out to be the largest ever made in North America and plans were drawn up for an 800-mile pipeline to extend from the North Slope to the ice-free port of Valdez.

Because the pipeline had to cross land that Alaska Natives claimed, the discovery at Prudhoe Bay immediately created pressure for a land claims settlement to access the oil fields. The Alaska Native Claims Settlement Act (ANCSA) of 1971 transferred title to 18 million ha of land and $962.5 million to Alaska Natives. The land and money were not given

directly to individual Natives but, rather, the act divided the state into 12 regions and required that a state-chartered Native corporation be formed for each region with the provision that undeveloped Native corporation land was to be untaxed until 1991. There were problems of inequity because of the wide variation in exploitable natural resources. Natives who held claim over what became the North Slope Borough stood to profit from oil field leases far more than their neighbors. Although originally skeptical of Native claims regarding the critical importance of subsistence livelihoods, in 1987 some key amendments were made to ANCSA by which Congress recognized that the Native subsistence economy and culture are indeed significant factors in the management of Native lands and so attempted to provide for their protection. Subsistence provisions were also set forth in the Alaska National Interest Lands Conservation Act of 1980.

Since coming on line, the Prudhoe Bay/Kuparuk oil fields, via TAPS, have accounted for approximately 25% of the oil produced in the United States. Approximately 85% of the Alaskan state budget is derived from taxes and royalties collected on oil production. BP Exploration (Alaska), Incorporated and Phillips Alaska (formerly ARCO Alaska) are the two principal oil field operators and are both among the top 10 private employers in the state. At its peak in 1987, the North Slope produced an average of 1.61 million bbl of oil per day (bpd). In 2002, daily output declined to approximately 0.54 million bpd. Estimates of the recoverable reserves from the so-called 1002 area of ANWR vary widely from 4.3 to 30 billion bbl. This range has partly to do with economics because when market prices are less than $35 per barrel, a larger volume of technically recoverable oil is considered to be economically recoverable. However, politics also plays a role in that different players prefer to publicize higher or lower estimates. In comparison, the great Prudhoe Bay field was originally estimated to hold approximately 9.2 billion bbl in total reserves, but this was later increased to 23 billion bbl of oil and 26 trillion ft^3 of natural gas.

2.2 Canada

Canada is the world's third-largest natural gas producer, after Russia and the United States, with approximately 50% of its 6.5 trillion ft^3 of annual production destined for the U.S. market. Overall, Canada supplies 16% of the gas consumed in the United States, double its share a decade ago. In the Canadian Arctic, the major petroleum reserves lie in the Mackenzie River valley, delta, and Beaufort Sea region.

In the early 1900s, native Dene first led geologists to the site they called Le Gohlini, or "where the oil is," near Norman Wells on the lower Mackenzie River just north of the Arctic Circle. This led to the drilling of the first test well in 1919 by Imperial Oil, which confirmed the presence of rich oil fields. World War II led the U.S. Army to oversee the fast-track construction of the strategically located Canadian Oil Pipeline (Canol) almost 3000 km from Norman Wells to Whitehorse, Yukon. However, completion of the pipeline in less than 2 years coincided with the end of the war, and the project was quickly abandoned. In the early 1980s, Imperial Oil brought its Norman Wells operation to full capacity, and oil began flowing through the 870-km Norman Wells pipeline to Zama, Alberta. As of 2003, the pipeline averaged 10 million bbl per year (bpy) and was Canada's fourth-largest oil-producing field. Natural gas is also produced at Norman Wells, mainly for local use and for reinjection to enhance oil recovery.

Farther north, in the 1970s, some reserves of oil and gas were located in the high Arctic by Panarctic Oils. Feasibility studies revealed that a pipeline was not economically viable. Since the 1980s, there have been some shipments of oil eastward from Panarctic's Bent Horn field on Cameron Island and several experimental shipments of oil westward from Gulf Oil's Amauligak field in the Beaufort Sea. However, Canada's oil production is primarily south of the 60th parallel and gas comprises a much larger component of the nation's petroleum production. In recent years, exploration has been expanding off the coasts of Newfoundland and Labrador, where the federal and provincial governments are trying to replace the declining fishing industries with energy prospecting. Canada is also considering lifting a moratorium on oil and gas development off British Columbia.

The vast natural gas reserves of the Mackenzie River delta region were discovered in 1971. Whereas the Prudhoe Bay area of Alaska is estimated to contain as much as 100 trillion ft^3 of natural gas, an additional 64–73 trillion ft^3 lies in the combined onshore and offshore reserves of the Mackenzie delta and adjoining Canadian portion of the Beaufort Sea. A proposed 3500-mile Mackenzie River valley pipeline linking the American and Canadian fields would cost an estimated $26 billion and take 7 years to build. A shorter pipeline exploiting only the Mackenzie delta field would cost approximately $3 billion. The latter pipeline would have a capacity of approximately

1 billion cubic feet per day, equal to approximately 2% of U.S. consumption, whereas a pipeline joining northern Alaska would carry 4–5 billion ft^3 per day.

For the longer pipeline, energy company engineers have been studying three possible routes from the Arctic Ocean to connect via Norman Wells to pipelines in Alberta. Proponents of an Alaskan route estimate that they could start pumping gas south in 6 years. They believe that they can work more quickly because permits and an international regulatory framework have existed since the late 1970s to place a gas pipeline parallel to the TAPS, which would then run along the Alaska–Canada Highway. Another plan would cut a new overland route across the Brooks Range and northern Yukon, and a third route would run up the Mackenzie River valley and have a submerged section running 15 ft below the floor of the Arctic Ocean for 300 miles to connect the Mackenzie River delta to Prudhoe Bay.

The latter route is the one officially favored by the government of the Northwest Territories, which has frequently been at odds with the government of the Yukon Territory over the choice of a pipeline route. The northern Yukon is estimated to have reserves of 3.3 trillion ft^3 in the Eagle Plains and Peel Plateau and could potentially contribute 200 million ft^3/day to a Mackenzie Valley pipeline. The main hub for regional development and administrative activities is Inuvik, Northwest Territories, with a population of 3000, making it Canada's largest community north of the Arctic Circle. Like Prudhoe Bay, it is accessible year-round by road from the south.

As of early 2003, the Aboriginal Pipeline Group was raising money to cover its share of the costs for preliminary design and regulatory work, regardless of the chosen route. Meanwhile, TransCanada PipeLines Ltd. was positioning itself to play the dominant role in delivering arctic gas to southern markets, although Calgary-based Enbridge was working to be heavily involved as well. In June 2003, a consortium consisting of TransCanada, Imperial Oil, and ExxonMobil's Canadian unit completed a partnership agreement with the Aboriginal Pipeline Group to build an 800-mile portion of the Mackenzie Valley pipeline.

2.3 Greenland

Greenland may be sitting on oil reserves comparable in size to those of the entire North Sea according to the Home Rule government's Bureau for Minerals and Petroleum (BMP). North Sea fields have produced approximately 29 billion bbl of petroleum to date and proven remaining reserves stand at more than 15 billion bbl. A consortium led by Norway's Statoil and U.S. Phillips Petroleum has been awarded exploration licenses in waters off the southwest coast of Greenland. The BMP acknowledges that gigantic fields would be necessary to economically justify opening up the area.

2.4 Russia

Large-scale energy exploration and exploitation in arctic Russia have been going on for several decades. A coal mine at Vorkuta in northernmost Komi Republic began production as a gulag camp under Stalin in the late 1930s with a railway link to Moscow and other Russian regions. It grew quickly to a large complex of connected mining towns with an eventual peak population of 280,000 and coal production of 22 million tons per year by the late 1980s. Since 1991, the population has declined by approximately 30% and coal production has fallen well below levels from the mid-1970s. Petroleum has also long been under production in the Russian north, especially in the northern boreal and subarctic lowlands of western Siberia. Western companies began exploring projects in Russia even before the collapse of the Soviet Union, but more than a decade later they can point to few successes after combined investments of more than $5 billion.

ExxonMobil, the world's largest oil firm, is focused mainly on its huge oil and gas project on Russia's far eastern island of Sakhalin and is therefore not directly involved in any truly arctic ventures. Shell, the world's second largest oil firm, signed a memorandum in the late 1990s to develop oil and gas condensate deposits at Gazprom's huge Zapolyarnoye gas field in western Siberia, but the deal was never finalized. BP, the world's third largest oil firm, has had extensive projects in the Russian north via its 50% interest in Tyumen Oil (TNK), which produces 1.2 million bpd and has reserves of 5.2 billion bbl. In June 2003, U.K. Prime Minister Blair and Russian President Putin jointly announced the creation of a new oil company, TNK-BP, which will lead to an additional $6.15 billion investment by BP in Russia. TotalFinalElf, the world's fifth largest oil company, is developing a medium-sized oil field in Russia's north together with Norway's Norsk Hydro, Kharyaga, which produces 30,000 bpd and holds 710 million bbl of reserves. Total also acquired in 2000 the giant but remote Vankor field in eastern Siberia and has plans to develop with Gazprom the giant offshore arctic Shtokmanovskoye gas field. Other firms

actively engaged in Russian energy production and transport include ConocoPhillips, Finland's Fortum group, and Germany's Ruhrgas, which are involved in the financing, planning, and building of pipelines to European markets, mainly via the terminal facility at Primorsk, 100 miles (160 km) northwest of St. Petersburg.

In general, Russia faces enormous transport problems in getting its petroleum resources, for the most part deep in Siberia, to export markets. This makes scenarios for shipping oil to North America profitable only at times of high prices. Most of Russia's oil and gas goes to Europe. In the short term, U.S. oil companies could raise Russia's oil output by investing more in Russia. However, U.S. companies have been reluctant to invest there because of shifting tax codes and regulatory policies and have called for binding legislation before investing more money in the country. Specifically, they have been unwilling to do this without production sharing agreements, which Russia's Duma has been reluctant to grant foreign firms.

2.4.1 Murmansk Terminal

As the world's No. 2 oil exporter, Russia is seeking new markets outside Europe, whereas the United States, the world's largest oil consumer, wants to cut its reliance on the oil-rich but volatile Middle East. Under this scenario, Murmansk would become the main port for oil export to the United States. By 2010, Russian companies hope to cover 10–15% of crude oil consumption in the United States. Indeed, in November 2002 Presidents Bush and Putin pledged to strengthen energy ties between the two countries. The project is part of a blossoming relationship between the former Cold War rivals. However, Washington wants more than simply increased Russian oil imports out of its new energy relationship with Moscow. It is also keen to open Russia's vast oil reserves to U.S. investors.

In November 2002, Russia's top four oil companies—Lukoil, Yukos, TNK (since merged with BP), and Sibneft (since merged with Yukos)—announced their plan to sign a preliminary deal to build a 1-million bpd capacity oil-export terminal in Murmansk, Russia's only ice-free Arctic port. Oil to supply Western Europe and North America is expected to come primarily from the Timan–Pechora fields, at least initially. Timan–Pechora has one of the region's largest known reserves of oil, estimated to be approximately 126 billion bbl. Currently, ConocoPhillips produces approximately 25,000 bpd (10 million bpy) from its Polar Lights facility, a joint venture with Lukoil along the border between the Nenets Autonomous Okrug (NAO) and Komi Republic. It also wants to develop a neighboring area, Northern Territories, believed to contain 4.25 billion bbl of crude under Russian standards, which tend to give larger estimates than Western rules. Transport would be either by ice-strengthened tankers loaded at the Lukoil-operated Varandei terminal in the NAO or via a proposed 80-million tons per year pipeline.

There are two options for the pipeline route. The first route is western Siberia–Usa–Yaroslavl–Archangelsk–Murmansk. It is 2500 km long, including a short section which runs along the floor of the White Sea. The second route is western Siberia–Ukhta–Murmansk, which is 3600 km long. This route is fully on the ground and allows additional switching of the Kharyaginskoe field of Lukoil and TotalFinaElf in the NAO to the transportation system. There are also proposals to modernize an existing pipeline, Uhkta–Yaroslavl, which transports oil from the Lukoil fields in the Komi Republic. The costs of the project are estimated to be $3.4 billion for the first route and $4.5 billion for the second route.

This is the first project of its kind and scale in Russia in which the companies plan to undertake the development essentially on their own. This would mean little or no participation by the state, which normally defines oil transportation via the trunk pipelines as a monopoly activity. To date, the fact that pipelines are built solely by state monopoly Transneft has allowed President Putin to maintain control over the up and coming petroleum oligarchs. However, most analysts insist that the development of such a grandiose project as construction of a large oil export facility in Murmansk, in combination with development and transport of the hydrocarbon reserves of Timan–Pechora, Yamal, and the Barents seabed, will not be possible without any state support. It is widely acknowledged that Russia has already reached an oil production bottleneck and cannot increase export capacity before expanding its transport infrastructure (ports, pipelines, and railways) and replacing a great deal of obsolete technology.

Russia's daily output is 8 million bpd, of which approximately 5.1 million bbl is exported. In comparison, U.S. domestic crude oil production averaged 5.8 million bpd in 2002, whereas oil imports averaged 9 million bpd for the same year, spiking to 9.4 million bpd in October. It is widely believed that the Russian arctic seabed may well become one of the main sources of oil in the 21st century. Moreover, oil resources of the North Sea are

steadily decreasing and it is estimated that reserves of the Norwegian sector are sufficient for only another 25 years and that Europe will soon import up to 85% of its energy supplies. Currently, Russia provides only approximately 20% of Europe's natural gas needs and 16% of its oil.

2.4.2 Yamal

In response to the situation described previously, Gazprom and Rosneft Oil Company and its affiliates for the exploitation of arctic oil and gas resources created Sevmorneftgaz as a joint enterprise. At the same time, many agreements between Russian and foreign consortiums have come and gone since the collapse of the Soviet Union. Amoco Eurasia (since merged with BP), for example, pulled out of Yamal in 1996 after several years of negotiations and feasibility studies. One reason why major Western companies are prepared to risk a return to Russia is the price of oil. Diving to $10 a barrel in 1998, it has climbed steadily since and, despite a downward dip after the terrorist attack of September 11, 2001, has been buoyed by tensions in the Middle East.

In January 2002, Gazprom and the administration of the Yamal–Nenets Autonomous Okrug (YNAO) sent the federal government a draft law intended to make Yamal a "region of strategic interests." The aim is to ensure the company's goal of increasing its annual output to 530 billion cm by 2010 as production from its massive Urengoi and Yamburg fields begins to decline. In doing so, Gazprom demonstrated its intention to concentrate on developing its Yamal reserves over the natural gas potential of eastern Siberia. One reason is the relative ease of transporting gas from the Yamal Peninsula. Whereas eastern Siberia is almost devoid of infrastructure, the established Yamal–Europe pipeline is capable of pumping 18 billion cm of gas annually, which could increase to 60 billion cm once a second line is completed, most likely via Poland.

There are 25 known large fields of natural gas on Yamal, with estimated total reserves of 10.4–13 trillion cm and hypothetical reserves of up to 50 trillion cm. Developing them to the extent that it would be possible to begin export of shipments in commercial quantities would require more than $40 billion according to Gazprom's estimates from the early 1990s. By March 2003, Gazprom's board of directors had plans to adopt a "program for the comprehensive industrial development of the Yamal Peninsula fields."

On Yamal Peninsula, the Bovanenkovo and Kharasavey gas condensate fields are the most thoroughly explored and best prepared for production. Their development scenario calls for the construction of a liquefied natural gas (LNG) plant at the Kharasavey field and with LNG shipments by the NSR. This program will become the foundation of the company's strategic development until 2010. As such, the Yamal Peninsula and the estuaries of the Ob and Taz Rivers are expected to be major regions for the expansion of Gazprom's gas production. Adopting the Yamal Development Program will mean that other large fields, especially the gigantic Shtokmanovskoye field in the Barents Sea, will be developed in the more distant future. The simultaneous implementation of two major projects would be too costly for Gazprom and might result in intense competition between gas sellers in domestic and foreign markets.

2.4.3 Shtokmanovskoye

Discovered in Soviet times, the Shtokmanovskoye gas field in the Barents Sea is estimated to hold 112 trillion ft^3 (3.2 trillion cm) of natural gas and 170 million bbl of crude oil and is due onstream in 2010 under a $19- to $21-billion development scheme. It is believed to contain the world's largest natural gas deposits. Houston-based ConocoPhillips, the world's sixth largest energy company, and TotalFinalElf each want a 25% stake in the Shtokmanovskoye project. However, as with the terminal facility in Murmansk, there is substantial skepticism among the major foreign players as to whether the project can really be developed.

As a long-term strategy, Gazprom must either focus on the development of midsized fields and deeper horizons of currently developed fields in the Nadym–Pur Taz District of the YNAO or undertake the full-scale development of fields on the Yamal Peninsula. The third option is the development of arctic offshore fields such as Shtokmanovskoye, but as of summer 2003 the Yamal Peninsula appeared to be the main development target until at least 2010.

3. TYPES OF IMPACT

The causes of environmental degradation commonly associated with the petroleum industry are many and have historically included drilling pads and roads and the excavation of the gravel and sand quarries necessary for their construction; blowing sand and dust from quarries and especially roads; housing; processing facilities; pipelines and power transmission lines; waste fluids from drill holes; oil spills; marine, air, and ground traffic, including rutting from off-road tracked vehicles; and seismic survey

trails. Some of these impacts (e.g., vehicle tracks) have become relatively rare occurrences in the North American Arctic since the institution of strictly enforced mitigation regulations in the 1970s. On the other hand, most of these impacts continue to be common and widespread in the Russian Arctic despite the existence of relevant regulations since the 1980s, primarily due to a lack of enforcement.

In March 2003, a panel of experts convened by the U.S. National Academies published a major review titled "Cumulative Environmental Effects of Oil and Gas Activities on Alaska's North Slope." They reported on the overall influence of 35 years of oil exploration and production activities in and around Prudhoe Bay and classified the impacts into four categories: effects on the physical environment, effects on vegetation, effects on animals, and effects on the human environment. The panel's aim was to assess not only known impacts but also future cumulative effects should production expand, for example, eastward into ANWR. The 1.5-million-acre coastal plain of ANWR occupies 5% of Alaska's North Slope and is somewhat smaller than the state of South Carolina. It encompasses six ecological zones and is considered to contain the greatest biological diversity of any protected area in the Arctic. This is probably due to its location within what is known as Beringia, a region at the crossroads of two continents during the ice ages of the Pleistocene. As a result of this geography, Alaska is home to a number of species associated primarily with North America or Eurasia as well as a fair share of endemic species.

Less tangible than the obvious impacts described previously, but also acknowledged by the panel, was that the "wilderness" or "wildlands" value of ANWR would invariably be degraded by petroleum development. This would violate, in their words, "perhaps the most prominent of the values ANWR was established to protect." Although many Alaska Natives disagree over the appropriateness of wilderness designation, there is general agreement that industrial "structures and activities [would] also violate the spirit of the land, a value that is reported by some Alaska Natives to be central to their culture."

In terms of physical and vegetation impacts throughout the Arctic, perhaps the most important factor distinguishing energy development there from that of other regions is the presence of permafrost. The late arctic–alpine biologist Dwight Billings referred to permafrost as the "glue" that binds arctic tundra ecosystems together. Permafrost exerts major influence over surface and subsurface hydrology, and thus affects substrate temperatures and the pattern and productivity of vegetation. A large share of the global carbon budget is stored in permafrost, and there is a strong linkage between carbon dioxide (CO_2) exchange and methane (CH_4) formation and emission rates in tundra ecosystems. However, as frozen ground warms sequestration processes are affected and tundra soils can turn from carbon and methane sinks to sources. The atmospheric input of methane from permafrost regions has been estimated to be 20–40 Tg CH_4/year, which is almost 25% of the total emissions from natural sources globally. It is well-known that the types of surface disturbance associated with energy development lead to soil warming and can easily lead to thermokarst, thus threatening the maintenance of permafrost in affected areas.

In addition to direct disturbances of the ground surface, other less visible impacts can accumulate over time. These may occur independently of each other or may be exacerbated through synergy among various proximal effects. These indirect impacts, which fall under the umbrella of cumulative impacts, are well documented, and although they were formerly unforeseen, we can now predict them in many cases. According to Skip Walker of the Institute of Arctic Biology at the University of Alaska Fairbanks (UAF), cumulative impacts differ from simple additive effects in five major ways: (i) The disturbances are so close in time that the system cannot recover (time-crowded perturbations); (ii) the disturbances are so closely spaced that the effects are not fully dissipated between them (space-crowded perturbations); (iii) combinations of disturbances produce effects that are different from those of any single disturbance (synergistic effects); (iv) the effects are delayed in time or space from the original disturbance (indirect effects); and (v) large regions are affected by many seemingly insignificant perturbations (nibbling), somewhat analogous to the process of fragmentation during deforestation.

The panel convened by the National Academies concluded that the effects of oil field infrastructure are

> *manifest not only at the physical footprint itself but also at distances that vary according to the environmental component affected. Effects on hydrology, vegetation, and animal populations occur at distances up to several kilometers, and cumulative effects on wildland values, especially visual ones, extend much farther, as can the effects on marine mammals of sound caused by some offshore activities. All effects attributable to the structures and the activities associated with them accumulate, and many will persist as long as the structures remain, even if industrial activity ceases.*

During the construction of TAPS, more than 78,500 ha (785 km^2) of land was directly disturbed, of which 31,700 ha (370 km^2), or 40%, was for gravel borrow sites or quarries extracted from both surface sources and streambeds. According to agronomist Jay McKendrick, Professor Emeritus at UAF, this extraction of gravel fill for drill pads and roads is the most extensive tundra disturbance. It has been calculated that approximately 0.04% of Alaska's Arctic Coastal Plain (or 0.1% of the area between the Colville and Canning Rivers) has been affected by gravel fill. In the Russian Arctic, by comparison, exploration and development activities at a single gas field at Bovanenkovo on the Yamal Peninsula had by 1990 resulted in the loss of 127,000 ha (1270 km^2) of tundra and 0.14% of the total area on Yamal. On neighboring Taz Peninsula, the figure has reached 1.5%, or approximately 6000–7000 km^2. Geographer Arkady Tishkov estimates that the area of destroyed ecosystems within the tundra zone of Russia comprises 8% of its total territory.

Regarding spills of liquids, from 1974 to 1977, when TAPS was first built and operated, more than 16,000 hydrocarbon spills, totaling more than 22,200 bbl, occurred along the pipeline route. During 1985 and 1986, 952 spills were reported on the North Slope, totaling 6137 bbl. In the Russian north, 7–20% of the oil extracted each year is lost through accidents along oil pipelines. A large spill of 103,000–126,000 tons near Usinsk in 1994 was reported in the world media and generated international concern, albeit briefly. However, such events are not uncommon and occur every 2 or 3 years according to Russian geographer Gregory Vilchek. Because Murmansk does not lie in the permafrost zone, its proposed oil export terminal would therefore mainly be a threat to coastal and marine ecosystems via potential spills. On the other hand, the proposed supply pipeline across the Kola Peninsula from the fields at Timan–Pechora (via Archangelsk) would certainly affect a large swath of land.

Impacts associated with energy development are complex in that various human activities can influence ecosystems simultaneously and can have both immediate catastrophic and long-term effects, leading to the aforementioned cumulative impacts. Sometimes, in practice, it is difficult to distinguish between direct and indirect impacts and scientists may use different methods for classifying disturbances. For example, Russian authors distinguish three main classes of disturbed areas: *ochagovyi* (local), *lineinyi* (linear), and *fonovyi* (spatial). The most striking example of the first type is sites surrounding petroleum boreholes (drill sites). Transport corridors appearing in connection with road and pipeline construction constitute linear disturbances. Large territories affected by air pollution (e.g., coal burning) are examples of spatial disturbances.

4. ECOLOGICAL IMPLICATIONS OF ENERGY DEVELOPMENT

The previous section described the major existing and planned energy developments around the circumpolar North. What are the implications of these various schemes for procuring enough energy at affordable prices? Is it possible to be efficient economically as well as to mitigate major environmental degradation? What are the true environmental costs of energy extraction along the entire route from source to consumption? What if societies and cultures other than those producing or buying the energy are adversely affected during the exploration and extraction phases to the extent that their health and traditional livelihoods are threatened? These are far from trivial questions.

The following example illustrates the scope of the process of just one contemporary energy production scheme in which the full costs are not necessarily accounted for by either the producers or the end users. During a debate on whether to build a fifth nuclear reactor in Finland, some "environmental" opponents declared that purchasing natural gas from neighboring Russia would be a cleaner and safer alternative. However, others pointed out two problems with this reasoning, which they criticized as the rationale of "out of sight, out of mind." First, much of the gas consumed in northern and central Europe is derived from fields in western Siberia, where indigenous groups dependent on traditional livelihoods (e.g., reindeer herding, hunting, gathering, and fishing) have been powerless to stop widespread habitat degradation within their ancestral homelands. Second, Russian pipeline construction standards have traditionally been well below Western levels, so that much of the gas ends up leaking into the atmosphere during transport. When burned properly, natural gas emits approximately 60% less carbon dioxide to the atmosphere than coal and approximately 30% less than oil. However, gas released directly to the atmosphere as methane has many more times the heat-trapping capacity than CO_2, making it a potentially powerful contributor to the greenhouse effect. These are just some of the

issues that need to be considered during the ongoing development of international energy networks.

Anthropogenic activities in the Alaskan Arctic up to the present time have generally created small but locally intense terrestrial disturbances ($<1\,km^2$ and often $<100\,m^2$), and in total they occupy small proportions ($<10\%$) of oil and gas fields. These small-scale disturbances may affect wildlife out of proportion to their spatial extent by creating microscale heterogeneity with patches that can either attract or repel animals. As mentioned previously, in portions of Arctic Russia, such as northwest Siberia, the realized and potential impacts are greater by an order of magnitude as a result of little or no adherence to or enforcement of regulations aimed at mitigation.

Much of the debate concerning the ecological implications of energy development revolves around habitat loss in the North American Arctic. Habitat is the place where an organism is found, including both biotic and abiotic factors. In general, the distribution of a population within its habitat at a given time is a measure of habitat value. Loss of certain portions of the species' habitat may affect the species more immediately and more severely than loss of other portions of its habitat. Loss of high-value habitats could have immediate adverse consequences for the populations that they support. Russia faces not only major losses of habitat but also the direct losses of wildlife and local species extinctions because rampant poaching of fish, wildlife, and semidomestic reindeer in and around arctic petroleum fields and along transport corridors is a major problem.

Petroleum deposits in western Siberia were first identified and tapped during Soviet times, mainly in the more accessible subarctic zones south of the arctic tree line. Those original oil and gas fields were developed recklessly with little or no concern for the technical longevity of the fields or the environmental damage resulting from the exploration and exploitation phases. It is certain that Russia will need foreign expertise in both extraction and environmental mitigation, in addition to capital investments, to develop new fields in the Arctic.

In terms of raising this capital, it makes little difference who becomes Gazprom's partner—Russian oil companies, major gas traders such as Germany's Ruhrgas, or multinationals such as BP or Shell. However, the environmental implications are potentially profound because the traditionally state-owned Russian monopolies have had few incentives for environmental protection. Western companies, on the other hand, are highly competitive and increasingly sensitive to their image. For example, BP Amoco PLC is one of two dominant oil companies on Alaska's North Slope and has been trying to enhance its image globally during the past several years, beginning with a new sunburst logo and slogan "Beyond Petroleum" in summer 2000. Although BP pumps more than 300,000 bpd from Alaska, it has made efforts elsewhere to increase its production of cleaner-burning natural gas over crude oil and also invested heavily in solar power. Nevertheless, in December 2002, a U.S. judge tightened controls over BP by requiring the company to provide unrestricted access to its Alaskan operations to verify compliance with federal, state, and local environmental, health, and safety laws. The merger of BP with TNK raises hope for mitigation as its new Russian fields are developed.

In North America, proponents of the future development of ANWR argue that the lessons learned during the past 30 years, combined with new exploration and drilling technologies, allow engineers to design oil fields with an ecological footprint half that used in the Prudhoe Bay oil field. However, opponents point out that the switch from gravel to winter ice roads is leading to the depletion of surface and groundwater in some areas. Furthermore, the cumulative impacts from past development described previously are not yet fully understood, although it is clear that even small disturbed patches of vegetation and soils can persist indefinitely.

It is known that environmental regulation can make a positive difference. Studies of disturbance associated with exploratory well sites in northern Yukon Territory found significantly less terrain damage and thermokarst topography after the introduction of territorial land-use regulations in the early 1970s. Improvements in industry operating conditions (e.g., the use of vehicles equipped with low-pressure tires) and strict application of the land-use regulations (e.g., the restriction of cross-tundra vehicle movement to winter months) are important factors in the reduced impact observed. In this light, the potential for the most serious terrain and environmental damage is now associated with the drilling operation, which may sometimes extend into the critical summer months, and the disposal of waste drilling fluids. That the disturbances in the Yukon were neither as obvious nor as severe as in the Mackenzie River delta and the islands of the High Arctic was attributed, respectively, to the relative absence of ice-rich permafrost and the ameliorated subarctic climate conditions.

With regard to wildlife, the impacts of the oil development at Prudhoe Bay on the caribou of

the Central Arctic herd (CAH) are heatedly debated. On the one hand, the CAH has increased from 3000 animals in 1973 to 29,000 today, and the animals can be seen grazing among the oil field infrastructure in summer, even using the roads for relief from insect harassment. On the other hand, the population growth coincides with a period of favorable climate conditions that may not last. Studies have shown that mothers pregnant with calves tend to stay at least 4 km from roads and that the calving grounds have shifted away from the infrastructure over the years from the most productive habitats to less productive areas. At the same time, the Porcupine caribou herd (PCH), which migrates into ANWR from Canada, has been declining since 1989. There are concerns that if the refuge is developed the additional stress will cause an increase in calf mortality and a dramatic reduction in herd size. Concerning the proposed pipeline route, some analysts believe that using the TAPS and Alaska Highway corridor would have less impact because it would primarily use existing corridors. Opponents believe that a submerged Mackenzie Valley pipeline could endanger both marine and terrestrial ecosystems.

Concerning offshore development, the World Wildlife Fund and others have acknowledged that safe transportation with minimum pollution poses serious challenges for environmental organizations in general and marine environmental science in particular. The Arctic Operational Platform project, funded by the European Union during 2002–2004, is intended to demonstrate the development capacity of the NSR. The port at Varandei in NAO remains the only Russian Arctic stationary terminal for oil transportation and is expected to grow. Other terminals, such as the one on nearby Kolguev Island, are functioning only on a temporary basis.

There is concern that Gazprom is launching into the gas liquefaction business in an area with some of the most extreme natural and climatic conditions in the world. Frozen seas would complicate shipment of liquids and LNG via the NSR. The cold climate means that the biodegradation of oil spills on both land and in ice-covered waters would occur at a much slower rate than in more temperate ecosystems. Most of the spills of liquids on Alaska's North Slope have consisted of refined petroleum products and occurred on water or in gravel pads, although some have occurred on terrestrial vegetation. Oil does not penetrate deeply into saturated soils, but spills on dry sites are absorbed by mosses and the underlying organic material and mineral soils. Sedges and willows are the first vascular plants to reappear following a terrestrial oil spill. Recovery from diesel spills is extremely slow, showing little change after approximately 30 years and probably after even half a century. By comparison, recovery from spills of crankcase and crude oil in the low Arctic generally occurs more quickly (<30 years) in wetland habitats. Recovery can take much longer in the colder, drier habitats of the high Arctic, not to mention in ice-covered waters.

NSR transport projects supporting the development of the Bovanenkovo and Kharasavey gas fields on Yamal require the construction of a port at Kharasavey for the import of extraction equipment and the export of liquids. At the same time, a railroad is being laid from the Ob River gulf to Bovanenkovo and a parallel service road is planned to continue from Bovanenkovo to Kharasavey. There has been a great deal of damage along this corridor, especially due to quarrying. All quarries—sand, gravel, and rubble—are slow and difficult to revegetate either naturally or with assistance and are therefore generally kept to a minimum by companies active in the North American Arctic. In the best case scenario, a complete plant cover is possible over a period of 20–30 years, although costly subsidies of nutrients, organic matter, and water are typically required to achieve this. Furthermore, the majority of plants that are either planted intentionally or eventually colonize the site naturally are not likely to be those that occurred there originally.

Another factor to consider when dealing with tundra vegetation is climate change. A warming arctic climate may offer both opportunities for revegetation efforts and risks from migrating exotic species that may compete with native species. However, with or without climatic change, we cannot expect the distribution of weedy plants, or even whole plant communities, to remain static at their northern limits. There is concern that expansion of corridors and increasing human relocation from southern regions will likely continue to provide a ready source of introduced species. A recent effort by the United Nations Environment Program to model anthropogenic impact, GLOBIO, predicted that by 2050 more than 50% of the Arctic may be affected by critical levels of disturbance. Much of the impact is expected to occur along the growing network of transport corridors and related infrastructure (e.g., housing, power lines, and airports).

Soon after the strike at Prudhoe Bay, oil companies and TAPS arranged for environmental studies of their own and supported research at the Institute of

Arctic Biology at UAF into revegetation and rehabilitation methods for tundra disturbed during the course of engineering operations and infrastructure development. Based on early experiments, seeding of three grasses [*Arctagrostis latifolia* (Var. Alyeska), *Festuca rubra* (Var. Arctared), and *Poa glauca* (Var. Tundra)] became a standard practice. On medium-texture, mesic soils, seeding and fertilizing usually produced grass stands within three growing seasons. In the long term, seeding these commercial grasses has frequently delayed natural recolonization where seeded grasses established and persisted. Examples are overburden stockpiles at gravel mines. Where such stockpiles were seeded, the commercial grasses have resisted invasion by other tundra plant species for at least 15 years. It is believed that competition from the seeded grasses is responsible for the delay of indigenous plant invasion during the process of succession.

Although there are still important gaps in our understanding of natural tundra ecosystems, it is becoming increasingly clear that there are varied and critical functions to be served by restoration procedures in disturbed ecosystems. Among the most important applications are the prevention of erosion, rehabilitation of degraded wildlife habitat, and protection of permafrost and associated benefits from carbon sequestration. Most applications to date have taken place in subarctic and low Arctic ecosystems. In the early years, research was necessarily concentrated on assisting recovery (i.e., establishing a simple plant cover as quickly as possible). Recently, however, ecological restoration has come to be seen as an aim in itself. Although plants are selected primarily to prevent erosion, many of the chosen species also provide important food for wildlife. Since it is standard practice to apply organic matter and/or chemical fertilizers to subsidize the initial stages of growth, managers need to be wary about the access of herbivores (e.g., caribou and reindeer) to sites either naturally recovering from disturbance or actively revegetated.

5. SOCIOCULTURAL IMPLICATIONS OF ENERGY DEVELOPMENT

In the discussion of the impact of development of ANWR, referred to by some as the Serengeti of the North, much of the focus has been on the area's wildlife and wildlife habitat. As a result, the human dimension is often overlooked. However, in North America, as in Russia, many communities depend to a greater or lesser extent on fish and game for nutritional and cultural purposes. Just as onshore drilling can negatively affect calving caribou and therefore hunting opportunities, offshore oil developments may prove destructive to populations of fish, marine mammals, or birds on which local residents depend for subsistence needs. Similarly, oil or gas operations may generate forms of water or air pollution that are physically harmful to local residents. Political scientist Oran Young of the University of California at Santa Barbara observes that large-scale development involving oil or hydroelectric power in the far north may also severely disturb or distort important social institutions or central elements of the preexisting indigenous way of life, such as subsistence economies, cultural norms of sharing, and traditional authority structures. Similarly, construction projects associated with the development of northern resources may produce severe stresses on delivery systems for health, education, and welfare even in larger modern settlements.

Relative to their North American counterparts, Russia's arctic indigenous groups, the so-called small-numbered peoples of the North, lack significant political clout. Researcher Gail Osherenko of the University of California at Santa Barbara suggests that title to land may be essential to their cultural survival in the face of extensive arctic resource development. Unfortunately, despite the advent of glasnost and perestroika, there are still risks for speaking out on such issues. Some of the more vocal political activists in western Siberia have been jailed.

For groups that still practice traditional livelihoods, such as nomadic reindeer herding, the last generation has been one of adaptation to significant upheaval. The Yamal Nenets, for example, have survived first Tsarist and later Soviet dreams of establishing state and religious authority over even the most remote human populations. However, nothing has challenged them like the ongoing search for petroleum beneath their ancestral lands. The data discussed previously concerning the amount of destroyed tundra and forest–tundra are of critical sociocultural significance because virtually all of the lands once comprised reindeer grazing pasture. A culture that has changed little in 1000 years is suddenly endangered because of the havoc wrought by petroleum development. In addition to environmental degradation, the infusion of southern workers to the oil and gas fields has ushered in a host of health and demographic problems that did not exist 20 years ago.

Concerning development of the NSR, Alona Yefimenko of the Arctic Council's Indigenous Peoples' Secretariat is skeptical about measures to protect indigenous livelihoods. She believes that "practically, most of us know that real consultation and equal participation and representation by indigenous peoples requires a legal and political infrastructure that does not exist." In her view, the existing examples of energy development in Russia's north show "a very sad picture": ruined reindeer pastures, deserted oil and gas derricks, roads dissecting reindeer migration routes, etc. Nenets leader Dmitri Khorolya, president of the Reindeer Herders' Union of Russia and director of Yarsalinski sovkhoz, the largest collective management unit on Yamal Peninsula, has voiced similar alarm. In June 2001, he observed that

> *the vulnerable ethnic–economical systems of reindeer peoples are frequently exposed to hard market conditions, particularly where oil and gas mining has become the principal factor in the development of Arctic areas. Industrial activity in the North has resulted in the destruction of many thousands of hectares of reindeer pasture. The process is continuing. In some regions pasture degradation threatens preservation of reindeer husbandry and the anxiety of reindeer herders for their future should be heard by the world community*

The pasture degradation results not only from the direct impacts by industry. Additional losses occur as the animals are forced onto progressively smaller parcels of land each year, resulting in sometimes severe overgrazing and desertification of the remaining pastures.

As in Russia, the proven and potential natural gas reserves of arctic Canada occur mainly on lands inhabited by indigenous peoples or First Nations. The difference is that the political clout of the Canadian First Nations was sufficient to halt development of the Mackenzie Valley pipeline in the 1970s. However, most of the First Nations groups that once opposed drilling on legal, environmental, and cultural grounds have abandoned their protests and now favor exploiting their region's energy resources. As a result, the government of the Northwest Territories is currently pressing Ottawa for an ambitious road and bridge construction program that would lower production costs. Stephen Kakfwi, premier of the Northwest Territories, predicts that the pipeline will soon be built and that "many communities will become twice the size, and all will have paved roads." His recently elected counterpart in the Yukon, premier Dennis Fentie, is similarly supportive of the development plan.

Native attitudes toward the development of ANWR are somewhat less homogeneous. The inland Gwich'in settlements of northern Yukon and Arctic Village in neighboring Alaska depend on the caribou of PCH and are bitterly opposed to any further development of the coastal plain. At the same time, the Iñupiat of Kaktovik on the coast of Alaska are just as strongly in favor of development.

Glossary

crude birth rate The number of births per 1000 population.
crude death rate The number of deaths per 1000 population.
demographic transition A transition from high to low birth and death rates.
epidemiological transition A transition from high, variable death rates to low, stable death rates.
infant mortality rate The number of infant (under 1 year of age) deaths per 1000 live births; this is considered one of the best overall measures of a society's level of health and welfare.
least developed regions The United Nations designation for the world's poorest 48 countries, mostly from sub-Saharan Africa, South Asia, Laos and Myanmar in Southeast Asia, and Haiti in the Caribbean.
less developed regions The United Nations designation of poorer countries; includes most of Asia, except Japan; Africa, except South Africa; and Latin America.
more developed regions The United Nations designation for the world's wealthy, industrial nations.

The basic outlook of a long-term positive relationship between population growth and energy use is complicated by observations of different historical periods. The early modern period, in the 15th and 16th centuries, saw a new technology that harnessed wind for sails, bringing an increased population growth in Europe and Asia and a demographic collapse in the Americas. Modern population growth from the 18th through the 20th centuries was based on fossil fuels and industrialization, with distinct differences between the North Atlantic community and the rest of the world. The present is marked by great increases in both population and energy use at the global level, with considerable variance at the level of individual countries.

1. A BASIC OBSERVATION

1.1 A Close Correlation

The basic picture of population growth in our era, the past 1000 years, is a familiar one. Figure 1 traces only the past 1000 years. The margins could easily be pushed back 100 or 200,000 years without altering the basic pattern. We have had thousands of years of slow growth, followed by exponential rates of very rapid growth over only the past three centuries. This basic pattern of growth, presented in Fig. 1, can be related to the pattern of growth in energy consumption. For this measure, a surrogate, carbon emissions, provides a picture of the past two centuries. Although this does not directly indicate energy use, it indicates the major source of energy for the past two centuries. Combustion releases carbon into the atmosphere in the form of carbon dioxide. First wood, then coal, and finally oil were the major sources of energy for the recent past (Fig. 2).

The correspondence of the two growth patterns seen in Figs. 1 and 2 is striking and indisputable. Together, these charts suggest that population growth produces increased energy consumption, or that increased energy consumption produces population growth. To be sure, if population growth were considered to occur with a constant technology (for example, using wood for heating and cooking), the juxtaposition of the growth curves would be wholly understandable. More people means more wood is needed for heating and cooking. But there are complicating conditions.

1.2 Population Growth and Energy: A Complex Relationship

Ben Franklin, for one among many, showed how humans could build a more efficient stove, using less wood for more heat. Thus a change in technology can change the tight correspondence between population and energy use. This can be seen more clearly if the data in Fig. 1 are complicated by adding an indication of major changes in energy technology and social organization. This is seen in Fig. 3, which shows that the recent pattern of population growth was accompanied by a revolution in energy, from animal to sail to fossil fuels, and by an even more radical revolution in human social organization, from rural agrarian society to urban industrial society. This implies a complex change in both energy converters (animals, sailing ships, and heat engines) and sources of energy (animal feed, wind, and carbon sequesters). Obviously, the causal paths run in both directions. It is this observation that has led to a more complex picture of the relation between population growth and energy. It is a perspective borrowed from the discipline of human ecology. The basic model is seen in Fig. 4, but can easily be stated here: There is no direct relationship between population growth (or decline) and energy. All relationships between population and energy flow through and are mitigated by some form of human technology and human social organization.

The complex population and energy relationship can be seen in three distinctive historical periods over the past five centuries. The first period shows a small population growth spurt in the 16th century after the revolutionary progress in wind energy opened the world to a new trading system. The second shows how the modern "North Atlantic" population community grew to its present state, related to the beginnings of the fossil fuel energy system. The third focuses on the past half-century, when a new and more rapid period of population growth outside the North Atlantic Community occurred. This has been accompanied by a worldwide intensification of energy

use as the less developed countries of the world began to push for modern economic development. It has also been accompanied by both a demand and a vision for a new energy revolution that will lead to "sustained development." In all of these illustrations, it can be seen how human social organization and human technology affect the relationship between population growth and energy.

2. EARLY MODERN POPULATION GROWTH AND ENERGY USE

Perhaps one of the most dramatic illustrations of the complex relationship between population and energy is to be found in the 15th and 16th centuries. As Fig. 2 suggests, there was a great energy transformation in the 15th and 16th centuries and a slight increase in population growth rates. Until 1500, most of world trade and production were carried on by animal and human power. The Silk Route moved goods (and microbes, of which more shortly) between Asia, the Middle East, and Europe for at least the past 2000 years. In all this period, the Americas were isolated and free of Euro-Asiatic contact. That changed in the latter part of the 15th century. Columbus made the sea link between Europe and the Americas in 1492; Vasco da Gama made the sea link between Europe and Asia in 1498, and Magellan's ship completed the first circumnavigation of Earth in 1523. In the words of J. H. Parry, the west "discovered the seas" and tied the continents together in what would become a single ecosystem.

These new sea links were based on a remarkable revolution in technology, especially in naval architecture, between 1400 and 1450. This has been called the transformation from oars and swords to guns and sails. Until the 15th century, Western European, especially Mediterranean, naval architecture was based on two types of vessels. For war, there was the oar-propelled "galley," manned by slaves or freemen moving what was basically an infantry to engage in hand-to-hand combat on the sea. For trade, there were crude single-masted, square-rigged ships, often using only a large oar over the lee stern for steering. In the first half of the 15th century, the Portuguese developed the caravel, a revolutionary three-masted ship. The square sail amidships was balanced with a lateen sail in the stern and a third sail forward; all supported by rigging between the three masts. Ultimately, the hull was raised higher out of the water and fitted with canons. This new ship proved exceptionally powerful, using wind and gunpowder to carry men and goods and to fight at sea throughout the world. It did more as well; it provided the basic design for sailing ships that grew larger and larger for the next 500 years. With this new rigging design, masts could be extended upward and increased in number, adding acres and acres of wind-catching sail. An immediate result of this new energy transformation included two dramatically different impacts on world population. The population growth rates in Europe and Asia rose from their long-term rate of less than 0.1% per annum to about 0.2% per annum. In the Americas, on the other hand, there was a massive demographic collapse.

European and Asian populations grew as new crops from the Americas quickly found their way across the seas and raised the carrying capacity of the land. Potatoes, sweet potatoes, beans, ground nuts, tomatoes, chili peppers, and corn became standard new crops in Asia and Europe, enhancing the calorie-producing power of the land, reducing mortality, and increasing population growth rates. This was an early example of what has come to be called the epidemiological transition. Historically, death rates have been both high and variable. In agrarian societies, annual changes in the weather could produce large swings in the death rate. A long winter and bad summer meant reduced nutrition and higher death rates. Better weather the following year would see an increase in nutrition and a substantial reduction in the death rate. With modernization, the death rates declined, and they also became more stable.

In return for the new crops, the Americas were given Euro-Asian microorganisms. Two millennia of Euro-Asian trade had moved diseases back and forth and had created a degree of immunity in those populations. Lacking such contact for more millennia, the Americas developed no such immunities. Measles, typhoid, and small pox proved to be deadly imports to the Amerindian populations. Within a century of Columbus' landing, the entire native population of the Caribbean was wiped out. The large and concentrated Aztec and Inca populations were literally decimated. Later, the same thing would happen to the smaller and more scattered tribal Indian societies in the rest of South and North America. This is perhaps one of the most dramatic illustrations of the complex nature of the impact of energy changes in population. The specific outcome was the result of a technological change that increased energy use, which had dramatically different impacts on different populations. The sail revolution can be argued to involve a decline in

energy use, at least in the human and animal energy used to produce and transport goods. It can also be seen as a net gain in energy: the energy gained by sails in comparison with the energy required to harness the wind. It also overcame a major limitation of the swift and maneuverable galleys, which were tied to the land because of the food and water required to feed the men who moved them. In any event, this was a technological innovation that made extensive and efficient use of a form of energy previously used only sparsely and inefficiently. This energy transformation directly produced an increase of population growth in one part of the world, and a demographic collapse in another.

TABLE I

Regional Distribution of World Population, 1500–2050

	Year[a]					
Region	**1700**	**1800**	**1900**	**1950**	**2000**	**2050**
World population[b]	610	902	1622	2515	6057	9322
Europe	20%	20%	24%	23%	12%	6%
North America	<1%	1%	5%	7%	5%	5%
Asia	68%	69%	60%	55%	61%	58%
Africa	10%	8%	7%	9%	13%	21%
Latin America	2%	2%	4%	7%	9%	9%

[a] Percentage of worldwide population in a given year.
[b] Millions.

3. 1700–1950: THE FIRST MODERN POPULATION GROWTH SPURT

The early modern population growth spurt brought European and Asian population annual growth rates to about 0.2% by 1700. From this point, Asian growth stagnated for the next two centuries while Europe began a new growth spurt. This was the result of what has come to be known as the demographic transition, or the transition from high to low birth and death rates. From about 1700, mortality in Europe began a long-term secular decline. Trade, agricultural, and industrial revolutions, plus a moderate global warming, gradually increased the standard of living, which lowered crude death rates from about 25–30 to 10 by about 1900. It was especially the industrial revolution that saw a dramatic rise in energy consumption. The new steam engines were powered first by wood, then the dramatic shift was made to fossil fuels, coal, and, later, oil and natural gas. Here increased energy use reduced mortality and led to increased population growth.

Although the mortality rate was decreasing throughout the 18th and much of the 19th centuries, the past levels of high fertility (crude birth rate: 30–35) remained high, producing a period of rapid population growth. In 19th-century Europe and its American extension, annual rates of population growth were about 0.8–1.0%. By the end of the 19th century, however, birth rates began to decline, coming into line with low death rates by about 1950. Thus this early demographic transition, from high to low birth and death rates, was completed in about two centuries. This coincided with the transition from rural agrarian to urban industrial society, which, among other things, transformed children from an economic asset to an economic liability. This helps to explain the decline in fertility. In addition, the period saw the expansion of the European population to the Americas, and especially to North America, creating a new "North Atlantic" community marked by the new form of urban industrial society. Thus again, the relationship between population growth and energy appears as a complex and indirect one. Increased energy consumption came with the expansion of the machines of the new industrial society. Greater energy consumption implied lower costs of transportation and higher levels of human productivity. This facilitated urban living, implying both a decline in the economic value of and an increase in the economic costs of children. This ultimately led to lower levels of fertility and population growth. Thus, increased energy use led first to more rapid population growth, and finally to a slowing of population growth. This population growth spurt was region specific. The most rapid growth occurred in Europe and North America, changing the regional distribution of the world's population. This can be seen in Table I.

4. 1950–2050: THE SECOND MODERN POPULATION GROWTH SPURT

The demographic transition that was completed in the Western World by the mid-20th century is now taking place throughout Asia, Latin America, and Africa. In its population reports, the United Nations refers to this part of the world as the less developed regions (LDRs). The World Bank and others refer to it as "the world of developing or less developed"

countries. The "least developed" regions, consisting basically of much of South Asia and sub-Saharan Africa, are a subgroup of the LDRs. The United Nations contrasts this with what are called the more developed regions (MDRs), i.e., the North Atlantic community, Australia, New Zealand, and Japan.

The pattern of this new demographic transition is the same as in the past: mortality decreases first while fertility remains high, producing a period of rapid population growth. Then fertility declines, coming into line with the lower mortality, and the overall growth rate slows. Although the pattern is the same, the rates, absolute numbers, and timing are radically different. First, levels of mortality and fertility in the LDRs at the beginning of the transition were much higher than they were at the beginning of the earlier MDR transition. Second, the mortality decline in the LDRs came very rapidly, following major medical advances that reduced mortality rapidly after World War II. Declines that took two centuries in the MDRs now came in two to four decades. This produced a much higher rate of population growth in the LDRs. Whereas annual population growth rates in the past transition were about 1% or less, population growth rates in this current transition are 2.5% and higher. Third, the fertility decline that is now taking place in the LDRs can occur more rapidly than it could in the past. Past fertility declines that might have required one or two generations in the past can now take place in two decades, or one generation.

The major cause of the change in the speed of the transition lies in two technological breakthroughs and associated changes in public policy and large-scale organizations. In the middle of the 20th century, a new medical technology was developed that could attack infectious diseases. Antibiotic drugs could stop infections and chemical pesticides could kill the vectors of infectious diseases such as malaria. These new techniques could be carried rapidly to the LDRs via newly created worldwide organizations such as the United Nations World Health Organization, nongovernmental organizations, and expanding private market organizations. The result was an exceedingly rapid decline in mortality and a rapid rise in population growth rates. World population growth rates stood at 1.79% in 1950/1955. They peaked at 2.04% in 1965/1970, then began to decline. For the LDRs, however, the peak in 1965/1970 was 2.51%. The MDR population growth rates peaked at 1.20% per year in 1950/1955 and have been declining steadily since then.

The modern fertility decline that is now occurring, and has been completed in many of the LDRs, can also occur more quickly than in the past. This is due in large part to the development of non-coital-specific contraceptive technology, which emerged only in the 1960s. Like new medical technology, new contraceptive technology can be disseminated by large-scale organizations, which developed rapidly after 1960 in the form of private and public national and international family-planning programs. Moreover, these technological and organizational developments were accompanied by a radical change in national and international population policies. Most national population policies before 1952 were pronatalist. Governments supported high fertility and often banned programs and activities that promoted birth control or deliberate fertility limitation. This changed in 1952, when India became the first government to announce a national policy to reduce population growth by reducing fertility in marriage. This began what has come to be called the "antinatalist policy revolution." Comparable policy changes became common in the rest of Asia, followed by Latin America and Africa in the next three decades. In 1968, the United Nations resolved that it is a basic human right that couples be allowed to choose the number and timing of their children and to be assisted in doing so. Today most countries in the LDRs have policies that promote or allow the promotion of fertility control programs and contraceptive distribution. Notable exceptions are found primarily in select group of Muslim countries, though many Muslim countries, such as Bangladesh, Indonesia, Iran, and Tunisia, actively promote effective national family planning programs.

Just as the first modern population growth spurt differed by world region, the current transition also differs by world region. Asia led the way in policy and reproductive behavior changes, followed by Latin America and then by Africa, which still lags considerably behind in fertility decline and thus shows continuing high growth rates. The resulting changing rates of population growth in these regions over the past 50 years can be seen in Table II.

5. MODERN POPULATION GROWTH AND ENERGY

The relation between population growth and energy currently shows two different patterns, at the global level and at individual country levels. At the macro (worldwide) level, there is a close correspondence between population growth and energy consumption,

TABLE II

World Population Growth Rates by Region, 1950–2050[a]

Region[b]	Annual average (%)					
	1950–1955	1965–1970	1970–1975	1980–1985	1990–1995	2000–2005
World	1.79	2.04	1.93	1.71	1.49	1.23
MDRs	1.20	0.83	0.78	0.59	0.44	0.16
LDRs	2.06	2.51	2.35	2.06	1.76	1.48
Asia	1.93	2.42	2.25	1.85	1.58	1.26
Africa	2.17	2.59	2.61	2.87	2.54	2.33
Latin America	2.65	2.58	2.45	2.08	1.72	1.42

[b] MDRs, More developed regions; LDRs, less developed regions.

with some highly suggestive changes in the past two decades. At the micro (individual country) level, there is considerable variance in the relationship. Each requires some discussion and illustration.

5.1 Global-Level Population and Energy

For the past two centuries, there has been a very close correspondence between world population growth and energy consumption, as measured by atmospheric carbon emissions. Figure 5 shows the overall global relationship; Fig. 6 shows the relationship between carbon emissions and emissions per capita of world population. Both figures show a clear positive relationship between population growth and energy consumption. Energy consumption grew only slowly in the 19th century but showed exponential growth in the 20th century. The urban industrial society based on fossil fuels brought with it higher standards of living and substantial population growth. In the 20th century, energy consumption grew more rapidly than population did, imposing an increase in per capita energy consumption. This has begun to change in the past two decades, however, because per capita consumption, or carbon emissions, appear to have reached a plateau and may even be declining slightly. As shall be seen shortly, this declining per capita consumption has a number of causes. First, there has been a change from more polluting to cleaner fuels, so that carbon emissions can decline even as actual energy consumption rises. Second, there has been a structural change in the industrial world, showing a decline in the manufacturing and agriculture industries, based on the proportion of wealth they generate, and a rise in the service industries. The service industries are less

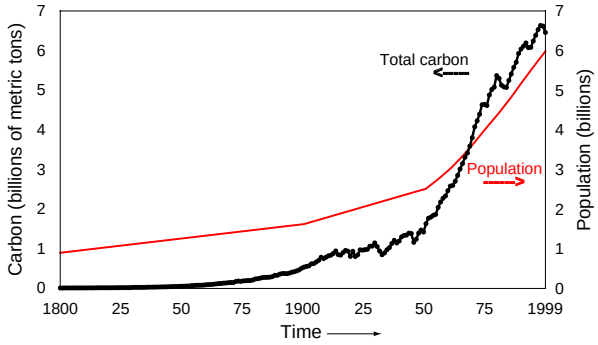

FIGURE 5 World atmospheric carbon emissions and total population.

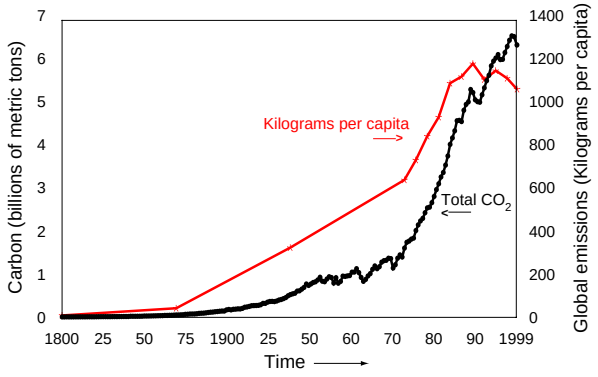

FIGURE 6 World total and per capita atmospheric carbon emissions. Adapted from CDIAC (2002) and Ness (1993).

energy demanding compared to the older manufacturing industries, thus energy use can decline even as population grows and economic development progresses. Finally, the technology of energy consumption has become much more efficient, requiring less energy for a growing population and growing wealth.

None of these changes has been universally constant, however. The specific conditions of individual countries and blocks of countries have broad effects. Individual countries differ by resource endowments, by levels of development, and by specific energy policies, both explicit and implicit. To understand these patterns requires turning to a series of individual country illustrations and comparisons.

5.2 Individual Country Variance

There are three important points to note here. First, the wealthy countries differ from the poor countries in levels of energy consumption and in the trajectories of growth. Second, wealthy countries differ greatly among themselves in energy consumption and its trajectory. Third, the less developed countries also differ among themselves in levels of energy consumption and patterns of population change.

5.2.1 Wealthy Countries and Poor Countries

The first point can be seen readily in Table III. The populations of the more developed regions are growing only very slowly; their per capita energy consumption is about six times as high as that in the LDRs. At the same time, energy consumption is actually declining slightly, though it can be seen that this is due largely to Europe's substantial 20% decline from 1987 to 2000. This was primarily due to the economic collapse of the Soviet Block countries, however, as well as improvements in efficiency in other parts of Europe. Compared to the MDRs, the LDR population and per capita energy use are growing much more rapidly.

In the proportion of energy from renewable sources, there is also a substantial difference between the wealthy and poor countries. Poor countries derive about a quarter of their energy from renewable sources, and for the poorest, the proportion can reach 90%; the rich countries take only 6% from such sources. But the differences are even greater than this implies. A great part of the renewable source in the poor countries is wood, implying a low technology. In the wealthy countries, much of the renewable sources are high-technology sources such as waste recovery, hydroelectric, solar, and wind.

Economic development and technology are the forces driving the changing patterns of energy consumption, and they come with low population growth rates, which have even turned negative in some cases.

5.2.2 Differences among Wealthy Countries

Most wealthy countries have seen an increase in energy efficiency, implying a slower growth of per capita energy consumption and even a reduction in the energy costs of increasing wealth. Figure 7 illustrates this process over a long time series in the United States. Over the past 130 years, U.S. real per capita output has steadily increased. At the same time, the national population has grown from 40 million to 280 million. Carbon emissions from fossil fuel emissions per $1000 GNP have increased steadily throughout the first two decades of the 20th century then began a steady decline. Many countries experienced similar trajectories as coal was replaced with oil and natural gas and combustion processes were made cleaner and more efficient.

In the latter half of the 20th century, wealthy countries began to differ markedly in their patterns of energy consumption. As can be seen in Table III, Europe has begun a substantial reduction, 20% in the past 13 years, of total energy consumption. As noted, however, this comes primarily from the Soviet economic collapse, which has also been accompanied by a dramatic reduction in population growth rates, even to actual declines in population. Still, both Japan and Europe have much lower levels of per capita energy consumption than do the United States and Canada, for what is essentially the same standard of living. France has lowered fossil fuel consumption with a large shift to nuclear power, which now accounts for about 42% of domestic energy consumption. Japan has also built a substantial nuclear facility, which gives it about 16% of its energy. Both Europe and Japan levy heavy taxes on gasoline consumption, leading to more extensive use of smaller and more efficient vehicles. The United States oil tax policies do not encourage the kind of efficiencies found in Japan and Europe. Thus, low population growth rates in the wealthy countries are accompanied by a wide range of different policies and technologies. These produce very different levels of energy consumption.

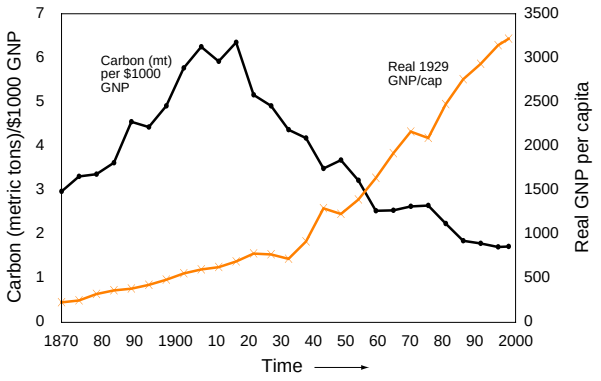

FIGURE 7 United States real gross national product (GNP) per capita and carbon emissions per $1000 real GNP.

5.2.3 Differences among Poor Countries

There are considerable differences among poor countries in the relationship between population growth and energy. This, too, is due to different ecosystems and resource endowments, but more importantly to different policies with respect to economic and social development and environmental protection. Almost all poor countries officially espouse the aim of promoting economic development. Most also promote, either actively or passively, some form of fertility limitation to reduce population growth and promote human health. They differ remarkably, however, in their capacities to turn those aims into effective programs. Thus they differ in the population growth–energy relationship. Table IV uses three pairs of roughly comparable countries, chosen primarily for their differences in levels of welfare, as measured by the infant mortality rate.It shows their population levels and growth rates, energy consumption, and level of economic development.

Bangladesh and Pakistan are two large, poor, Muslim countries in South Asia. They share a long history of Hindu–Muslim culture and more than two centuries of British colonial rule. Both countries actively espouse aims of economic development and human welfare. Both are experiencing the recent demographic transition now sweeping the less developed regions. Bangladesh has made more progress than has Pakistan in reducing its fertility and thus its population growth rate. This has also given it a slightly higher level of human health and welfare, as indicated by its lower infant mortality rate. But its per capita rate of energy consumption is only two-thirds that of Pakistan, and its energy consumption growth rate is also only two-thirds that of Pakistan. It is slightly poorer than Pakistan, but at the moment its rate of economic development is substantially greater than Pakistan's. Here, then, slower population growth and lower economic development are

TABLE IV

associated with slightly lower levels of energy consumption.

Thailand and Myanmar also share a long history of Theravada Buddhist culture in a riverine wet rice ecosystem. Myanmar came under British colonialism in the early 19th century, achieving independence in 1948, after about a century of colonial rule; Thailand managed to stave off colonial penetration through astute diplomacy, balancing British and French overseas interests. Both countries emerged in 1950 with strong aims of promoting economic development and human welfare. Thailand has been far more successful than Burma in both its development and population policies. With one of the world's most effective national family planning programs, it brought fertility from high traditional levels to below replacement in just two decades. Its associated health and education programs have given it a much higher quality of life, with an infant mortality rate about a quarter of that in Myanmar. It is wealthier and has experienced much higher rates of economic development, and its energy consumption has greatly outstripped that of Myanmar. Both countries began in 1950 with roughly equal levels of energy consumption; today Thailand's total consumption is almost four times Myanmar's and its per capita level is about three times Myanmar's. In this case, much slower population growth and more rapid development are associated with greatly advanced energy consumption.

In southeastern Africa, Zimbabwe and Mozambique share roughly similar landscapes. Until relatively recently, Zimbabwe had a relatively progressive and effective program for economic development and social welfare. Its fertility limitation program helped bring down fertility and the rate of population growth, producing a welfare benefit, as seen in its lower infant mortality rate, which is only about half that in Mozambique. Zimbabwe is substantially wealthier and consumes almost twice as much energy per capita as does Mozambique. As in Southeast Asia, slowed population growth and greater welfare are associated with higher level rates of growth in energy consumption.

Finally, Costa Rica and Guatemala share the topical ecosystem of Central America, the long period of Spanish colonialism, and almost two centuries of political independence that failed to bring much development until the past half-century. During this time, Costa Rica embarked on a program of democratic economic development and welfare promotion that has made it one of the most advanced societies in Central America. It has had an effective fertility limitation program that has brought down the population growth rate and improved human welfare. Guatemala lagged

considerably, under both external pressures and an internally repressive government. Costa Rica is also substantially wealthier than Guatemala, yet Guatemala consumes about a third more energy per capita than Costa Rica, and its growth rate of energy consumption is about four times that of Costa Rica. Here, then, is a case in which slower population growth and higher wealth and welfare are associated with lower levels of energy consumption.

Although these are only illustrations, they show clearly how the relationship between population growth and energy consumption can be highly complex and highly varied. The near future holds promise of some striking changes in both population and energy. Population growth rates have been declining worldwide since 1965 and are expected to continue that decline. Current United Nations projections foresee a world of some 9.3 billion in 2050. The MDRs will continue to grow very slowly to 2025, when they are projected to reach 1.218 billion, after which they will decline slowly. The LDRs, on the other hand, are expected to continuing growing from their current 4.9 billion to 8.1 billion in 2050, when they are expected to be still growing at 0.57%. Because the biannual projections over the past few decades have consistently reduced the expected totals and growth rates, it is quite possible that the current estimates will turn out to be too high as well. The rising LDR population will surely increase the demand for more energy. It remains unclear what that energy will be. Certainly fossil fuels will continue to play a major part in consumption. But just as clearly, major changes can be expected. There is likely to be a gradual increase in energy efficiency, which will reduce the energy costs of economic development. There may also be a major revolution to renewable sources of energy, which will dramatically change the population–energy connection. It is expected, however that that connection will continue to be indirect, complex, and many faceted.

Glossary

economic potential The energy savings achieved if all new investment and retrofit were based on the most energy-efficient technologies that were cost-effective at that time.

energy intensity The amount of energy required to produce a unit of economic output.

market potential The energy saving that is expected to be realized given the existing energy prices, consumer preferences, and energy policies.

suppressed demand When the demand for energy services is low due to income, access, and infrastructure constraints, not because of consumer preferences.

technical potential The achievable energy savings that result from introducing the most energy-efficient commercial or near-commercial technology at a given time, without taking into account the costs or the life of the equipment to be replaced.

welfare potential The economic potential for energy savings when external costs and economic opportunity costs are included.

This article presents the potential for improvements in energy efficiency in developing countries. It begins by discussing the relevant development context as well as additional barriers that energy-efficiency programs face in poor countries. Then, regional overviews of the potential for energy efficiency within key sectors are presented.

1. INTRODUCTION: THE CONTEXT FOR ENERGY EFFICIENCY

1.1 The Development Context in the South: Poverty and Suppressed Demand for Energy Services

The context for end-use energy efficiency improvements in developing nations is their current energy poverty and the large share of the world's population that uses almost no commercial energy. Per capita consumption of primary energy in Africa, for example, is only 13% of the average in Organization for Economic Cooperation and Development (OECD) countries, whereas for all developing countries it is less than one-fourth (Fig. 1). The gap is even greater for electricity consumption (Fig. 2).

It is common in many poor countries for families not to be able to afford enough energy to heat their

 © 2004 Elsevier Inc. All rights reserved.

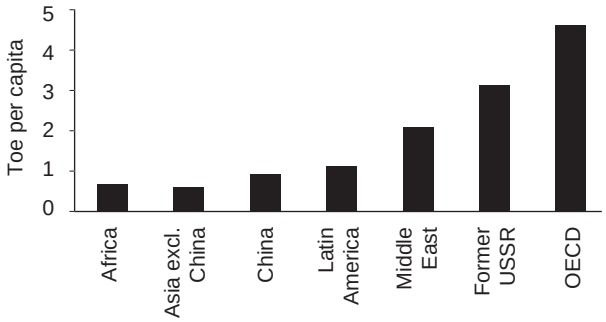

FIGURE 1 Total primary energy consumption per capita. Toe, tons of oil equivalent.

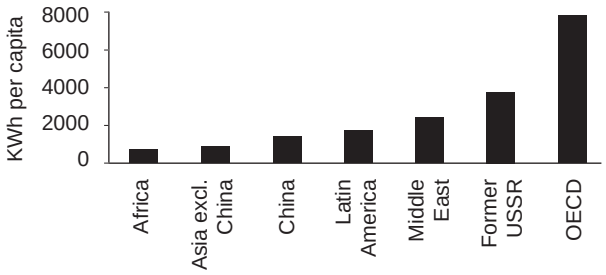

FIGURE 2 Electricity consumption per capita.

homes comfortably and cook sufficient food, let alone benefit from high-quality lighting or television. This energy poverty implies massive unmet (or suppressed) demand for energy services in these countries, with demand constrained by lack of energy infrastructure as well as income. In many African countries, for example, less than 10% of the population has access to electricity, and it is common for more than 80% of residential energy demand to be met by fuel wood.

Given these low levels of energy consumption, how do we know that there is a potential for improving end-use energy efficiency? First, it must be remembered that although developing countries' share of fossil fuel consumption is small, rapid population and economic growth will result in a substantial increase in this share in the early 21st century. From 14% of world primary energy demand in 1971, developing countries will account for 40% by 2010 if present trends continue. Even with aggressive policies to promote energy efficiency, their energy demand is likely to increase 5- to 10-fold during the next 30–40 years, resulting in a 3-fold increase in world energy demand.

Second, one measure of the potential for energy efficiency improvements in developing nations is their much higher energy intensity [energy use per unit of gross domestic product (GDP)] compared to

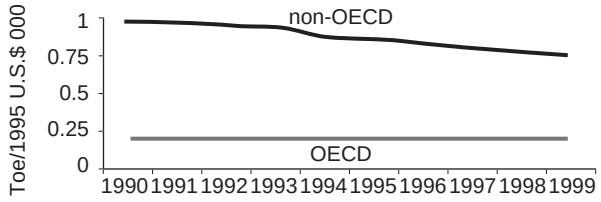

FIGURE 3 Energy intensity (energy use per unit GDP) in the developing and industrialized world.

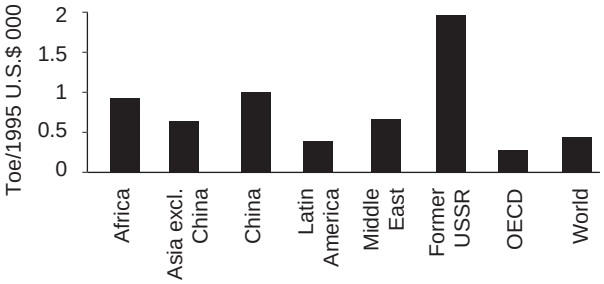

FIGURE 4 Energy intensity by region (energy use per unit GDP).

that of industrialized countries. As Fig. 3 shows, based on International Energy Agency data, energy use per dollar of GDP in the developing world is almost three times that of the OECD countries. If we consider the difference in purchasing power of developing currencies, this picture changes, with developing countries being only approximately 30% more energy intensive. For products that are traded, particularly those exported by developing countries, purchasing power parity does not really matter. In other words, if India is exporting steel and using two or three times as much energy to make a dollar's worth of steel, that is a very high cost and a competitive disadvantage. Of course, it also represents an opportunity to increase energy efficiency in a cost-effective manner. Even within the developing world, however, there are vast differences in energy intensity, as shown in Fig. 4.

1.2 Additional Barriers to Energy Efficiency in Developing Nations

Although barriers to the uptake of energy efficiency have been generally described elsewhere, they take a different form in many developing countries, and some are unique to developing countries. Before discussing different regions, however, it is useful to highlight some of the more significant barriers in developing countries.

1.2.1 Affordability and Financing

Investment in energy efficiency improvements is often constrained by the limited and irregular cash flow in poor households and difficulties in accessing additional finance; they frequently have to rely on hire purchase agreements or "loan sharks." Poor households sometimes invest in fuels and appliances that, ironically, are inefficient in both energy and economic terms. Poverty dictates overlooking long-term factors such as the life cycle costs, efficiency, and safety of an appliance.

For fuel purchases as well, households are often constrained by income flows, with a decision on purchase depending on the availability of money at a particular time. When there is little, kerosene and coal stoves are used because one can buy these in small amounts. Householders know that buying fuels this way is expensive, but not enough money is available to buy in bulk.

Even within industry, a shortage of capital or high interest rates are significant barriers to normal equipment upgrades, not to mention the purchase of more expensive energy-efficient equipment. This means that the rate of capital stock turnover is lower than for similar industries in industrialized countries.

1.2.2 Information

Information and awareness programs need to take into account the wide range of stakeholders involved in the delivery of energy efficiency services. For example, poor consumers may have low levels of literacy or need materials in local languages. Other stakeholders include local government, utilities, manufacturers, developers, builders, and nongovernmental organizations—all with different informational requirements. Often, awareness programs tend to provide broad conceptual information when the target audience requires more sophisticated information. Where people are already aware of broad notions of energy efficiency, for example, information may be needed on practical implementation, such as how to build an energy-efficient house or install a ceiling, where to access financing, how to mobilize capital to finance energy efficiency for the poor, and how to facilitate community participation.

1.2.3 Physical Access to or Availability of Fuels

In certain circumstances, low-income households are unable to secure the best mix of fuels because certain fuels are not readily available. For example, although kerosene networks are good in many countries, with both fuels and appliances being readily available, many poor household do not have electricity connections. Although a few developing countries have started to develop residential bottled gas networks, this is the exception rather than the rule. The coverage of distribution networks is often weak and inhibited by poor transport infrastructure and a lack of access to transport.

1.2.4 Split Incentives: Construction, Ownership, and Use

In the delivery of housing, those making the initial capital investment in constructing a house are generally separate from those who will live in it and pay the operating costs. It is not common, therefore, to find developers investing in energy efficiency. The consequence is that the low-efficiency house has high operating costs. This is a major problem in developing countries with large public housing programs because the government priority is to deliver as many houses as quickly as possible; for both government and contractors, the tendency is to cut corners and minimize initial cost. It is also a problem in industrialized countries.

1.2.5 Lack of Tenure and Urban/Rural Commitment

In many urban informal settlements, appliance ownership is constrained by space and tenure problems. Lack of space, for example, means that in informal electrified settlements and backyard shacks, more households own two-plate electric stoves than stoves with ovens. More important, the tenure problems in informal unplanned settlements and shacks play a direct role in purchasing electrical appliances or other expensive investments in efficiency. Migrant workers continue to play a large role in many countries' urban communities. They are committed to their rural households and view urban life as temporary and thus tend to save or remit money for the maintenance of the rural households, which obviously implies an even lesser willingness or ability to pay a higher cost for efficient appliances.

1.2.6 Multiple Fuel Use and Household Needs

Multiple fuel use means that households use more than one fuel for the same end use. It is common to use gas, kerosene, coal, and/or electric stoves for cooking. Gas might be used for specific tasks (such as cooking special quick foods) and kerosene appliances used for foods that take a longer time to cook. Therefore, although gas may be a more energy-efficient cooking fuel than kerosene or electricity (and healthier than kerosene), households may not completely stop using kerosene after they buy a gas

stove. For example, they may use kerosene for cooking certain foods or if they run out of gas and do not have enough cash to buy an entire gas canister since kerosene can be purchased in small quantities. Also, in some contexts one appliance serves more than one purpose, as in the case in which a kerosene or coal stove is used for cooking and space heating.

1.2.7 The Symbolic Value of Appliances

Not surprisingly, poor consumers do not simply consider the economics of appliance choices when making decisions: Symbolic value can be as important as functional value. For example, many formal households tend to replace their nonelectrical appliances with modern and sophisticated appliances immediately after electrification, not simply because electricity is cleaner and a more convenient fuel. There is a general perception that nonelectrical appliances are not appropriate for formal households. Having electric appliances attracts respect and envy, as symbols of modernity and comfort, and many people will go far to acquire them: The bigger the appliance, the better. Therefore, consumers may not be attracted to smaller, more efficient appliances unless other features enhanced the sense of "modernity."

1.2.8 Technical and Managerial Skills

Compared to industrialized countries, the industrial and commercial sectors in developing countries have lower levels of skill in both the technoeconomic dimension of energy efficiency and the managerial skill to develop and administer programs. There may be many qualified analysts and professionals, but resources are spread too thinly across huge economies and social needs. This is particularly a problem for small to medium firms.

2. TYPES OF POTENTIAL FOR INCREASED END-USE ENERGY EFFICIENCY

As a background to describing the potential for increasing end-use energy efficiency, it is important to understand the different types of energy efficiency potential. The most important categories are technical, ecnomic, and market (Fig. 5):

- Technical potential is the achievable energy savings that result from introducing the most energy-efficient commercial or near-commercial technology at a given time, without taking into account the costs or the life of the equipment to be replaced. Realizing the full technical potential means scrapping existing appliances and equipment, although sometimes a phased technical potential is described, meaning that all new equipment is replaced with the most energy-efficient technology.

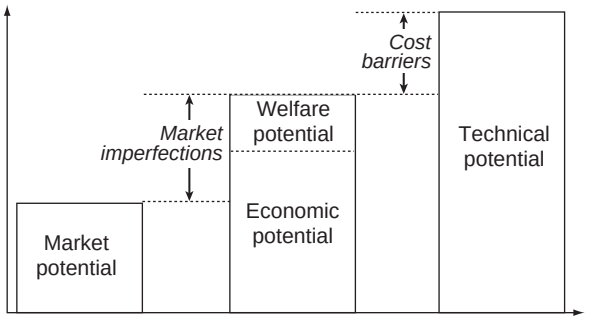

FIGURE 5 Types of potentials for energy savings.

- Economic potential is the energy savings achieved if all new investment and retrofit were based on the most energy-efficient technologies that were cost-effective at that time. Cost-effectiveness at a minimum must include the energy and operating savings on the benefits side and the additional capital, any additional maintenance or control costs, and future replacement costs on the cost side. There are several perspectives on cost-effectiveness. For an individual firm or household, we would only consider the costs and benefits mentioned previously. In a macroeconomic perspective, however, we would need to consider the costs of implementing the energy efficiency programs. We would also include the benefits that could accrue to the broader economy, such as changes in technology costs over time through learning and economies of scale, or other spillover effects and nonenergy productivity gains. Finally, if we consider the societal perspective, we should include the avoided external costs of the energy saved by end-use efficiency measures. This would increase the economic potential since the benefits (avoided costs) increase. This is called the welfare potential of energy savings.
- Market potential is the energy saving that we expect to realize given the existing energy prices, technology, consumer preferences, and energy policies. This definition must take into account the social obstacles to energy efficiency and other market imperfections (i.e., no internalizing external costs) that block the realization of the full economic potential. In addition, market potential may consider whether energy users choose to use their energy

savings to buy more of what is essentially a less expensive service. This is called the take back or rebound effect.

These definitions also help us understand that the role of energy policy in promoting end-use energy efficiency is to both remove the market barriers that keep market potential below economic potential and address cost issues(e.g., through targeted research and development) that can bring the economic potential closer to the phase-in technical potential. Later, when we discuss the potential for energy-efficient improvements, we refer to economic potential unless otherwise noted.

3. ECONOMIC POTENTIAL FOR ENERGY EFFICIENCY BY MAJOR DEVELOPING REGIONS

3.1 India

3.1.1 Trends in Energy Intensity and Consumption per Capita

India, the world's second most populous nation, has seen its population explode from 300 million in 1947 to approximately 1 billion today. Energy consumption has grown rapidly through the process of development. Aggregate consumption has increased approximately 50% during the past decade. The share of commercial energy consumption increased from 26% in 1950–1951 to approximately 60% in 1994–1995. With an elasticity of commercial energy demand (i.e., the percentage change in energy demand for a 1% change in income) of approximately 0.92, and with the objective of rapid economic growth of 6% per annum, a high growth in commercial energy demand is expected. India is the second largest commercial energy consumer within non-OECD East Asia (after China), comprising 19% of the region's total primary energy consumption.

The current low per capita energy consumption (3% of that of the United States and 9% of that of Korea) is an indicator of huge potential for growth in energy demand. Despite an annual approximate 5% growth rate in electricity generation, unmet demand for electricity continues. Although 75% of India's population lives in rural areas, only 29% of rural households have electricity supply and there is no power supply network in many rural areas. In addition to geographical constraints, sparse distribution of dwellings, low ability to pay, and low load make extending the distribution network either impossible or uneconomic for many remote villages. Noncommercial energy still meets 40% of the total energy consumption, which shows the extent of demand that awaits to be met by commercial and more efficient forms of energy.

Energy demand in India has always been greater than supply. Thus, in view of shortages and restrictions, the past trends in consumption of commercial energy do not really represent the growth of energy demand but reflect the growth of its availability. Energy consumption by fuel is dominated by coal (54%) and oil (31%). There is wide scope for enhancing end-use energy efficiency. In addition to replacing outdated technologies and removing market barriers such as pricing distortions, overall economic potential would increase by simply changing the scale of production of many production activities. Such potential exists in all of the energy-using sectors.

Sectoral demand for energy arises mainly from lighting and cooking demand in the residential sector, irrigation and other operations in the agricultural sector, transport of passengers and freight in the transport sector, and fuel requirements in the industrial sector. Fig. 6 shows the use of energy by sector, whereas Fig. 7 shows the trends in energy intensities of these sectors. Decomposition analysis of the energy intensity trends shows that in India increasing economic activity is the main driving force for rising energy consumption, not increasing energy

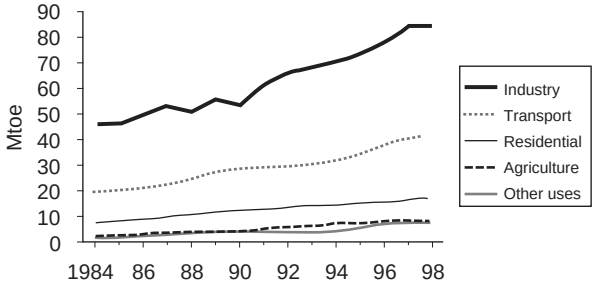

FIGURE 6 Trends in consumption of commercial energy in India, 1984–1998.

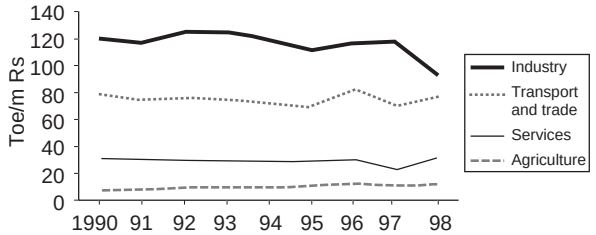

FIGURE 7 Sectoral energy intensities in India (energy/real GDP).

intensity. Since it is difficult to restrict energy demand due to increased output or activity directly at the early stage of development, improved energy efficiency is essential.

A number of efforts to improve energy efficiency, especially through exploration of technical potential, have resulted in a declining trend in energy intensity. The Eighth Plan (1992–1997) included a National Energy Efficiency Program that has the potential to save 5,000 MW in the electricity sector and 6 million tons of oil in the petroleum sector over the 5 years. India established an energy efficiency center as a major agency to implement programs and an energy conservation fund to finance them. On the other hand, electricity prices are far below marginal costs throughout most of the country, as are prices for natural gas and coal. This is a substantial barrier to energy efficiency investments and essentially subsidizes energy sources with environmental and health costs from pollution. One of the major challenges in a country with such high unmet demand is how to correct prices and provide incentives for investment in energy efficiency while protecting the social needs of the poor. A subsidy program for efficient vehicles or appliances without a move toward cost-reflective prices, for example, could substantially increase overall energy demand, as consumers buy more of a much needed service, and not reduce environmental impacts from the sector.

3.1.2 Industrial Sector Potential

In general, Indian industry is highly energy-intensive and its energy efficiency is far below that of industrialized countries. For example, in nitrogenous fertilizer manufacturing, older manufacturing units generally require 8.4–10.5 tons of oil equivalent (toe) per ton of ammonia produced, whereas the standard achieved in a plant in Bristol, England, is only 4.6 toe. An improvement in energy efficiency also includes energy conservation undertaken by a producer or a consumer that reduces losses of energy. In the electricity sector, it has been estimated that older power plants in many developing countries consume 18–44% more fuel per kilowatt hour of electricity produced than plants in industrial countries. Since India has vast reserves of coal, this is the primary fuel in the industrial sector. India has always relied heavily on coal for generating electricity with a low average conversion efficiency of 23%. There is potential for at least a 10% improvement in the conversion efficiency of existing plants. Greater energy efficiency can be implemented through technological enhancements, more research and development, improved energy management, and better operational practices.

A World Bank-sponsored study (1995) of energy demand in five major Asian countries (China, India, Indonesia, Korea, and Thailand) concluded that the industrial sector has the largest potential for energy conservation. This sector accounts for the largest share of final energy consumption in India and is dominated by energy-intensive industries. Higher energy intensities are ascribed to (i) slow capital stock turnover and utilization of out-of-date processes, (ii) poor energy management, and (iii) lack of incentives for firms to invest in energy efficiency due to low energy prices. In addition, scale is a major issue in many industries. In nearly all states in India for the cement and paper sector, and in a few states for aluminum, increasing the scale of production could reduce inefficiency in energy use.

We can also consider a recycling strategy in which secondary materials are fed into the original process, thereby lowering per unit energy consumption. Examples include the substitution of waste paper for paper pulp and using recycled glass and plastics. To improve overall industrial energy efficiency and reduce pollution, there is greater potential from adopting available clean technologies at the beginning of industrial operation rather than "end-of-pipe" solutions, which can actually increase overall energy use.

Technical energy efficiency improvement potential is shown by comparing specific energy consumption (i.e., energy consumption per unit of output) in industrial subsectors. For example, the energy efficiency of ammonia plants can be increased by revamping and modernization. A typical energy efficiency revamp of a plant would reduce the energy consumption for individual plants installed before 1980 by 0.8–2.2 Mtoe and for plants installed between 1980 and 1990 by approximately 0.6–0.7 Mtoe, depending on the feedstock used. The age of the technology, the scale of the plant, and management practices have a major impact on energy efficiency of the overall process. Energy savings potentials are highest for naphtha and fuel oil/low-sulfur heavy stock-based plants built before 1980. With current installed capacity of 5.09 Mt production, energy savings in pre-1980 ammonia plants alone would account for 6.02 Mtoe per year.

In the iron and steel sector, there is a large potential for efficiency improvement. Worldwide, specific primary energy consumption is decreasing with rising scrap-based electric arc furnace production. In India, however, due to a scarcity of scrap metal, this may not be a good option. Still, efficiency

improvement may be achieved indirectly by improving power-generation efficiency that feeds iron and steel plants through modernization and captive combined heat and power generation. In addition, technology conversion (e.g., to induction furnaces) and retrofitting, recycling, and waste heat recovery promise major savings. Although most measures are cost-effective and provide net benefits within a short time, only a few have been or are currently being implemented in the iron and steel sector. Lack of dissemination of information on energy-efficient technology as well as specific information on saving and benefits of saving potential contribute to the low uptake of energy efficiency improvements.

For the cement industry, there is not much scope for improvement in dry processes, but there is more in semidry and wet processes. Besides the technical potential when compared to world best-practice technology, efficiency improvements can be achieved through increased use of additives such as fly-ash and blast furnace slag in manufacturing cement. Structural change toward more production of portland slag cement reduces energy consumption, and using a higher share of blast furnace slag compared to clinker leads to lower energy intensity as well. In India, 20% of final energy could be saved by this twofold structural change, which would decrease the clinker-to-cement ratio by 20%. It has also been estimated that better maintenance and monitoring of plant activity can minimize downtime of machinery and plant, thus avoiding excess energy needed for restarting the process.

In the aluminum sector, the potential for energy efficiency improvement varies across companies. For example, whereas the National Aluminum Corporation could achieve 17%, the Hindusthan Aluminum Corporation could achieve 40%. Energy savings potential in smelting range from approximately 16 to 30%. Better monitoring and control can conserve an additional 2 or 3%. Potential from retrofitting ranges from 10 to 15%, and the costs of this retrofitting and modernization are 25–35% lower than the cost of building an entirely new plant. Table I summarizes the industrial sector potentials for energy efficiency improvements by comparing Indian specific energy consumption to worldwide best practice. Worldwide best practice reflects the best available technology adjusted for India-specific structural factors. For paper, best practice reflects the average energy consumption abroad.

Research on the responsiveness of the Indian industry to changes in energy prices indicates that price-based policies could be effective in improving energy efficiency. Pricing policy in the fertilizer sector, for example, has shown that energy price increases would push less productive and inefficient plants (mostly smaller ones) out of the market or force them to immediately improve productivity and efficiency. It has been estimated that with all other economic variables constant, India industry could achieve worldwide best practice in specific energy consumption by 2005 or 2010 with an average annual nominal energy price increase of approximately 6 or 4%, respectively, measured as an increase in the fuel price index relative to other input prices.

3.1.3 Residential and Commercial Sector Potential

In the residential and commercial sector, the demand for energy is mainly for lighting, cooking, space cooling, and, to some extent in higher altitudes, space heating. The residential sector in India accounts for 40–50% of the total energy consumption. For cooking, 77% of households in India use traditional fuels such as firewood, animal dung, and agricultural residues, 0.3% use electricity, 4% use coal or charcoal, 8% use liquefied petroleum gas (LPG), 7% use kerosene, and 0.5% use biogas. Experience

TABLE I

Specific Energy Consumption in Indian Industry and Worldwide Best Practice, 1993

		India			India
Sector	Units	Average energy consumption	Best practice (marginal plant)	Worldwide best practice	Savings potential (%)
Aluminum	GJ/ton aluminum	86–100	87	65.2–81.9	5–35
Cement	GJ/ton cement	4.00	~2.93	3.06	24
Fertilizer	GJ/ton ammonia	39.2	36.4	28	29
Iron and steel	GJ/ton crude steel	35.4	31.4	17.1	52
Pulp and paper	GJ/ton paper	51.6–80.0	NA	32.0–40.9	~43

tells us that in the ladder of fuel-use transition, households usually move from traditional fuels to kerosene/coal (depending on availability), LPG, and electricity; the use of traditional fuel is indeed an indicator of unmet demand for more efficient fuels.

In India, urban and rural energy problems differ. In urban areas, introducing energy-efficient lamps, better space-cooling devices, and solar passive building structures can enhance efficiency in electricity and fuel use enormously. In the absence of any major demand-side management through policies or appliance standards, however, there is hardly any incentive for the households or commercial sector to enhance efficiency in use. Adopting energy-efficient appliances could provide up to 50% savings in electricity consumption in these end uses. This is particularly important in India, where demand for electricity is expected to grow by 7% per year and the gap between peak demand and peak supply today is more than 11,000 MW.

In rural areas, where almost 75% of the Indian population lives, biomass (primarily firewood) accounts for more than 90% of energy needs. It may not be possible to replace this entirely with more modern energy forms and developing modern biomass technologies will be a key element for addressing the needs of rural areas. One of the important constraints in the wider utilization of renewable energy is the high initial capital cost. India has potential for renewable energy generation, particularly wind and hydropower, and programs in these areas, aided by Global Environment Facility (GEF) funding, are under way. At the same time, India presents a unique opportunity for the large-scale commercial exploitation of biomass gasification technology to meet the needs of the agricultural and rural residential and small-industries sector. The gasifier power could solve the problems of technical and economic inefficiencies to a large extent, thereby reducing the social cost of power supply. Currently, commercial activity in most rural areas depends on power supply from the privately owned, decentralized, diesel power-generating sets, whereas residential lighting is typically met with stand-alone kerosene lamps. Use of kerosene for lighting is particularly inefficient, with only 1% of the energy in the kerosene producing useful light. The Ministry of Non-Conventional Energy Sources aims to replace low-efficiency kerosene lamps in rural areas with efficient renewable lighting technologies.

3.1.4 Transport Sector Potential

Transport shows a constantly rising trend in fuel demand. Decomposition analysis shows that it is the rising demand for overall transportation service that is driving up fuel demand. With relatively low substitution possibilities and high income elasticity for privately owned vehicles, it is expected that fuel demand in the transport sector will increase along with vehicle ownership for years to come. In recent years, fuel switching has been attempted by introducing compressed natural gas in public transport in metropolitan cities. Fossil fuel-based transportation may also be reduced through development of the rail network. Pricing reform is playing an important role in reducing inefficient use of energy. In terms of technical interventions, studies have shown that inefficient use of fossil fuels often results from poor design of public buses, which are not using best-practice technologies. Efficiency in transportation fuel can also be increased remarkably by improving the urban road conditions and reducing traffic congestion.

3.1.5 Agricultural Sector Potential

In the agriculture sector, power use for irrigation holds significant potential for improving energy efficiency. Currently, diesel generator-based water pumps with efficiencies of less than 33% are used to draw underground water; an adequate electricity supply would allow a shift to more efficient electric pumps. Where electricity is now available for agriculture, it is heavily subsidized and charges are not linked to consumption, leading to inefficient use. Correction of prices would lead to increased efficiency through better water and irrigation management. Just an important, more efficient use of water for irrigation would decrease agricultural energy demand for the same agricultural output.

Table II summarizes the potential for energy efficiency improvements in India based on a wide range of studies.

3.2 China and Southeast Asia

3.2.1 Trends in Energy Intensity and Consumption per Capita

China has demonstrated significant improvements in energy efficiency since the 1980s. Energy use per unit GDP declined from 2.18 toe per thousand U.S. dollars in 1980 to only 0.73 in 2000, as shown in Fig. 8. During this period, commercial energy consumption increased 2.3 times, whereas the GDP increased more than six times. However, commercial energy intensity in China is double that of OECD countries and triple if noncommercial energy is included (Fig. 4). Many factors affect energy intensity, including economic

TABLE II

Summary of Energy Efficiency Potentials for India

Sector	Technological options/area	Economic potential (% of current use)
Industry	Fertilizer	29
	Cement	20–24
	Electrical	17
	Thermal	27
	Pulp and paper	20–40
	Textiles	23
	Iron and steel	15–50
	Aluminum	5–35
	Refineries	8–10
	Brick-making	15–40
	Foundries	30–50
	Industrial cogeneration	3500 MW (sugar)
Residential	Lighting	10–70
	Refrigerator	25
	Air-conditioning	10
Agriculture	Pump sets	25–55
Transport	Two- and three-wheelers	25
	Cars	7.5–10
	Trains (diesel)	5–10
	Trains (electric)	5–10

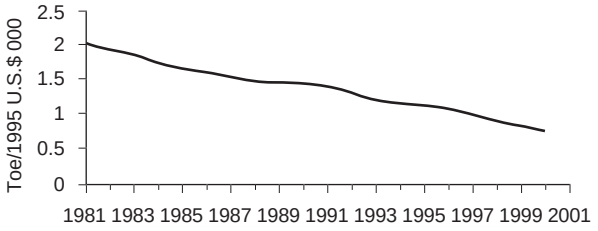

FIGURE 8 Energy intensity (energy/GDP) trends in China, 1981–1999.

structure, product mix, exchange rates, energy resource mix, and technical efficiency. In general, industrial sectors, especially heavy industry such as the iron and steel industry and cement industry, consume more energy per unit of economic output than do light manufacturing, finance, and service sectors. In China, for example, the relative energy consumption per unit of value added in primary (e.g., resource extraction and beneficiation), secondary (e.g., manufacturing and construction), and tertiary (e.g., finance and services) sectors was 12, 68, and 20, respectively, in 1999.

Changes in economic structure have contributed significantly to China's energy intensity improvement. Fig. 9 shows that economic structure has

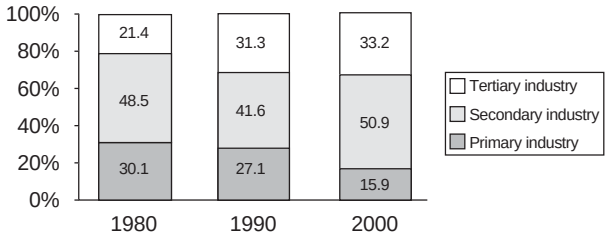

FIGURE 9 Composition of GDP in China, 1980–2000.

changed in China, with a decline in primary industry replaced by rapid growth in the tertiary sector. This trend is expected to continue, and the share of tertiary activities in the total economy will increase. Even within the secondary sector, subsectors with higher value-added and lower energy intensity, such as computer manufacturing and telecommunications equipment production, are developing faster than the traditional heavier manufacturing industries.

China is one of the few countries where coal is the dominant resource for energy use, which is part of reason for China's high energy intensity. For example, even using the latest technology, the highest energy efficiency for combined heat and power generation based on coal as a resource is 60%. Natural gas, on the other hand, can obtain conversion efficiencies of more than 80%. China is currently promoting clean energy production and importing cleaner technologies, which will result in energy efficiency improvements. In Southeast Asian countries, energy intensity is much lower than that of China. Because of the financial crises in the mid-1990s, however, the primary energy consumption per GDP increased, as shown in Fig. 10.

To provide a regulatory framework for energy efficiency interventions, many Southeast Asian countries and China have enacted a range of energy efficiency laws, with differences based on culture, political ideology, and existing institutional structures. Although the scope varies, common provisions include mandatory auditing for industries, mandatory energy building codes, developing performance standards for energy-using equipment, information dissemination, and capacity building. In most cases, implementing the legislation is carried out by existing energy agencies involved in energy efficiency promotion. In Thailand, an energy conservation fund to finance activities and programs for energy efficiency promotion has been set up, whereas for other countries the law specifies budget allocations for energy efficiency programs. For countries without specific legislation, energy efficiency activities are limited to programs that do not require specific

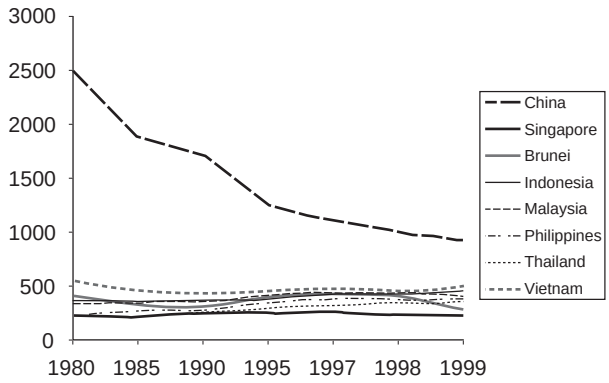

FIGURE 10 Primary energy consumption per unit of GDP.

regulation, such as publicity campaigns, demonstration projects, and programs that can be funded by external grants and loans, government budgets, or payments by consumers and end users. Some energy efficiency programs, such as mandatory appliance standards, appliance labeling, and building energy codes in the Philippines, Malaysia, and Singapore, are implemented through regulation but without reference to any specific law. A wide variety of policy instruments are used in promoting energy efficiency and accelerating the diffusion of energy-efficient technologies. These include appliances standards and building energy codes, appliance labeling, and financial incentives.

Since opening up to the outside world, the Chinese government has paid significant attention to energy conservation projects, including energy policy objectives to "carry out conservation and development of resources simultaneously but giving priority to conservation." To address energy shortages, environmental protection, and sustainable development, the Energy Conservation Law was passed in 1997, providing broad guidance for energy efficiency improvement in all sectors. Since then, governments at national, provincial, and local levels and industrial associations have issued a number of energy efficiency policies and adopted measures for the law's implementation.

3.2.2 Industrial Sector Potential

China's industrial sector is extremely energy intensive and accounted for 76% of the country's total energy used in 1997. It is estimated that the overall final energy use efficiency in the industrial sector was 46% in China, 20% lower than that of OECD countries. The largest energy-consuming industries are chemicals, ferrous metals, and building materials. The energy use per unit of product output provides a better comparison than energy use per unit of production value added. Because of outdated production technologies and processes, slow capital stock turnover, small-scale operation, and poor management and training of staff, most industrial enterprises in China consume more energy to produce a unit of product than applies in developed countries. Even within China, the product energy intensities are quite different in various enterprises. Table III compares energy intensity for selected products between developed countries and China.

There are several technologies available for energy efficiency improvement in industrial sectors. For example, in the cement industry, wet to dry process conversion, on-site cogeneration of heat and power, and coal ash utilization can significantly decrease energy consumption. Based on the available research, it is reasonable that energy efficiency in industry could be increased by 15–20% in China, with a similar situation in Southeast Asia (Table IV).

3.2.3 Residential and Commercial Sector Potential

In 1999, the Chinese residential sector consumed 78 Mtoe commercial energy, accounting for 14% of total final consumption of commercial energy. Including biomass, total residential final consumption was 289 Mtoe. The commercial sector accounts for a further 3% of commercial final consumption. Most residential energy consumption is for space heating, followed by cooking and lighting. Electricity consumption for appliances is increasing rapidly, and the use of air-conditioning is especially important for commercial buildings and it is being used increasingly in households as well.

The rate of construction of new buildings is high due to increases in population, rising standards of living and demands for more living space per person, and the continuing process of urbanization as people migrate toward areas with greater economic development. The majority of the new buildings, however, have poor energy performance. This is not unlike what happened in Europe in the years of reconstruction after World War II. The urgency of supplying new housing and commercial space, pressure to hold down initial investment costs, and low energy prices mean that little attention is paid energy performance. Designs are not adapted to local climatic conditions and ignore the potential for day lighting in commercial buildings.

As a result, energy costs are much higher than expected on economic grounds, even without considering the positive environmental and health impacts of better building design. In the northern part

TABLE III

Energy Intensity in China and Industrialized Countries for Selected Products

Product	Specific energy use	Country	Year
Steel (GJ/ton steel)	60	China (average)	1980
	41		1996
	32		1999
	21	China (best)	2001
	25	United States	Mid-1990s
	18	Japan	
	21	Sweden	
Cement (GJ/ton cement)	6	China (large and medium-sized)	1980
	5		1996

	24	OECD countries	
Cotton yarn (kWh/ton)	2300	China	
	2100	OECD countries	

of China, energy consumption for space heating during winter is approximately twice as high as in areas with similar climatic conditions in industrialized countries. As the new building energy code is implemented, new buildings are expected to have a 20% energy use savings compared to existing buildings.

3.2.4 Transport Sector Potential

In recent years, the number of automobiles has increased dramatically in China, especially private cars, but also those for freight and passenger transport. Compared to rail, road transport uses much more energy but is generally faster and more convenient. Energy intensity for overall transport sector increased from 19 kg oil equivalent per ton-kilometer (kgoe/t-km) to 23 kgoe/t-km between 1990 and 1997.

Railway transport in China has been undergoing a transition from steam to diesel and electric locomotives, which has greatly improved energy efficiency because diesel and electric locomotives are 30 and 25% thermally efficient, respectively, compared to 8% for steam locomotives. This shift decreases the energy needed to move passengers and freight by approximately three-fourths. Nonetheless, China's energy consumption per ton-kilometer of freight is still 60% higher than that in the United States and 30% higher than in Germany.

Improved energy efficiency in road transport will derive from using more new automobiles and improving the transportation management system. These trends are already starting to emerge in China in fright transport, with the energy use per ton-kilometer decreasing 15–20% since 1980. For passenger transport, however, energy intensity (measured as energy per passenger-kilometer) has actually increased during the past two decades as a result of lower load factors for public buses.

3.2.5 Agricultural Sector Potential

As China continues to modernize the agriculture sector, mechanization will result in increased energy use. Nevertheless, significant potential for increasing energy efficiency can be achieved with more efficient water-pumping and agricultural equipment. The Chinese government is generally emphasizing rural energy development as supplying more clean and convenient energy to farmers but not the efficient use of that energy.

3.3 Africa

The major challenge for energy development in Africa is how to increase most Africans' access to modern energy services while taking into consideration the economic costs and environmental impacts of these energy sources. Africa has vast energy resources but extremely limited energy and industrial development and the lowest rates of access to electricity in the world.

3.3.1 Trends in Energy Intensity and Consumption per Capita

As mentioned previously, energy consumption in Africa is among the world's lowest, although energy

TABLE IV

Summary of Energy Efficiency Potentials for China and Southeast Asia

Sector	Technological options/area	Southeast Asia 2020 (%)	China 2010 (%)
Industry	Fertilizer	20	10–20
	Iron and steel		15–25
	Nonferrous metals		3–16

Agriculture	Pump sets		20–50
	Motors		10–30

intensity is relative high. Despite the low base, primary energy consumption per capita has increased by less than 1% per year during the past two decades (Fig. 11). At the same time, energy intensity has actually increased, so African countries need more energy to produce $1 of GDP (Fig. 12). This is true even considering the purchasing power parity difference between Africa and the rest of the world. Data for the continent, however, obviously hide vast differences between countries (Fig. 13).

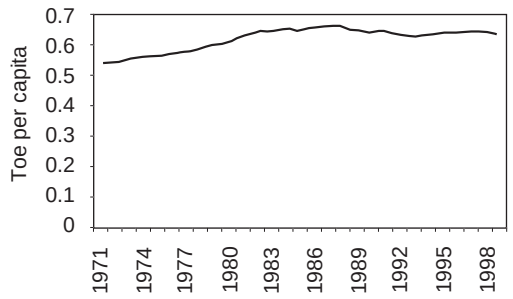

FIGURE 11 Energy consumption per capita in Africa.

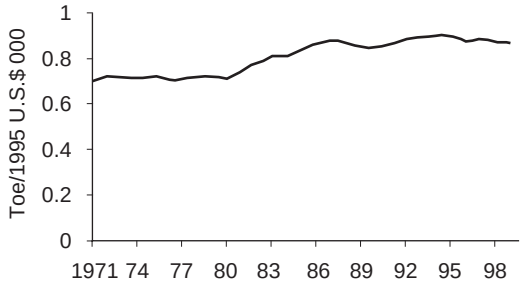

FIGURE 12 Energy intensity trends in Africa (energy use per unit GDP).

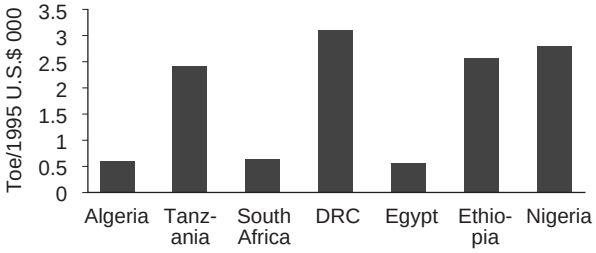

FIGURE 13 Energy intensity in African countries (energy use per unit GDP).

Although a number of African countries have included energy efficiency as part of their national energy policies, few have taken concrete steps toward legislation or specific programs and measures to promote it. Only Tunisia and Ghana have implemented mandatory appliance standards, whereas South Africa is implementing a mandatory commercial building code and has a voluntary residential building energy guideline. Ghana has created an independent body with multistakeholder support called the Energy Foundation, which has been highly successful in implementing energy efficiency programs in a range of sectors. Egypt is also considering a similar path and has set up an energy efficiency council to help develop a national energy efficiency strategy.

3.3.2 Industrial Sector Potential

Many African countries have relatively small industrial sectors, with the exception of large resource extraction industries such as mining and oil production. Even those countries, such as South Africa and some in the north, that have larger industrial sectors tend to rely on heavy, energy-intensive industrial subsectors and processes. Moreover, several southern African countries' dependence on coal, which tends to have a lower conversion efficiency in industrial boilers and power stations, also implies significant opportunities for cost-effective energy savings. An example of this is shown in Fig. 14, which compares the specific energy intensity (i.e., energy use per unit of sectoral output) of Zimbabwe to benchmark international energy intensity levels in industrialized countries.

Key industrial end uses for which industrial energy efficiency can be improved include electric motors, compressed air, lighting, process heating (boilers), and efficiency heating, ventilation, and air-conditioning (HVAC) systems. A wide range of studies suggest that the economic potential for energy efficiency in the industrial sector is 20–30%. In other words, achieving these savings is possible without increasing the cost of production, given current energy prices and technology availability.

Another useful set of examples derives from analysis of major industries in South Africa, in which better compressed air management, lighting, boilers, and changing to variable-speed drives can save 20% of the energy use for those end uses at paybacks of less than 5 years.

An important area that is not covered in the summary table for Africa is the possibility of fuel switching, particularly from coal or oil to natural gas for industrial boilers. As Table V shows, gas boilers are considerably more energy efficient. Although electrical process heat is efficient at the point of use, the large losses in power stations mean that the overall system efficiency is closer to 25%.

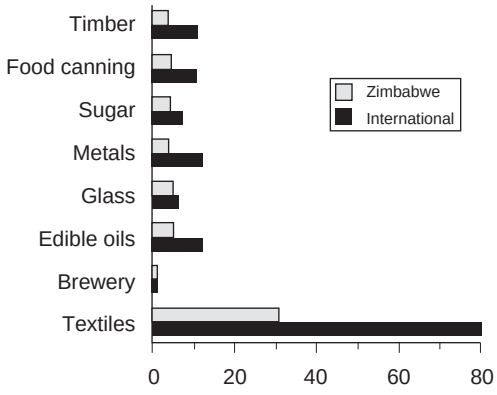

FIGURE 14 Examples of relative energy use efficiencies in industry (GJ/ton).

3.3.3 Residential and Commercial Sector Potential (Buildings and Appliances)

The majority of households in Africa rely primarily on biomass for energy services, particularly cooking. Given that traditional use of wood and charcoal for cooking is only 15–20% efficient, whereas kerosene, LPG, and electric stoves are approximately 40, 55, and 65% efficient, respectively, an important intervention is to move households to commercial fuels for cooking. In addition, improved biomass stoves can increase efficiencies to 25–30%. The problem with assessing the economics of these options is that traditional fuel wood is generally collected and thus outside the commercial energy market. Even purchasing an improved biomass stove costs money, and purchasing fuels for stoves adds even more to household energy costs. Nevertheless, kerosene is preferred over fuel wood in most areas where it is available, and a number of successful programs to increase the use of LPG and electricity for cooking have been implemented, such as in Senegal, Botswana, and South Africa.

Where electric appliances are used in the home or for commercial applications, the potential for savings is significant. Switching to compact fluorescent lighting, for example, can save two-thirds of the lighting energy use, and proper passive solar design of houses along with ceilings and insulation (especially in low-cost housing) can save 60–70% of space-heating energy from a variety of sources. Commercial energy intensity, as with industrial energy use, tends to be high, with many opportunities for improving the efficiency of HVAC systems, lighting, and office

TABLE V

Energy Efficiency of Boilers by Fuel

Fuel technology	Overall efficiency including steam system losses (%)
Electrical process heating	75
Coal-fired boilers	60
Oil-fired boilers	65
Wood-fired boilers	60
Gas-fired boilers	70

equipment. Many housekeeping measures can save energy with almost no capital cost.

3.3.4 Transport Sector Potential

As with industry, South Africa and most north African countries have much higher levels of motorization than other countries in Africa. Road transport is the main mode in Africa. Most vehicles are imported and generally old and poorly maintained, which decreases their efficiency, as does their operation in congested urban areas and on poor-quality road networks. Improving the quality of the road network, maintaining vehicles properly, and shifting road transport to rail could all significantly improve the energy efficiency of transport. Providing affordable, safe public transport systems would also shift passenger travel away from road traffic and increase energy efficiency as well as reduce traffic congestion. The estimates in Table VI are based on a combination of shifting to public transport and improved road and rail transport efficiency.

TABLE VI

Summary of Energy Efficiency Potentials for Africa

Sector	Technological options/area	Economic potential (% of current use)
Industry	Total industry	15–35
	Industry, compressed air	>20
	Industry, variable-speed drives	>20
	Industry, efficient motors	>1–5
	Industry, efficient HVAC	>10
	Industry, efficient boilers	15–20
	Iron and steel	7
	Cement	10–15
	Aluminum (secondary)	45
	Refineries	6
	Inorganic chemicals	19
	Consumer goods	25
	Food	16–30
	Cogeneration	20–25
Residential	Total energy	5–20[a]
	Electric appliances	11–25
	Lighting, compact fluorescent lights	50–70
	Refrigerators	30
	Space heating	60–70
Commercial/ public	Commercial air-conditioning (heat and cool)	50
	Commercial lighting	10
	Computers	10
		20–25
Transport	Cars, road system	30
	Total transport	30
	Road transport	30

[a] Market potential.

3.4 Latin America

During the last decade of the 20th century, the energy sector in Latin America underwent profound changes. In many countries, formerly state-owned monopolies were privatized, electricity and gas sectors restructured, and energy markets liberalized. Foreign direct investment in the energy sector in Latin America has been higher than in any other region in the world. Interconnections between countries are increasing and the market penetration of natural gas is changing the energy mix in many countries. Although energy prices are declining due to competition and alternative sources of commercial energy, many of the notorious problems of energy supply in the region have remained as serious and urgent as they were before the reform process started. Among these problems are (i) disparities of energy supply in more developed urban and less developed rural areas, (ii) insufficient access to clean and convenient energy services by the urban and rural poor, (iii) poor quality of service and protection of consumers, and (iv) only marginal attention to energy efficiency and decentralized renewable energies in official mainstream energy policies. The efficient use of energy in the whole supply chain, from energy extraction and transformation to the end user, could be drastically improved to allow for the expansion of energy services while safeguarding sustainable economic and social development.

3.4.1 Trends in Energy Intensity and Consumption per Capita

Energy intensity in Latin America is substantially higher than in industrialized countries but lower than that of many developing regions (Fig. 4). At the same time, energy consumption per capita is only one-fourth that of industrialized countries (Fig. 1). As shown in Figs. 15 and 16, the energy intensity of Latin American economies has remained quite constant during the past 30 years, whereas the total primary energy supply per capita has increased only 30% during this period, with stagnation during the 1980s and early 1990s. Both energy intensity and per capita consumption differ substantially among different countries of the region (Fig. 17).

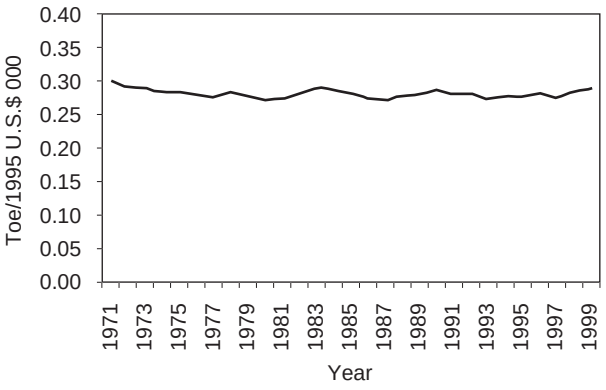

FIGURE 15 Energy intensity in Latin America.

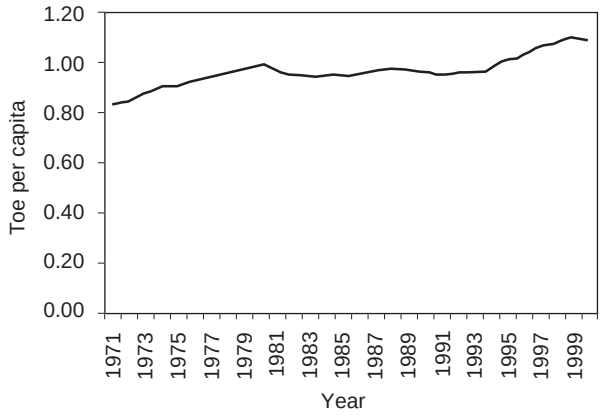

FIGURE 16 Primary energy consumption per capita in Latin America.

The use of noncommercial energy such as fuel wood is still high, particularly in rural areas, whereas low-grade and polluting fuels, such as charcoal and kerosene, are widely used in low-income urban areas. In Peru, for example, 63% of the energy consumption in the residential and commercial sectors in 1995 was fuel wood, 13% kerosene, and 6% animal dung compared to 9% electricity, 6% LPG, and 0.1% natural gas.

During the 1980s and 1990s, energy efficiency programs and legislation were developed and implemented in various countries of the region. Pioneers in this area are Brazil and Mexico, followed in the early 1990s by Costa Rica and later by other countries, such as Argentina, Colombia, Chile, Ecuador, and Peru. These energy efficiency programs were financed partly from own national sources but also with contributions from international donors. Although foreign funds have been crucial, the lack of commitment of national governments has in some cases impeded the wider uptake of the energy

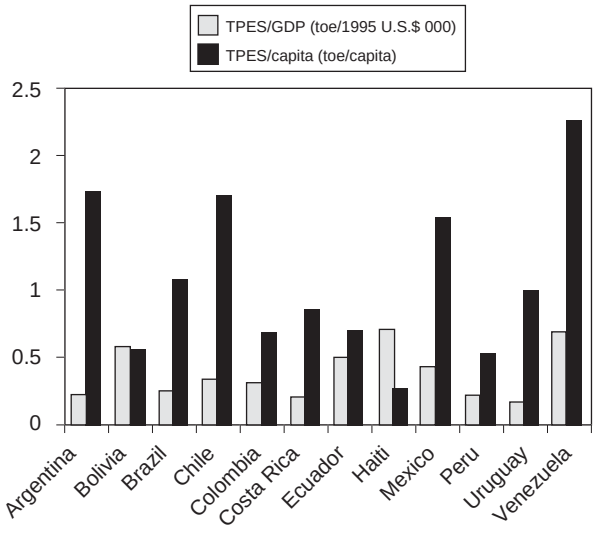

FIGURE 17 Energy intensity and per capita consumption in various Latin American and Caribbean countries, 1999.

efficiency message by the market and society. Brazil, Colombia, Costa Rica, and Peru have introduced new specific legislation for the promotion of energy efficiency and renewable energies, and bills for energy efficiency laws have been presented in other countries. These energy efficiency laws basically define the authority of governments to act in specific areas, such as information dissemination, energy efficiency standards and labeling, mandatory energy audits, the promotion of energy service companies or fiscal incentives. For example, although the elaboration of technical standards and energy efficiency labeling schemes is gaining momentum in various Latin American countries, important and visible schemes have been implemented only in Brazil and Mexico. Although the application of the standards in Mexico is mandatory and includes minimum levels of energy efficiency, the labeling scheme applied in Brazil has been voluntary. However, mandatory minimum efficiency standards are under serious consideration following the energy crisis in 2001 (Table VII).

3.4.2 Industrial Sector Potential

The market opening during the 1990s has forced many industries in Latin America to modernize their production processes in order to compete with foreign companies in domestic and international markets. Foreign direct investment has taken place in many industrial sectors and substantial technology transfer has been achieved. The modernization of industrial processes often involves higher energy efficiency and fuel switching. An example is the

TABLE VII

Summary of Energy Efficiency Potentials in Latin America

Sector	Technological options/area	Economic potential (% of current use)
Industry	Industry, efficient motors and drives	15–30
	Industry, process heat	20–50
	Industry, refrigeration	15–40
	Industry, efficient boilers and steam systems	20–40
	Iron and steel	10–30
	Cement	10–40
	Food and beverages	20–30
	Textiles	20–30
	Cogeneration	20–30
Residential	Total residential	20–40
	Electric appliances (general)	20–40
	Lighting, compact fluorescent lights	30–50
	Refrigerators	35–50
	Space heating	25–50
Commercial/ public	Total commercial/public	15–40

	Commercial lighting	30–40
	Public lighting	20–45

large-scale substitution of pyrometallurgical processes in the Chilean copper industry by modern, more efficient electrochemical processes. Whereas large industries are successfully adapting to more efficient processes, small- and medium-scale industries in Latin America often face many problems adapting to the more competitive environment.

The energy-intensive sectors cement, iron and steel, chemicals, and food and beverages consume approximately 60% of industrial energy in Latin America. Several studies carried out during the 1990s estimate that the energy conservation potential in these activities is 10–30%. The same range of savings potential also applies for the textile, other nonmetallic minerals, and machine building industries, with the majority of measures having favorable payback periods. Electrical motors and drives, process heat, and refrigeration are important areas of industrial energy end use. The energy savings potential in the field of electrical motors and drives is up to 30%, depending on the kind of measures taken. Losses in industrial thermal processes are as high as 70%, and energy conservation potentials in industrial steam systems are as high as 40%. There is also a significant potential for industrial cogeneration in Latin America, which is largely untapped because of unfavorable legal frameworks.

3.4.3 Residential and Commercial Sector Potential (Buildings and Appliances)

Residential, commercial, and public buildings offer high energy savings potentials throughout Latin America. Building codes, where existing and enforced, do not normally include requirements concerning thermal insulation. This is particularly relevant for housing for the poor, where low-cost materials and designs are usually applied. Forthcoming standards for energy certification of residential, commercial, and administrative buildings in Chile are an encouraging step in the right direction.

Another area with major energy savings potential is household appliances. The widespread use of low-grade fuels, such as kerosene, fuel wood, and charcoal, in rural and poor urban households leads not only to high levels of pollution but also to high energy losses (up to 90%). Studies indicate that the economic potential for energy efficiency improvements in residential end uses such as cooking, lighting, and refrigeration is 20–50%. On a national basis, the Costa Rican government estimates that the combined energy savings potential of efficient refrigeration and lighting systems in the residential and commercial sectors is 12–22% until 2015, taking into consideration different levels of efficiency and market penetration of the equipment. Similar potentials for end-use efficiency (typically 20–40%) exist in commercial and public buildings (e.g., shopping centers and hotels) and in street lighting.

Social problems, such as poverty and unequal distribution of income, are an important barrier to a more rigorous transformation of the residential end-use sector. Attention to energy efficiency is dampened because of more urgent, basic service needs, and new, efficient equipment and housing are often not affordable to low-income households. Several projects in the region funded by the GEF focus on end-use efficiency in the residential, commercial, and public sectors, particularly on efficient residential and street lighting.

3.4.4 Transport Sector Potential

Road transport is the most important transport mode in Latin America, with problems such as traffic congestion, air pollution in cities, and poor fuel economy due in part to the age of the car and truck

fleet. Effective transportation systems combined with supportive urban planning, building on the model originally established in Curitiba, Brazil, in the 1970s, and the increasing use of compressed natural gas and LPG in passenger and goods transport in Argentina, Brazil, and other countries are examples of measures taken to mitigate this situation. Nevertheless, energy use in the transport sector is growing and will further grow with increasing welfare and consumption levels. Measures to reduce the energy intensity of the transport sector would require improving the quality of roads, implementing effective regulation to maintain vehicles properly, as well as incentives to use cleaner and more efficient fuels and cars, introducing effective transport systems in more cities and revitalizing railway transport in Latin America. Energy savings potential due to more efficient driving habits and preventive maintenance have been estimated to be 15–25% of the fuel consumption in passenger cars, trucks, and buses.

Glossary

capital asset pricing model Predicts that an asset's risk-adjusted rate equals the risk-free rate plus an asset's beta multiplied by the expected return on the market portfolio (aggregate wealth). An asset's beta is its covariance with the market portfolio divided by its variance.

cointegration The property that a linear combination of data series is stationary while the individual series is not stationary.

marginal cost The cost of producing one additional unit of a good.

stationarity The property that the expected mean and variance of a series do not change over time.

The earliest energy product for which there are prices is wood. Wood has other, and higher valued, uses than as a source of energy. It is also expensive to transport per British thermal unit provided, hard to burn efficiently, nonuniform in composition, and very high in potentially polluting by-products. For these reasons, it has been supplanted in the energy-intensive developed world. However, it remains an important source of fuel in less developed countries. Coal rapidly supplanted wood as the fuel of the industrial revolution, and as a product of British society (and its American offshoot) there are long series of data available on the price of coal, or coales as it was first called. The percentage share of coal in the energy market has decreased for reasons of transport and environment. Efficient transport for coal is now provided by dedicated trains (unit trains), although water transport, including canals, was the principal method until the late 19th century. The need for expensive fixed transport has made coal hostage to railroad pricing policies and to government regulations. Water power was also an important industrial energy source in the early industrial era, but it was harnessed in a local fashion (mills on streams), and so we are unaware of price series for this direct use. Later, of course, water was used to produce electricity, and there are ample records of electric prices and estimates of hydropower costs. Nuclear power is likewise used to manufacture electricity, although it has been used only since the late 20th century. Price records are for electricity, regardless of its source, although cost estimates are available for nuclear power. The gas industry began with manufactured gas, usually derived from coal, which was used for lighting. In the United States, Baltimore was the first city to have piped gas in 1816. The transmission of natural gas began in 1872, but the 8-in. pipeline from Greenstown, Indiana, to Chicago in 1891 was the first large commercial natural gas venture. Natural gas, lacking the carbon monoxide of manufactured gas, was suitable for heating. Natural gas is now an important source for

[1] The views expressed are those of the authors and do not necessarily reflect the views or policies of the U.S. Department of Agriculture.

heating and power generation. Its emission profile is more favorable than that of coal or oil, which helps account for its growing usage. Price series for natural gas are not nearly as long as for coal because large-scale commercial use only began in the 20th century. Oil is the last fuel mineral that we consider. The first oil well was drilled in 1859 near Titusville, Pennsylvania, and oil rapidly became the fuel mineral of choice. Oil burns cleaner and is easier to transport than coal. It is also easier to use because oil furnaces have no need for ash removal or other hand work. Oil price history is well recorded. Because of Standard Oil, the Texas Railroad Commission, and the Organization of Petroleum Exporting Countries, oil prices are part of modern political debate and consciousness.

1. THE LONG HISTORICAL SWEEP

Figure 1 presents Hausman's real price index series for wood and coal for Great Britain from 1450 to 1989. Hausman normalized the index to 100 in 1600 in the belief that by then coal was cheaper than charcoal so that the figure would understate the advantage of coal over wood as a fuel. There is not sufficient evidence concerning heat content to normalize the two series in that fashion. The series are meant to capture the price of the fuel source and are net of transportation or taxes. The figure clearly shows the increasing price of wood and decreasing price of coal in the 1600s. In fact, coal does not begin to rapidly increase in real price until nearly the beginning of the 20th century. In addition to cartels, strikes, and recessions, which account for some of the peaks and dips in Fig. 1, the major change in the U.K. coal industry was nationalization after World War II. The overall increase in 20th-century price is due to the quality of U.K. coal deposits and the depletion of more favorable seams. This is peculiar to the United Kingdom.

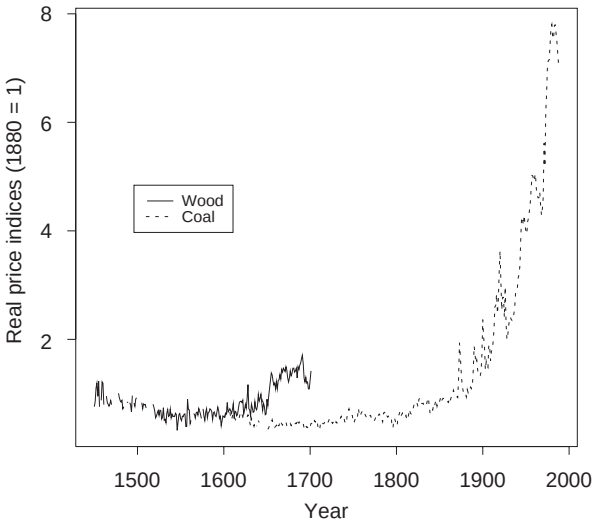

FIGURE 1 Historical prices for Great Britain fuel—wood and coal. Adapted from Hausman (1995).

Figure 2 shows the prices of the dominant energy minerals in the United States from 1870 to the present. The prices are in real 1970 dollars per British thermal unit (Btu). The price of oil decreased significantly from 1870 to the energy shocks of the 1970s and 1980s and then returned to prices not unusual in the early 20th century. A more complete discussion of the energy shocks is provided later. Coal prices are less than those of oil, reflecting oil's greater portability and cleaner burning. Coal prices increased along with oil prices after the 1970 energy price increases. Natural gas was regulated until 1979 and then deregulated during the next decade. Particularly after 1970, the clean burning characteristic of natural gas made it a desirable fuel. This property and the end of regulation account for the change in the relative prices of coal and oil.

Figure 3 shows U.S. energy consumption by source, and it indicates the increasing importance of natural gas, oil, and coal and the decreasing

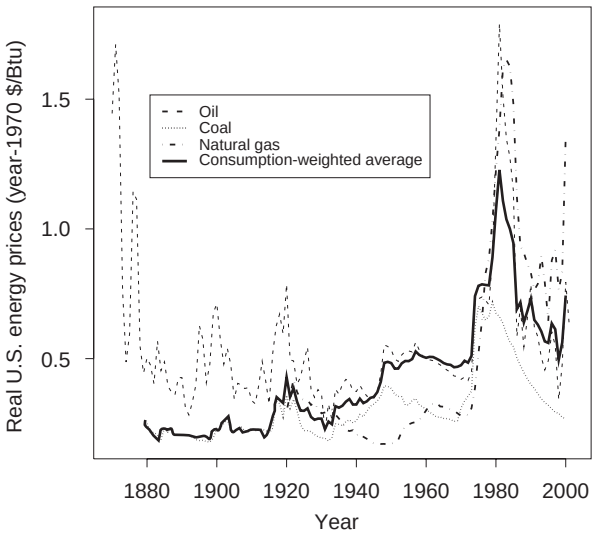

FIGURE 2 Historical prices in the United States, 1870–2001. Annual data on current prices for the raw resource products were obtained from the Energy Information Administration (EIA) and converted to 1970 dollars using the consumer price index. These values were converted to approximate dollars per Btu based on the following data from the EIA: In 1970, electric utilities paid on average approximately 28¢ per million Btu of natural gas, 31¢ per million Btu of coal, and 42¢ per million Btu of petroleum.

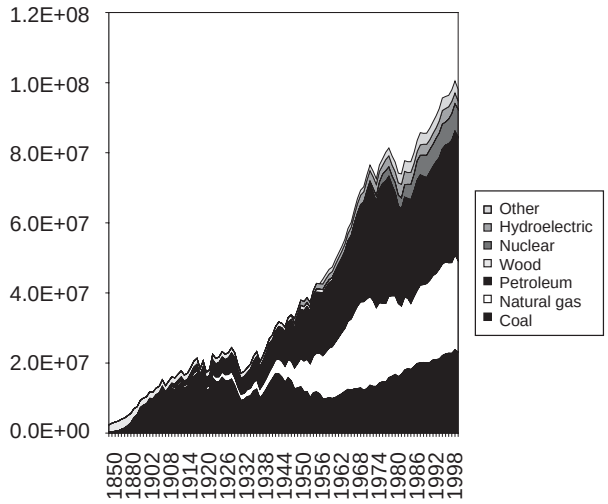

FIGURE 3 U.S. energy consumption by source (trillion Btus). Data from the Energy Information Administration and historical statistics.

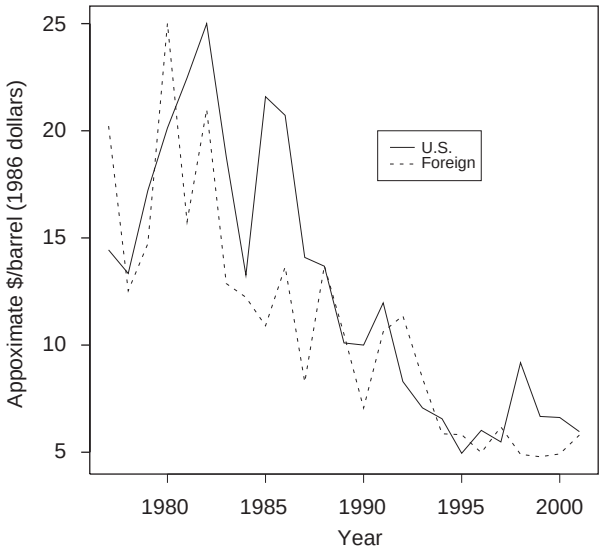

FIGURE 4 Cost to find oil and gas. Estimates for the cost to find oil were derived from data obtained from the Energy Information Administration, Form EIA-28 (Financial Reporting System). The left axis represents total expenditures on exploration and development divided by new additions to reserves. Total reserves include both oil and natural gas. Natural gas reserves were converted to barrels using the average September 1998 prices for natural gas and oil.

importance of wood. Coal was the first energy mineral to produce significant energy output. Coal energy usage increased slowly during the 20th century. At the beginning of the century, coal accounted for approximately 73% of U.S. energy use, with wood accounting for nearly all the rest. Today, coal, gas, and petroleum account for approximately 22.6, 24, and 39.4% of use, respectively, with the remainder coming from renewable sources, primarily nuclear and hydropower.

2. THE COST OF FINDING OIL

The private cost to the economy of using a barrel of oil is the cost of finding a barrel of new reserves of the same quality to replace the used-up barrel. If the oil business were competitive, which it is not, then the market price of oil would be the finding costs plus the development costs plus the marginal costs of production. For this monopolistic business, it is the cost of finding oil that provides the most information about oil's ultimate scarcity. The cost series for finding oil are necessarily very incomplete and lack certainty. The series developed by the Energy Information Administration (EIA) comprise expenditures on exploration and development divided by oil and gas reserve additions. The latter series is subject to considerable uncertainty since for many years it is unknown how much oil (and gas, valued as oil equivalent) was actually found. Additions to reserves can be dominated by changes in the estimates of existing fields, whereas it is the cost of developing new sources that is of most interest. Information was collected for the years 1977–2001 for both foreign and domestic activities of U.S. reporting firms and is plotted in Fig. 4. For 1977, the cost was calculated in 1986 dollars as $14/barrel U.S. and $20/barrel foreign. Domestic costs peaked at $25 in 1982, declined to $4.95 in 1995, increased again, and then settled at $6/barrel in 2001; foreign costs mostly declined during the period and ended at $6. It is believed that the cost of finding and developing oil in the Persian Gulf is less than these figures.

3. THE ORGANIZATION OF PETROLEUM EXPORTING COUNTRIES AND THE OIL EMBARGOES

On October 17, 1973, the Organization of Petroleum Exporting Countries (OPEC), which was originally formed in 1960, announced a progressive embargo on the sale of oil to the United States and other countries that supported Israel in the 1973 Yom Kippur war. They also announced a 70% increase in the reference price for crude oil, an artificial price that determines how much oil companies must pay in taxes. Given that the United States bought only 5% of its oil from

OPEC, an embargo of the type announced was unlikely to inconvenience the United States or substantially raise prices. However, Saudi Arabia decreased its production 35% below the September output and increased the price an additional 6¢. Combined with the nationalization of oil company interests, the cutbacks in production resulted in major increases in the price of oil and a major redistribution of the rents from oil production to the oil-producing companies. In retrospect, it is clear that these actions by Saudi Arabia, with some support from the rest of OPEC, were largely commercial in nature and U.S. attempts at bilateral relationships and other diplomacy had no effect. Production limitation became an effective tool for raising prices far above discovery and production costs.

The next increase in prices occurred in 1978–1981 as a result of a secret OPEC program to impose production controls and due to turmoil in Iran, including the Iran–Iraq war. When Iran's oil output decreased, Saudi Arabia did not increase its output. With Iran not producing at all in January 1979, Saudi Arabia decreased production by 2 million barrels per day on January 20. Its output vacillated for the next several months, always well below capacity, with the result that oil prices topped $20/barrel in October 1979. Prices increased until 1982, when the Saudi export price reached $33.50/barrel. In this period of war-induced uncertainty, oil companies and oil users hoarded significant amounts of oil.

Adelman attributes the price decline in 1982 to the end of a speculative bubble. The continued slow decline until 1986 was the result of increased supply from non-OPEC members and the consequence of lagged demand elasticity. In 1986, prices declined considerably, presumably a function of the substantial non-OPEC output. The lowest price was reported by Adelman as $6.08 for Saudi Light; in August of 1986, OPEC again set production quotas, with cooperation from some non-OPEC members.

The next major price event was the Gulf War in 1991, again producing a spike in prices. The war directly ended the sales by Iraq and Kuwait and spurred the building of precautionary supplies. Because there was sufficient capacity without the output of these two countries, prices rapidly subsided.

4. COAL PRICES

In the time of Queen Elizabeth I, the coal trade in England (i.e., coal sold into the London market) was monopolized. Monopolization was possible because the London market was served by two rivers, the Tyne and the Wear, and the coal lands adjacent to these rivers. The land involved was not so extensive as to defy ownership by an oligopoly. The key issue in the early coal trade was water transport, with coal lands situated near canals or rivers with major markets being valuable and other lands being of lesser value.

Although oligopoly was in existence as early as 1517, it was formalized with royal charter as a monopoly of coal and also of political power in Newcastle by Queen Elizabeth on March 22, 1600. Other important dates cited by Sweeney include an act of Parliament to make restriction of trade in coal illegal in 1710, an allocation document fixing the quantities of coal among major owners in 1733, a lack of regulation in the period 1750–1771, a resumption of regulation in 1771 or 1772, and on-and-off regulation through 1850. Although the detailed history is not provided here, the British coal series should be interpreted in the light of the on-and-off nature of the quantity regulation. Price changes may reflect temporary changes in the Lerner index as much as changes in capacity or demand.

Coal prices in the United States during the 20th century were subject to a very different sort of government regulation. Because of the need to reduce sulfur emissions in the air, the U.S. government required new and substantially modified power plants to reduce sulfur emissions in such a way that there was no advantage to the use of low-sulfur rather than high-sulfur coal. In effect, since 1990 the emissions permit trading program no longer disadvantages low-sulfur coal as a way to reduce emissions.

5. NATURAL GAS PRICES

In the United States, natural gas was regulated and sold at a low price until gradual deregulation from 1979 to 1989. Thus, the prices after 1989 were free to increase in response to increased demand, driven by the desire to switch from expensive oil to gas and by environmental restrictions that allow the burning of gas but restrict oil and coal. For the data plotted in Fig. 2 prior to 1979, the correlation between gas price changes and oil price changes is 0.067; after deregulation, the correlation is 0.605.

6. ENERGY PRICES TO USERS

Although there is a world market in many of the energy minerals, national governments' tax and

allocation policies create very different prices for end users in different countries. In general, the United States has among the lowest prices of consuming nations to end users of energy products, and all countries generally price consumer products higher than industrial products.

In comparing prices across countries, one must keep in mind the problems of converting currencies and the qualities of the fuel. The following discussion is in terms of conversion at the official exchange rate as opposed to purchasing power parity. The exchange rate is the best choice for industrial uses, especially where the end products (e.g., cars, steel, and airplanes) are widely traded. Particularly in countries less well attached to the international trading system, exchange rates can be very different than purchasing power parity, and the use of dollars as the official exchange rate would provide a poor estimate of the burden on consumers of energy purchases relative to a basket of other goods. In order to make industrial and household prices comparable, we use exchange rate conversion throughout. There is also an issue of heat equivalent [or heat equivalent net of the energy needed to remove water from the fuel, gross caloric value (GCV) and net caloric value (NCV), respectively.] When comparing prices across fuels (oil versus coal) or across different types of the same fuel (U.S. bituminous coal versus Czech brown coal), the most accurate comparisons are in terms of ton of oil equivalent or NCV. In order to use tax information, we use the reported metric tons (tonnes).

Perhaps the most traded energy commodity is fuel oil. The following section reviews the evidence that fuel oil is one international market; that is, the prices in different countries increase and decreases simultaneously, with differences only in transportation costs. For 2001, the range of prices for high-sulfur fuel oil for industry, in U.S. dollars per tonne, was 103 to 258. The lowest price in the International Energy Administration's (IEA) data set was for Mexico, which is a net exporting nation. (The data do not include the Gulf States.) The U.S. price was $147/tonne, that of France was $154.4/tonne, and that of Turkey was $181.7/tonne, whereas the Organization for Economic Cooperation and Development (OECD) average was $189/tonne. France levied taxes of $16.6/tonne, whereas the United States levied no taxes; therefore, the pretax price in France was cheaper than in the United States. Turkey's tax was $42 and its pretax price was cheaper than that of the United States, which should not be surprising given that Turkey is a transshipment point of Mideast oil.

Automobile fuel is refined from oil. Apart from issues of taxation, the prices of automobile fuel should be very similar throughout the world, just as the ex-tax prices of fuel oil are very similar. Consumers pay the price with tax, which varies greatly from country to country. Of the countries that report a price for regular unleaded gasoline, the United States has the lowest at $0.39/liter. Germany has a price of $0.90 and Denmark is highest at $0.97. France reports a premium leaded price of $1.00 and Turkey $0.99, and Mexico reports a premium unleaded price of $0.65 per liter. This variance in pricing is attributable to taxation. Although it is not reported in the IEA data, there can also be a vast difference in the attributes of gasoline. In order to meet its obligations under the Clean Air Act, the state of California requires the use of a much more refined gasoline than is used in the rest of the United States and this gasoline carries a hefty premium in price.

Coal is a basic energy source both for industry and for electric generation. Coal is more difficult to transport than oil (railroads and slurries versus pipelines) and major deposits are often not near ocean transport, unlike oil. Coal is also more likely to be used without much preprocessing (for pollution control purposes, it can be washed, whereas crude oil is always refined), so coal must be matched much more closely to boilers than crude oil needs to be matched to its ultimate customers. For these reasons, there should be a greater variance in the underlying price of coal than there is in the underlying price of oil. Again examining IEA data, the prices for steam coal (for industry or electric generation as opposed to coking or metallurgical coal), the U.S. price was $36/tonne and that of Japan was $32/tonne, with many other countries in the $30 range. Germany was highest with a price of $52/tonne. Coal can also be measured in tons of oil equivalent to compensate for different caloric outputs per ton, and the pattern is much the same.

Electricity is generated from a variety of processes, including burning of coal, oil, and natural gas, nuclear reactors, hydropower, wind, photovoltaic, and even tide power. A country's electricity prices to industry and to consumers represent a mix of the costs of these methods. Countries such as Norway, or areas of countries such as the U.S. Pacific Northwest, that have significant surpluses of hydropower can have very low costs of production, as can countries that are willing to burn coal, particularly with minimal pollution control. Variation in electric rates across countries is thus explained by natural abundance of cheap methods, preferences for clean air, and taxation. In

2000, the U.S. price for households was $0.082/kWh (excluding tax) and it was $0.042/kWh for industry. Denmark had the highest household price at $0.197/kWh, and the Slovak Republic had the cheapest at $0.05/kWh. The Slovak price is probably related to the burning of brown coal, with its concomitant problems of air pollution. Norway's household price was $0.057, reflective of both hydropower and petroleum reserves. Industrial prices in Europe are much lower than household prices, largely due to taxes. France's industrial price was $0.036/kWh compared to its household price of $0.102/kWh. Italy, Japan, and Turkey are outliers in the IEA data set because they had industrial electric prices of $0.089, $0.143 (1999), and $0.080/kWh, respectively.

Natural gas for households on a toe-NCV basis also show great variation among countries, with the U.S. price at $417, slightly above the OECD average of $391 in 2001. This is quite different from 1994, when the U.S. price was $274 compared to an OECD average of $383. Presumably, this change in relative price is related to shortages of both pipeline space and gas at the wellhead. Despite the clear preference in the United States to generate electricity with natural gas for air quality reasons, we expect that the price will decrease. With a price of $788, Denmark has the highest price in the dataset.

Taxation represents a large percentage of the delivered price of energy-containing products, particularly consumer products. Automotive fuel taxes represent half or more of the value of the product in all but 4 of the 29 countries included in the IEA dataset. In the United Kingdom, they are 76.9% of the value.

The earlier years in the IEA data set tell much the same story as the later years. Pricing to consumers tends to have more taxation and more idiosyncratic variation than pricing to industries.

7. A MARKET FOR "ENERGY": COINTEGRATION OF PRICES

Energy is not a homogeneous resource and the prices of the various energy minerals do not necessarily track each other well over time. Oil is the most transported of the energy minerals, much of it originating in the Persian Gulf and transported by tanker. The differences in the prices of oil at different ports can be explained largely by transport costs. One way to test the hypothesis that oil is traded in a single market is to determine whether the series are cointegrated. Two price series are cointegrated if there exists a linear combination of the two series that is stationary (the mean and variance do not change over time). In other words, the two series move together.

An example of this type of test is to regress the price of Saudi Light landed in southern Europe on the price of the same oil landed in Rotterdam and then test the residuals of the regression to determine if they are stationary. Given the oil series are both stationary in differences, a finding that the residuals of this regression are also stationary means that the southern Europe price series is a linear function of the Rotterdam series, and any remaining differences between the two series can be accounted for by transport costs. It means that oil price shocks affect both series at the same time. Cointegration tests for oil at different ports find cointegration and support the notion that oil, in Morris Adelman's words, is a single large pool.

Coal contributes to world energy somewhat less than oil and so if there were one price for "energy," then oil and coal prices would also be expected to be cointegrated. Similarly, coal prices in different localities would be cointegrated. There is little evidence that coal prices move together or that they move with oil prices. Figures 1 and 2 show the prices of coal for the United Kingdom and the United States. In these long series, the price in the United Kingdom increases approximately eightfold, with the strong trend being upward. The price in the United States shows a peak in the early 1980s and then a sharp decline to its previous value. It is dubious whether the U.S. price is differenced stationary rather than just stationary. The U.K. price is clearly stationary only in differences. Thus, these two prices are not cointegrated. Similarly, there is little evidence that the German and U.K. prices are cointegrated.

Although the US coal and oil prices are not found to be cointegrated using the normal testing procedure, Fig. 2 indicates that the coal price does bear some relationship to the oil price, very notably in the price run-up in the late 1970s. One explanation for the difference in the U.S. coal and oil prices is that coal is sold on long-term domestic contracts and is not subject to supply disruptions. As a result, there is no incentive to hoard coal, whereas hoarding oil before the Gulf War was a major cause of the price increase.

There is a world price of oil, but the oil price is not closely related to the prices of coal in various countries, nor are the prices of coal closely related to each other. Energy is not one great pool and there

is no "price of energy," just a multiplicity of prices of energy minerals.

8. PRICES AND THE NONRENEWABLE RESOURCE PRICE THEORY

There is no convincing evidence of a trend in oil, gas, or coal prices. One theory on these prices that has empirical support is that the first differences are stationary with mean drifts of zero. In this case, there would be no deterministic trend in the prices, simply random variation. The best estimate of future prices would be today's price. Another possibility is that the prices revert to a quadratic trend that is stochastic. This view would lead to a prediction of a slight increase in prices. Based on the historical evidence in the time series for energy prices, there is no good evidence for forecasts of increasing price.

Examining the oil price series in Fig. 2, it appears that oil prices were distinctly declining in the early years of exploitation, then leveled off, and since 1980 have increased. Since 1980, prices appear to have followed a quadratic trend. Since 2002, prices seem to have reverted to pre-Iraq war levels. We conclude that analysis of the price path of oil does not lead to a prediction of increased prices.

The lack of a clear trend—deterministic or stochastic—in energy prices at first seems at odds with the theory of natural resources. Theory predicts that prices for these commodities will ultimately rise at the rate of interest, a classic finding by Hotelling. Hotelling reasoned that if one extracted a barrel of oil today and put the money in the bank for 1 year, then one should have exactly the same financial outcome as if one extracted the barrel in 1 year. If this equality were not true, then one would be better off extracting all of one's oil in just one of the time periods, whereas we observe extraction in all time periods. A barrel extracted today would earn its price, $R(0)$, and after 1 year at interest rate i it would be worth $R(0)(1+i)$. This must be equal to the value extracted in 1 year's time, $R(1)$ and $R(1)=R(0)(1+i)$. This theory predicts that mineral prices will rise at the rate of interest. However, the price that is referred to is the seldom-observed price of minerals still in the ground, which is called the mineral rent. The price of minerals that we observe, P, is the mineral rent R plus the marginal extraction costs c. The theory is not so clear about minerals that have already been mined or lifted, which is the series that we have presented.

Since energy mineral prices do not increase at 7–11%, which is the normal rate of return for financial assets, economists have posited that either technical progress or a decline in grade account for the slow or nonexistent rates of appreciation of energy mineral prices.

One possibility is that there is technical progress in the mining technology; that is, that c decreases over time. Then the marginal cost of mining would decline and the value of the underlying mineral would increase. The observed price is the sum of the two prices and so could increase or decrease. However, since the extraction costs are decreasing and the underlying price is increasing, eventually the extraction costs would be insignificant and the price increases in the rent would be dominant. This process requires the rent to become dominant; however, if it is true that undiscovered, but easily discoverable, reserves are very large relative to demand, then rents will be very small and prices will not exhibit an upward trend for a very long time.

Flat prices can also be reconciled with the Hotelling theory by considering the fact that depleting a resource affects extraction. The first units extracted are presumably the least costly, with each unit becoming progressively more costly as cumulative extraction progresses. In this case, part of the opportunity cost of extracting a unit today is increased cost in the future. Rents increase more slowly than the interest rate, but the difference is exactly offset by an increase in future costs. Thus, in the long term, prices still increase at the rate of interest, even if rents do not. The evidence for grade depletion as a worldwide phenomena is thin—there are substantial high-grade coal seams in the United States, and extraction costs (and finding costs) for oil in the Gulf remain very low.

Another way to reconcile the flat price path for energy minerals with the theoretical prediction of price increase is to calculate the required interest rate using the same logic used to determine the needed rate of return for common stocks.

In most of the theoretical literature, the interest rate is taken as a fixed market price of time preference: the marginal value of a dollar received tomorrow relative to its value today, with all else remaining the same. In a world of uncertainty, however, the marginal value of returns depends not only on the timing of returns but also on uncertain contingencies. Losing money on a stock market investment is likely to be more painful if one also loses one's job but less so if growth in one's home equity more than compensates for stock market losses. The fair rate of return of one investment

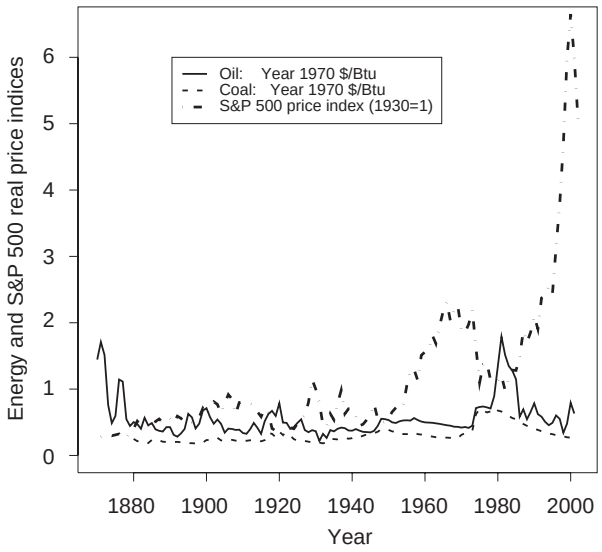

FIGURE 5 Long-term stock market returns and energy prices. The coal price and oil price data are those plotted in Fig. 2. The long historical series of the Standard & Poor's 500 was obtained from Robert Shiller (http://aida.econ.yale.edu/~shiller/data.htm).

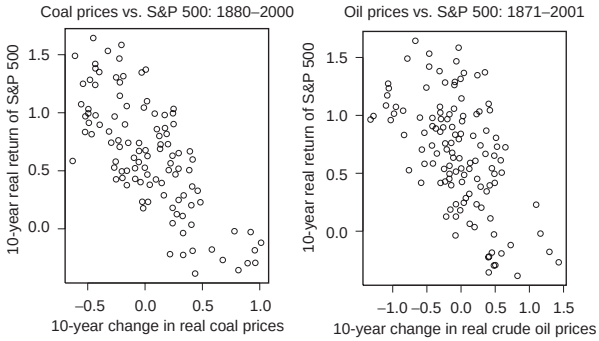

FIGURE 6 Long-term stock market returns and energy price changes. Returns on the Standard & Poor's 500 assume annually reinvested dividends. The long historical series of the Standard & Poor's 500 was obtained from Robert Shiller (http://aida.econ.yale.edu/~shiller/data.htm).

therefore depends on how its returns are correlated with those of other investments.

Interest rates reported for treasury bills and other assets are typically low-risk investments that yield the same amount regardless of other contingencies. In contrast, a decision not to extract and sell a unit of oil today is an investment with a return that depends on future oil prices, which are volatile and uncertain. Thus, interest rates on treasury bills or other low-risk investments may serve as a poor proxy for the rate of return that should be applied to nonrenewable resources.

The capital asset pricing model (CAPM) explains the difference in average returns across investments according to their differential risks. The model assumes that individuals, with all else being the same, prefer greater expected returns and lower risk. To mitigate risk, individuals invest in large portfolios of assets in order to average away the idiosyncratic risk of each asset against the idiosyncratic risk of all other assets. In equilibrium, individuals thus do not care about idiosyncratic risk; the only risk that matters is that pertaining to aggregate wealth—that associated with the entire portfolio of assets.

Theory predicts that assets having returns with a strong positive correlation with wealth should have high average returns. The strong positive correlation of these assets implies that they pay off most when wealth is high and marginal utility of wealth is low. Conversely, assets with returns having a negative covariance with wealth will earn low or even negative average returns. These assets provide insurance against aggregate losses, yielding higher outcomes when wealth and consumption are low and marginal utility is high.

Energy prices have a strong negative correlation with the aggregate economy and aggregate stock market returns and therefore should have a risk-adjusted average rate of return that is lower than that of low-risk investments such as treasury bills. The relationship between energy prices and the stock market, illustrated in Figs. 5 and 6, has received less attention but is more closely related to CAPM. The correlation between the 10-year return of the Standard & Poor's 500 and the 10-year change in coal prices is less than −0.7. Simple CAPM-based estimates of the risk-adjusted rates of return for oil, coal, and natural gas, regardless of the time horizon, are between −1 and 2% and are not statistically different from 0%. As long as price fluctuations for these fossil fuels are strongly negatively correlated with national wealth, theory does not predict that the prices will trend up.

9. CONCLUSION: SUPPLY FACTORS AND DEMAND FACTORS

The past century of energy prices is a history of shifts in supply factors, shifts in demand factors, and policies, such as taxes and trade restrictions. However, the most notable price spikes, including those that occurred following coal strikes in the early part of the 20th century and the oil embargo, OPEC activities, and Iraq wars, are all attributable to shocks that reduced supply or anticipated supply. The observation that supply factors were most

relevant to historical price fluctuations mirrors the negative relationship that has been documented between oil prices and the macroeconomy. Because energy resources are essential inputs, energy price shocks caused by unanticipated shifts in supply cause reductions in aggregate output. If aggregate demand shocks were driving price increases then the relationship between energy prices and aggregate output and stock market returns would be positive, not negative.

The history of energy prices therefore stands in contrast to the history of energy consumption, which has grown steadily with aggregate output and demand. Over the long term, prices have trended flat and have been highly volatile, with the drivers of price shocks stemming from shifts in supply. Supply volatility has caused prices to be negatively correlated with aggregate output and wealth, which in turn explains why prices have not trended up.

Glossary

alternating current (AC) Flow of electricity that constantly changes direction between positive and negative sides. Most transmission lines are AC.

direct current (DC) Electric current that flows constantly in one direction. A significant case of opposition to a transmission line in the l970s was to a DC system from North Dakota to Minnesota.

electric and magnetic fields (EMF) Invisible lines of force that surround any electrical device, such as a transmission line, electrical wiring, or an appliance. There is controversy about the health effects of exposure to these fields, especially magnetic fields.

electricity utility A firm established to provide electricity services. The traditional structure is one of vertical integration of generating, transmitting, and distributing services. The new structure in many countries separates these functions.

opposition group People organized to contest facility siting and building. They are usually organized in local groups interacting with others in communication networks. Groups usually include persistent activists as cadre and episodic participants in support.

siting authority The government entities authorized to make decisions about siting.

siting process The process of permitting or approving transmission or other facilities, including determining public need for them and their location or route.

transmission lines Heavy wires that carry large amounts of electricity over long distances from a generating station to places where electricity is used. The lines are held high above the ground on tall structures called towers in the United States and pylons in the United Kingdom.

Opposition is the most significant public response to transmission lines in Western industrial democracies. The study of this opposition reveals how people contest and resist transmission line siting by organizing in groups and networks, and by developing and communicating arguments about why the line is not needed and how it negatively impacts people and environment.

1. OPPOSITION TO ELECTRICITY TRANSMISSION LINES IS SIGNIFICANT, ORGANIZED, AND INFORMED

In the United States, the United Kingdom, and Canada and probably in other Western, industrially advanced democracies, the most observable and significant response of people directly affected by the siting and building of electricity transmission lines in their communities is their opposition to these projects. This article examines this public response of

 © 2004 Elsevier Inc. All rights reserved.

opposition. It considers how people organize to oppose and examines the main reasons that people and groups give for their opposition. Major reasons given for opposition are as follows: (1) need and alternatives, (2) size/length and voltage, (3) structure of industry, (4) sentiments, visual impacts and loss of control, (5) health and safety risks, particularly from electric and magnetic fields, (6) fairness, (7) environmental justice, (8) environmental quality, and (9) siting process. This article examines the first five reasons and mentions the others. These reasons constitute a system of interdependent ideas. As people oppose the siting of transmission facilities, they produce, learn, and communicate these reasons. People build local groups to contest a particular transmission project and build global networks to spread and exchange information. The article describes this organization, illustrating communication with examples of the flow of information about electric and magnetic fields.

2. *WHAT IS THE SIGNIFICANCE OF OPPOSITION TO ELECTRICITY TRANSMISSION LINES?*

People can respond in several ways to the information that an electricity utility proposes to site (locate and build) transmission facilities (line and/or substations) in or near their communities. They can actively oppose the line, passively accept it, or actively support it. This article is mostly about active opposition, also termed resistance or protest. It is about opposition in the 1970 s in United States and from the 1990 s through the time of this writing, 2003, in the United States, Canada, and the United Kingdom. Examples from case studies in these countries illustrate opposition. This section on significance introduces many of the examples used throughout this article and such examples are indicated by an asterisk.

Findings for this article were obtained by the author, using field research, conducting a document and media study, and, for cases since the 1990s, corresponding by e-mail and gathering information from the Internet. Sources include representatives of the main parties to transmission controversies: electricity utilities and trade associations and their consultants, government siting authorities, and especially groups opposing transmission siting. Efforts to obtain information from electricity utilities, trade associations, and citizen groups on the European continent, Japan, and India through e-mail inquiries were unsuccessful. Thus, their stories are not represented in this article. This article presents the ideas of people, especially of line opponents, but does not evaluate their accuracy. The article is about what people say and do, not what they should say and do.

This article is about opposition because this is the most observable significant response. Utility executives, consultants, government officials, and energy researchers state that opposition to the siting and constructing of transmission facilities has been one of three main obstacles to the construction of enough such facilities to meet their need and avert what some refer to as congestion of transmission. Many of these sources state that a second obstacle is the way local and state rules and processes to regulate and approve transmission facilities delay or make approval uncertain. Many also state that a third obstacle is the uncertainty about who will own and operate the transmission system and who will pay for grid expansion and improvement. This third obstacle has become important since the 1990s, as the electricity industry has been restructuring so that it is partly regulated and partly competitive. Opposition, approval process, and economic and structural uncertainty affect one another. Approval processes provide opportunities for people to organize and oppose. Opposition, including litigation, can delay approval and force modifications in transmission design and routes and the prospect of this increases uncertainties, deters investment, and provokes project cancellations.

2.1 What Utilities, Government, Consultants and Researchers Say

In 2000, 23 persons across the United States affiliated with electric utilities and related energy-producing and marketing firms, energy-related government agencies, industrial consumers, and environmental groups were interviewed about the need for and obstacles to the expansion of electricity transmission capacity by Eric Hirst, a consultant on electric industry restructuring, for his July 2000 report to the Edison Electric Institute (EEI), the trade association of the investor-owned electricity utilities. Hirst's interviewees mention the following as cases of transmission facilities not being built because they were opposed and/or did not meet requirements for approval.

- A 765 kV line proposed by American Electric Power (AEP) in Virginia and West Virginia (*AEP 765);

- Two lines [230 kV (Chisago) and 345 kV (Arrowhead-Weston)] between Minnesota and Wisconsin (*A-W 345);
- A 500 kV line between Georgia and Michigan;
- Expanded interfaces between Indiana and Michigan;
- Expanded interfaces between Pennsylvania–New Jersey–Maryland and New York and between New York and New England [notably, three projects led by Connecticut Light and Power (CL&P): *CL&P 345 & cable];
- Additional transmission between Wyoming and eastern Colorado;
- Additional transmission facilities needed to serve the growing loads of Boston, New York City, Long Island, San Francisco, and San Diego.

EEI official David Owens, in the July/August 2001 EEI Electric Perspectives, attributes the problems of building new transmission facilities to the many challenges in regulatory review and approval. However, he indicates that these challenges are importantly driven by the public sentiment against transmission expansion and the involvement of government agencies, courts, federal and tribal governments, and competing interest groups. The public sentiment against transmission expansion, he says, is represented by the phrases NIMBY (Not in My Backyard), NOPE (Not on Planet Earth), and BANANA (Build Absolutely Nothing Anywhere Near Anyone). In other words, permitting processes enable people to express what has become a generic opposition to siting new facilities. Owens also provides examples of transmission projects that have been delayed for many years because of opposition and process, mentioning some of the cases listed by Hirst: the project by Xcel Energy (Chisago-Apple River) to link transmission facilities in Minnesota and Wisconsin, proposed in 1996, and the project by AEP to link West Virginia and southwestern Virginia through a 115-mile, 765 kV system proposed in 1990. He also notes the rejection by the Connecticut Siting Council of a cable to run below Long Island Sound, linking Long Island to Connecticut. By summer 2003, the Chisago project had been cancelled, the AEP outcome was uncertain, and the Long Island cable projects were on hold. The AEP and Long Island projects are mentioned in news reports about the August 2003 Northeast Blackout as examples of how parochial interests block construction of interstate transmission. The AEP and Long Island cases are also mentioned in a May 2002 National Transmission Grid Study for the U.S. Department of Energy (DOE) as examples of how needed interstate transmission projects are significantly delayed through siting processes. The study indicates that the Federal Energy Regulatory Agency (FERC) may need to expedite siting.

In October 2001, Alan Schiber, Chairman of the Ohio Public Utilities Commission, testified before the U.S. House Committee on Energy and Commerce on behalf of the National Association of Regulatory Commissioners about transmission siting, especially about efforts to increase the federal role in this. He disagreed with "the presumption in Washington that the reason transmission systems are not being expanded or managed sufficiently to meet transmission need and prevent congestion is that State eminent domain and siting authority is inadequate." Instead, "a major impediment to siting energy infrastructure in general and electric transmission in particular is the great difficulty in getting public acceptance for these facilities." No matter where siting responsibility falls, with state or with federal government, siting energy infrastructure is not easy or amenable to a "quick fix." Schiber notes that people object to siting such infrastructure because they do not want to bear the impacts or the costs of the facilities (even though they do want the electricity).

Basin Electric Power Cooperative, which serves member systems in North Dakota, where it is based, and eight other western states, tells its customers in newsletters of its success in building needed transmission facilities, notably in 2003 a direct current system intertie near Rapid City, South Dakota. In interviews, its officers explain that public opposition is not an obstacle to transmission siting and that they successfully negotiate agreements with landowners (although Basin Electric newsletters do refer to the problems of the "not in my backyard" resistance to siting new transmission). Instead, they say, "A primary obstacle to the construction of transmission is the regulatory uncertainty associated with the deregulation effort and improper pricing methodologies for the high-voltage transmission system." In their October 2000 newsletter, Basin Electric's Vice President of Government Relations summarizes the consequences of the uncertainties by rhetorically asking: "Why would you build it if you don't know that you can use it and everybody has the same rights to it?" Basin's marketing manager asks, "Who should pay for it? Will there be a return on investment?" To obtain a return, Basin Electric calls for pricing in which all users pay their *pro rata* share of the average cost of the grid, a method known as postage stamp pricing. This differs from the currently dominant license plate pricing, which recovers costs for transmission facilities from

local ratepayers. Basin indicates that postage stamp pricing is opposed by parochial interests, presumably by states or localities with traditional low-cost electricity that fear that expansion of the grid will raise their costs by exporting their supply.

2.2 Opposition in the 1970s

Opposition to electricity transmission and recognition of its significance is not new. In the 1970s, electricity utilities began building high-voltage transmission systems to carry electricity long distances and people strongly resisted some of these projects. A notable example is that of the 1974–1979 resistance to the siting and building of a $\pm$400 kV direct current (DC) line across west-central Minnesota by the rural electric cooperatives United Power Association and Cooperative Power Association, collaborating as Cooperative United, or CU (*CU $\pm$400 kV DC). Farmers, rural townsfolk, and urban allies fought the line in the meetings and hearings of the siting process and by litigating in the courts, demonstrating in the fields, confronting surveyors, officials, local sheriffs, and state police, sabotaging towers, facing arrest, dealing with federal agents, and more. Reporters for state and national media covered the events. Researchers studied and reported the case in journals, books, and films, with some researchers calling it an example of a grassroots social movement. The line was built, but the struggle against it forced changes in legislation about siting such facilities.

Another case of note was resistance to the siting of a 155-mile, 765 kV alternating current (AC) line by the Power Authority of the State of New York (PASNY), connecting its system with that of Hydro-Quebec, in Canada. This project (*PASNY 765), proposed in 1973 and argued through hearings for several years, was also protested militantly through some of the same actions as occurred in Minnesota. Minnesota and New York power line resisters learned from one another through telephone, mail, exchange of newsletters, and visits.

Opposition made it difficult to build electricity transmission systems from the l970s on, in Minnesota, New York, and elsewhere. In its August 22, 1988 issue, *Newsweek* reported that there was a virtual moratorium in the United States on building new high-voltage power lines because of "community opposition and environmental worries."

2.3 Opposition Reported Worldwide on the Web

Opposition is not limited to the United States, as power line opponents are pleased to announce. From the late l980s through 2000, people opposing siting by Ontario Hydro of a 500 kV AC transmission line through their neighborhood in Bridlewood, Ontario, Canada (*Bridlewood O-Hydro 500) provided an information service to tell their local colleagues and later others across the world about why and how transmission lines were being opposed almost everywhere. This service appeared first as newsletters and later as a Web site dedicated to spreading the word about struggles against power lines and other technologies that produce electromagnetic fields. The site briefly summarizes approximately 50 cases in which the siting or operation of electricity transmission facilities was opposed by community groups or permitting authorities. Many of these cases are reported for localities across Canada and the United States, but also reported are cases in the Philippines, Spain, Morocco, Australia, Italy, Venezuela, Greece, Mexico, Ireland, and Antigua. The summaries are brief and not sourced. One purpose of this list and others like it is to advertise that opposition to transmission lines is legitimate and common.

The Bridlewood site was discontinued in 2000, a few years after the Hydro-Quebec transmission line was approved. However, people in southeastern suburbs of St. Paul, Minnesota, opposing Xcel Energy's project to upgrade a 115 kV power line in their neighborhood (*Xcel 115 upgrade), include the Bridlewood list of world power line struggles in their Web site. These protesters of Xcel have been in the news for contesting the upgrading project through 4 years of hearings and litigation. Their Web site is an important node in a worldwide network of transmission line opponents. One of these is the group Revolt, organized in North Yorkshire, United Kingdom, in 1991 to resist siting by the National Grid, a transmission only firm, of a 75 km, 400 kV AC link from Lackenby south to Shipton, near the city of York (*North Yorkshire 400). Their resistance apparently helped delay project approval until 2002.

Note that above-mentioned cases marked with an asterisk are discussed throughout this article to illustrate opponent ideas and organization. The designations, e.g., AEP 765, CU $\pm$400 kV DC, are the author's for this article and not necessarily used by utilities or government.

2.4 Counteropposition

Opposition is the main observable and most significant public response to transmission projects; however, there are some instances in which people

have organized as apparent grassroots proponents of specific transmission projects. Some of these proponents are criticized by opponents as front groups for industry, or "Astroturf lobbyists."

The 1970s CU ±400 kV DC case provides an instance of this. Midway during the conflict, scores of farmers and other rural people across Minnesota came to the state capital in St. Paul for a Line up for Power/Pro-Power demonstration of support for the line. These were customers and employees of local rural electric cooperatives that were served by the two associations building the line. Their cooperatives organized the event, bused them to it, fed them, and prepared placards for them to carry with slogans proclaiming the need for more power and mocking the slogans of line opponents. Opponents confronted these proponents on the steps of the capital and in debates with legislators. Most proponents seemed uncomfortable in their role and unable or unwilling to argue for the line as ably or fervently as opponents argued against it. The cooperatives did not repeat this effort.

In the late l990s, as many people and groups in West Virginia and Virginia were resisting the proposal by AEP to build a 115-mile-long 765 kV transmission line through their neighborhoods, others organized to promote this AEP proposal. Ron Nixon reports in the December 7, 1997 *Roanoke Times* that the promoters organized as the Coalition for Energy and Economic Revitalization (CEER). CEER's leader, Bill Tanger (who also chairs the Roanoke Valley's Sierra Club), called CEER "the largest grass-roots coalition in Virginia's history." Its aim, he says, is to prevent widespread electrical blackouts in southwestern Virginia and to foster economic development in Virginia and West Virginia. However, power line opponents claim that CEER people are paid by AEP and that they are not grassroots activists, but rather a front group for AEP and what public relations watchdogs term Astroturf lobbyists. The purpose of such lobbying is to make a planned program look like a spontaneous explosion of community support. Regulatory documents show that AEP paid more than $500,000 to CEER through Tanger and another $200,000 to the advertising agency that he runs. In contrast, the AEP line opponents spent nearly $300,000 over 6 years waging their resistance against the line.

2.5 Windmill Advocates

There is another type of advocacy for transmission line construction that is not considered a front for industry, but is supported by those otherwise opposed to new electricity generation and transmission. This is advocacy for facilities to transmit electricity from windmills and other renewable or "green" sources, particularly if these facilities are owned by farmers, ranchers, communities, and small businesses rather than large utilities. Wind/alternative energy advocates in the United States and Europe have long complained that transmission facilities are not adequate to incorporate electricity from these alternatives into the grid. In Minnesota, North Dakota, and South Dakota, states with considerable wind resources, some of the same people and groups who have opposed transmission lines from conventional generation facilities have supported the expansion of transmission and generation when these include electricity from wind turbines. In January 2003, Minnesota regulators approved a proposal by Xcel Energy to build high-voltage transmission facilities in southwestern Minnesota under conditions that require it to speed up its purchase of wind-generated energy by several years. The routes for the line remained to be permitted. Michael Noble, who directs an organization promoting sustainable energy, Minnesotans for an Energy-Efficient Economy, says that unlike power lines from conventional sources, which are controversial, this power line system will be supported by environmentalists and local communities benefiting from the generation and sale of wind energy. One strong supporter is George Crocker, who helped lead urban allies of west-central Minnesota farmers in their l970s fight against the CU line and helped lead people in Minnesota and Wisconsin in resisting the Chisago and Arrowhead-Weston lines in the 1990s and early 2000s. Crocker says these activities are consistent because all help farmers and other ordinary people to make a living and persuade industry to improve environmental quality.

In summary, opposition is the most significant and observable public response to the siting of electricity transmission lines and opposition combines with siting approval processes and financial and regulatory uncertainties to block or delay the construction of new transmission systems.

3. HOW DO TRANSMISSION LINE OPPONENTS ORGANIZE?

The siting of a transmission line is usually opposed by many groups, some organized specifically and locally, others participating as allies advocating related causes. Groups are composed of many

persons and leaders who vary in their commitment and persistence. They oppose transmission lines for many reasons and interact in multi-issued communication networks. They act as interest or pressure groups to influence political decisions more than they act as a movement to change society and culture, but they have the potential to promote such change.

3.1 Participation in Groups: Cadres and Peripherals

Some people oppose transmission facility siting as individuals, but most do so as participants in groups. Over time, the organization of opposition is often composed of many groups of varying types that interact in networks. Key groups are those organized among neighbors to resist the line and its impacts in their locality. These local groups may cooperate through umbrella organizations to contest the line over its whole length and in state or other centralized hearings or litigation.

Participants in the groups organized to fight the line vary in their depth of commitment and the time and effort that they devote to the fight. The result is that a local struggle against a transmission system is usually waged by a few core activists and a larger number of peripheral participants. Core activists represent the group consistently in public hearings and media interviews and constitute its cadre. They organize and direct the campaigns through which peripheral participants raise money, sign petitions, send letters, lobby officials, participate in hearings, demonstrate, and monitor surveying and building. Core activists also manage group newsletters and Web sites. The numbers of people participating peripherally oscillate widely. Hundreds come out for some events, notably important public hearings, but retire when their campaign seems either to have succeeded, for example, in forcing a rerouting of the line, or to have failed. However, hundreds again appear when they learn about new threats. Furthermore, some people on the periphery become more committed and join the core, even leading it when others tire.

3.2 Groups Divide and New Groups Form

People oppose transmission systems for many reasons or concerns and core groups may try to embrace the widest array of these. However, when people feel their concern is ignored, they may form a new group to express it. Also, people form new groups when they differ over tactics or use a different attorney. Furthermore, people tend to form groups in each of the many localities potentially impacted by a transmission project and as routes are decided or changed, those who escape impact often drop out and those who are newly impacted launch their defense.

3.3 Groups Organize a Division of Labor

Core activists usually organize a division of labor, allocating roles according to the capabilities and experiences of their participants. Often they also organize a weak hierarchy using the institutional models familiar to them. Someone becomes chair or president, another becomes secretary, and another becomes treasurer. Furthermore, core activists also name their group, commonly in words that describe their concerns and whose initials form a colorful acronym. Groups establish officers and organizational names in part to facilitate their participation in official public hearings and litigation, to raise and account for money, and sometimes to give their participants the legal protection of incorporation.

3.4 Many Groups with Diverse Issues Collaborate in Networks

Groups organized specifically to fight the line are often joined in resistance by representatives of groups already established to advocate other causes deemed related, such as environmental protection, environmental justice, native rights, or green energy. Also, representatives of established civic and commercial associations and local governments sometimes support opposition efforts. These various parties exchange information about transmission and companion issues with persons and groups across nations and the world sharing these concerns. The Internet facilitates this communication. A group's Web site details its resistance efforts and also links to Web sites of other groups that oppose transmission and generation facilities, promote alternative energy, or warn about the effects of electric and magnetic fields on health.

The groups organized locally and voluntarily to oppose a transmission line project are often criticized as having but a single issue, stopping a line, but over time some group participants work on many issues related to the generation, transmission, and use of electricity and the impacts of electricity technology on health and welfare. Opponents embrace many

issues because they find that the best way to oppose a specific energy project is to propose alternatives to it and to debate energy policy and the culture of energy use. Another reason people expand issues is that during their campaigns against the line, they collaborated with other groups concerned with these other matters. For instance, people organized to oppose the Arrowhead-Weston transmission line in Minnesota and Wisconsin allied with an environmental justice group, Just Energy, and the Split Lake Cree First Nation in Manitoba, Canada, to protest the impact on the Cree of the hydroelectric dams likely to transmit electricity over the lines. Thus, the line protesters expand their issues to include environmental justice and native rights.

3.5 Pressure Groups or a Social Movement?

Environmental justice and native rights activism, like environmentalism, are generally understood to be social movements. In contrast, transmission opposition groups are not referred to as movements, but rather as interest groups or pressure groups, terms that refer to their efforts to influence specific, local political decisions. A movement can usefully be defined as a group of people who are organized for, ideologically motivated by, and committed to a purpose that implements some form of personal and/or social and cultural change, who are actively engaged in the recruitment of others, and whose influence is growing in opposition to the established order within which it originated or which has controlled it. Transmission line opponents become more like a movement to the extent that they not only try to influence decisions about the siting of a specific line, but try to change energy policy and the culture of energy use among their fellows and elsewhere. They become more like a movement when they recruit ever more people to participate with them in promoting these changes and when their local groups interact with others holding similar ideas across the world. This potential is not yet realized.

Transmission line opponents are sometimes labeled environmentalists, participants in the environmental movement. However, protecting the environment is only one of the reasons people give for opposing transmission lines. As noted below, line opponents often complain that their farm or community is sacrificed to a transmission route because environmentalists and environmental protection legislation have exempted parks, forests, wetlands, or even scenic highway corridors from inclusion in the route.

3.6 Example of Organization and Constituency

Rural England Versus Overhead Transmission Lines (Revolt) provides an example of organization and constituency. Revolt has been led by a small core group since its founding in 1991 to oppose a 400 kV transmission system proposed to be sited in North Yorkshire, United Kingdom, by the National Grid. The Revolt chair, M. J. O'Carroll, writes that the core has worked especially with approximately 1000 households and 100 landowners and with them has obtained 8000 written formal objections and two petitions of 12,000 and 14,000 signatures opposing the proposals. Revolt describes its participants as a widespread mixture of people, urban and rural, living inside and outside the region affected by the line, as well as overseas. They range in income from affluent, to middle income, to poor; some are large rural landowners, some live in small towns and suburbs, and some are residents of government housing. Revolt has also been joined by local government authorities of main and minor parties. Its participants oppose the lines for many reasons. Some from urban Middlesbrough support the campaign because they value the surrounding countryside for recreation; others have different reasons. In the countryside, landowners and other residents worry that the lines will lower their property values, but some residents of a prosperous suburb of Middlesbrough favor the new transmission system because it will be followed by - the removal of an older 275 kV line from their neighborhood.

Even though the line was approved and energized by 2003, a few Revolt leaders continue to communicate ideas about transmission lines and other electricity and energy issues through their Web site. The site is linked to the sites of transmission line opponents around the world. Revolt has been an important node in the network of electricity transmission line opposition and contributes ideas about change, which inform a movement.

4. WHAT REASONS DO PEOPLE GIVE FOR THEIR OPPOSITION TO TRANSMISSION LINES?

People express many reasons for opposing transmission lines. What are these reasons and how do utilities and their consultants interpret these?

4.1 Understandable Feelings?

The director of transmission and distribution operations for the Tampa Electric Company (TECO) tells reporters for the August 18, 2003 *Tampa Tribune* "I understand how people feel. No one would want a (power line) pole in their back yard." TECO officials say that they had to build the line and its 125 ft tall, 3 ft wide concrete poles through Egypt Lake because the neighborhood grew up around their substation and right of way. They affirm that they strive to be a good corporate citizen (by lessening the impacts of facility construction), but have an obligation to provide economical and reliable power. Described by the article as "repentant," the officials say they are open to discussing how they can make the process of siting facilities work better.

4.2 Not in My Backyard?

One of the ways electricity utilities try to improve process and public relations is by having consultants explain why and how people oppose their projects. One such consultant, Anne Gunning, writes in a 2001 Edison Electric Institute pamphlet that whereas many project opponents may resist simply because they are opposed to anything in their backyard, increasingly people identify "real reasons" for their opposition. Gunning lists the popular acronyms that are used (by critics to explain resistance to their projects) and suggests that these acronyms and reasons have evolved. In the 1970s, there was NIMBY. In the 1980s, there was BANANA. In the 1990s, there was LULU (Locally Undesirable Land Use), NOPE, and CAVE (Citizen's against Virtually Everything). In the 2000s, there is TARR (There Are Real Reasons). TARR, according to Gunning, is something new and important, which utilities must recognize. Dismissing opposition as NIMBY will not advance a project, she says. People believe that science, law, or some other "real" proof is on their side, even though they also often agree that new energy infrastructure is needed. Gunning writes that the concerns can be about money, environment, health, or quality of life. Although she advises utilities to recognize this, she also states that the people holding these concerns "will not change their minds based on evidence." Furthermore, her presumption that it took people until the 2000s to base their opposition on real reasons rather than selfishness or obstructionism is incorrect. People have argued real reasons throughout the history of opposition and certainly since the l970s.

4.3 Many Reasons Summarized

People express their many reasons for opposing transmission line siting in many forums. In three of these, Web sites, public siting hearings, and agreements between utilities and publics, they summarize their reasons.

4.3.1 Save Our Unique Lands

Save Our Unique Lands (SOUL) was formed in 1999 to oppose a 345 kV transmission line, 250 miles long, from the Arrowhead substation in Duluth, Minnesota, to Wasau, Wisconsin. The line is proposed by Allete (formerly Minnesota Power) and Wisconsin Public Service. These utilities named the project "Power Up Wisconsin," reflecting their claim that this will ease a power shortage in Wisconsin and improve the reliability of the transmission system. SOUL opposes the line for many reasons, synthesizing these on its home page. Combining reasons of voltage, length, appearance, need, and fairness, SOUL refers to this as " a giant 345,000 volt 'bulk transfer' electric and fiber-optics line, proposed by two private for profit utilities, to slice a 250 mile permanent scar across the face of beautiful northern Wisconsin." Adding concerns about environmental justice, equity, and property rights, it calls the line a huge "extension cord," planned to cross the Ceded Territory of the Chippewa in order to transfer massive electric sales to points south and east and on through Chicago. It warns that the project's "great negative impacts of health risks, property devaluation and ruination of the 'north woods' would be carried on the backs of the 11,500 private property owners and the tribes, as the companies use eminent domain to 'take' private lands." There is "blood on the lines," because the electricity sold on the lines comes from "two devastating sources." One is coal plants in North Dakota, whose emissions add to global warming and deposit mercury in the northern lakes, contaminating fish consumed by women and children. Another source is the hydroelectric dams of Manitoba Hydro, "mega-dams," which have flooded an area the size of Minnesota belonging to the Cree. According to SOUL, traditional Cree communities have experienced "inhuman suffering" because of this. And, according to SOUL, the power carried by the lines is not needed "to keep the lights on" in Wisconsin," but instead is to be used to power cities elsewhere as well as proposed copper–nickel–iron mining in northern Wisconsin, mining that SOUL and its allies also oppose.

The line siting authority, the Wisconsin Public Utilities Commission (WPUC), did not determine that SOUL's reasons were sufficient to stop the line project, but instead found that the line was needed and approved a specific route for it by October 2001. But in November 2002, the American Transmission Company, a transmission-only firm, which will build and operate the line, filed a petition to reopen the case because its new estimated cost for the project was $420 million rather than the approved cost (of $165 million). The WPUC will go to new hearings and opponents have this cost increase as a new reason to object.

4.3.2 Revolt

In the United Kingdom, the group Revolt (it does not capitalize its acronym) also effectively summarizes on its Web site some of its main reasons for opposing the National Grid's proposed 400 kV transmission line in North Yorkshire:

1. It is not needed for public electricity supply, only for profit (for the electricity industry).
2. It will ruin large areas of treasured countryside.
3. It will ruin some families by massively devaluing their homes, without compensation.
4. It will promote uneconomic bulk transport of power from north to south, wasting valuable energy in generation and transmission, and cause environmental damage.
5. This conflicts with new government energy policy favoring efficient local generation combining cooling and heating.
6. It will cost consumers dearly, in capital to build and in revenue for increasing operating costs both for the line and for knock-on grid developments throughout England.
7. The great majority of landowners refused to grant wayleaves (rights of way), despite outrageous inducements.
8. There is overwhelming public and all-party local government opposition.
9. People fear possible health risks from electromagnetic fields, which new evidence is reinforcing.

4.3.3 Hearing Testimony Opposing AEP 765 kV

In 1998 and 1999, public hearings were held in localities in Virginia impacted by two possible routes for a 765 kV line and related facilities proposed by a subsidiary of AEP. In his October 2000 report of the hearings, the hearing examiner describes the witnesses, noting that over 500 witnesses testified. Some of these witnesses were members of a number of groups organized expressly to oppose the line in various localities. Some were members of local governments along the routes. Others represented established civic organizations, such as historic preservation committees. The examiner writes that the overwhelming majority of the public witnesses were opposed to any kind of transmission line in southwestern Virginia and he summarizes their reasons as follows: The line is viewed as a symbol of corporate greed at the expense of the cultural attachment of the people to their land and the scenic beauty of the region. The land is mostly pastoral—rolling fields and hills with mountain backdrops, and cattle and sheep farms with streams running through them. The line is described as a means of transporting electricity generated in the Midwest to sell in the Northeast, enriching corporate buccaneers and their stockholders. Risks to health and environment include contamination of ground and surface water from herbicides sprayed to keep rights-of-way cleared of vegetation, increased cancer caused by electromagnetic fields (EMF) radiating from the line, increased air and water pollution from the coal-fired generating plants providing power to be transported on the line, and noise from the line. Building the lines and towers will threaten caves and sensitive rock formations and old growth forests. Demand-side management and local generation provide alternatives to the line. The routes being considered are unfair in that they skirt National Forest land at the expense of the homes and land of ordinary people and in some places at the expense of poor people. The project will harm tourism and its benefits to local economy. Additional reasons were also given.

4.3.4 Agreement between Hydro-Quebec and Farmers in Canada

A summary of many of the impacts that transmission systems have on agriculture is found in the December 2000 statement of agreement between the Quebec farmers' association [Union des producteurs agricoles (UPA)] and the giant utility, Hydro-Quebec, in Canada. Hydro-Quebec explains that it is a government corporation that provides electricity primarily through hydroelectric plants often located more than 500 km from consumers. To reach consumers, it has constructed a vast power transmission system and its transmission lines run from east to west across many farms and woodlands. Hydro-Quebec and UPA agree that constructing such lines can have the following temporary and permanent impacts:

Temporary impacts during construction include:

- Impacts associated with the staking of rights-of-way;
- Reduced crop yields due to soil compaction;
- Alternation of underground or surface drainage systems;
- Alteration of irrigation systems;
- Damage to ditches;
- Broken fences, which can hinder livestock control;
- Noise produced by construction machinery, which can affect poultry and fur-bearing animals;
- Disruption of crop operations;
- Loss of time (during negotiations, for example);
- Loss of revenue (cash flow) while awaiting compensation;
- Impacts on areas or elements located outside the right-of-way, such as damage to farm roads, debris from tree felling, ruts and soil compaction, damaged trees, waste materials; and
- Construction debris and other waste materials.

Permanent impacts include:

- Loss of farmland or woodland;
- Loss of revenue, which could compromise the operation's profitability;
- Loss of time (e.g., time spent in negotiations or driving around the structure);
- Risk of farm machinery running into the structures;
- Creation of enclaves;
- Usage restrictions and other limitations associated with easements;
- Alteration of irrigation systems;
- Changes to crop operations;
- Impossibility or increased danger of using airplanes in agriculture.

The document also mentions that studies are being conducted to identify and analyze the biological impacts of electromagnetic fields on human and animal health.

4.4 Rules, Process, and Influence Are Also Reasons for Opposition

The impacts identified in Quebec are like those expressed by farmers in west-central Minnesota in the l970s about the CU $\pm$400 kV DC line. The Minnesotans, however, complained that their concerns about these impacts were not heeded by the utilities, the siting officials, or the environmental and transportation agencies. Like some in southwestern Virginia, the Minnesota line protesters complained that these agencies were constrained by environmental protection legislation to be more concerned about protecting parks, forests, wetlands, and highway corridors from power lines than protecting farmland. In other words, it was not only the decisions about the line that were wrong, it was also the process of making the decisions that was wrong. This is a common complaint in transmission line cases. Often opponents of transmission siting decisions also complain that even though they have presented many good reasons why a transmission project should be denied or fundamentally changed, ultimately the project is approved, perhaps with minor modifications. Government siting authorities say that they do heed the concerns of opponents. But they face a dilemma. On the one hand, people show that they want and need more electricity at an affordable cost. On the other hand, people do not want to be impacted by the facilities required to provide this electricity. They must reconcile the diverse interests and also manage the conflicts among these interests. Facility opponents may recognize the dilemma, but also suspect that the siting process favors energy companies, with their vast financial and political resources, and favors growth in electricity supply, since this accompanies desired economic growth.

In short, people present many reasons for opposing transmission lines. Some reasons concern the rules and processes used to make the decisions and many reasons concern the characteristics of the line, the need for it, and its impacts on environment but especially on human health and welfare. In the next section, this article explains in more detail how people argue against the line with respect to its need, its size, and the structure of the utility industry; its appearance and threat to their sense of well-being; and its threat to their health and safety.

5. NEED: THE FIRST DEFENSE AGAINST TRANSMISSION LINE SITING

Opponents of transmission lines quickly learn that the first defense against the line project is to declare that is not needed. If it is not needed to serve the public interest, then there is no reason for government to allow the electricity utility or transmission company to march the line over private property or community resources, using the power of eminent domain, and impacting environment, health, and welfare. Such logic is institutionalized in government

siting regulations. In the United States, state siting authorities decide whether an electricity-generating plant or transmission line is needed before, or as, they decide where to place the facility and whether the impacts on environment and people are acceptable or can be made so. The authorities usually decide this and award "certificates of need" and "environmental compatibility" through siting processes at the state and local levels. Processes usually include public participation, such as meetings in which the public is informed about the project and hearings in which the public critiques it. States vary in the structures and procedures that they use to make decisions about need and route, with some using one agency and others using multiple bodies.

5.1 Need Is Public

Need is defined as public. That is, siting authorities must determine that the facility serves the public interest rather than the interest of the utility. In the United States, it is has been the states that approve and regulate facilities within their borders and the people whose interests that must be satisfied by a decision by state authorities are the residents of this state. Opponents often talk about this when they ask questions about transmission systems that cross state lines. In Connecticut, for example, opponents of a projected transmission system that they suspect to be for the electricity supply of New York reminded their siting council at a 2002 hearing that "the state legislature has given the council jurisdiction to objectively balance the statewide public need for adequate and reliable services at the lowest reasonable cost to consumers with the need to protect the environment and ecology of the state for the construction and operation of facilities under its jurisdiction."

The utilities applying for a facility will also argue the public interest, claiming that they have the state-mandated requirement to meet the demand for electricity and that this demand is demonstrated by the evidence of public use. The president and chief operating officer of the Wisconsin utility proposing the Minnesota–Wisconsin Arrowhead-Weston line explains (in an EEI brochure about facility siting) that "customers expect electricity to be there when it's needed, so we have to make sure the delivery system can fulfill their expectation." How is expectation measured? Regulations tell the WPUC that the proposed facilities are to satisfy the *reasonable* needs of the public for an *adequate* supply of electricity (author's italics). Permitting agencies also often require that the applicant demonstrate that demand cannot be met more cost-effectively through other measures, such as more local generation, instead of long-distance transmission, or energy conservation and load management. Utilities, especially their economic and technical specialists, present detailed statistics and forecasts to argue their case before the permitting agency.

However, the utilities must also communicate need to the public, including those opposing or considering opposing the line. This public, particularly the opponents, will not only respond to claims of the utility, it will offer counterarguments, including counter-statistics to refute projections of use and counter-concepts about expectations and the meaning of reasonable and adequate. It was partly public opposition to electricity facilities and critique of need beginning in the l970s that led legislators in Minnesota to require that utilities in the 2000s show that their calculations of need include consideration of conservation and other alternatives to a proposed facility.

5.2 Need Is Argued Objectively and Subjectively and on Three Fronts

Need is argued using numbers. Numbers, statistics, graphs, calculations, and projections seem central to debates about need. The Connecticut Siting Council, for instance, puts public need and benefit at the top of its list of factors, which can be objectively presented and argued. However, need is also argued subjectively. For instance, the meaning of reasonable and adequate is open to debate, much as is the difference between needs and wants. Power line opponents certainly are willing to debate these and other questions about need to further their efforts to stop the line. Opponents challenge project need because this is a major defense and because they can find much about need to challenge even though proponents present need as manifest and can interpret opposition as "NIMBY" selfishness. There are three ways in which people contest the need for a project. One is by contesting projections of local electricity demand and calculations of supply, arguing instead that the electricity will be exported for a profit. Another is by claiming that energy demand can be met with alternative technologies or reduced through conservation. People also reject the rule that once a certificate of need is granted, need can no longer be contested.

5.2.1 Contesting Supply, Demand, and Fairness

Opponents contest the calculations that the utilities and government regulators use to argue that

electricity demand is increasing and must be met with new supply. Opposition groups often include people with the knowledge and skills to do this well. At a mid-l970s public meeting in Minnesota on the CU proposal for a ±400 kV DC line, one of the proposal opponents, a farmer with a doctorate in physics and previous employment in the aerospace industry, critiqued CU's extrapolations from the electricity consumption curves in west-central Minnesota. Speaking for the county group No Power Line, he argued that the curves showed a leveling of demand during the early 1970s so that power line construction could be postponed until the mid-1980s, when the technology of superconductivity would be advanced enough to put the line underground.

In 2002 hearings before the Connecticut Siting Council, Woodland Coalition opponents of the CL&P proposals to construct a 345 kV transmission system in southwestern Connecticut also contested the utility's projections. One said in written testimony: "If the definition of need is to be defined by the anticipated power consumption of southwest Connecticut, further supported by CL&P's own calculations of power consumption growth over the past 20 years, then I assert to this council that CL&P has fallen woefully short of proving its need for the amount of capacity expansion that it seeks." This critic goes on to argue that there is no need for an eightfold increase in generation capacity unless the council has expanded its definition of need to include connection to a regional and national power grid. It is this issue of transmission of electricity across jurisdictions that informs the most powerful challenge of need and its determination, namely, that the need being served is someone else's.

The Woodlands Coalition line opponents complain that the utilities will use the new facilities to sell electricity to Long Island and New York. Connecticut people have paid or will pay for the generating and transmitting facilities and will suffer the impacts of these on their environment, health, and quality of life. Long Islanders have not done their fair share of building energy facilities. One of the Connecticut line opponents used his expertise as a financial analyst to argue that the utilities want to build the transmission not to meet local need but to make a profit. He finds this particularly true of the unregulated energy trading company component of Northeast Utilities, the firm that will build and operate the transmission systems. He says that it is as wrong to give an unregulated and for-profit utility the rights of Eminent Domain as it would be to grant this right to Wal-Mart.

Similarly, opponents of other interstate transmission projects contest need on the grounds that these projects serve the financial interests of utilities. To this, they also add charges of unfairness. The utilities will provide electricity to those who did not pay for the facilities and, in addition, by exporting electricity, local prices will increase. Although utilities customarily argue that there is a need for more transmission, some, as noted for Basin Electric, also say that deregulation has made it unclear whether those firms and customers who pay for transmission benefit fairly from it.

In the l970s, well before deregulation, the west-central Minnesota farmers and rural townspeople opposing the ±CU line also complained that the line was not needed locally but instead was being used to power "the Cities," of Minneapolis and St. Paul. Sometimes these rural Minnesotan's pictured the people of the Cities, especially the suburbs, as using electricity wastefully, but they also recognized that many of these people were their relatives and tried to enlist their aid in fighting big industry and distant government. This theme of energy flowing away, to cities, is a continuing one, expressed in 2000, for instance, in the portrayal of the Arrowhead-Weston Line as a giant extension cord to Chicago. Even without deregulation, utilities and siting agencies would have difficulty persuading people that transmission through their communities served their local needs.

One main response of the utilities to such problems is to argue that transmission across states does meet local needs by contributing to overall system reliability. A number of Edison Electric Institute publications during the l990s make this argument. But it is an argument that is as likely to be as resisted as are other arguments for facility need, especially if the utility industry is increasingly put on a free market basis. James Creighton, a consultant on public participation for electricity utilities, wonders what will happen if state regulatory bodies say that it is unnecessary to issue a certificate of need for transmission lines because the market can decide need. This will reduce regulatory costs and may seem to speed up decision-making, something that some political leaders advocate. However, Creighton warns, the public is not accustomed to letting the market decide transmission need. It will challenge need and either the state will return to the issue or a plethora of local government entities will act to manage these challenges. The alternative to this is that the federal government, perhaps through the FERC, will act to determine need anywhere in the

country and perhaps also to make other transmission facility siting decisions. This has been advocated by some. But, as has been noted, state authorities resist this federalization because it threatens their traditional rights and they know it would be resisted by the public. Transmission line siting processes could become not only a battleground for making decisions about the need for and siting of electricity facilities but about state's rights.

5.2.2 Conservation and Alternatives

Another argument against the need for a new facility is that energy demand can be met with alternative technologies or reduced through conservation.

In the l970s CU ±400 kV DC case in Minnesota, line opponents pointed to technologies such as underground lines using superconductivity; wireless broadcasting of electricity using the ideas of Nikolai Tesla; and local generation using windmills, biomass, photovoltaic cells, and low-head hydroelectric dams. The quest for alternatives encouraged the power line opponents to ally with advocates of "soft," renewable energy sources.

Opponents of the generation and transmission of electricity through conventional technologies continue in the early 2000s to call for alternatives and to work with proponents of the latter. Sometimes the demand for alternatives seems initially a device to contest the need for a conventional overhead transmission line and legitimate resistance to it. However, advocates for alternatives have used the threat of public opposition to conventional facilities to induce utilities to include increasing amounts of wind and conservation in their energy mix. Mention has been made of the way that wind advocates work with utilities in the United States to support the need for more transmission lines if these also carry electricity from wind turbines owned and operated by farmers, ranchers, and rural communities. Efforts are also well under way in the United Kingdom and Europe to advance the use of wind resources by developing better ways to transmit electricity from these sources. However, in the United Kingdom, leaders of the group opposing the 400 kV line in North Yorkshire write that because wind resources are intermittent, incorporating electricity from them into a reliable grid is not efficient. Utilities must build too much infrastructure to do this, including more transmission lines. This argument is consistent with Revolt's criticism that large-scale transmission systems with remote power generation are inefficient. They lose vast amounts of energy transmitting over long distances. The need for new lines can be diminished by reducing this inefficiency and improving the efficiency of energy use. Energy supply can be improved by using new technologies that combine energy functions. Wind should be used to make a locally storable form of energy, such as hydrogen by electrolysis of water.

5.2.3 Contesting Rules about When Need Is Argued

In addition to contesting the need for a facility, its opponents also often argue that because of procedural rules they are unable to debate need at appropriate times. On the one hand, people criticize efforts to site facilities before need is demonstrated. The case of the CU ±400 kV DC line in 1970s Minnesota illustrates this. Because new state legislation governing energy facility siting had not yet fully taken effect, the siting authorities held hearings on where to route the line before they could hold hearings to determine the need for it. Those opposing the line argued that this made the hearings not legitimate and continually tried to question need during the routing hearings.

However, even though need is usually determined before debates about routes and impacts take place, opponents often never agree that there is this need or that they had adequate opportunity to argue against it. For one, fewer people come to the hearings to decide need than to those to decide a specific route. People are notified that they might be affected by a facility to meet such need because they are in a corridor from which a route could be selected. However, most do not come to hearings on need, apparently because they are busy, the corridor is wide, the threat of a route over them is distant, and the subject of need is general. Those few who do attend speak of the problems they have in persuading their neighbors to join them.

On the other hand, the rule that need, once decided, can no longer be at issue does not stop people from arguing against it when they are defending themselves against the actual threat of a line overhead. Furthermore, the rule itself is questioned. In early 2003, the Minnesota Center for Environmental Advocacy (MCEA) praised a change in the rules governing energy facility siting for not allowing approval of the construction of a new power plant or line when a less environmentally damaging alternative exists. MCEA argues, however, that continued useful and fair consideration of the alternatives is jeopardized by the rule. It envisages a situation in which people do not participate in deliberations on need because they do not know that this concerns them. When people find that the

facility may be built next to them, they can no longer raise the question of need and no longer do this by identifying and arguing for alternatives, such as conservation or different technologies. MCEA will likely lobby the legislature to change the rules.

6. "SIZE" OF THE TRANSMISSION SYSTEM AS A REASON

People find reasons and organizational opportunities to oppose transmission systems in what some term the size of the system and others term design and configuration. Size includes the width and height of towers, the length of the line, the voltage carried, and the complexities of the system. People can protest towers and lines of any size as invasive, but they usually find more reasons to protest larger towers and higher voltages. Furthermore, longer lines are more likely to impact more people, increasing the numbers and diversifying the skills of those who start or join local groups. Siting processes usually vary according to the size of the voltage and length of the line, with official opportunities for public participation (and thus opposition) often increasing as voltage and length rise over a certain threshold. States and other political units vary in their rules about size thresholds and in their criteria and procedures for making decisions. Thus, as lines extend across jurisdictional borders, they increase the exposure of line builders to different rules and procedures. Examples of how opposition groups respond to size are presented below.

6.1 High Voltage, Remote Siting, Long Distances

In their 1977 study for the Minnesota Department of Health on the health and safety effects of high-voltage transmission lines, researchers attribute much of the public worry about these effects to the fact that by the l960s and early l970s the electricity utility industry was constructing or proposing transmission systems much higher in voltage and much longer in reach than the public had hitherto experienced. These were 500 and 765 kV AC lines, then designated extra-high-voltage alternating current, and ±400 kV DC lines, designated high-voltage direct current. Physical efficiencies, new technologies, and perceived new needs and opportunities gave utilities incentives to use such systems. Demand for electricity was growing exponentially; however, utilities found it increasingly difficult to build generating plants near the main load (use) centers because of public opposition and regulations to protect air and water quality. One answer was to build power plants in remote locations. One such place was the Great Plains, where there were resources of coal or lignite fuels to be mined, river water for turbine cooling, and air that could suffer some degradation within clean air rules. Another was in Manitoba or Quebec, Canada, where there were rivers to be dammed for hydroelectric generation. New technologies enabled firms to build higher voltage lines from generators to load centers, taking advantage of physical efficiencies. The capacity of a line to carry power varies approximately as the square of its operating voltage. Thus, doubling voltage provides four times the power transfer on the same right-of-way.

6.2 1970s: CU ±400 kV DC

Responding to these conditions, two rural electric cooperatives based in Minnesota, Cooperative Power and United Power, collaborated through the Rural Electric Administration to plan and eventually build a system of generation and transmission that was termed innovative even by critics. The electricity is generated at a 1100 MW Coal Creek station along the Missouri River at Underwood, North Dakota, fueled by lignite coal mined in a giant strip mine next to the station. The alternating current produced by the generator is converted into direct current and transmitted on a ±400 kV DC power line 430 miles eastward to Delano, Minnesota, just west of the Twin Cities of Minneapolis and St. Paul, where it is converted to alternating current for distribution to customers of the cooperatives, organized as CU. CU officials could take pride in this large size, long expanse, high voltage, and complexity. But these characteristics provoked and facilitated opposition.

The opponents criticized the technology and built organization along its likely routes. They said that when CU used the designation ±400 kV DC, they were trying to hide the fact that this meant the voltage between the two pairs of wires of the system is 800,000 V, not 400,000 V. If the voltage difference between one of the pairs of wires and the ground is +400 kV and the voltage difference between the other pair of wires and the ground is −400 kV, the total, they say, is 800 kV. Only one other system in the United States, on the West Coast, has as high a voltage. CU's opponents said that they should not be made guinea pigs for new power line technology.

People organized opposition groups in different localities along the long corridor of the line in Minnesota and also shared information with a group in North Dakota that opposed the strip mine and power plant. These different groups contested the project locally, using particular approaches, but also cooperated. People also attacked the need for and fairness of the line by declaring that its 430 miles ends not in their lands, but in the suburbs of Minneapolis and St. Paul—the Cities. Yes, they need electricity and are willing to bear the impacts for such, but this is electricity for others. Some pictured these suburban and urban others as energy wasters.

6.3 1970s: PASNY 765 kV AC

In another case of remote siting and long-distance transmission in the early 1970s, PASNY proposed a 765 kV AC line to connect PASNY's system with that of the Canadian utility, Hydro-Quebec, rich in power from its dams. In testimony in April 1977 before a New York State Assembly committee reviewing protested siting decisions, a protester recalled that when she and her neighbors in upper New York heard about the proposed line through a series of meetings in 1973, l974, and l975 they were "unconcerned," supposing it would be "another power line like the 230,000 volt line in our area." But when she and others learned that it would be much higher voltage, they worried. Furthermore, when they looked at the long route of the line, they complained that it serves not them, in upper New York state, but New York City.

6.4 1990s and 2000s: A-W 345 kV, AEP 765 kV, CL&P 345 kV

Voltage and length continue to matter in the 1990s and 2000s. People organized as SOUL to fight the A-W 345 kV line in Minnesota and Wisconsin picture it as a giant extension cord for Chicago. Another example is found in the response to the AEP 765 kV line from West Virginia to Virginia. Persons interviewed by the *Roanoke Times* reporters R. Nixon and L. Caliri for their 1997–1998 series on the AEP project worry about the size of the line. The operator of an apple orchard notes that he and his workers already put up with a 138 kV line in the orchard and a 345 kV line nearby. But these are "nothing" compared to the 765 kV line. "Nobody's going to want to work under all that line." A vice president of the National Real Estate Appraisal Institute said that studies in some Florida counties show that high-voltage lines lower values in and near the easement.

In Connecticut in the early 2000s, the Woodlands Coalition opposed three related line-building projects of CL&P. Testifying before the state siting authority, a coalition activist who holds a Ph.D. in physics and heads a technology firm says that a 345 kV line is qualitatively different from 115 kV and lower voltage lines. It can produce a corona discharge, which produces potentially dangerous ionizing radiation, a health risk. The chair of the Norwalk Shellfish Commission testified that a 345,000 V system is used for long-distance transmission across open spaces and would be unsuitable for developed southwestern Connecticut.

6.5 Xcel 115 kV, More Risk from EMF?

Not all transmission line opponents point to high voltage as the problem. In St. Paul, Minnesota, the Power Line Task Force is contesting a proposal by a Xcel Energy to upgrade from a single to a double circuit its 115 kV transmission line running through their neighborhoods. Its Web site explains how 115 kV lines can be as dangerous as high-voltage lines, of 345 kV and above. Overall risks do rise as voltage increases. However, risks from EMF are associated with the amount of current flowing through the line rather than voltage. To deliver a given amount of power, utilities must push more current through low-voltage lines than through high-voltage lines. The magnetic field under a 115 kV line is often greater than that under a 345 kV line. Also, high-voltage lines are customarily built on wider rights-of-way than low-voltage lines so people live closer to them than they do to high-voltage lines. Thus, the site declares, low-voltage transmission lines (up to 69 kV) generally endanger human health more than do high-voltage lines.

In summary, people find reasons and opportunities in the size of transmission systems to oppose their siting.

7. STRUCTURE AND RESTRUCTURING OF THE ELECTRICITY UTILITY INDUSTRY AS REASONS

The structure of the electricity utility industry and changes in this structure provide people with reasons to oppose transmission lines.

7.1 Deregulation

In the United States in the 1970s, protesters argued that the electricity utilities were becoming too large and too vertically integrated. The CU project in North Dakota and Minnesota is an example. With loans and urging from the federal Rural Electric Administration, two large rural electric cooperative associations combined with a coal company to mine and burn coal and to generate, transmit, and distribute electricity. However, in accord with changes in federal and state legislation, the U.S. electricity industry has, since the early 1990s, been changing its structure away from such vertical integration, regulated primarily at the state level, to one shaped by competitive markets. By 2002, 23 states and the District of Columbia had enacted restructuring legislation and most other states were initiating or considering such a change. Utilities are dividing into regulated and nonregulated entities and are separating generation from transmission and transmission from distribution. Firms whose sole function is to build and operate transmission systems are established. Regulation is giving way to competitive markets. Markets enable firms specializing in trading to buy electricity where it is cheapest and sell it anywhere—if they can transmit it. Such transmission requires that transmission systems at the state level be integrated into regional and national grids. This calls for the building of new transmission lines. These are opposed.

In the United Kingdom, the electricity industry says that their country is a model in the development of open energy markets. A privatization process begun in 1990, shaped by the Electricity Act of 1989, has created a competitive market with open access to transmission and distribution networks, particularly in England and Wales. The grid owners (National Grid for transmission and 12 regional distribution companies for distribution) are regulated monopolies, whereas generation and supply are privatized.

Opponents of specific transmission projects find reasons for opposition in these structural features and changes. Examples of these reasons are noted in this article. In essence, people argue that new transmission lines are not needed to serve the interests of those impacted by the transmission and generation project, or the general public, but rather to profit the few who own the transmission, generation, or trading systems. This idea underlies arguments about need, fairness, and environmental justice.

7.2 Expanding Federal Control

Another structural issue that affects opposition is the projected expansion of the role of the federal government in siting and permitting electricity facilities and designing the system of electricity marketing. As argued in the 2002 National Transmission Grid Study for the U.S. DOE, the U.S. transmission system is a national public good that must be modernized by building new facilities. The study does not directly attribute failure to build these to opposition, but instead it focuses on flaws in the approval process that, among other things, fails to obtain public acceptance and fails to overcome the competing interests of local authorities and state and federal agencies, for instance, in land use. It also finds fault in business uncertainties, such as those mentioned by Basin Electric. As a remedy, the DOE expects that the FERC can play a larger role in siting and making rules. One role could be to grant designated entities the right of eminent domain to acquire property for rights-of-way when states do not. There are many who oppose such FERC expansion. The objections of the National Association of Regulatory Commissions have been noted. Also, some groups resisting specific transmission projects object to the expansion of the FERC and to deregulation and seek to influence state and federal legislation accordingly.

8. SENTIMENTS ABOUT VISUAL IMPACTS AND LOSS OF CONTROL AS REASONS

Power line opponents describe the way that transmission lines and towers mar landscapes and even utility executives agree that these facilities are “ugly.” Opponents also feel the lines and towers symbolize their loss of control.

8.1 Visual Impacts in Rural England

On their Web site, Revolt writers warn that the visual impact of 229 pylons—many taller than York Minster or the Statue of Liberty—will be catastrophic. They write that the overhead line will run through countryside of outstanding beauty, skirting a national park and impinging on ancient woodland, historic buildings, and sites of special scientific interest. They include a poem that William Wordsworth wrote in 1802, praising the magnificence of the horizon that the giant pylons will deface.

In interesting contrast, the National Grid Web site, under the title "Overhead or Underground?" includes a 1932 poem by Stephen Spender that likens pylons to whips of anger, to nude, giant girls that have no secret, and to the quick perspective of the future. However, National Grid also asks: "Everything being equal, wouldn't we all prefer electricity cables to be buried out of sight than straddling the countryside on big, ugly pylons?" Since everything is not equal, undergrounding has its own environmental, financial, and operational costs, so that it is usually not a viable option for high-voltage transmission lines. National Grid says that undergrounding may be the best option where overhead lines are not practical, as in densely populated areas. However, National Grid did agree to underground a small segment of the North Yorkshire 400 kV line because officials agreed with opponents that the pylons and line at this segment would jeopardize the views of some especially cherished landscape features of rural and parkland and that thousands of people enjoyed these views. Revolt's chair writes that one reason that Revolt has attracted the participation of many city people not under the line is that they do not want the countryside marred.

Appreciation of rural landscapes is strong in English culture. This motivates groups organized specifically to protect the quality of life and environment in rural England to include in their programs opposition to overhead transmission lines. For instance, the Campaign to Protect Rural England and the Friends of the Lake District and Cumbria have campaigned vigorously over past decades for overhead wires to be undergrounded to preserve the English countryside, especially special landscape areas. They argue that this has become economically feasible.

8.2 Visual Impacts in Minnesota

It is not only in the English countryside that people object to the appearance of transmission lines and towers. In their l970s protest of the CU line, rural Minnesotans sounded somewhat like rural Englanders in decrying the way that the towers and lines would ruin their landscape, a landscape that they appreciated for its open farm fields and rolling hills dotted with lakes and woods. Expressing the sentiments of many, one said, "You see, these wide open spaces are why we're here. If you have these big old monsters, you suddenly have an encroachment on your space. And it would destroy our peace of mind. It would destroy the quality of our life."

8.3 Lines and Towers as Symbols of Invasion and Loss of Control

Such words point to another reason that people oppose transmission lines. They represent the invasion and taking of their land by powerful others. In their 2000 environmental impact assessment for the Arrowhead-Weston line, analysts for the Wisconsin Public Utilities Commission recognize aesthetics and visual impacts as legitimate public concerns. They recognize that the aesthetic effects not only interfere with public enjoyment of landscapes, but also represent an invasion of landowner rights.

Under the category of "social concerns," the analysts note that people may feel that they have lost control of their lives when the towers and line are built on their land. When people learn that the line may expose them involuntarily to electric and magnetic fields and that these fields may pose risks to their health, they may interpret this as a threat to their freedom to choose their risks. The comments of power line opponents agree with these assessments. Landowners can be compensated with money for taking their land, but this may not compensate for the intangible threats to their sense of well-being.

8.4 Political Leverage of Sentiments

Sentiments about the ugliness of transmission lines and loss of power and control are important forces motivating people to oppose transmission projects. Utility officials and government regulators may accord them some legitimacy. However, public participation specialist James Creighton, claims that risks to health and safety are more potent politically than ugliness and invasiveness. He intimates that protesters know this and base their objections on such risks.

The article next examines health concerns, notably those about electric and magnetic fields.

9. HEALTH, SAFETY, AND ELECTRIC AND MAGNETIC FIELDS AS REASONS

Opponents of overhead transmission lines often claim that these lines and supporting facilities put their health and safety at risk. Of the health risks, those of exposure to EMF have become the most argued, controversial, and politically significant. Electricity utilities and health departments define

EMF as invisible lines of force that surround any electrical device, such as a power line, electrical wiring, or an appliance. Electric fields are produced by voltage and easily shielded by objects. Magnetic fields are produced by current and these fields pass through most materials. Both fields weaken with increasing distance from the source. EMF has become an issue in transmission line siting because findings from research beginning in the early 1970s have suggested that magnetic fields may be associated with increased risks of cancer and perhaps other health problems. Opponents of transmission lines have learned about this, spread word about it across their networks, argued it in siting hearings, and helped to make the effects of EMF an issue in science and energy policy.

9.1 EMF Concerns in 1970s in Minnesota and New York

This story begins in the mid-1970s in Minnesota, where people opposed the proposed ± 400 kV DC line of CU. As part of their effort, these opponents identified others who were opposing transmission lines elsewhere and they also gathered information about transmission systems and their impacts. Several individuals in the group No Power Lines (NPL) read papers on long-term exposure to low-level electric and magnetic fields by Andrew Marino, a biophysicist and attorney, and R. Becker, a medical doctor, and an English translation of a paper in Russian that mentioned Soviet studies on railroad workers exposed to fields from a 500 kV substation. The Marino and Becker papers reported that rats exposed to the fields suffer adverse health effects. The Soviet studies suggested adverse effects on humans.

In 1975, NPL participated in public hearings held by the Minnesota Environmental Quality Council (EQC) to make decisions about the CU proposal. NPL introduced as evidence correspondence from Marino and the Soviet paper. EQC officials and the CU lawyer discounted the latter because it referred to a study not in evidence, a translation, and not the original paper of the original study. The EQC gave more weight to the analysis by an expert witness for CU, which found no significant biological effects from exposure to electric and magnetic fields. NPL participants were angered by this decision and by the way their evidence was dismissed and their abilities demeaned.

NPL and other groups continued their fight sufficiently to keep the EMF and other health and safety issues alive even after EQC issued a construction permit for the CU line. In September 1976, the groups, organized as a regional coalition, petitioned the EQC to "modify, revoke, or suspend" the permit on the grounds that the line "would be dangerous to the public health and the environment." They cited the direct testimony of Marino and Becker before the New York Public Service Commission, which, responding to its own power line protest, was conducting major hearings on the health and safety effects of two 765 kV transmission lines in New York State. The EQC Board denied this petition from CURE. However, the Board told the Minnesota Department of Health (MDOH) to conduct its own study of effects. Protesters said findings would arrive too late to stop the project. The MDOH study, a survey of the literature, was reported in October 1977, after construction was under way. Its authors concluded that adverse biological effects had not been demonstrated to exist either empirically or in the laboratory nor had they been explained by a reasonable hypothesis. They also declared it a logical impossibility to state conclusively that there are no such effects.

A main source of information for the MDOH researchers was the Common Record Hearings of the Public Service Commission (PSC) of New York State. In 1975–1976, PSC conducted an exhaustive inquiry through testimony and cross-examination of 26 scientists and engineers into the health and safety effects of two proposed 765 kV AC transmission lines in New York. One would connect the system of PASNY with that of Hydro-Quebec. Strong resistance to this line did much to persuade the PSC to conduct this inquiry.

At the hearings and in subsequent rebuttals of the PSC findings, Marino and Becker testified that biological effects might occur from exposure to high-voltage transmission line electric and magnetic fields and recommended that the 765 kV lines as designed not be built. However, PASNY presented four specialists in medicine, radiation biology, and biophysics who testified to the contrary. The PSC Board decided to authorize the line. However, it reserved the right later to require protective measures to protect the public health and safety from exposure to fields, including a wider right-of-way than proposed and reasonable restrictions on operating voltage and loading. In contrast to its Board, the PSC staff found that "the 765 kV line will probably cause biological effects in humans exposed to them on a chronic basis." It recommended relocation of residences and more research. The PSC decision was

challenged and testimony rebutted. It was not until January 1977 that the hearing was closed. Construction began but resistance continued, sometimes through militant demonstrations in the fields. These decisions and events were reported in the media and Minnesota opponents of the CU line learned about them through their New York contacts.

The Minnesota opponents continued to resist the line for 4 years after the EQC granted the construction permit in 1976. They held mass rallies at construction sites and the state capital. They picketed and harassed surveyors and workers, threatening some with violence. They confronted local sheriffs and then state police. Someone shot through the windshield of a security guard's pickup truck. Over 120 opponents were arrested but the charges against most were dropped and only 4 were convicted. As the line was constructed and tested in 1978 and 1979, some opponents shot out thousands of insulators and, over many months, some toppled 14 towers by removing bolts. The opponents called this sabotage, likening it to resistance against an invader and claiming that it was necessary to protect them from the intolerable effects of the line on their health. These effects, they declared in letters to their legislators, the governor, and the state energy agency, included headaches, skin rashes, nosebleeds, respiratory problems, dizziness, and fatigue. In addition, some reported that their livestock were aborting fetuses and producing less milk. Officials held hearings at which people told of these effects. A Department of Health researcher referred to studies by University of California (Berkeley) researchers to raise the possibility that the effects were caused by a concentration of positive ions in the air in the vicinity of a $\pm$400 kV DC line. These might cause a secretion of serotonin, a neural hormone that can produce the symptoms mentioned by the farmers. Power line opponents and officials then argued over how best to investigate these health effects and make decisions about the future of the line. The opponents said that if the line were allowed to continue operating while its effects on their health were being studied, they would be human guinea pigs. Officials did not agree to stop operation, but they did survey residents along the line about their interpretations of health effects and they did hire the Berkeley researchers to prepare updated reports about transmission line effects. Meanwhile, CU and state officials asked the federal government to help them by federalizing the line under the Rural Electric Administration and to make attacks on it a federal offense, subject to FBI investigation. No one was arrested or charged for toppling the towers. By 1981, the line was completed and overt resistance had ended; the $\pm$400 kV DC system has been operating since then and, CU says, serving Minnesotans well. The new health effects studies were inconclusive, proving neither that people suffered adverse effects under the line nor that they did not. By the early 2000s, the debate about these effects had diminished in Minnesota, although some former opponents continue to say that the effects are real.

9.2 EMF Concerns in Ontario, Canada, 1984–2000

In Canada, residents of Bridlewood, Kanata, Ontario, outside Ottawa, began opposing proposals by the electricity utility, Ontario Hydro, to site two 500 kV lines through their neighborhood in 1984, approximately 2 years before they learned about the health effects of electromagnetic radiation and referred to these in lobbying against the line. According to their Web-published "History of the Bridlewood Hydro Line Struggle," these power line opponents learned about EMF risks by reading a 1986 article on the health effects of electromagnetic radiation in the *Ottawa Citizen*. This news, as well as the failure of efforts to stop the line through local government proceedings, led them to mobilize against the line as the Bridlewood Residents Hydro Line Committee (BRHLC). This group tried to stop the line by communicating information about its costs and risks, lobbying Ontario government, and suing in the courts. They also picketed a visit of the Premier and blockaded Ontario Hydro construction vehicles. However, the lines were approved and built. Yet, BRHLC leaders say that they did have some victories—notably, the raised awareness of the EMF health and safety issue, locally, nationally, and internationally. They talked about the issue on national television news programs and spread word about it through handouts and, later, the Internet.

Two registered nurses in the group researched health effects through libraries. Two electric engineers in the group worked with Ontario Hydro technical officials to gather and assess information. Others established a community information network through Internet sites using the new National Freenet. There, people and groups exchanged information about transmission line issues, particularly about EMF. Eventually this was institutionalized in a Web site as the Bridlewood Electromagnetic Fields Information service. The service includes an

extensive bibliography on electromagnetic fields and health. Its hundreds of references include reports in major science journals and utility industry publications of research findings about the characteristics and effects of EMF and popular articles warning about the risks of exposure to EMF.

9.3 EMF Issues on the Internet

Although the BRHLC lost its fight against Ontario Hydro, a few participants continued to maintain the information service site and the bibliography. When the original administrator of the site resigned in February 2000, others maintained it. BRHLC also founded an open, unmoderated mailing list on Yahoo for the discussion of electromagnetic radiation. Participants around the world tell about the health effects of EMF from transmission lines and other sources, especially cell phone transmission masts; about their struggles against the siting of these facilities; and about technical details, such as regulations governing exposure to EMF. In 2000, the site's founder discontinued participation, but others, graduate engineers, carried on. They consider it important that "the EMF community" has this as a means of communication that belongs to it "collectively" and that is "open and unfiltered." Thus, even though a particular struggle against a transmission line ends in defeat, some participants continue to express their concerns about transmission line issues.

9.4 EMF and Transmission Line Opposition Networking, 1999–2003

The Bridlewood Electromagnetic Fields Information Service Web site also contains links to other groups opposing transmission lines, just as these groups link to Bridlewood. EMF effects provide one of the main concerns that these various groups can share. As mentioned, one of the linked groups is the Power Line Task Force in the southeastern suburbs of St. Paul, Minnesota, which from 1999 through at least 2003 challenged the project by Xcel Energy to upgrade its 115 kV transmission line running through their neighborhoods. The group leader, a financial planner with a doctorate in economics, established a Web site to publicize the group's fight, but also to spread word of EMF issues around the world. The group objects to the size of the towers of the Xcel project; however, its Web site chiefly attacks the effects of EMF. Xcel Energy insists that the upgrading will reduce exposure to these fields, but the protesters disagree. They cite studies, particularly one by the California Department of Health in 2001, that they interpret to show that EMF can cause childhood leukemia, adult brain cancer, Lou Gehrig's disease, and miscarriage. Xcel Energy disagrees.

The powerlinefacts Web site links to the Web site of the group Revolt, just as Revolt links to it. The Web site of Revolt critiques the many impacts of a 400 kV transmission system proposed in 1991 by the National Grid for North Yorkshire and in operation in 2003. Revolt's Health Issues pages links to some 20 sites on EMF subjects. Some offer published scientific assessments of health effects, such as a much-quoted report released in 1999 by the U.S. National Institutes of Environmental Health Sciences and reports of the International EMF Project of the World Health Organization. Other links are to media reports of these assessments, new research findings, scholarly discourse about EMF effects, and risk management theory and policy.

9.5 Scientific Studies of EMF and How They Are Interpreted

Revolt, Powerlinefacts, the Bridlewood Bibliography, and other opponent publications refer to the reports of scientific studies about EMF and other transmission line health effects. Since the l980s, there have been many such studies. Researchers from many disciplines, especially epidemiology, cellular biology, biostatistics, and risk assessment, have reported their findings in scholarly journals. Governments, health agencies, and research institutes at national, local, and international levels have convened panels of researchers to assess these findings. Utilities, their opponents, and siting authorities all refer to these studies to make their arguments or decisions.

Many of these studies were reviewed, summarized, and synthesized in 2002 by an Interagency Working Group in Minnesota and presented as a White Paper on Electric and Magnetic Field Policy and Mitigation Options to inform decision makers. This White Paper exemplifies many EMF studies. It distinguishes among findings from epidemiological studies, findings from laboratory studies, and the determination of a biological mechanism for how magnetic fields may cause effects, notably cancer (childhood leukemia and chronic lymphocytic leukemia in occupationally exposed adults). The paper concludes that epidemiological studies have mixed results. Some show no statistically significant association between exposure

to EMF and health effects. Some show a weak association. Newer laboratory studies fail to show such an association. Furthermore, the studies, with one notable exception, fail to establish a biological causal mechanism. Thus, most studies conclude that there is insufficient evidence to prove an association between EMF and health effects. However, many studies also conclude that there is insufficient evidence to prove that EMF exposure is safe.

These conclusions lend themselves to diverse interpretation and each major party in transmission line siting cases imposes its own meaning on them according to its interests and understandings. In essence, opponents say that these research studies and assessments show that the risks of EMF from power lines are significant enough to make government regulators deny approval of projects that site overhead transmission lines near human habitation or at least delay approval until more studies are conducted to determine risk. A weak association still means that there is risk and it is unjust to impose this risk involuntarily on people. Some also say that the applicant utility must prove that the transmission lines will not put people's health at risk from EMF before a project is given approval, rather than require that the opponents prove that there is a risk. Utilities say that the reports demonstrate that the risks from EMF are not sufficient to deny approval. They also disagree that the burden of proof of no risk be on them. Government siting authorities usually say that the reports show that EMF risks are not sufficient to deny approval. Some also recognized that if the burden of proof of no harm is shifted to the applicant, this could establish a new principle in regulatory policy, the precautionary principle. However, the siting authorities sometimes indicated that exposures would be mitigated if later scientific studies showed this was necessary. Siting authorities, legislatures, and international agencies continue to request such studies.

Meanwhile, scientists continue their studies, but their contributions seem likely to give the parties to the issue more to argue about. Findings and analysis reported by researchers at Bristol University in the United Kingdom provide an example. It will be recalled that scientists could not determine a biomechanical explanation of how EMF might produce health effects. However, on the basis of their research in the l990s, including 2000 experiments near pylons in 1999, Denis Henshaw and colleagues at Bristol hypothesized a biomechanism. They report that high-voltage AC transmission lines produce corona ions that charge particles (aerosols) from automobile exhaust and other pollutants in the atmosphere, near and downwind of the pylon. The deposition of these particles on the skin and in the lungs is increased, elevating the risk of diseases such as skin and lung cancer. Henshaw's propositions have been communicated to the public through the mass media. Revolt and other opponents of transmission lines mention the "Henshaw hypothesis" on their Web sites and the hypothesis has been used by opponents to bolster their testimony against line siting.

The media reports that scientists working for the electricity industry refuted the Henshaw results. The industry also notes in public announcements that the U.K. National Radiological Protection Board found an earlier small-scale study of the same phenomena by Henshaw to be flawed in method and theory and its results "implausible and highly speculative." In addition, industry and some government regulators point to the results of other studies that offer epidemiological and laboratory evidence that they say contradicts the implications of Henshaw, including studies for the National Radiological Protection Board (NRPB) by the renowned Sir Richard Doll.

In 2003 in the United States, researchers at the Electric Research Power Institute (EPRI) requested funds to assess the Henshaw Hypothesis. EPRI is the research arm of the electricity utilities industry. The debate about the hypothesis and the effects of EMF exposure is likely to continue. For example, Revolt reports that Henshaw's research provides further evidence that the hormone melatonin, involved in the body's circadian rhythms as well as in certain types of cancer, is also affected by magnetic fields. Revolt says uncertainties about the effects of EMF call for the use of the precautionary principle in siting transmission lines. Referring to positions taken by the European Court of Justice, Revolt says precaution means that in the face of such uncertainty, preventive measures may be taken without having to wait until the reality of the risks become apparent.

9.6 Perception and Communication of EMF Risks

Some analysts argue that the public is becoming unduly alarmed about the risks of exposure to EMF because they do not understand the meaning of statistical associations and probabilities as reported erroneously in the news. In an online review in the *British Medical Journal*, Simon Chapman, Professor of Public Health at University of Sydney, Australia,

discusses responses to news of a 2001 NRPB study on EMF risk. This study estimated that additional risk from power lines meant an extra case of childhood leukemia every 2 years: from approximately 1 in 20,000 to 1 in 10,000. Chapman writes that this is a very small risk, but that the media in Australia and the United Kingdom reported it under alarming headlines such as "Power lines double cancer risk." Chapman writes that because of such exaggerations of EMF effects, anxious Australians living near power lines have called cancer agencies asking whether they should sell their house or have their children tested. Others, such as John Farley in his Quackwatch Web site, attribute public fears about EMF to the exaggerations of quacks, who sell devices to detect EMF or medicines to cure it, or to the alarmist writings of journalist Paul Brodeur, who claims that government and industry are conspiring to hide the truth about EMF risks.

The American Physical Society (APS) also finds the risks of EMF effects exaggerated and not understood. In 1995, APS, the major professional association of physicists in the United States, published its official assessment of the effects of EMF on health. It stated that unsubstantiated claims that EMF are threats to health provoke fears among people and these fears lead to expensive mitigation efforts and, in some cases, to lengthy and divisive court proceedings.

As noted above, health agencies at the state, national, and international levels seek to communicate what is known about EMF effects in order to facilitate decision-making. However, D. G. MacGregor, P. Slovic, and M. G. Morgan suggest from their psychometric research on perception and communication of risks that even careful and scientific presentation of the uncertainties about EMF exposure will increase people's concerns and that people interpret new evidence according to naive conceptions about how EMF interferes with normal biology.

9.7 Is EMF Fear a Cause or an Effect of Opposition to Transmission Siting?

The Chapman and APS statements indicate that it is fear of EMF that causes people to oppose transmission lines. It will be recalled that utility consultants say that people oppose transmission lines because they are ugly or simply because they do not want them in their "backyard," but express concern about EMF and other health effects as their reason because health is politically more powerful and legitimate. Which of these suggestions about cause is correct? Probably neither. It is difficult to determine cause-and-effect relationships in complex social phenomena (just as it is difficult to determine these in complex biological phenomena). This article shows how concern about the effects of EMF is part of an array of concerns held and learned by transmission line opponents. It is impossible to know how much it is concern about EMF that induces people to oppose transmission siting or how much it is concern about other impacts that induces people to learn about EMF risks and present these as reasons for opposition. When people work with others to oppose transmission line siting, and do so in contest with proponents of the line, they engage in a process of cultural learning. They learn why and how to oppose. They develop a system of reasons and other ideas about why the transmission project is wrong and as they do they also develop an organization to express their ideas and fight to stop or alter the project. Some of them continue to work on EMF and other electricity and energy issues after their fight ends. It usually ends because the line project is approved. But the project is usually approved only after their resistance has long delayed it and altered it.

10. SUMMARY

Organized opposition, informed by key ideas or reasons, has been the most observable and significant response to efforts to site and construct electricity transmission lines in the United States, the United Kingdom, and Canada. This is probably also the case elsewhere in Western industrial democracies, that is, where authorities permit people to oppose projects important to industry and government. Opposition is one of three major obstacles to the siting and constructing of new transmission lines. Opposition affects and is affected by the other two obstacles, namely, the complexities of official processes of obtaining approval and the uncertainties of obtaining sufficient return on investment. People organize their opposition to a transmission project by forming a local group that interacts in communication networks with other groups opposing the project and with groups elsewhere holding related concerns. People develop many reasons for opposing the line and communicate these in many forums, especially in public hearings, Web sites, and newsletters. Their main reasons are these: The line is not needed

because there are alternatives to it in generation, transmission, and consumption. The line is too high in voltage and carries electricity to other states or regions. It will be used chiefly to profit its owners rather than to serve the public it impacts. It is ugly and invasive and represents a loss of control. Unfairness and injustice mark the way the line was approved and in how its impacts and the impacts of generating its sources of electricity are distributed. Building and operating the line damages agriculture, farm economy, and the environment. The line threatens the health and safety of people living along it, especially from its electric and magnetic fields. People develop these reasons into a system of related ideas as they argue with utilities and siting authorities. They are usually understood to act as interest or pressure groups. However, these groups might become parts of a movement of change as they work to change the culture of energy use as well as energy policy.

3. **The Public's Environmentalist but Conflicted Tendencies**
4. **Public Opinion on Energy and Demographic Characteristics**
5. **Public Opinion and Political Orientations**

Glossary

economic issues Political issues that relate to the distribution of wealth in society.
party identification A way in which people think of themselves; a psychological and emotional attachment to a political party.
social issues Political issues that relate to values and morals.

The term public opinion refers to the factual beliefs and preferences about issues of interest to the general population. Whether people believe that oil exists in the Arctic National Wildlife Refuge (a factual question) and whether people believe that the refuge should be opened to oil exploration (a preference) are typical examples of public opinion questions. Public opinion is normally measured using survey methods. Pollsters contact randomly selected samples of adults and ask them a series of questions to measure their opinions on current policy issues. The results of these surveys often play a major role in policy making.

1. DEFINITION AND IMPORTANCE OF PUBLIC OPINION ON ENERGY

What the public thinks about energy is important because public opinion is a major force influencing public policy on energy production and consumption. The fact that elected officials generally follow their constituents' wishes on high-profile issues is well documented by political scientists. Studies certainly show the influence of major industries, such as petroleum and nuclear power, but that influence generally occurs on low-profile issues. Most studies show that on major issues that receive a good deal of press attention, such as nuclear power and offshore oil development, the public generally gets what it wants.

Academic studies aside, observers can easily see the influence of public opinion in the cases of both nuclear power and offshore oil development. Public opposition to nuclear power, especially after the 1979 Three Mile Island accident, helped block the construction of new nuclear power plants. In the aftermath of the accident, public support for nuclear power dropped sharply, and every proposal for a new nuclear facility was met with mass protests. Public opposition, coupled with soaring construction costs, ended the growth of the nuclear power industry. No more nuclear power plants were ever ordered.

In the case of offshore oil drilling, the California public has moved through intermittent periods of quiet acceptance and intense opposition during the past century. The 1969 spill in the Santa Barbara Channel crystallized public opposition, and—some historians argue—helped launch the modern environmental movement. During the 1980s and 1990s, public opinion polls consistently showed overwhelming opposition to further drilling. In order to curry favor with California voters, President George H. W. Bush ordered a moratorium on new oil drilling leases in federal waters in 1990. President Clinton continued it in his administration, and President George W. Bush has allowed the policy to stand. In the case of offshore drilling along the Florida coast, public opinion against oil drilling was so intense that in June 2002 President Bush ordered the Interior

 © 2004 Elsevier Inc. All rights reserved.

Department to buy back some offshore oil leases that had been sold to oil companies and asked Congress to pass legislation to repurchase other leases. The official explanation for the buy-back from Department of Interior Secretary Gail Norton was that offshore oil development in Florida was opposed by "public opinion."

One can also see the influence of public opinion on policy makers in every energy crisis from that of 1973–1974 to the gasoline and electricity price spikes of 2000–2001. Every time shortages appeared and prices soared, the public demanded laws to lower energy prices. Politicians leapt to do the public's bidding, despite the fact that lowering energy prices encourages consumption, making the energy situation worse.

The initiative process gives voters a measure of direct control over public policy. In the 23 states and hundreds of counties and cities with the initiative process, voters can do more than demand that their elected officials pass the laws they want: Voters can pass the laws themselves. In these cases, public opinion controls energy policy. In California, for example, voters have passed both local and statewide initiatives limiting oil development. Although antinuclear power groups were not able to persuade California voters to pass an initiative to block nuclear power in the state in 1976, they came close enough to scare the state legislature into passing tough nuclear safety legislation that effectively blocked efforts to build more nuclear power plants. Moreover, the threat of an initiative vote against any controversial, proposed power source is clearly a deterrent to potential investors.

What the public wants does not always determine public policy. The influence of public opinion varies depending on a number of factors, including the attention given to the policy by the news media and the public, how much the public cares about the policy, expert opinion, and the interest groups arrayed for and against various policy choices. Nevertheless, in some circumstances, the public can get exactly what it wants—even against seemingly overwhelming opposition from the oil and gas, nuclear power, or electricity industries and their political allies. The public's policy preferences may not always be wise or well informed, but they can be influential.

2. THE PUBLIC'S KNOWLEDGE ABOUT ENERGY

One of the best known findings of public opinion research is that most of the public pays little attention to politics and, consequently, few people know much about politics or public policy. The list of facts not known by a majority of the public is stunning. What do the words "conservative" and "liberal" mean? What is the federal minimum wage? What majority is needed in the House and Senate to override a presidential veto? Who is the Speaker of the House of Representatives? Who is the Chief Justice of the U.S. Supreme Court? In national, representative surveys of adults, fewer than half the respondents offered correct answers to any of these questions.

These findings should not be exaggerated. The public is not ignorant or stupid. In fact, only a small percentage of the population knows virtually nothing about politics. Rather, most people do know something about politics, just not a great deal. The public's modest level of knowledge stems from the fact that few people are interested in politics. In areas that people do care about—their jobs, their communities, their hobbies, and their favorite movies or sports teams—people know a great deal. Politics and public policy just do not draw much attention or interest.

Given these findings, one should not expect the public to know much about energy policy. There are a few aspects of the energy situation that almost everyone should grasp—for example, that the United States imports oil from the Middle East, whether gas prices are rising or falling, wind mills can be used to generate electricity, or waste from nuclear power plants is radioactive and hazardous. However, most aspects of energy policy are complicated and difficult to understand without some specialized knowledge or training. How much would new oil drilling in the Arctic National Wildlife Refuge or along the Florida or California coasts add to national oil supplies? Can the United States ever become energy independent? What are the effects of deregulation of the wholesale electricity market on prices? What are the trade-offs between clean air and electricity production? How safe is nuclear power? What is global warming, what causes it, and what are the policy options for doing something about it? None of these questions can be answered without a fair amount of knowledge. Because most energy policy questions are complicated, we should not expect the general public to understand them.

Table I presents selected survey results illustrating the public's lack of knowledge about energy matters. Questions 1 and 2 show that despite the Arab–Israeli wars, the gas lines, and the sharp gasoline price hikes, in the 1970s only approximately half the public realized that the United States had to import oil to meet its energy needs. The failure to realize this

TABLE I

Selected Knowledge Questions, U.S. Samples

Question	Year: % correct
1. Do you think the United States has to import oil to meet our needs, or do we produce as much oil as we need?	1977: 48 1979: 51 1980: 63 1991: 50
2. Using the card, at the present time, how much of the oil used in the United States would you say we have to import from other countries? (Five choices)	1977: 29 1978: 30 1981: 27
3. About what proportion of its oil would you say the United States imports from other countries? Would you say two-thirds or more, about half, about one-third, or less than one-third?	1984: 33 1990: 49
4. There is a debate about whether this country should become less dependent on oil imported from foreign countries. Please give your best estimate of which phrase comes closest to describing how much of our oil comes from foreign countries—about a fourth, about half, about three-fourths.	2002: 34
5. Here is a list of different companies. All of them have operations here in the United States. But, would you go down that list and for each one would you tell me whether, to your knowledge, the main headquarters is located here in the United States or located in a foreign country?…	1978: 78 1986: 76
5a. Exxon?	1978: 17
5b. Shell?	1986: 19
6. From what you've heard or read, do you think a nuclear power plant accident could cause an atomic explosion with a mushroom-shaped cloud like the one at Hiroshima.	1979: 33
7. To your knowledge, what percentage of the nation's electric power is currently supplied by nuclear power plants?	1979: 5 1986: 6
8. In 1979, about 20 years ago, there was a nuclear power plant breakdown near Harrisburg, Pennsylvania. Would you happen to remember the name of that nuclear plant, or not?	1999: 38

Sources. Items 1–3 and 5–7 are from Delli Carpini, M.X., and Keeter, S. (1996). "What Americans Know about Politics," Appendix 3; Yale Univ. Press, New Haven; CT. Item 4 is from the Associated Press poll, February 22–27, 2002 ($N = 1016$). Item 8 is from the Gallup poll, March 19–21, 1999 ($N = 1018$). Both Items 4 and 8 are reported by Polling Report.Com (http://www.PollingReport.com/enviro.htm). Note: Delli Carpini and Keeter do not identify the surveys or sample sizes for the surveys, but all surveys were conducted by major reputable firms and are archived by the Roper Center for Public Opinion Research.

fundamental fact about the U.S. energy situation during the 1970s may seem astonishing, but it is consistent with other findings about the level of the public's knowledge. Large blocks of information are missing, and only a relatively small number of people have much detailed knowledge about any public policy issue. The other results in Table I add to the picture of the public's limited knowledge about energy policy.

Questions 3 and 4 show that the public lacks knowledge about our dependence on foreign oil continues. Question 5 shows that despite the political rhetoric about foreign and multinational oil companies, only a small portion of the public can identify them.

The next question about the possibility that a nuclear power plant could explode in a mushroom-shaped cloud is particularly revealing. The question was asked soon after the Three Mile Island accident. Even though television, newspapers, and news magazines reported extensively on what might happen during the Three Mile Island nuclear power plant accident, only one-third of the public knew that a "mushroom-shaped cloud" was not possible. The Jack Lemon/Michael Douglas/Jane Fonda movie, "The China Syndrome," which premiered just before the Three Mile Island accident and offered a clear description of what might happen in the event of a nuclear power plant accident, may have been a critical and box office success, but an educational success it was not.

Table II presents results from a survey of Californians. The first question in Table II asks how long the world's oil supply will last. This is a difficult question because the topic has not been the subject of many news reports since the 1970s and because experts disagree. It has been the subject of some news coverage, however. Coincidentally, it was the subject of a *Scientific American* article published only weeks before the survey. Despite this, half the respondents admitted they did not know the answer and declined to guess. The answers from the other half ranged from less than 5 to more than 1000

TABLE II

Selected Knowledge Questions, California Sample

Question	% correct
1. As you know, the amount of oil in the world is limited. Do you know roughly how many years it will be before experts believe the world will run out of oil? [Probe if necessary]: Just your best estimate.	23
2. Do you happen to know whether it is currently safer to transport oil using oil tankers or using oil pipelines? By safer, I mean the way which is least likely to result in a major oil spill.	58
3. How often do you think a typical offshore oil platform along the California coast is likely to have a major oil spill—once every 5 years, once every 10 years, once 20 years, once every 40 years, or less frequently than this?	15
4. When a major oil spill occurs, how much threat does it pose to human life—a great deal, some, only a little, or no risk at all?	6

Source. California Offshore Oil Drilling and Energy Policy Survey, March 1998, conducted by the Field Institute ($N = 810$).

years. A reasonable estimate is somewhere between 50 and 100 years. Taking any number in this range as correct, we see that only 23% of our sample could make a reasonable guess.

The next three questions in Table II differ from the previous questions because they not only measure factual knowledge but also the public's perceptions of risk. In the abstract, this difference may sound trivial, but in practice people who feel threatened respond by demanding that politicians do something about the risks. In the case of oil, those demands are to limit or end offshore oil development.

The first risk question asks respondents whether it is safer to transport oil by using oil tankers or pipelines. The answer, pipelines, should be relatively well-known because most of the world's catastrophic oil spills have been tanker disasters, including such well-known ships as the Castillo de Bellver, the Amoco Cadiz, the Torrey Canyon, and the Exxon Valdez. Because tanker spills have received so much news coverage, one might expect most of the public to know this answer. The survey, however, showed that only 58% of the California respondents correctly identified pipelines as the safest way to transport oil. That is only slightly higher than the 50% who would have gotten the answer correct if they had guessed based on coin tosses.

The second risk question asks respondents to estimate how frequently a typical offshore oil platform will have a major oil spill. The public's answers to this question reveal seriously exaggerated fears. Twenty-three percent of the California public said that they expected a major oil spill every 5 years from a typical platform. An additional 25% said that they expected such a spill once every 10 years. Although the exact meaning of "major oil spill" is not stated in the question, by any definition major oil spills from a typical platform are far less frequent than once every 10 years. If we were to use 1000 barrels of oil as the standard for a major oil spill, we would have to conclude that the correct answer—given by only 15% of the sample—was "less than once every 40 years" because there were only 11 spills of that size from all U.S. offshore platforms from 1964 to 1992 (and none since 1980). Even using a far smaller number of barrels as the standard would still yield less than once every 40 years as the correct answer because of the huge number of offshore oil platforms in operation in U.S. waters (more than 3800 platforms in 1990). This exaggeration of risk, or lack of knowledge, presumably contributes to the public's opposition to further offshore oil drilling.

The answers to the next question about oil spills also help us understand people's fears. The question asks how much threat a major oil spill poses to human life. Again, we see that the public seriously exaggerates the threat posed by oil. Thirty-one percent of the statewide sample responded that a major oil spill would pose a serious threat to human health. An additional 36% believed that it would pose some threat. In fact, oil spills pose only a negligible threat to human life. They certainly pose a substantial threat to many other kinds of life but not to human beings.

The public's low level of knowledge about energy policy is important because of the public's influence on policy makers. When the public forms opinions and makes demands on politicians based on misinformation, public policy may suffer. As the data in this section show, the public is often misinformed about even the most basic aspects of energy policy.

3. THE PUBLIC'S ENVIRONMENTALIST BUT CONFLICTED TENDENCIES

When the public does turn its attention to energy issues, it tends to prefer environmentalist policies. That is, the public generally favors conservation;

favors alternative, sustainable energy sources (wind and solar power); and opposes conventional energy development (oil, nuclear power, and coal). However, the public also displays a clear preference for government action to maintain low energy prices, despite the fact that low prices lead to excessive and wasteful energy consumption. These inconsistent preferences seem to result from a mix of people's misunderstandings about the energy situation and their distrust of the energy industry.

Evidence for the environmentalist tendencies of the public can be seen in a variety of survey results. Figure 1 shows the percentages of people who said in response to a series of Gallup polls that they preferred more conservation or more production as a solution to U.S. energy problems. The solid line represents the percentage indicating that they preferred conservation, and the dotted line represents the percentage indicating that they preferred production. Even at the height of the gasoline price hikes in 2001, the public preferred conservation by a substantial margin. By March 2002, when prices had stabilized and the public was becoming accustomed to higher prices, conservation was preferred by a margin of 60 to 30%. (The remaining 10%, not shown in the figure, either responded "both" or "neither.") Figure 2 shows the results of a related question in which respondents were asked in March 2001 and March 2002 whether they would give priority to development of energy supplies or protection of the environment. The environment won by a 52 to 40% majority. Figure 3 presents another trade-off. Respondents were asked whether they believed "protection of the environment should be given priority, even at the risk of curbing economic growth, or economic growth should be given priority, even if the environment suffers to some extent." By wide and consistent margins from 1984 to 2000, the polls showed a strong public preference for environmental protection. Support for environmental protection ranged from 61 to 71%, whereas the number giving priority to economic growth ranged from only 19 to 32% and was only 28% when the question was last asked in April 2000.

On more specific policy questions, polls show that the public strongly supports investment in environmentally friendly energy sources and generally opposes the development of any conventional energy

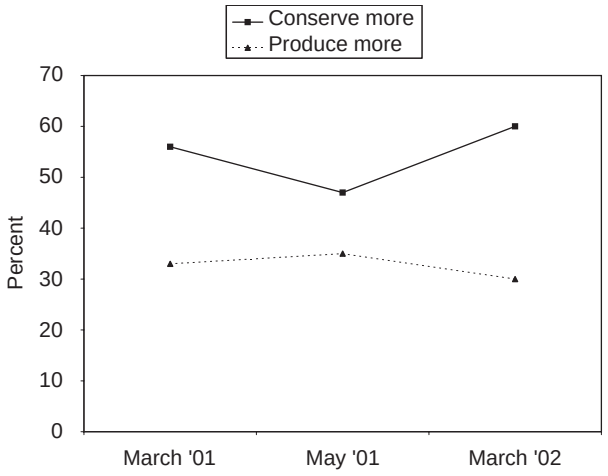

FIGURE 1 Energy solution: More conservation or more production. Source: Gallup polls.

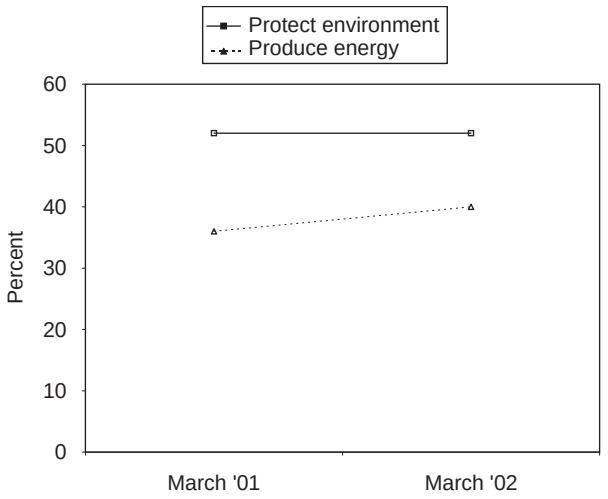

FIGURE 2 Environmental protection vs energy production. Source: Gallup polls.

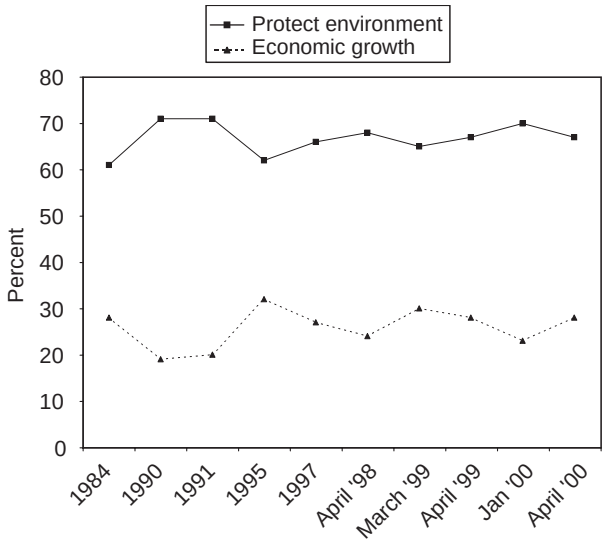

FIGURE 3 Environmental protection vs economic growth. Source: Gallup polls.

sources that are criticized by environmental groups. Table III shows the public's response to several policy proposals for dealing with U.S. energy problems. The public is nearly unanimous in calling for more support for solar, wind, and fuel-cell technology. Requiring automobile companies to build more fuel-efficient cars is also strongly supported. The proposals that fail to win majority backing are drilling for oil in the Arctic National Wildlife Refuge and nuclear power.

Further questions in other polls show majorities opposing drilling for oil and natural gas along the California coast or weakening environmental protections, such as automobile or industrial emissions, in order to increase energy production.

Despite evidence that a substantial majority of the public holds environmentalist views, there are signs that the public does not consistently follow through on those stated preferences. The public supports conservation in principle but opposes a variety of conservation policies because they place burdens on consumers. Simply stated, the public wants the benefits of cheap, plentiful energy but does not want to pay the costs.

The best behavioral evidence of the public's conflicted views can be seen in sales figures for sport utility vehicles (SUVs). According to a March 2000 Gallup poll, approximately one-fourth of U.S. households own at least one SUV. Moreover, in 2000—a year of sharply rising gasoline prices—nearly half of all new car sales were gas-guzzling SUVs, minivans, or light trucks. Thus, although the public says that it wants fuel-efficient cars, it actually buys fuel-inefficient cars (and trucks and SUVs).

Survey data also reveal the public's desire for low-cost energy. During the spring of 2000, when oil prices surged, a Gallup poll found that 80% of the public favored lowering state fuel oil taxes, 75% favored reducing federal gasoline taxes, and 59% favored drawing oil from the U.S. Strategic Petroleum Reserve to put more oil on the market and cut prices. In a similar vein, when asked whether they favored or opposed the proposal of "giving tax breaks to provide incentives for drilling for more oil and gas in the U.S.," Gallup poll respondents in March 2001 favored the idea by a 53 to 43% margin. In addition, the proposal to set "legal limits on the amount of energy which average consumers can use" was solidly opposed by a 62 to 35% margin. The 2000–2001 electricity crisis in California provides further evidence of the public's desire for cheap energy. A May 2001 Field Institute poll asked Californians, "Is it a good thing or a bad thing for the federal government to cap energy prices?" Seventy percent said it was a good thing.

Most economists tell us that capping or subsidizing energy prices during shortages is foolish. If prices are allowed to rise freely, consumers will use less energy, and the energy problems will be resolved by free market forces. In contrast, if prices are capped or if energy consumption is subsidized, more energy will be used and shortages will worsen—potentially leading to lines at gasoline stations, electricity blackouts, or other problems.

Unlike economists, most of the public likes energy subsidies and dislikes free market solutions to energy shortages, but this does not mean that people are rejecting free market economics. Instead, many people believe that energy shortages are faked by energy companies to increase prices and profits. A 1974 Roper poll showed this when it asked, "Some people say there is a real shortage of gasoline and fuel oil because demand has outrun supply. Others say there really isn't a shortage of gasoline and fuel oil and the big companies are holding it back for their own advantage. What do you think—that there is or is not a real shortage of gasoline and oil?" Seventy-three percent said there was no real shortage. During the next energy crisis in March 1979, the CBS/*New York Times* poll asked, "Do you think the shortage of oil we hear about is real or are we just being told there are shortages so oil companies can charge higher prices?" Sixty-nine percent responded that they were just being told that shortages existed, and another 11% said they were not sure. Only 20% believed the shortages existed. Similar survey findings were reported during the gasoline price hikes immediately before the 1991 Persian Gulf War, during the 2000–2001 gasoline price hikes, and during the 2001 California electricity crisis.

TABLE III

Public Support for Energy Alternatives

Alternative	Favor (%)	Oppose (%)
1. Investments in new sources of energy such as solar, wind, and fuel cells	91	8
2. Mandating more energy-efficient cars	77	20
3. Opening up the Arctic National Wildlife Refuge in Alaska for oil exploration	44	51
4. Increasing the use of nuclear power as a major source of power	42	51

Source. Gallup poll, November 8–11, 2001.

Apparently, the public's reasoning is that the energy industries cause supply shortages and high prices by manipulating energy markets. In other words, high prices are the result of illegal or unethical activity. Given this situation, people can easily jump to the conclusion that the government should step in and fix the problem with price caps, subsidies, or other measures.

Here, the public's lack of knowledge about energy policy plays a role. In every energy crisis the United States has faced, politicians and activists have accused energy companies of manipulating prices. Certainly in the case of the oil crises, when people who do not even know that the United States needs to import oil to meet its energy needs hear those charges, they will be especially likely to believe them. More broadly, a mix of people's misunderstandings about the energy situation and their distrust of the energy industry may lead to poor judgments about the best energy policies for the government to adopt.

Public opposition to increases in energy prices affects more than government behavior during energy crises. Proposals for a carbon or Btu tax, such as the one offered by President Clinton in 1993, face a skeptical public. The idea behind Btu taxes is to increase the price of fossil fuels, causing consumption to decline and consumers to switch to using other fuel alternatives. Such proposals face two problems in winning public support. First, the proposals are complicated and require at least a moderate understanding of both economics and energy. Second, the proposals call for raising energy prices. These are both serious obstacles to Btu taxes.

In summary, the public generally favors environmentalist policies such as conservation and the development of alternative, sustainable power sources. However, the public also wants the government to take steps to guarantee low, stable energy prices. The contradictions among these views remain unresolved.

4. PUBLIC OPINION ON ENERGY AND DEMOGRAPHIC CHARACTERISTICS

To understand the sources of people's opinions about energy policy, it helps to examine the larger context of public opinion across a range of issues. Public opinion scholars have found that the best way to describe public opinion on domestic issues is to divide issues into two broad categories—economic and social. Economic issues are those that relate to the distribution of wealth in society—the tax system, Social Security, Medicare, welfare, regulation of businesses and unions, etc. Social issues are those that relate to values and morals—abortion, birth control, free speech, civil rights, women's rights, sexual preferences, etc. This distinction is useful for two reasons. First, people tend to have similar opinions on the two types of issues. That is, if someone is liberal on one social issue, he or she is likely to be liberal on others. Second, the two types of issues have different causes and demographic correlates. Opinions on economic issues generally vary with income and self-interest, whereas opinions on social issues usually vary with education and age.

At first glance, energy policy would seem to be a classic economic issue. Energy production is a huge economic sector. Most disputes over energy policy involve the government regulating private businesses. Regulations affect company profits, create new jobs for some people, and eliminate existing jobs held by other people. From pollution controls to protections for endangered species, regulations on the energy industry have substantial economic impacts.

In some respects, attitudes toward energy policy do respond to events in ways that are consistent with people looking at energy policy as an economic policy. An excellent example of this is the way public support for offshore oil drilling along the California coast parallels the inflation-adjusted price of gasoline. Figure 4 shows a fairly close fit between support for offshore oil drilling and the real price of gasoline. When the price of gasoline increased in the late 1970s, so did support for offshore oil drilling. When the price of gasoline decreased in the 1980s, support for offshore oil declined as well. The 1989 survey shows a sharp decline in pro-development feelings that is not matched by gasoline prices, but it does

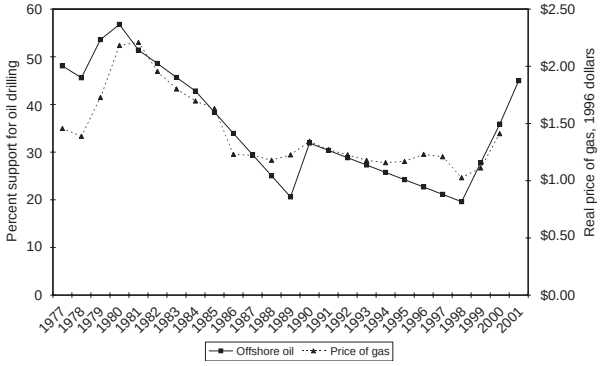

FIGURE 4 Support for oil drilling and the price of gasoline.

correspond to the Exxon Valdez oil spill. The post-1998 increase in support again parallels the increase in gasoline prices.

There is also some individual-level evidence that people think of energy issues in economic terms. For example, as the distance people commute to work increases, they become more likely to favor offshore oil drilling and other steps to increase oil production and cut prices. That is, economic self-interest affects attitudes toward energy policy in some cases.

However, the classic patterns of economic issues do not appear. Opinions on energy issues generally do not vary with income, occupation, or other measures of social class. A few studies have found that attitudes on energy policy vary with income, but these studies are outnumbered by the studies that found no relationships.

For the most part, attitudes toward environmental issues, including energy issues, behave like attitudes toward most social issues. Two key indicators of this pattern are the relationships that energy attitudes have with education and age. On virtually every social issue, the most liberal people in the population are the well educated and the young. The basis for the education–social issue relationship seems to be that education brings people into contact with new ideas and new types of people and broadens the perspectives of the well educated. This process develops a greater tolerance for people who are different—blacks, the disabled, gays and lesbians—and a greater appreciation of ideas such as the value of the environment.

Age is also related to opinions on social issues, but not because age causes beliefs or opinions. Instead, age is related to opinions on social issues because age reflects the generations in which people grew up and were socialized. Throughout the past century, the United States has been moving in a more socially liberal direction. Ideas such as racial and gender equality, which were once considered radical, are now generally accepted. Ideas such as gay rights, which were once never even discussed, are now on the leading edge of social change. Similarly, the modern environmental movement began in the 1960s. Therefore, people who grew up and were socialized before the 1960s are less likely to hold environmentalist views than those raised during the environmental era.

The relationship between education and the trade-off between protecting the environment or finding new sources of oil and gas is typical of relationships between education and questions about energy policy. Figure 5 presents the results of an April 2001 *Washington Post* poll, which showed that 51% of Americans with a high school education or less said that environmental protection was more important than finding new oil sources, whereas 58% of college graduates held that view. The better educated the respondents were, the more they favored protecting the environment.

The relationship between age and the environment–energy sources trade-off in the *Washington Post* poll is even stronger. As Fig. 6 shows, 66% of the 18- to 30-year-old respondents favored protecting the environment, whereas only 38% of those 61 or older did so—a 28% difference across the

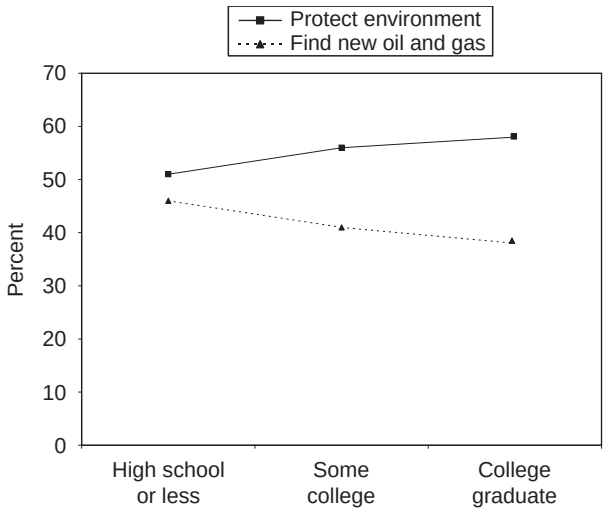

FIGURE 5 Energy vs environmental protection by education. Source: *Washington Post* poll, April 2001.

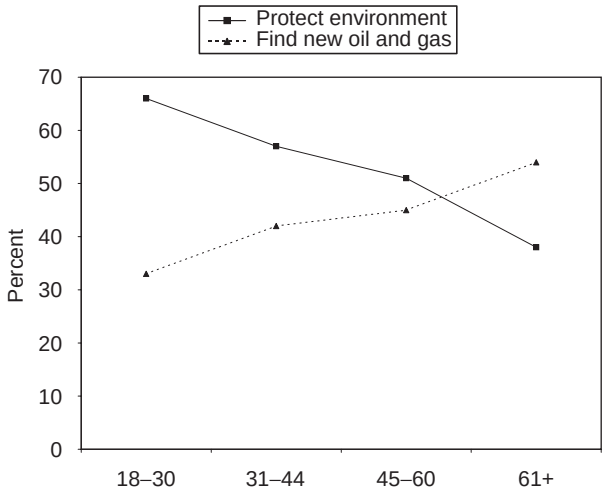

FIGURE 6 Energy vs environmental protection by age. Source: *Washington Post* poll, April 2001.

generations. This finding is typical in that age has been found to be the demographic characteristic yielding the strongest, most consistent differences on environmental issues.

Other demographic variables are also related to opinions on environmental and energy-related issues, although not as strongly or consistently as education and age. Gender is usually related to attitudes toward energy issues, but only if the issue entails some aspect of risk to people. When risk is involved, women tend to take the pro-environmental stand. For example, women tend to oppose nuclear power more than men do because many people in the public regard nuclear power as risky. In contrast, men and women usually hold similar opinions about offshore oil drilling because it is not seen as inherently risky by the public.

Race, ethnicity, and whether one lives in a rural or urban area have also been found to relate to environmental and energy issues in a number of studies, but the relationships do not consistently fall in a single direction. That is, in some studies blacks have been found to hold more pro-environmental views than whites; in other studies, the reverse pattern has been found. Studies of urban and rural dwellers yield similar results. The relationships often can be seen to depend on the exact issue in question. Location of hazardous waste dumps, for example, is of more concern to people living near proposed sites than those living at great distance. The demographic characteristics of those living near the dumps, therefore, may determine what studies find. Consequently, broad generalizations are difficult to make.

5. PUBLIC OPINION AND POLITICAL ORIENTATIONS

A second way to explain public opinion on energy issues is to examine people's political orientations and worldviews. By far the most important political orientation is party identification. Party identification is a way in which people think of themselves—a psychological and emotional attachment to a political party. People identify with political parties in the same way they identify with ethnicities or religions. Native-born Americans typically acquire a party identification from their parents by age 9 or 10—long before they understand anything about the substance of politics.

The importance of party identification stems from the way in which it influences people's opinions and behavior. Party identification influences people's opinions because it guides their decisions about what to believe or disbelieve when they listen to the news or political discussions among friends. People who think of themselves as Democrats, for example, are far more likely than others to believe Democratic politicians and doubt Republican politicians. Similarly, Republicans trust fellow Republicans but not Democrats. As a result, both groups' view of reality is filtered through their partisan beliefs. In addition, party identification influences people's values. When a politician of one's political party says that preserving the Alaskan wilderness is vital, or that America desperately needs Alaskan oil, one's opinion is likely to be swayed. As a result of differing beliefs about the facts and differing opinions, the behavior of Democrats and Republicans differs as well. In voting and in a wide range of political activities, Democrats and Republican normally choose opposing sides.

In the world of politics, the Republican Party generally represents business interests and the wealthier segments of society, whereas the Democratic Party represents the working-class and lower income segments. Because environmental regulations are constraints on businesses, Republicans have usually been far less supportive of them than have Democrats. As a result, Republicans have generally leaned in a pro-development direction, whereas Democrats have generally leaned in a pro-environment direction.

These partisan patterns can easily be seen both in national political disputes and in public opinion data on energy issues. The fight over whether to open the Arctic National Wildlife Refuge for oil exploration and drilling is a good example. In the 2000 presidential election, the issue that drew the most public attention was the rising price of gasoline. Other issues garnered more press coverage, but drivers were reminded of the high prices every time they filled their cars' gas tanks. As a result, public interest remained high throughout the year. Both presidential candidates responded to the public's concerns. Governor George W. Bush, a former Texas oil man, declared that the way to lower prices was to produce more and, in particular, to open the Arctic National Wildlife Refuge in Alaska for oil drilling. Vice President Al Gore countered that the way to cut gasoline prices was to conserve energy and to pressure major oil-exporting countries such as Saudi Arabia to produce more oil for the world market. He stoutly opposed relaxing environmental standards to make it easier to drill for oil in the United States, and he insisted that the Arctic National Wildlife Refuge be kept closed to oil exploration.

The partisan division among the two parties' presidential candidates is mirrored in public opinion

data. Figure 7 shows the partisan breakdown of support for the proposal to deal with the energy situation by "oil exploration in the Alaskan Arctic Wildlife Refuge." Republicans supported the idea by a 54 to 43% margin, but Democrats opposed it by a 65 to 27% margin. People who did not identify with either political party—that is, those who call themselves independents—fall between Republicans and Democrats in their policy views.

Similar partisan differences exist across many energy-related and environmental issues. The same May 2001 Gallup poll found sharp differences regarding whether to invest more money in natural gas pipelines (favored by 76% of Republicans but only 54% of Democrats), whether to drill for natural gas on federal land (favored by 75% of Republicans but only 55% of Democrats), and whether to increase the use of nuclear power (favored by 59% of Republicans but only 45% of Democrats). Other national and state polls routinely find similar partisan differences, with Republicans typically comprising the group that prefers conventional energy development and Democrats comprising the group that prefers conservation and alternative energy sources.

Another political orientation that helps explain public opinion on energy and environmental issues is ideological self-identification—that is, whether people consider themselves to be liberal, moderate, or conservative. Ideological self-identification is a curious characteristic. Pollsters ask respondents a question such as "Generally speaking, in politics do you consider yourself as conservative, liberal, middle-of-the-road, or don't you think of yourself in those terms?" The terms liberal and conservative are in wide use in public debate. However, repeated studies for more than 50 years show that only approximately half the public can offer even crude definitions of what the labels mean. Typically, approximately one-third of respondents say "I don't know" when asked for a definition. Another one-sixth will offer definitions that are not even remotely recognizable. Nevertheless, the ideological labels that people give themselves predict their opinions relatively well, including their opinions on many energy issues.

Environmental problems emerged as political issues relatively recently in comparison with traditional economic conflicts over labor laws, welfare systems, and tax codes. Nevertheless, when they did begin to draw the public's attention in the 1960s, liberal leaders argued for laws imposing clean air standards, clean water standards, and other pro-environmental regulations. Conservative leaders argued against allowing the government to impose new regulations on businesses. Environmentalism quickly became an established part of liberalism, whereas pro-development views became part of the conservative agenda. This liberal–conservative distinction on environmental issues spread quickly among both political leaders and the public.

Figure 8 shows the ideological divisions over the dispute about offshore oil and gas drilling along the California coast. Seventy-seven percent of the people who say they are "strong liberals" oppose more drilling, whereas only 34% of strong conservatives oppose it. On the pro-development side, the figures

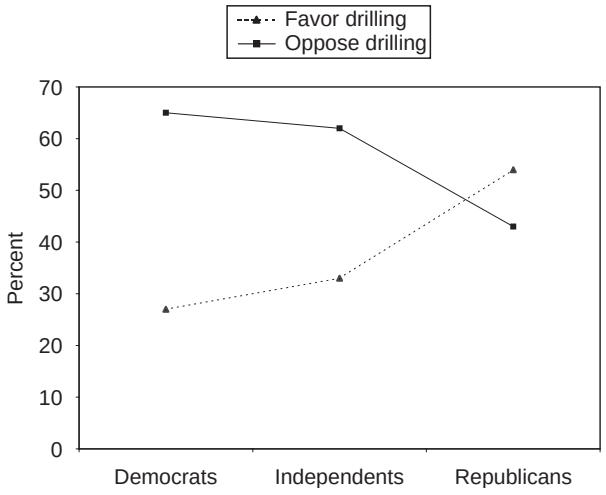

FIGURE 7 Support for oil drilling in the Arctic National Wildlife Refuge by party. Source: Gallup poll, May 2001.

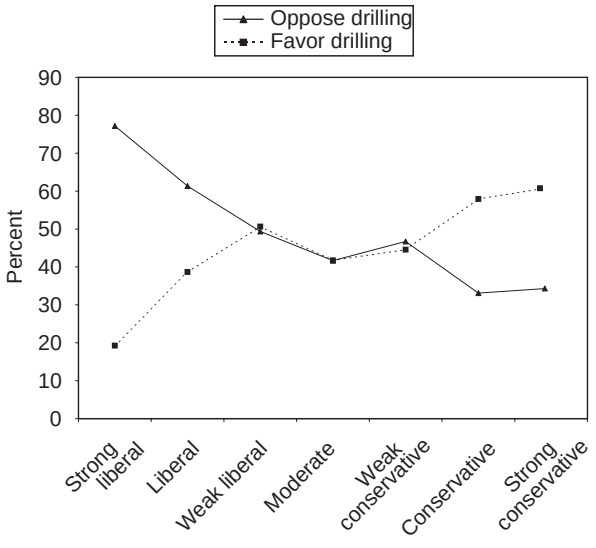

FIGURE 8 Californians support for offshore oil drilling by ideology. Source: Field Institute poll, May 2001.

are reversed, with 61% of strong conservatives but only 19% of strong liberals favoring more drilling.

Taken together, party identification and ideological self-identification do a much better job of explaining public opinion on energy issues than do demographic variables. Nevertheless, opinions on environmental and energy-related issues are not understood or explained as well by public opinion scholars as opinions in other areas (e.g., welfare and civil rights). Given the importance of public opinion to policy makers, research in this area continues.

Glossary

energy The capacity for doing work. Energy may be stored, and it may be transferred from one form into another. Forms of energy include electrical, chemical, thermal, and mechanical.

global warming Atmospheric gases such carbon dioxide and other greenhouse gases make the earth warmer than would direct sunlight alone by trapping heat from the sun as it is reradiated off the earth's surface and absorbed in the atmosphere rather than escaping into space.

greenhouse gases Atmospheric gases that trap the heat of the sun in the earth's atmosphere. Carbon dioxide, methane, nitrogen oxides, and ozone are common examples.

nuclear energy Power obtained by splitting (fission) or joining (fusion) atoms of radioactive materials, such as uranium.

nuclear waste The materials, both liquid and solid, left over from the production of nuclear energy. Nuclear waste exhibits varying amounts of radiation and can be harmful to humans.

power The rate at which energy flows.

radiation The flow of energy via electromagnetic waves. Radiation is produced by radioactivity.

radioactivity Produced when nuclei are undergoing transformation and emitting radiation.

reactor A device in which a controlled nuclear chain reaction can be maintained to produce heat. The heat is then typically used to produce steam, which in turn is used to run conventional turbine generators to produce electricity.

uranium A radioactive element found in ore. Uranium atoms can be split to create energy.

The harnessing of the atom, opening the way for the generation of electricity with nuclear energy, was met with a technological enthusiasm perhaps unmatched in modern history. Nuclear energy was a technology with unprecedented potential. Early in its development, nuclear power was claimed to be the cheapest form of electricity and was projected to provide a substantial portion of the electricity needs in the advanced nations of the world. History, however, conspired to stall the march of nuclear power with the result that these projections were never realized despite the technology's continuing potential. Standing in the way of its destined path to triumph, a variety of unanticipated technological, social, and political obstacles cloud the technology's future nearly everywhere. This article examines the key social obstacles leading to the stalemating of nuclear power.

1. BACKGROUND

Although born of war, nuclear fission technology was soon converted to the "peaceful" generation of electricity. The emergence of nuclear power as an energy source and the high hopes it engendered were hardly surprising in an evolutionary context. Passing through stages from early to mature industrialization was synonymous with a substitution process—the substitution of more readily abundant, less expensive, energy potent fuels for dwindling, more expensive, less potent fuels. With the appearance of fission technology, the generation of commercially produced electricity seemed the rightful heir to propel this evolutionary process forward. After all,

 © 2004 Elsevier Inc. All rights reserved.

the technology could convert puny amounts of raw fuel into usable energy so vast that it would be "too cheap to meter," displacing the reliance on fossil fuel electricity in the process. However, standing in the way of nuclear power's destined path to success were a wide variety of unanticipated technological as well as social and political obstacles that cloud the technology's future nearly everywhere.

The tension between the technology's potential and its public acceptance was captured in the most repeated quote in nuclear history–by Alvin Weinberg, the doyen of nuclear power:

> *We nuclear people have made a Faustian bargain with society. On the one hand, we offer—in the catalytic burner—an inexhaustible source of energy. But the price that we demand of society for this magical energy source is both vigilance and a longevity of our social institutions that we are quite unaccustomed to.*

Another price demanded of any centralized technology promoted by the national state is acceptance by its citizens. Public reactions to nuclear technology in the United States and elsewhere produced a checkered history for the technology that evolved in five overlapping phases: an era of initial enthusiasm, a rejection at the local level, a rise in general public concern and the assertion of alternative technologies, a period of ambivalence, and the current era of persistent pragmatism. Earlier phases prefigured later ones. Therefore, the evolution of public opinion about nuclear power in the United States can be understood as the dynamic and historically contingent intersection between the actions of the federal government, private utilities, industrial contractors, social movement organizations, and the general public in relation to this complex technological system perceived as promising but risky.

The decade of the 1960s, the earliest phase of nuclear power development in the United States, was unquestionably one of unbridled optimism, based, as it was, on the promise of nearly unlimited supplies of cheap electricity. During this period the federal government crystallized its roles as both promoter (with massive investments in R&D and industry subsidies that may total more than $1 trillion) and as regulator of the technology—roles it continues to fulfill today. The eventual recognition of the inherent conflict of interest in the two roles led to their separation in 1974 by the creation of the Energy Research and Development Administration to fulfill the promotion role (in 1977 to be absorbed into the newly created Department of Energy) and the Nuclear Regulatory Commission to fulfill the regulatory role. During this optimistic phase, the nuclear industry was most vigorous in its promotion of the technology. For example, beginning in 1963, plants were offered to utilities for the first time on a strictly commercial basis with so-called "turnkey" contracts, so named because the purchasing utility was guaranteed that the plant would be completed at a fixed price and needed to do little more than "turn the key" to begin operations.

As the initial developer of nuclear technology, the United States became the world leader in efforts to build nuclear power plants, to commercialize them, and to promote the technology among the industrial nations. It continues to exercise major influence on the industry worldwide. Also, its commitment to nuclear, with only slight variation, has persisted through 10 successive presidential administrations. Hence, this early and lengthy experience with nuclear energy makes the United States an especially suitable focal point for examining the evolution of public acceptance of the technology. Although this examination focuses principally on the U.S. experience, it closely reflects the experience of other countries, such as Germany, Canada, Japan, the United Kingdom, and leading promoter France, although France exhibits certain deviations from overall patterns.

2. NUCLEAR GENERATION

In January 2003, 31 countries worldwide produced electricity with nuclear energy in 441 power reactors. World generating capacity totaled 359 GW (359,000 MW), representing 16% of total worldwide electricity production. With the completion of the 32 plants currently under construction, generating capacity is expected to increase by 7.5%, and it may increase another 10% if the 32 additional planned plants (35% larger, on average) are eventually completed.

Table I presents data for each of the world's nuclear nations. In terms of total generating capacity, the United States leads the world with 98.2 GW (104 reactors), followed by France with 63.1 GW (59 reactors), Japan with 44.3 GW (54 reactors), Germany with 21.3 GW (19 reactors), Russia with 20.1 GW (30 reactors), South Korea with 14.9 GW (18 reactors), the United Kingdom with 12.1 GW (31 reactors), Ukraine with 11.2 GW (13 reactors), and Canada with 10 GW (14 reactors). As a percentage of total electricity, Lithuania leads the way with more than 80% of its electricity produced by nuclear, followed closely by France (the largest

TABLE I

Nuclear Capacity and Operations of the World's Nuclear Nations

Country	Nuclear generating capacity (Gwe)	No. of nuclear power reactors (as of February 2003)	Nuclear as a % of total electricity generation (as of 2002)
Argentina	0.935	2	7.2
Armenia	0.376	1	40.5

United Kingdom	12.052	31	22.4
United States	98.230	104	20.3
Total	358.46	441	30[a]

[a] 16% of world total.

exporter of nuclear energy) at approximately 80%, Belgium at 57%, Ukraine at 46%, Sweden at 45%, Bulgaria at 47%, Switzerland at 40%, Japan at 34%, South Korea at 38%, the United States at 20%, Canada at 12%, and Russia at 16%.

Generating 16% of all electricity consumed in the world, nuclear power clearly remains a significant energy source. However, the significance diminishes considerably when placed in the context of projections made in the 1960s and 1970s during the heyday of the technology. One estimate projected 3000 plants worldwide by 2000 (nearly 7 times actual capacity), whereas another estimate, the 1972 Atomic Energy Commission's most optimistic estimate for the United States alone, called for 1200 plants by the same year (nearly 12 times actual capacity). Not a single plant was ordered in the United States after 1978, and every plant ordered after 1974 was eventually canceled so that not a single reactor built in the United States was ordered after 1973.

A number of industrial nations have chosen to forego the nuclear option, especially in the post-Chernobyl era: Australia, Austria, Denmark, Italy, Ireland, and Norway. Sweden continues to operate its 11 nuclear reactors (1 was closed in 1999) and has extended the 2010 date calling for the shutdown of all plants due to a 1980 national referendum, but it continues its policy of phasing out nuclear power. Germany, an early enthusiast for nuclear energy, passed legislation in 1998 for the eventual phase out of nuclear power but subsequently modified the policy in 2001 to limit the operational lives of existing plants to 32 years, thereby deferring any immediate closures. Japan, 80% dependent on imported energy, has scaled back its design for nuclear because of a September 1999 accident in Tokai, Mura, Ibaraki Prefecture, where two workers died from severe radiation and dozens of others were exposed.

A clear exception to this general pattern for the trilateral nations is Finland, the first nation in the world to have an approved site for the disposal of high-level nuclear waste and whose parliament in mid-2002 approved the building of a fifth nuclear power plant. Finland's success with its nuclear program may be the harbinger for a jump-start of the sagging nuclear programs of the majority of Western nations, or it may be an anomaly stemming from other unique features of Finnish history (e.g., its recent transformation from an agrarian to industrial society) and its unitary form of democracy.

Apart from Japan, nuclear capacity continues to grow in Asia (at the world's fastest rates), especially in China, the Republic of Korea, Taiwan, India, and Pakistan. As of 2002, more than two-thirds of the more than 32 reactors in 11 countries under construction throughout the world were located in Asia. Whether these nations will continue to experience growth uninterrupted by social and political obstacles or whether they will encounter difficulties similar to those experienced by Western

nations will be the subject of considerable scrutiny throughout the world.

In summary, although nuclear energy has assumed a significant and durable role in the energy mixes of a number of nations, its share of that mix is far short of the projections of three decades ago and with current technology it is projected to grow only moderately or even decline by midcentury. Furthermore, nuclear power is stalemated in many countries. What accounts for the striking underperformance of this technology? A number of factors conspired to derail nuclear's trajectory to predicted success: shifting energy markets, geopolitics, capital shortages, historical turns, and a failure to gain widespread public support. To what extent will these factors persist to obstruct a nuclear future?

A proper assessment of the future prospects for nuclear power requires consideration of those features of the historical context that are undergoing change. Two features loom particularly large in this respect, an internal one and an external one. Recognizing fundamental flaws in past reactor designs, such as the mushrooming of alternative designs and plant sizes and of limitations in safety systems, the world nuclear industry is working toward the development of generation IV reactors, a series of designs that are simpler, more fuel efficient, and arguably safer. The second, larger context is the scientific consensus over the warming of the planet due to the accumulation of greenhouse gases, especially CO_2. The evolution of these contexts is discussed in the next section.

Despite past experience and what appears to be a propitious new environment for nuclear power, the future of the technology will rest, ultimately, on public acceptance. Hence, the remainder of this article is devoted to the evolution of public attitudes toward nuclear power and to the implications the historical patterns have for the future of the technology. It is organized around three general themes: the evolutionary status of public attitudes toward the technology, the willingness by publics to see nuclear growth, and how publics view the technology abstractly.

3. EVOLVING CONTEXTS

3.1 New Reactor Designs

Nuclear power reactors are typically categorized in generational terms, reflecting evolutionary changes in design, size, and operational uses. Generation I reactors, the earliest to be developed in the 1950s and 1960s, were typically small (often based on submarine designs), with few still in operation today. Generation II reactors are the most common type of reactor in use today, dominated by U.S. light-water technology. Generation III reactors, an advanced design, are still in their incipient stages of development, with only a handful in operation in Japan. Generation IV reactors are the most advanced designs currently under development by 12 nuclear nations.

Comprising more than six different designs and systems, generation IV reactors all have in common higher (often much higher) operational temperatures than those of reactors currently operating. For some designs, this will allow for hydrogen production. Among the many other benefits arguably resulting from this generation of reactors are simpler designs and operations, thereby increasing safety; improved fuel efficiency, thereby improving the competitiveness of nuclear electricity; and use of a closed fuel cycle, thereby reducing the amount of high-level wastes to be managed.

Whether the increased safety of this new generation of reactors will attract widespread support for nuclear power will depend on a safety record that confirms the safety claims and whether publics trust the proponents of the new designs.

3.2 Global Climate Change

The emergence of a scientific consensus over global climate change has shed a new spotlight on nuclear power. Because it does not emit the principal greenhouse gas, CO_2, nuclear power is now viewed by many observers as a principal source of future energy poised for renewed, rapid growth. If there were dramatic new growth in nuclear power it could indeed reduce the rate of CO_2 emissions, but it should be recognized that nuclear is not the sole solution to global warming. Nuclear energy currently accounts for only 2.5% of total world energy consumption (8% in the United States and 33% in France), and its growth is limited by electricity's meager 16% share (the only type of usable energy produced by nuclear) of world energy consumption. The 16% share could increase as a function of electricity's growing fraction of total energy use, but nuclear's potential for addressing climate change issues nevertheless remains relatively small.

Whether public recognition of the seriousness of climate change and nuclear's ameliorative role in curbing it will swing the pendulum of public opinion to majority support is a difficult question to assess. Among the many unresolved issues the question raises is how citizens will balance a very diffuse and

perhaps distant risk whose observable consequences are not immediately known (climate change) against a very proximate risk (nuclear accidents) for which some of the consequences are known. The social psychological literature suggests that the proximate risk would trump the diffuse one.

4. PUBLIC REACTIONS TO NUCLEAR POWER IN THE UNITED STATES

4.1 Long-Term General Trends

4.1.1 Building More Nuclear Power Plants

As noted previously, the ultimate fate of nuclear power rests with public acceptance. The longest running nuclear time series, providing the best available window for assessing the evolution of public opinion, concentrates on attitudes toward the continued growth of nuclear power. Similar, but not identical, growth questions have been asked by leading polling organizations Louis Harris and Associates and Cambridge Reports Research International. The evolution in opinion about nuclear plant construction, including opinion reversal, can best be seen by charting trend lines for these data series. Figure 1 presents a trend line from the Harris data and Fig. 2 presents a trend line from the Cambridge data.

The Harris item asking for opinions about building more nuclear plants was first asked in 1975 and repeated until 1990. In general, until the late 1970s a majority of Americans supported, often by wide margins, growth in nuclear power (an exception is the April 1976 result showing a plurality of support). Then, immediately following the accident at Unit 2 at Three Mile Island (TMI) in Pennsylvania in April 1979, this support eroded considerably but still consistently exceeded opposition. With the May 1979 survey, support had regained its majority position but appeared to be standing on much shakier ground than before the accident: Over the course of 12 surveys conducted over the next 22 months, support for nuclear power, although generally consistent, vacillated between bare majority and plurality. In one case, May 1980, opposition actually exceeded support by

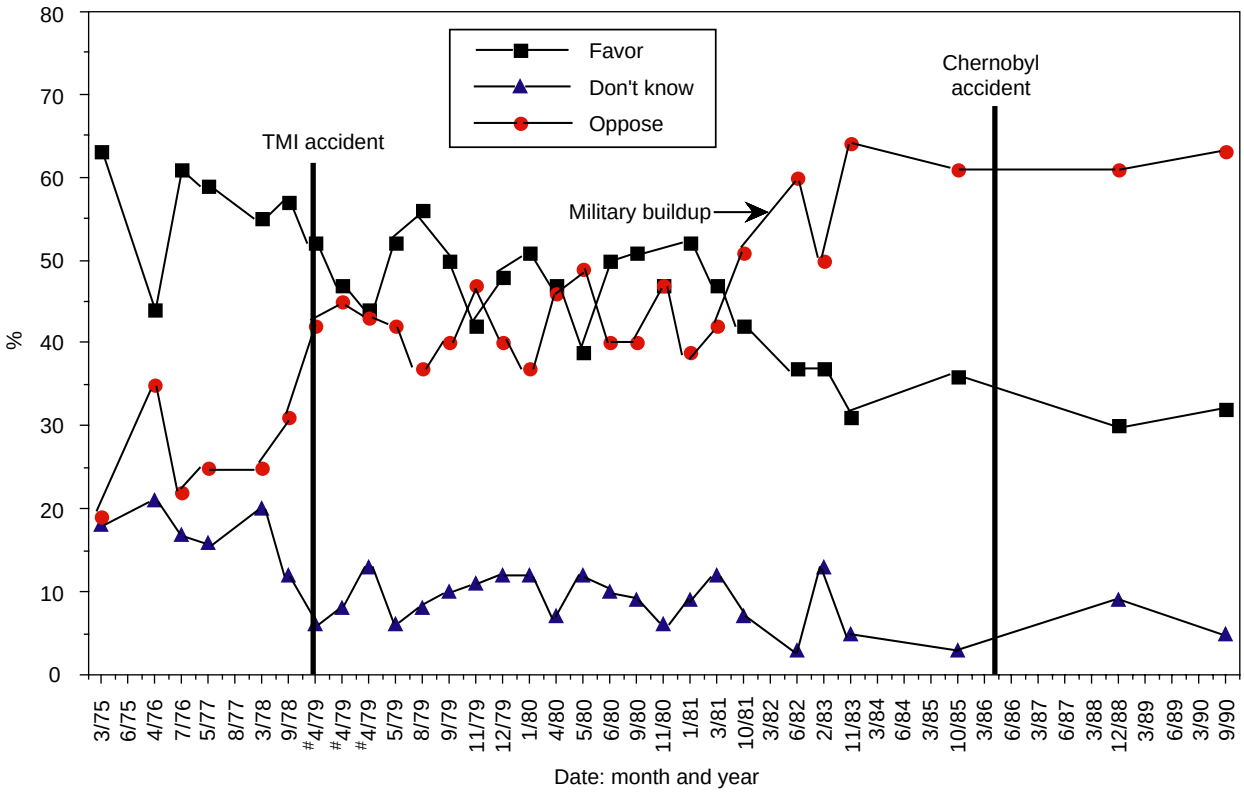

FIGURE 1 Public attitudes toward building nuclear power plants in the United States. Question: "In general do you favor or oppose the building of more nuclear power plants in the United States?" TMI, Three Mile Island. #Indicates multiple surveys in the same month. Source: Louis Harris and Associates national samples.

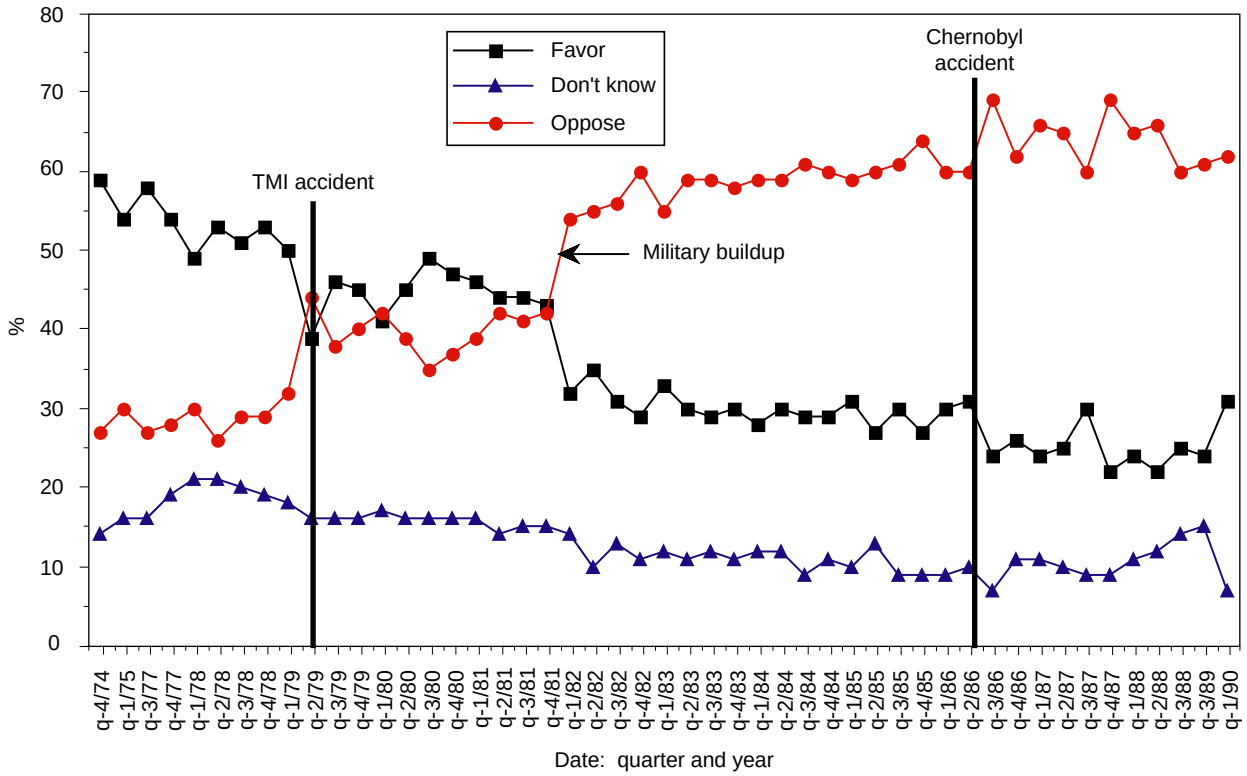

FIGURE 2 Public attitudes toward building nuclear power plants in the United States. Statement: "I am going to read you a list of proposals for dealing with the energy crisis, and I'd like you to tell me whether you generally favor or oppose each one … Building more nuclear power plants." TMI, Three Mile Island. Source: Cambridge national samples.

10 percentage points, but this was a temporary setback lasting for only a short period of time.

In contrast, the October 1981 result showing majority opposition signaled not just a temporary setback but also a break with the past—indeed, a reversal in public preference for nuclear growth. Since then, opposition has consistently exceeded support. In fact, over the past 4 surveys spanning 7 years, opposition exceeded support by a margin of approximately 2:1, a complete reversal from the earliest Harris survey.

Cambridge, likewise, queried the public repeatedly about whether to build more nuclear power plants. In the fourth quarter of 1974, Cambridge began asking Americans their views about building more nuclear power plants as a way of dealing with the energy crisis. That Cambridge contextualized its question within a concern for the energy crisis is perfectly understandable given that it first polled the public on the subject in the months following the Arab oil embargo of 1973–1974 when national agendas were dominated by the idea of an "energy crisis." This contextualization distinguishes the Cambridge series from the Harris one, and one might expect it to have a noticeable affect on the overall trends. With the notion of crisis in mind, citizens might be willing to accept any energy source that would mitigate or eliminate the crisis, including nuclear power. It might also be the case that in later surveys, long after the idea of crisis had receded from public consciousness, the effect could be in the opposite direction: Because a crisis no longer exists, there is no urgent need to build more nuclear power plants.

Figure 2, presenting the Cambridge trends, exhibits similar patterns to the Harris results; nuclear power enjoyed consistently strong support throughout the 1970s, at least up until the TMI accident in April 1979. The effect of the accident on public attitudes is apparent, as opposition exceeded support for the first time in the second-quarter 1979 survey. By the third quarter of that year, however, support had rebounded sufficiently to outpace opposition, but not by as large a margin as before the accident. Furthermore, while support remained consistent during the next $2\frac{1}{2}$ years, covering 10 surveys, it was only a plurality of support, and sometimes barely that. Then, sustaining the pattern of the Harris results, a sharp reversal in opinion appeared

(showing up for Cambridge in the first quarter of 1982), with a majority of respondents expressing opposition to further nuclear plant construction. What is most noteworthy about this shift from majority support to majority opposition is the fact that it endured across all subsequent surveys over the course of 8 years. Furthermore, for most surveys the ratio of opposition to support approaches or exceeds 2:1—again, a near-perfect reversal of public preference in the early 1970s. Finally, the substantive similarity between the Harris and Cambridge results suggest that wording effects, if there are any, do not markedly alter the overall patterns.

In general, despite the slight wording changes between the polling organizations, a common and persistent pattern of growing opposition to the building of more nuclear power plants emerges. The pattern comprises three distinct stages: an early stage in the 1970s when Americans were enthusiastic about nuclear growth, a second stage of ambivalence following TMI when a less enthusiastic plurality of citizens consistently supported growth, and a third stage emerging in the early 1980s when a decisive majority of Americans opposed building more nuclear power plants in the country. Apace with the decline in support for nuclear power plants was the decline in the proportion of "don't knows," reflecting, perhaps, the eventual crystallization of attitudes.

A focus on the timing of the reversal illuminates still another striking feature in the overall pattern: the change in attitudes, with opposition overtaking support, occurred more than 4 years before the Chernobyl nuclear accident in the Ukraine. This was apparently due to a renewed fear of nuclear war stimulated by the Reagan administration's bellicose posture toward the Soviet Union and the accompanying buildup of nuclear arms. Whatever the reason for the striking shift in attitude, it set in motion a steady growth in opposition that continued to the very end of each data series. With such a high level of opposition, there was little room for further opposition, so the Chernobyl accident evidently did not have a marked impact on public attitudes: At the time of the accident, opposition already exceeded support (best seen in the Cambridge results in Fig. 2) by nearly two to one. Whatever effects Chernobyl may have had, they were apparently negligible compared to the sustained long-term decline in support for new nuclear power plants.

Although these data provide a clear picture of the evolution of opposition to nuclear power, the question about building more nuclear plants has not been repeated for more than a decade. Given the propitious new winds for nuclear power noted previously, how can we be certain that opposition to the building of more plants remains at this high level? Four polls address this question. A March 1999 poll of registered voters found 60% opposed and 26% in favor of building more nuclear power plants. A March 2001 Gallup poll of all adults found less but still majority opposition (51 vs 44%). Two 2001 polls of all adults by ABC News/*Washington Post* sustain the conclusion that opposition to the building of nuclear power plants is still in the majority. In its January poll, 60% were either somewhat or strongly opposed, whereas 37% were somewhat favorable or strongly favorable. Its June poll revealed some relaxing of opposition but still with a majority (52%) opposed, whereas 41% were in favor.

Clearly, the American public does not support the construction of additional nuclear power plants. This is the unmistakable message contained in the longest running time series assessing nuclear opinion, reaffirmed by recent survey data.

The public opinion experience of other countries deviates somewhat from the pattern in the United States but available data suggest that citizens in most nuclear nations have lingering reservations about the technology. For example, although opposition to nuclear power in Sweden has softened during the past two decades, opposition still outpaces support for the technology. Available public opinion data in Japan show a very similar pattern to that of the United States, except that opposition's overtake of support did not occur until the Chernobyl accident in 1986, and recent data show the Japanese to be more fearful of a nuclear accident than any other nation.

In comparison to the nuclear stalemate in much of the world, France has experienced nearly uninterrupted success with its nuclear program. This has repeatedly prompted nuclear proponents to point to France as the exemplar of not only a successful nuclear program but also a model for other nuclear nations to emulate. Whether France is an appropriate model for other nations to follow is subject to considerable debate. Key differences distancing France from other nuclear programs include its monopoly ownership by a single government utility, Electricité de France; its unique system of training for its technological elite; its strategy of adopting a single design for all its reactors; its practice of siting multiple reactors at a single location; its unitary democratic structure; and its policy style (called technocratic etatism), in which individual liberties are subordinated to the will of the state.

Added to these obvious differences are others more subtle but no less important to France's nuclear success. In public opinion polls, French citizens are consistently more supportive of nuclear than their American counterparts. What accounts for this persistent pattern? In the only comparative opinion study between French and American publics it was found that perceptions of the risk of nuclear power were virtually identical between the two publics, thereby eliminating risk as an explanation for the national differences. French citizens distance themselves from Americans in their strong belief in the need for nuclear power, their more fatalistic viewpoint about its risks, their greater trust of nuclear management, and especially their greater trust in experts and civil authority (a feature of etatism). There are likely similar differences between the French and citizens of other nuclear democracies.

4.2 Proximate Trends

4.2.1 Nuclear Power as a Source of Electricity

The sole commercial use of nuclear power is the generation of electricity. Despite the long-term trends showing a growing dissatisfaction with the building of more nuclear power plants in the United States, perhaps the public is more supportive of the technology when it is connected directly to its instrumental purpose: the generation of electricity. In a poll taken soon after the Chernobyl accident, the public was evenly split on the use of nuclear power to generate electricity, but a strong 55% majority favored nuclear in a follow-up poll in 1989. Other polls on public attitudes toward nuclear power as an electricity source followed. For all three polls conducted between 1992 and 1993, a majority of respondents favored (strongly or somewhat) the use of nuclear power to generate electricity. It should be noted, however, that these polls did not ask for unqualified support for nuclear power but as one of the ways of providing electricity. Americans are apparently aware that nuclear is already an important energy source for the generation of electricity. Two surveys in 1986 and 1989 asked how important nuclear was in meeting the nation's electricity needs today. A sizable majority in both (70%) agreed that it was important. The most recent data show a considerable softening of support, although the general pattern is sustained.

4.2.2 Local Siting of Power Plants

It is one thing to have an opinion toward the construction of nuclear power plants in the abstract; it is another thing to be confronted with the prospect of having a plant built nearby. Figure 3 presents trend data from national samples that asked about having the local electric company build a nuclear power plant in the area.

The early siting of nuclear power plants was hardly a controversial matter. Indeed, in five of the earliest polls 55% responded favorably, nearly twice the level of opposition. However, opposition to local nuclear facilities began to increase as early as 1974. By 1976, a slight plurality, and by 1978—before the TMI accident—a clear majority of respondents opposed the construction of a nuclear power plant within 5 miles; in less than a decade the opposition reached 73%. Polling asking whether citizens would be willing to have a nuclear power plant within 10 miles of their community attracted 54% opposition in 1999 (compared to 21% in favor) and 50% opposition in 2000 (compared to 22% in favor). In a 2001 poll, 63% of the adults sampled were somewhat or strongly opposed to the construction of a nuclear power plant "in their area," whereas 33% were somewhat or very favorable to the idea.

It might be expected that, as had been the case regarding the building of nuclear power plants in the abstract, Americans would be more tolerant of local nuclear plants if they were reminded that the purpose of the technology was to provide electricity. Cambridge and Gallup, using an identically worded item, attempted to assess this possibility in a series of polls from 1986 to 1990. The most popular of three possible responses, attracting near-majority to clear-majority support, was to "reserve judgment"—perhaps reflecting, on the one hand, a reluctance to reach a firm position until apprised of the specific circumstances surrounding such a decision and, on the other hand, a willingness to leave open the nuclear option as a hedge against future electricity shortages. Of those who had evidently formed an opinion about a local plant, opposition consistently outweighed support, but by a declining margin over time.

4.2.3 Local Host Communities

As suggested by the data (Fig. 3) about the local siting of nuclear power plants, in the early years of nuclear commercialization communities hosting plants were quite supportive of the technology. Indeed, a number of communities actively sought to attract nuclear power plants for economic reasons and as a matter of technological pride. This early enthusiasm is sustained by the trend data in Fig. 4, a summary of 36 host community surveys.

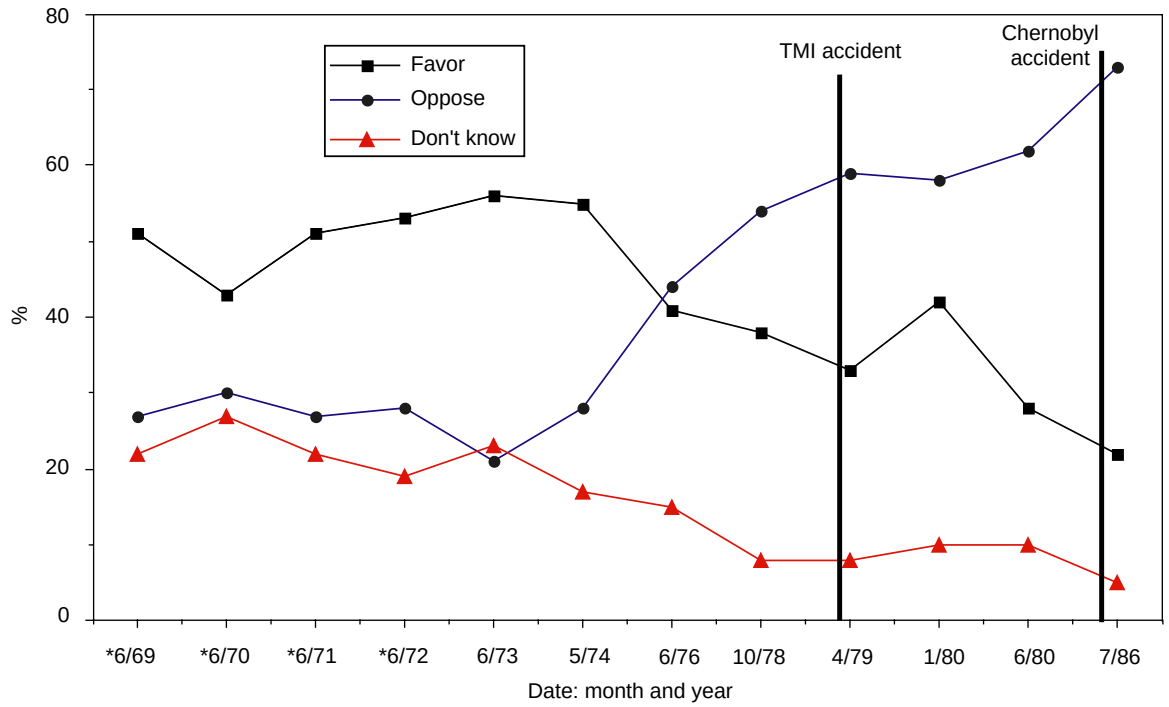

FIGURE 3 Public attitudes toward construction of local nuclear power plants. Question: "Suppose your local electric company said it wanted to build a nuclear power plant in this area. Would building such a plant be all right with you, or would you be against it?" TMI, Three Mile Island. *, Month survey conducted not reported in original sources. Midyear dates were assumed. Source: Cambridge national samples. Boulder, CO.

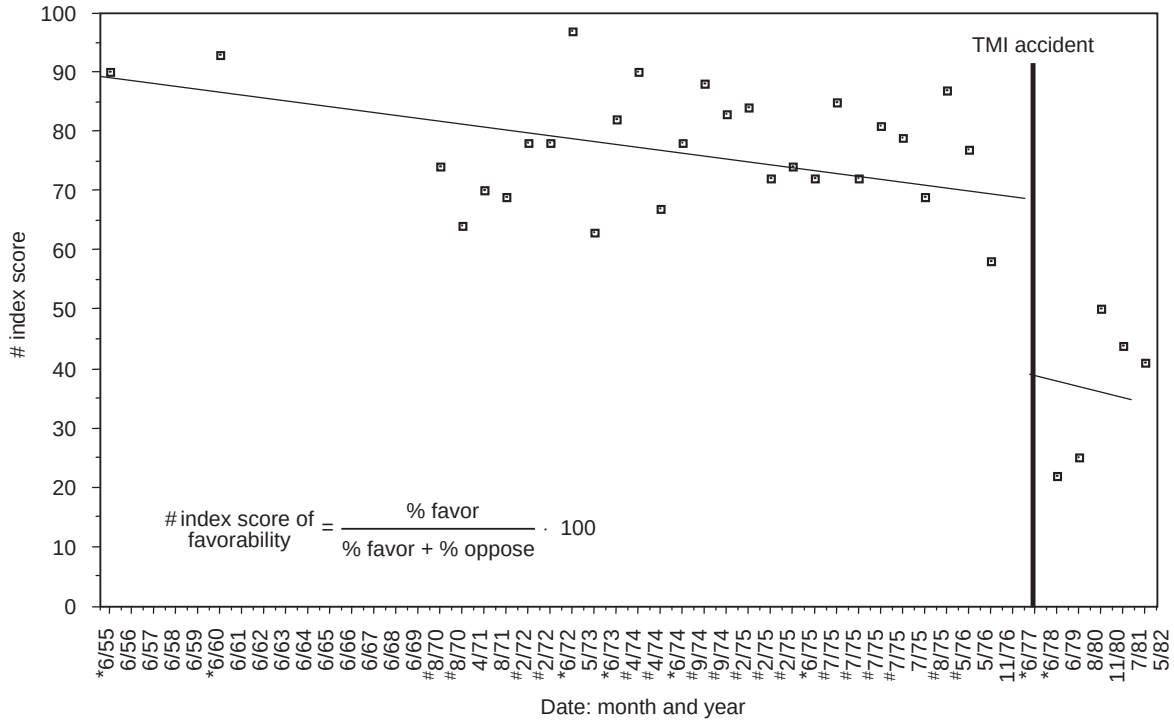

FIGURE 4 Host community attitudes toward nuclear power plants before and after the Three Mile Island (TMI) accident. *Month survey conducted not reported in original sources. Midyear dates were assumed. #Indicates multiple surveys in the same month. Source: Cambridge national samples.

Post-TMI data suggest, however, that host community support can no longer be taken for granted. In none of the surveys conducted before the TMI accident was opposition found among more than 33% of respondents; in no known survey after the accident has there been less than 50% opposition. Regression analysis shows that more than 70% of the explained variance across the surveys is due to the TMI accident. Host communities in the United States, once supportive of nuclear facilities in their vicinity, now show considerable reservation about having those facilities nearby. Also, the siting of nuclear facilities is a persistent problem in a number of nuclear nations.

5. ENVIRONMENTAL CONSCIOUSNESS AND NUCLEAR'S FORTUNES

The presented trend data clearly illustrate the dramatic impacts key events (the TMI accident and military buildup) had on public opinion about nuclear power. However, preceding the reversal in general attitudes by several years was growing disenchantment with local nuclear facilities—the principal fault line in the growth of nuclear power. What accounted for this early disenchantment?

In the late 1960s and early 1970s, the Western world experienced a profound cultural change in collective consciousness in which environmental impacts, previously a set of disparate concerns, coalesced into an environmental consciousness. Signature features of this change were the passage of the National Environmental Protection Act in 1969 in the United States, a model for similar legislation elsewhere, and the first Earth day in 1970, the largest public demonstration in the history of the planet—attracting many millions of participants worldwide. Although these events did not immediately lead to a reversal in nuclear's fortunes, they established a cultural framework of unprecedented scrutiny of the technology. Early local opposition to nuclear power plants reflected the emergent consciousness with environmental issues such as thermal pollution (release of heat to rivers and lakes) and threats to marine species as the rallying cries for protest.

When the accidents at TMI and Chernobyl took place, publics everywhere were predisposed to see the events in the most negative light. Another element of the new consciousness, later to impact nuclear directly, was ever-greater demands on policy makers to more actively engage the public in decisions regarding large-scale technologies.

The emergence of a consciousness potentially critical of nuclear energy was one side of the energy supply coin. Missing was the other side of the coin that provided a coherent alternative, a revolutionary vision of an energy supply mix absent a nuclear component. In the 1970s, many scholars were attracted to the issue, but none could match the impact of E. F. Schumacher's "appropriate technology" vision or Amory Lovins's "soft path" vision. Now, instead of a focus on nuclear technology versus its alternatives, the focus was broadened to a criticism of the megascale, centralized energy supply systems of industrial societies. Lovins went further, developing a detailed blueprint of renewable energy systems absent a nuclear component.

6. THE PRESENT AND THE FUTURE

6.1 Pragmatism

Does the sizable opposition to the building of more nuclear power plants translate into a deep-seated aversion to the technology, into an unreflective rejection of all matters nuclear or even a willingness to get rid of the technology completely? Is the opposition the result of sensible caution about a large-scale technology that is neither simple nor risk-free? In one survey, respondents were asked whether nuclear power was a good choice, a realistic choice, or a bad choice. Strong pluralities to majorities consistently said it was a realistic choice. The remaining 40–50% of the public was more likely to say it was a bad choice, but sometimes by only narrow margins.

With regard to eliminating nuclear power, only minorities of Americans have supported this option. The most frequently chosen option, attracting sizable pluralities to majorities, favors the status quo: Let the existing nuclear plants operate, but do not build any more. Taken together, the picture that emerges from these items is not one of a knee-jerk public passionately committed to the riddance of nuclear energy but of a pragmatic public weighing technological risks against unforeseeable future energy needs. As a hedge against a shortfall in future energy supply, the public appears willing to leave the nuclear option open.

6.2 Nuclear Futures

What does the public believe the future holds for nuclear power? The longest running time series, the

Harris and Cambridge ones, asking about building more nuclear plants are of limited use in addressing this question because the time orientation of these items is ambiguous. The ambiguity can be avoided with questions that specifically refer to the future, as have a number of polls.

Since 1985, Americans have repeatedly been asked how important they think nuclear energy plants will be in meeting the nation's electricity needs in the years ahead. The trend data of responses to this question are presented in Fig. 5.

It is clear that sizable majorities of Americans see an important role for nuclear power in the future. Three-fourths of respondents have consistently thought nuclear power will play a very important or somewhat important role in meeting the nation's future electricity needs. This finding is consistent with public knowledge of the importance of nuclear-generated electricity and with the public's pragmatic acceptance of the status quo. The picture changes somewhat when Americans are asked whether the nation should rely more on nuclear power in the future. In two polls, respondents were slightly more inclined to opt for less nuclear power in the future.

6.3 Nuclear as a Trade-Off Choice

Nearly all imported oil is used for petroleum products and not for the generation of electricity. Nevertheless, Americans have been asked whether they would favor nuclear power if it would reduce the nation's dependence on foreign oil. Presented with such a trade-off, majorities of the public favor nuclear power—often by sizable margins.

The modern trade-off context is the question about substituting nuclear for fossil fuels (especially coal) in the generation of electricity to reduce greenhouse gas emissions. What is the level of public support for nuclear power to address global warming? Data directly addressing this question are meager. Surveys from the 1990s show that majorities believed that nuclear energy could cut greenhouse gas emissions and air pollution and vast majorities would favor using nuclear energy to cut greenhouse gases and air pollution. Recent data, however, contradict that finding. Asked whether they would favor nuclear power as a means "for dealing with the pollution that causes climate change," a majority of citizens (55 vs 42%) were opposed. Thus, we have a far from complete answer to this question.

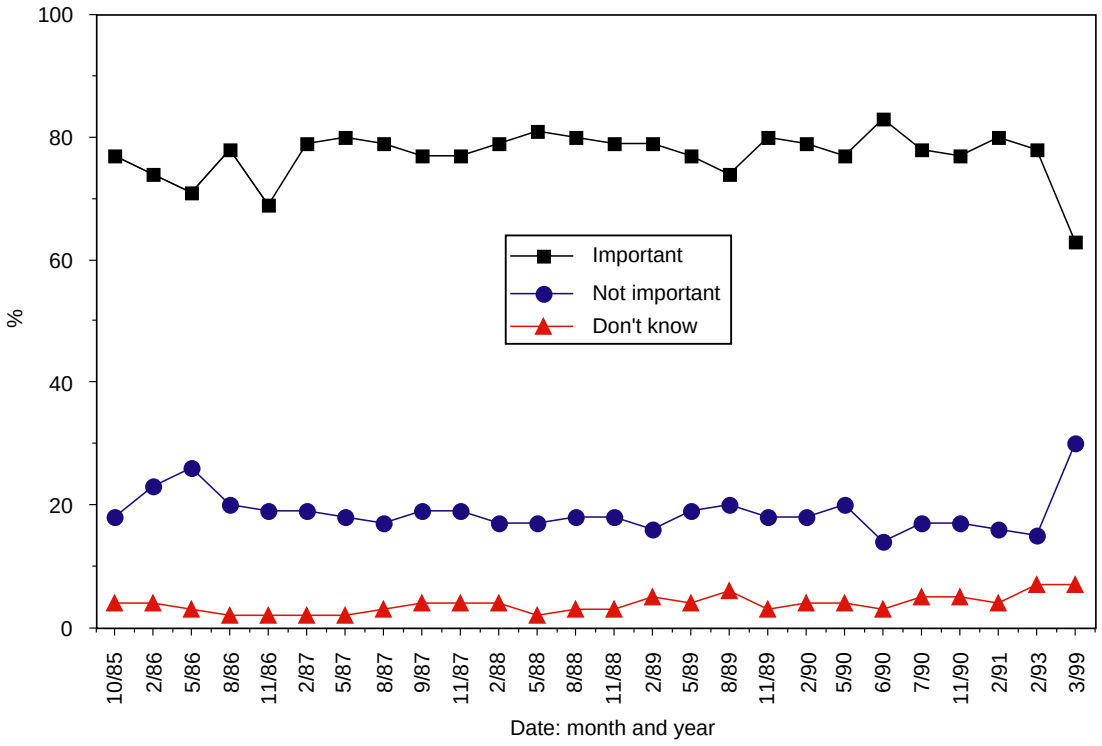

FIGURE 5 Importance of nuclear power in the future. Question: "How important do you think nuclear power plants will be in meeting this nation's electricity needs in the years ahead?" Source: Cambridge reports and Gallup national samples.

6.4 Interpreting the Public Mood

Taken together, the overall results may appear contradictory, perhaps even irrational. On the one hand, solid majorities of the American public oppose the construction of more nuclear power plants and are likewise opposed to their local siting. On the other hand, equally solid majorities believe nuclear power will be an important energy source in the nation's future, although this is not necessarily their first choice. What accounts for the apparent contradiction? In our view, the results do not reveal a contradiction but instead a pragmatic logic whereby the public distinguishes between nuclear power in principle and in practice.

For nuclear power, it appears that the collective public's preference for specific policy actions can be quite different from its general attitudes. Thus, Americans appear generally to support a role for nuclear power in the future and are solidly behind the idea of leaving the nuclear option open—perhaps as a trump card against possible future energy shortages. However, when it comes to the specific instrumental means for achieving that future—namely, the siting and construction of nuclear power plants—they are solidly opposed. What are the key impediments to the realization of the public's expected nuclear future?

7. NUCLEAR IMAGERY

Underlying attitudinal responses and global assessments of nuclear energy are a variety of cognitive filters as well as images that shape thoughts and dispositions toward the technology. Although nuclear energy is Janus-like, with inherent benefits and risks, there is considerable evidence showing negative imagery is much deeper than positive imagery, overpowering the positive with salient thoughts of danger, toxicity, death, sickness, destruction, pollution, and the like. Some researchers have gone further, arguing that nuclear facilities, especially nuclear waste facilities, attract stigma—a deeply discrediting or devaluing feature that marks them for special concern or avoidance. Although the claim for stigma may stretch the available evidence, it is unequivocally clear that images associated with things nuclear are predominately negative and militate against the unreserved acceptance of the technology. There is little doubt that the future of nuclear energy is heavily dependent on overcoming this deep negative imagery.

8. NUCLEAR WASTE

One of the unavoidable by-products of nuclear-generated electricity is the production of a variety of highly radioactive wastes. Originally believed to be a tractable, and solvable problem, a solution to the disposition of nuclear waste still eludes the nuclear establishment worldwide. Although there is a universal scientific consensus that deep geological isolation is the preferred solution to the disposition of wastes—especially high-level wastes with their extremely long radioactive half-lives—no nuclear nation has built a geologic repository or has emplaced any waste. With few exceptions (e.g., Finland), no nation has even been able to achieve a sufficient level of political and public support to reach an uncontested final decision on the siting of a repository. In the meantime, the waste produced by nuclear energy accumulates in pools at reactor sites or at military installations.

A failure to solve the waste problem proves to be especially challenging in gaining public acceptance of the technology. Publics everywhere hold deep negative images of nuclear waste—even deeper than for nuclear power—and are opposed to siting a repository not only in their immediate vicinity but also just about anywhere. When asked to indicate the closest distance they would be willing to live in the vicinity of a variety of facilities, a nuclear waste facility typically ranks last—in one survey at 200 miles away (twice the distance from the next most undesirable facility, a chemical waste landfill, and three to eight times the distances from oil refineries, nuclear power plants, and pesticide manufacturing plants).

Particularly revealing of the depth of negative imagery associated with nuclear waste are results from a survey in which citizens were asked to associate freely about the concept of a nuclear waste repository. The vast majority of images elicited were extremely negative, punctuated by such categories as dangerous/toxic, death/sickness, environmental damage, and bad/negative.

Thus, a failure to solve the nuclear waste problem could be the Achilles' heel of nuclear power, ensuring a continuation of the technology's cloudy future or worse—its ultimate failure. That the ultimate success of nuclear power is conditioned by a solution to the waste problem is underscored in a 2001 Eurobarometer poll conducted in 15 European Union (EU) countries. When asked, "If all waste is managed safely, should nuclear power remain an option for electricity production in the EU?" 51% of the 16,000 respondents answered in the affirmative, whereas

near equal percentages rejected this option (25%) or had no opinion (24%). This conditional favorability, however, is tempered by the strong plurality (46%) of the same respondents who said they thought that there was no safe way to dispose of the waste.

9. CONCLUSION

If it were written in ancient times, the history of nuclear power in the United States and elsewhere would be written as a drama between two mythical figures: the Phoenix and Hydra. Like the mythical Phoenix that arose from its own ashes, the nuclear establishment—a combination of scientific, commercial, and policy interests—counters each setback to nuclear's fortunes with either organizational or technical fixes. The emergence of a fourth generation of reactors, presumably much safer than their predecessors, is the most recent manifestation of this pattern. In contrast, since the mid-1970s the general public has viewed nuclear power as a many-headed Hydra in which as soon as one of its concerns is addressed—or recedes from consciousness—two others spring up to take its place.

Since the first sustained chain reaction at Stagg Field at the University of Chicago in 1942, commercial nuclear power has experienced paroxysms of enthusiasm and growth, followed by extended periods of reflection and reconsideration. Public support for the technology began with unrestrained enthusiasm, only to be followed by extended periods of doubt and reservation. Currently, two clouds of uncertainty continue to shroud public acceptance of the technology: the safety of nuclear plants and the challenge of disposing of nuclear wastes, especially high-level wastes.

Whether public acceptance can be regained with a new generation of reactors with advanced designs—argued to be inherently safer than the current generation of reactors—will depend on a sequence of contingencies. It will depend on whether the claims about safety are credible, whether credible arguments about safety can overcome the deep negative imagery that shrouds the technology, whether alternative technologies emerge and are economically competitive, and on the vagaries of the future geopolitics of energy supplies. It will also clearly depend on solving the nuclear waste problem.

Irrespective of the regaining of public trust for nuclear power and its management, it is unlikely that the technology will be abandoned worldwide—at least not in the foreseeable future. Too much has already been invested in nuclear infrastructure (including many national and international institutions), too many national states see a significant role for nuclear in their future energy mix, and too many powerful technological elites remain committed to promoting its growth. However, many questions remain. Will nuclear power remain in steady state (eventually resulting in its demise as the current inventory of plants reach the end of their usable lives) or grow again? Will it be able to grow absent a successful program for the disposal of nuclear wastes? If it does grow, will it be in a supportive public climate or a climate of continuing tension, forcing the government to take a more active role in overcoming or circumventing those tensions—perhaps with legislative or regulatory actions that erode the democratic process? All these questions embed even deeper and more challenging ones about technological knowledge, historical contingency, political culture and climate, and the evolution of democracies. It will be the answers to these hoary questions that will determine the future of nuclear power.

Glossary

attitudes Unlike physical objects, attitudes cannot be seen or weighed. Instead, they are more like the biological concept of life—difficult to define but sufficiently important and pervasive to have attracted considerable study. In general, they are seen as being like opinions but more deeply connected to one's overall orientation toward the world (and hence less likely to change) while not as deeply connected as values. In most of the technical literature, attitudes are seen as having three components—relatively factual beliefs, more emotional evaluations, and in many but not all definitions, "conative" or behavioral orientations, involving intentions to act in certain ways but not others.

Continental Shelf The relatively shallow ocean-bottom lands close to the edge of a continent. In many but by no means all cases, these lands do form a literal shelf, sometimes extending for dozens or even hundreds of kilometers beyond dry land before dropping off into deeper waters. In the United States, the outer Continental Shelf includes the ocean-bottom lands beyond the limits of state jurisdiction (generally 3 miles from land).

Dutch disease A term that is sometimes used to describe almost any case of economic weakness in the face of resource exports but that more formally refers to economic weaknesses resulting from twin problems experienced in The Netherlands in the wake of its North Sea oil discoveries: (i) a significant increase in the strength of national currency (making its other exports more expensive) and (ii) a tendency for the oil sector to draw people and capital away from other sectors of the economy, such as manufacturing and agriculture.

economic multiplier Many approaches to socioeconomic impact assessment divide local or even national economies into two broad sectors: economic base (or export) activities, which bring cash into an area through the selling of goods and services to people who live elsewhere (e.g., agriculture, oil extraction, and tourism), and nonbasic (or service) activities, which can create additional jobs by keeping the cash circulating locally (e.g., when people use that cash while visiting local shoe repair shops, restaurants, grocery stores, etc.). The ratio between basic and nonbasic activities provides the economic multiplier, although actual multipliers from new activities (e.g., new oil drilling) have often proven to be much lower in practice, in recent decades, than the ones that have been put forth in the proponents' economic models.

social multiplier Just as one economic base job can help to support other nonbasic jobs in the same community or region, one person who works for a given industry is likely to have many friends and relatives nearby, particularly in the case of an established industry. Since people tend to care not just about their own well-being but also about the well-being of their friends and acquaintances, there can be much stronger political support for an important industry (e.g., agriculture in Iowa and oil in Texas) than might be expected simply on the basis of the number of people or jobs supported by that industry directly.

tidelands controversies A series of battles during the mid-20th century involving political control over (and tax revenues from) new activities of offshore oil drilling in U.S. waters. The controversies were largely brought to an end by two pieces of legislation, one of which gave control and revenues to specific states for drilling taking place in territorial waters (generally those within 3 miles of shore) and the other of which granted control and revenues to the federal government for activities farther offshore.

 © 2004 Elsevier Inc. All rights reserved.

It was more than a century ago when humans first thought of the idea of drilling through water, as well as land, in search of oil, and during the course of this century, the attitudes or views about potential oil developments have varied widely. Rather than representing relatively random reactions, or anything approaching universal approval or opposition, local attitudes tend to vary more systematically across time and space. These attitudes, in turn, shape the policies and policy actions that can cause offshore oil development to be easier or more difficult to pursue. This article discusses the historical background and geographic extent of offshore oil development and the importance of three factors with regard to a region's attitudes toward offshore development: the region's historical relationship to oil development; the biophysical environment of the region, such as its coastal and marine topography; and relevant sociocultural conditions, such as educational levels, social networks, and prior economic adaptation.

1. INTRODUCTION

The first offshore drilling was actually done from a set of oil derricks along a pier that jutted into the Pacific Ocean off the shores of Summerland, California, southeast of Santa Barbara, in 1898, and the first offshore oil controversy erupted a few miles away the very next year. When an oil company began to construct an oil derrick off the shores of Montecito, California—the highly affluent Santa Barbara suburb that is adjacent to Summerland and that occupies the few miles of coastline between Summerland and Santa Barbara—a local mob, described approvingly on page 1 of the *Santa Barbara Morning Press* the next day as "a party of the best known society men of Santa Barbara, armed to meet any resistance," attacked the rig and tore it down.

The local "society men" seem not to have suffered any noteworthy legal repercussions from their actions, despite having been so well-known, but oil companies did: The graphic expression of local attitudes proved effective in blocking further drilling along that stretch of coastline for decades to come. Elsewhere in the world, however, for at least the next 50 years, most such efforts to find oil—offshore as well as on—were much more likely to be the focus of celebration, not protest. Had this article been written in 1953 rather than in 2003, it almost certainly would have included a discussion of what were known at the time as the "tidelands controversies," but as noted later, these controversies had to do not with opposition to offshore oil but with the virtual opposite, involving competition over which political jurisdictions would be able to enjoy the accompanying tax benefits.

Today, offshore exploration and production have spread throughout the world, taking place off the coasts of Africa, Australia, Central and South America, and Europe. In the United States, offshore oil is limited to a handful of rigs off Alaska's North Slope, 21 rigs off California (all in the Santa Barbara region, just a few miles away from Summerland and Montecito), and a vastly larger number of less famous oil rigs (approximately 3500) in the Gulf of Mexico, where some platforms are producing oil in water that is 2 miles deep.

As these patterns suggest, public attitudes toward offshore oil activities are far more diverse than once might have appeared to be the case. To understand what has happened in the century or more since the derricks first appeared on the Summerland pier, and to understand the variations in public attitudes toward offshore oil activities, it is useful to begin with a brief history. Following the historical summary, we present an overview of the variations that can be found in some of the key offshore regions of the world and then provide a more detailed examination of what appear to be the two polar cases—the two regions, both in the same country, where attitudes appear to be the most and the least favorable.

2. HISTORICAL OVERVIEW

The original impetus behind the search for offshore oil came just 17 months after the displeasure of the Montecito mob, when the world's first major petroleum reservoir, Spindeltop, was tapped on January 10, 1901, near Beaumont, Texas. Compared to the petroleum reservoirs that had been found in Pennsylvania and elsewhere during the latter part of the 19th century, Spindeltop was huge; its discovery transformed the petroleum industry, both in the United States and throughout the world. For purposes of this article, however, the key point is that the reservoir proved to be located under the limestone cap that covered the top of a salt dome. Not surprisingly, this discovery led to interest in other such domes, many of which are located off the shores of Louisiana and Texas.

Despite the early discoveries off the shores of south-central California—or perhaps in part because

of the reactions they inspired—it was not until the 1920s that offshore oil development began to be pursued in earnest. The pursuit took place largely under the waters of Lake Maraicaibo in Venezuela and more extensively in the marshes and the shallow, protected waters of the Gulf of Mexico. By far the greatest development took place along the Louisiana deltaic plain—the lands that were formed by the delta of the Mississippi River—once the development of nondestructive exploratory (seismic) techniques allowed oil companies to locate and explore the numerous salt domes along the Louisiana and Texas coasts of the Gulf of Mexico.

At the time, it may not have occurred to many of the oil companies that explored the Louisiana marshes, or the people who lived nearby, that they were involved in the early stages of developing what would become one of the great industrial innovations of the 20th century. What almost certainly did occur to them was that it was no simple matter to drill oil wells through the unstable soils of the region, especially in that the best oil prospects were often situated in marshes, swamps, and the shallow waters of bays and lakes. The initial techniques involved the construction of a platform on pilings that were driven into the coastal marshes, with drilling equipment brought to the site on barges and installed on the platform. From there, drilling proceeded much as it would have been done on land, except that transportation to and from the site was often by boat, and additional costs were created by the need to build a platform for each exploratory well. In addition, pilings driven into the thick layers of silt have no solid foundation, relying entirely on the friction between the pilings and the mucky bottom. Since drilling machinery produces significant vibrations, up to 250 pilings were needed for a single exploratory platform. As interest in deeper prospects increased, these early techniques became too costly, since the nonrecoverable cost of platform construction was a constant regardless of the outcome of the drilling.

The technological breakthrough that facilitated large-scale exploration came in 1933 when the Texas Company (later Texaco) introduced the "submersible" drilling barge: A drilling rig was simply mounted on a barge, which could be towed to a drilling site and flooded. Sitting on the shallow bottom, the barge provided a stable base for drilling; once the job was done, the barge could be refloated and towed to a new location. Lake Pelto, Louisiana, behind Last Island, east of the mouth of the Atchafalaya River, was the site of the first successful test of the technology, opening a new era in marine drilling. Within a decade, these rigs were in use throughout the marshes and shallow coastal waters in Louisiana and Texas, sparking a growing support sector for marine drilling.

Throughout the 1930s and 1940s, the submersible drilling rigs evolved, becoming larger and more powerful, allowing them to tap the deeper oil-bearing formations along the Gulf Coast. Steam engines were replaced by diesel-electric rigs, and the tungsten carbide drilling bit was introduced in 1952. By 1955, inland submersibles were setting world drilling depth records of 22,500 ft. Much of the initial exploration, drilling, and production occurred in eastern St. Mary Parish, Louisiana, and residents of nearby towns, primarily Morgan City and Berwick, appear to have been eager to help provide labor and support to the oil firms that were drilling in the challenging areas nearby.

As inland drilling rigs were evolving, the focus was shifting offshore. In 1946, the Magnolia Petroleum Company (which later became part of Mobil), using pilings driven into the sea bottom, constructed a platform in the open Gulf on a site leased from the state of Louisiana. The site was south of Morgan City, 5 miles from the nearest land. Although the attempt was an economic failure (a dry hole), it was the key forerunner of what most observers today would consider to be a truly offshore effort, and it was a technological success in that it demonstrated that exploration in the open Gulf was feasible.

Following Magnolia's lead, and using the same type of technology, Kerr–McGee established the first producing well on the outer Continental Shelf in 1947, 12 miles off the Louisiana coast, almost due south of the mouth of the Atchafalaya River, on what is now Ship Shoal Block 32. This sparked additional interest offshore, and by the middle of 1948, in addition to offshore production by Kerr–McGee, 13 locations were in various stages of development off the coasts of Louisiana and Texas and plans were under way for drilling in 14 other locations. Within the next decade and a half, production platforms would be found in more than 200 ft of water, although the offshore bottoms of the Gulf of Mexico were sufficiently gradual that these platforms were being placed many miles offshore.

3. THE U.S. TIDELANDS CONTROVERSIES

The virtual explosion of offshore drilling activities during this era provided the backdrop for what came to be known during the Truman administration and

afterwards as the Tidelands controversies. These controversies, which continued until the subsequent Eisenhower administration pushed two new laws through Congress, were focused squarely on offshore oil drilling, but contrary to what many present-day readers might expect, they had almost nothing to do with public opposition. Instead, they had to do with what political body would reap the benefits of offshore oil—the states or the federal government.

In addition to the oil-friendly states of Texas and Louisiana, which were engaged in legal battles with the federal government, California and Florida—despite the intense opposition that both states would later express toward offshore oil and that at least some areas of California had shown a half century before—also showed strong interest in the offshore oil industry. As one observer informally summarized the tenor of that earlier time, looking back from a perspective of three decades later, "The basic attitude was, 'Good luck—hope you find some oil—and if you do, send us a check.'" The main concerns of the time had to do with whether the regulations and the public revenues from offshore oil would be the business of the federal government or the states.

Contrary to the Truman administration, which had inspired the controversies by favoring federal control, the Eisenhower administration espoused a "states' rights" position. This position aligned well with the preferences of the oil companies (which expected more favorable regulatory policies from the states than from the federal government) and with the relevant states (which were mainly located along the Gulf of Mexico and which were keenly interested in the public revenues that oil development could generate). The Eisenhower administration's first piece of legislation thus inspired considerable support from the relevant states and the oil companies by giving the states the legal and financial rights to all oil developments taking place within 3 miles of their shores. The second piece of legislation, which appears to have been the focus of much less attention at the time, gave the federal government the rights to the undersea lands that were farther away from the continent, along what came to be called the outer Continental Shelf, or the subsea lands that were out beyond the 3-mile limit of the states' jurisdictions.

4. THE INTERNATIONAL GROWTH OF OFFSHORE TECHNOLOGIES

Throughout the 1960s and early 1970s, most of the technology and the expertise still came from the Louisiana and Texas shores of the Gulf of Mexico. In 1968, for example, the Glomar Challenger, a state-of-the-art drill ship from Orange, Texas, began a series of worldwide trips for the Scripps Institute, taking deep-bottom cores for research purposes and using technology that would have been inconceivable only a few years before. Before the trips were over, the Glomar Challenger would drill a hole almost 3000 ft deep in an ocean-bottom location that was more than 16,000 ft below the surface of the sea.

As exploration and production continued to expand, however, offshore energy development came to be an increasingly worldwide phenomenon. By the mid-1960s, exploratory drilling had begun in the Persian Gulf, along the western shores of Africa (especially off Nigeria), in the Far East (Indonesia, Japan, Borneo, and Australia), and along the Cook Inlet in Alaska. By 1967, 75 countries were exploring for offshore oil and gas, and 20 of these were producing oil and/or gas offshore.

It was the North Sea experience, in particular, that may have provided the clearest early warnings of what would follow. Interest in offshore petrochemical extraction from the North Sea had begun in the late 1950s, just a few years after the passing of the Eisenhower-era legislation in the United States, and growing significantly in 1959 with the discovery of the Groningen gas field off Holland. By 1962, when the size of the Groningen field was better understood, that region saw a multimillion-dollar drilling effort, which was in full swing by the mid-1960s, with the first North Sea production in 1967. As offshore drilling efforts continued to expand, however, the offshore industry found itself in waters that were literally as well as figuratively deeper and more hostile. The loss of the drilling rig Sea Gem in the North Sea in 1965 indicated the dangers associated with the new environment, and increased emphasis was placed on adapting the Gulf of Mexico technology to more hostile conditions.

Particularly after the 1969 Santa Barbara oil spill just a few miles away from the first offshore oil derricks—in a location where the Nixon administration had insisted on proceeding with oil production despite local worries about just the kind of spill that actually occurred—the major oil companies devoted increasing attention to other areas of the world, reinforcing the already aggressive efforts by drilling and support companies that were searching for offshore discoveries. By the mid-1970s, for the first time since the earliest days of offshore drilling,

the majority of the world's offshore drilling operations were located in countries outside the United States, with approximately 75% of the activity in other countries, and with the North Sea being the prime area.

As previously mentioned, however, in testing the waters of the North Sea, oil companies encountered much colder temperatures than they had experienced in the Gulf of Mexico, politically as well as climatically. Rather than being able simply to "send a check" after finding oil, the oil companies (which in the case of Norway included a state-owned oil company) needed to spend years in negotiations with the citizens and leaders of the region. In both of the nations exercising political jurisdiction over key areas of the North Sea—Norway and Great Britain—affected citizens expressed a range of concerns and demonstrated a level of political resolve that would have been almost unimaginable along the Gulf of Mexico in earlier times. In a nation that takes great pride in its long history of Scandinavian distinctiveness, its widespread public participation, and its careful planning for environmental preservation, Norway understandably provided a very different context for operations from that of the oil industry's previous experiences in the Gulf of Mexico. Similarly, in Great Britain (particularly in Scotland and the Shetland and Orkney Islands, which would have had the most to gain or lose from offshore development), there were extensive discussions of the kinds of conditions under which the development of North Sea oil would be allowed to proceed.

The net results of the extensive discussions in both Norway and Great Britain included numerous measures for environmental protection, for local as well as national economic benefits, and for local socioeconomic impact mitigation, which were seen as innovative or even revolutionary by many analysts, especially against the backdrop of previous U.S. experiences. Norway, in particular, emphasized the combining of environmental protection with economic development measures (including a state-owned oil company, but also a number of private enterprises) that eventually led the country to become one of the world's leaders in offshore technology, allowing it to emulate the Gulf Coast pattern of selling not only its oil but also its technology. Several years later, when development began on the giant Hibernia oil field off the coast of Newfoundland, Canada, most observers saw far more similarity to the North Sea model than to previous experiences along the Gulf of Mexico.

5. THE EVOLVING RANGE OF VIEWS THROUGHOUT THE WORLD

There is no single or universal attitude toward offshore development. Instead, as can be seen by contrasting the regions that represent the two most extreme ends of the continuum—a task to which we will soon turn—the attitudes that are encountered are likely to reflect the specific physical, historical, and socioeconomic conditions that are in effect for any given place and time. To the extent to which there are shared characteristics across locations, most of the main reasons for supporting oil developments in a given locality are economic ones, and most of the reasons for opposing the same developments are environmental ones. Even this generalization, however, is oversimplified. As discussed later, many of the regions that have hosted oil development have had fewer economic benefits than they expected. However, at least in the decades since the Santa Barbara oil spill of 1969, the most often feared environmental problem of offshore drilling, the oil spill, has proved to be quite rare—at least in offshore drilling and production, as opposed to the far more numerous spills associated with the transportation of oil, particularly the well-known tanker spills from the Exxon Valdez, the Braer, and other such ships. Particularly in industrialized nations, the environmental and economic challenges and problems that are of greatest concern to nearby residents may have little to do with oil spills, having to do instead with the onshore activities that support the offshore platforms. Some of these activities and businesses, including those involving diesel mechanics, suppliers of drilling muds, and the many tons of pipes and other supplies, can conflict with other ways of using prized coastal locations, many of which are also quite important economically as well as esthetically, with uses ranging from fishing to high-value homebuilding.

It is important to be particularly cautious, however, about drawing many firm conclusions about public attitudes in less developed countries, because systematic research on attitudes in most such countries is relatively rare. Far from displaying high levels of concern or sensitivity toward local attitudes, in fact, many of the less prosperous nations that have developed their oil resources have shown tendencies toward political repression that many observers have found disturbing. So pronounced is this tendency—onshore as well as offshore—that after examining cross-national data from 113 nations, Michael Ross published his findings under the title "Does Oil Hurt

Democracy?" The answer, he concluded, appears to be in the affirmative.

In broad terms, to the extent to which the reactions of many different nations have been examined, the most common focus has involved the financial and, to a lesser extent, the political implications of offshore development. As a useful simplification, three main patterns have emerged across time. The first and by far the most common pattern in some respects reflects a combination of the earlier tidelands controversies in the United States and the efforts by Norwegian leaders to use planning and politics to extract greater economic benefits from the vast flows of revenue that are involved in offshore oil development. The second involves an underlying pattern of concern regarding the kinds of democracy-harming tendencies noted by Ross. The third pattern provides an ironic contrast against the first, involving a problem that is sometimes called Dutch disease, as will be discussed later.

In Venezuela, the discovery of oil under the waters of Lake Maraicaibo in the early 1920s was followed by more than a half century of economic growth, during which oil revenues were used to provide a wide range of economic development benefits. For most of the next 50 years or more, Venezuela was seen by most observers as one of Latin America's most notable models of democratic stability and social peace, and the common conclusion was that the political as well as the economic benefits could be traced in large part to oil-based prosperity. Since the oil price collapses of the 1980s, however, Venezuela's political stability has been seen by some to be as questionable as its prosperity, with clear signs of tension between the middle/upper classes and Hugo Chavez (the current President at the time of this writing in 2003). Recent assessments are much more likely to call attention to class warfare than to social stability.

A similar pattern is visible in Indonesia, which provided the lion's share of "Dutch" oil for Royal Dutch Shell for nearly half a century, during which time the former colony was generally known as the Dutch East Indies, before achieving independence after World War II. For a period of several decades after the former colony became an independent nation, its leaders were seen by most observers as showing considerable political acumen in their efforts to obtain economic and developmental benefits from indigenous oil resources. Rather than attempting to "nationalize" or take over the oil companies that were operating in Indonesia at the time, Ibnu Sutowo—a close personal associate of Presidents Sukarno and Suharto and the key force behind Indonesia's state-owned oil company, Pertamina—emphasized a more gradual approach. One component involved the motto "Learn while you work, work while you learn" for the Indonesian nationals who continued to work in the oil fields until the old patterns of colonial dominance (and the old colonial Mining Law of 1899) were finally brought to an end. Another, more tangible component involved the relatively gradual process of ending the earlier patterns, beginning when Article 33 of the new Constitution of 1945 declared all of Indonesia's natural resources to belong to its people but not fully completed until approximately 20 years later, when the Petroleum Act of 1960 and then the production sharing contract arrangement of 1966 ultimately came into effect.

Even after Indonesia passed its new law in 1960, the major oil companies were not taken over by the Indonesian state; instead, the companies experienced a transition from a previous legal status of "concessionaire" (i.e., enjoying concessions that had been granted under Colonial Dutch rule) to a new status of being contractors to the state enterprise, Pertamina. The transition was completed after Sutowo and the Indonesian state instituted production sharing contracts, which required foreign contractors to bear the full cost of exploring for oil but reserved approximately 40% of the oil for Pertamina and the Indonesian government. Under other contract provisions, most of the lands that were leased to the oil companies reverted back to the government within a decade or less, and the Indonesian share of the profits would increase as world oil prices increased.

Not surprisingly, it appears that at least the financial implications of Indonesia's increasing control over its oil and the associated revenues won considerable praise from most Indonesians for many decades. Indonesia has also been seen by many scholars as an exception to some of the threats to democratic development that are of concern to authors such as Ross. The oil revenues were reinvested in a wide range of other enterprises that were seen as contributing both to the development of the growing national economy and to the integration of what is not only the most populous petroleum-exporting nation but also the most heavily populated Islamic nation on Earth. This latter point is a major one, given that Indonesia embraces what most Western observers find to be a surprisingly diverse and far-flung collection of peoples. It encompasses more than 1000 islands and hundreds of native languages spread across a distance of more than

3000 miles of land and water. Through investments in everything from schools to steel factories, Indonesia used its oil revenues as an important resource for building a stronger and more prosperous nation.

Particularly in the later years of the Suharto era, however, Indonesians became increasingly critical of the "crony capitalism" and corruption that appear to have become increasingly pervasive, both in Pertamina and in the broader society, and of the increasing extent to which the income derived from offshore oil and gas fields was used to support military repression. As suggested by the fact that some of the more troubled areas of Indonesia also happen to have rich offshore petroleum deposits—including Aceh, East Kalimantan, and the now-independent nation of East Timor—the degree of Indonesian "exceptionalism" may be less than previously thought.

Finally, off the western shores of Nigeria, very few observers have seen the kinds of exceptionalism once thought to exist in Indonesia and Venezuela. Instead, particularly after what the Nigerian government characterized as the "execution" of the noted human rights activist, Ken Saro-Wiwa, there has been extensive international attention to what many have seen as heavy-handed and antidemocratic central government repression of local opposition to offshore oil development and its attendant onshore impacts, particularly among the native people of the area, the Ogoni.

Economic benefits have sometimes proved elusive, as well. Although the vast sums of money involved in offshore oil development often lead to expectations for rapid economic growth in oil-exporting countries, careful analyses have tended to find much less desirable outcomes, economically as well as politically.

Perhaps the best known description of the economic problems is the notion of Dutch disease. Given its catchy alliteration, this phrase has been attached to almost any example of economic weakness in the face of resource exports, but more formally the phrase is understood to involve the combination of two factors that appear to have led to a generally unexpected slowdown in the economy of The Netherlands, even in the face of that country's increased revenues from its own North Sea petroleum reserves. First, a sharp increase in exports led to a significant increase in the strength of the national currency—a fact that meant other exports from the country became more expensive for people who lived outside The Netherlands, reducing international demand for Dutch products. Second, the booming resource sector was seen as drawing people and capital away from other sectors of the economy, such as manufacturing and agriculture, raising the effective production costs in the other sectors over time. These concerns led to deliberate efforts, particularly in Norway, to offer increased inducements for investment in non-oil sectors—efforts that may well have been warranted in any case. However, subsequent analyses have indicated that unexpected combinations of rich resources and poor people appear to be more widespread than can be explained by the Dutch disease hypothesis alone.

6. FACTORS ASSOCIATED WITH DIFFERING VIEWPOINTS IN THE UNITED STATES

There is no one or universal pattern of public attitudes toward offshore oil development. Instead, attitudes vary widely in response to local conditions and the nature of oil development that is proposed. Of all the places that have been studied systematically, however, it appears that the widest variations in attitudes are found between two different areas of the same country—northern California and southern Louisiana. It is clearly not the case that the opposition is a straightforward function of the environmental damage that has been created in each region. Indeed, with the possible exception of the Santa Barbara oil spill (which took place along California's south-central coastline, in any event), the environmental impacts of offshore oil development have actually been far more significant and widespread in southern Louisiana than in northern California. Instead, the variations in public attitudes between these two regions tend to illustrate the broader points we are making in this article, reflecting the historical, physical, and social characteristics of the regions in question. Thus, a comparison of the two regions provides a useful way to bring this article to a close.

Historical factors are important both because of changes in broader historical factors and local cultural characteristics, and because differing regions experience an activity (in this case, offshore oil) during different periods of that historical transition, in effect resulting in different local histories. When oil exploration started in Louisiana's coastal marshes in the 1920s, the prevailing attitude toward the environment almost everywhere in the United States was an exuberant one, involving the "conquest of nature" and the fresh legacy that remained from the mythic

conquest of the western frontier. Although environmental concern was not completely unknown, it certainly had little of the character or strength that it would have a few decades later. In nearby Florida, for example—where later decades would see a level of organized opposition to offshore oil drilling comparable to that of California—essentially all of the offshore lands that were seen as potential oil-bearing prospects were leased to oil companies by the state of Florida well before anyone there had ever heard of Earth day.

In addition however, important aspects of the development of offshore technology were unique to southern Louisiana. When oil exploration began to move into the coastal marshes, the marshes were viewed not as ecologically vital wetlands but as hostile territory that needed to be subdued for human benefit. Louisiana also had a long history, dating back to the early 1800s, of resource harvest (fish, shrimp, oysters, and fur cypress lumber) in coastal areas. Furthermore, oil and these earlier extractive activities, especially fishing, proved to be highly compatible in several important ways. First, oil companies had no experience with coastal and offshore waters, but the fishing industry did. When Magnolia Petroleum Company drilled the first offshore well in 1946 south of Morgan City, boats from the local shrimp fleet were hired for the initial survey and the transportation of workers and supplies. Local people supplied the navigation knowledge for early offshore oil, and some of them later became crew and supply boat captains.

Second, the scheduling of offshore oil work allowed for individuals to maintain traditional coastal occupations. The movement into the marsh and estuaries of the Louisiana deltaic plain was large scale and relatively permanent. However, since it involved environments in which human settlement was not really possible, and in which distances and transportation difficulties meant that commuting had to be limited, an innovative form of concentrated work scheduling soon evolved. The common pattern for offshore work became one in which employees meet at a prearranged site to "go offshore" either by boat or, recently, by helicopter. The stay offshore varies, but is typically 7, 14, or 21 days. Following the stay offshore, the employees return to the meeting site and have a period of time off, typically the same length as the stay offshore. Because of this schedule, many such workers chose to continue their traditional occupations. This meant that boats, gear, and knowledge were maintained and did not fall into disrepair, as might have occurred if oil jobs in Southern Louisiana had been scheduled for five days a week. When the oil patch crashed in the mid-1980s, many coastal residents found it useful to fall back on these skills and equipment to feed their families.

In addition, oil development in Louisiana started gradually, and it grew as the product of local innovation, which understandably generated considerable pride. In contrast, when the first offshore development appeared in California in the late 1960s, not only was environmentalism emerging as a national trend but also the huge rigs that were by that time associated with offshore oil were seen by a largely urban population as foreign and threatening. When the Nixon administration insisted on moving ahead with offshore leasing just a few miles away from the beaches of Summerland and Montecito in the face of stiff local opposition, and after the Santa Barbara oil spill a few years later provided a tangible indicator of the validity of local concerns, Californians' opposition to further offshore oil activities became all the more intense.

Physical factors, or to use the more technical terminology, coastal geomorphology, can also be seen to differ quite distinctly between the two states. There are fundamental differences between the Louisiana and California coasts, both in coastal topography and in marine topography. The coastal regions of Louisiana differ from those of California, as well as from most other areas of the United States, in three main ways: Coastal wetlands limit land-based access to the coast, estuaries offer many opportunities for harbor space, and low relief and low energy levels characterize most of the coast. As a result, the distribution of populations and roadways in Louisiana is very different from that found in most coastal states. Few of the state's population lives on or near the coast and, with the exception of Grand Isle, it is often almost impossible to get anywhere near the coast by road. Most of the coast is lined with a broad and virtually impenetrable band of coastal wetlands that are far better suited for the abundant fish and wildlife of the region than for human habitation. In most coastal states, especially Florida and California, where proposals for outer Continental Shelf (OCS) development have met with intense opposition, the situation is completely different. Most of the population lives on or near the coast, and virtually all of the coast is readily accessible by road. In California, Florida, and much of the rest of the coastal United States, the coast is seen as a valuable public resource, a thing of beauty, and a source of popular recreation—in part because the coast is actually seen by so many people, so often.

Because of the coastal wetlands in Louisiana, not only is the coast rarely seen, but local residents' descriptions of their state's coastal regions are more likely to involve alligators and mosquitoes than spectacular scenery.

The second key feature of Louisiana's coastal topography is the presence of an extensive estuary system. Although it is difficult to reach the Louisiana coast from land, it is easy to do so from the water. Louisiana is characterized by numerous waterways that intersect the highway network farther inland, and that provide coastal access for marine interests. To those familiar with other coastlines, the concept of harbor is probably a common one. A harbor is generally thought of as an enclosed, protected water body with orderly docks, designed to maximize the number of boats that can be stored in the limited protected waters. Outside of the New Orleans metropolitan area, the concept is little used in coastal Louisiana, where people simply live among their boats. There is no shortage of places to put a boat in coastal Louisiana. The natural levees of the many bayous that traverse the area provide innumerable places both to dock boats and to live. People do both. The geomorphology of the Louisiana coast even allows oil field and fishing vessels to use many of the same facilities. There have been a few cases, such as Morgan City in the boom years of the 1970s and early 1980s, in which the demand for dock space became so intense that the shrimpers were crowded out. Generally, however, fishing and oil field boats have in the past, and do today, coexist peacefully. Along the coast of California, by contrast, most of the available harbors are small, and dock space is quite limited. A 250-ft offshore supply vessel represents a considerable threat to local fishing interests.

The third key feature is that Louisiana is a region of extremely low relief and generally low energy. When Louisiana residents do reach the shoreline of their state, they see flat water and flat land, with comparatively low-energy beaches. They see water that is seldom clear because of the discharge of silt by the Mississippi and Atchafalaya Rivers. In areas of the country that are farther removed from the "muddy" Mississippi, including the areas to the east in Florida, the waters are generally clearer. In northern California, residents frequently observe the power of the sea where it meets the coast, and they often comment on it with what they call "awe." In contrast, the Gulf of Mexico off of Louisiana is generally a more sedate body of water, and even when the Gulf does inspire awe, such as during tropical storms and hurricanes, its displays have rarely been seen by people who are alive today. As noted previously, only a small percentage of the population lives on the Gulf, and a combination of modern weather forecasting and centuries of experience have led to routine evacuations of coastal and low-lying areas as tropical storms approach.

The distinctiveness of the Louisiana environment, however, also extends offshore and to what is literally below the surface—that is, the marine topography. Most people in Louisiana do not see offshore oil as an issue, and many are particularly bewildered by the fact that fishing interests in other locations have expressed so much concern over offshore developments, given that marine use conflicts have been so notably absent in the Gulf. Many fishing boats, both commercial and recreational, will actually tie up to the oil rigs to fish, and in New Orleans the Aquarium of the Americas includes a large display, complete with the title "From Rigs to Riches," pointing out the advantages of oil platforms as a form of habitat for many of the fish species of the Gulf. Given the Louisiana experience, why would there be so much opposition to oil structures from fishing interests in other regions? The reasons are not so obscure as they first appear. In addition to the historical factors previously noted, there are two key aspects of the marine environment that have helped to limit the potential for conflicts between OCS development and other marine activities, particularly fishing, off the coast of Louisiana. One has to do with the gradual slope of bottoms along the central Gulf of Mexico, and the other has to do with the presence of silt bottoms that limit the number of obstacles likely to be encountered.

Off the coast of Louisiana, the gradual slope of the Continental Shelf presents very different conditions from those found in areas where offshore oil development has been most contentious. In most areas of the country, particularly along the Pacific Ocean, the Continental Shelf drops off much more dramatically into the ocean basin, meaning that it is also much narrower than the shelf that exists in the Gulf.

As a result of this difference in sea-bottom slopes, the available area of the Louisiana Continental Shelf is far larger than is the case in California, reducing significantly the probability of use conflicts. The gradual slope also reduces the number of problems that are likely to be created by any given obstacle. Even if a fishing boat needs to make a quarter-mile detour around oil operations, for example, there will be little significant impact on the boat's ability to keep its nets in contact with the sea floor. In contrast,

in areas such as the Pacific Ocean off the California coast, the steeper slope makes the Louisiana experience largely irrelevant in two ways. First, the actual area available for use is smaller, meaning that even an apparently small loss of area for OCS activities can have a proportionately major impact on the area available for fishing in a given region. Second, given that bottom-dragging operations need to work along a contour line, following sea bottoms at a given depth, the presence of an oil platform can mean that fishing boats would need to make a detour that would correspond to a difference of several hundred feet in water depth, effectively precluding the option of "fishing around" many such structures.

An additional feature of the marine environment of the Gulf of Mexico involves the presence of silt bottoms. Although the heavy silt discharges by the Mississippi and Atchafalaya Rivers mean that the water is seldom clear, reducing many concerns over esthetic impacts, the nature of the bottom also means that fishing operations encounter few obstacles such as rock outcroppings that would lead to the loss of nets and other gear. In regions such as California, the frequent presence of rocky outcroppings can severely limit the ability of fishing boats to change their trawl runs.

One consequence of the difference in bottom types is that, to reiterate a point that often comes as a surprise to the opponents of oil development in other regions, oil rigs actually can provide a significant advantage for fishing operations on silt bottoms of the Gulf of Mexico. Certain types of commercially important fish can only survive in the kinds of habitat known collectively as hard substrate—rocky bottoms, reefs, rock outcroppings, and the like. In the central Gulf of Mexico regions where oil development activities have been the most intense, natural outcroppings of this sort are so rare along the predominantly silty bottoms that oil-related structures now comprise approximately 25% of all hard substrate. In effect, the oil rigs serve as artificial reefs, concentrating and probably increasing the fish populations, which is precisely why it is quite common to see fishing boats literally tied up to oil rigs in search of fish.

In summary, in Louisiana the coastline is inaccessible to most land-based populations, and accordingly low in social salience, while offering enough potential harbor space to meet the needs of offshore oil development as well as potentially competing uses such as fishing operations. The offshore seafloors, meanwhile, tend to have such gradual slopes as to offer vast areas of virtually level bottoms, relatively free of obstacles but also so devoid of natural reefs that the oil rigs provide a valuable service for fishing operations. As was the case for the historical factors, most of these characteristics are almost precisely reversed for the coastal regions of much of the nation, particularly the northern California coast; the very considerations that have contributed to the ready acceptance of offshore oil in Louisiana tend to exert the opposite effect in California.

Social factors provide a third broad category of reasons why the attitudes toward offshore development can differ so widely, even within the context of a single country. As a useful simplification, four social factors appear to have encouraged the easy acceptance of offshore oil in Louisiana relative to what might be expected in other areas of the United States: the average educational levels, the patterns of social contacts, the importance of prior extractive industries, and the potential for overadaptation that characterized the coastal regions of Louisiana as offshore activities were first being developed.

Given that support for environmental protection is quite strong in the United States, as it is in most countries of the world today, very few sociodemographic characteristics show strong correlations with environmental concerns. For example, studies show that blacks are as supportive of strong environmental controls as whites, and poor people tend to be as supportive as wealthier people. One consistent exception, however, has to do with educational levels, with better educated persons generally expressing higher levels of environmental concern. Thus, it may be significant that, particularly as offshore development was picking up speed in the 1930s and 1940s, coastal Louisiana had some of the lowest educational levels in the country. In St. Mary parish, the scene of initial offshore activity, only 47.2% of the adult population had 5 years of education in 1940, and only 12.2% had graduated from high school. Other rural areas of southern Louisiana had similarly low educational levels. In comparison, more than 78% of adults in the United States had a high school education or more by the 1990 Census.

Second, the other industries that most characterized coastal Louisiana at the time of initial offshore development were ones that involved extractive uses of the coast. Like oil development, they involved the extraction of raw materials from nature. Local residents obtained products from the Atchafalaya Basin (cypress lumber, fish, crawfish, water fowl, and moss for furniture stuffing) and from the coastal marsh (furs, shrimp, and oysters). The export of such raw materials had provided the mainstay of the

economy in coastal Louisiana for almost a century prior to offshore development. In areas where extractive activities are dominant, as in Louisiana in the 1940s and 1950s, there tends to be less resistance to additional extractive activity. In most coastal regions of the United States today, and certainly in those regions of California where proposals for offshore oil have been met with the stiffest resistance, the economy has come to be far more dependent on the amenity values of the coast than on its extractive values. The proportion of the population depending on the extraction of coastal resources is small and shrinking, whereas not just tourism but also other amenity-related forms of development, including many high-value economic activities, depend on high levels of environmental amenities. These growing economic interests place high importance on maintaining relatively pristine environmental conditions. Thus, in California's coastal areas, and increasingly in other areas as well, the likelihood of finding support from extractive workers can be expected to continue to decline.

Third, social interaction patterns can exert powerful influences on individuals' attitudes. One particularly powerful, if often overlooked, pattern involves what we have called a social multiplier effect: Even if a given individual does not work in the offshore oil industry, that person's attitudes may be affected by whether his or her friends and relatives do. Given the historical, biophysical, and other social factors summarized previously, the "average" resident of coastal Louisiana in the 1940s would be expected to have known many friends and neighbors who were employed in the oil industry. By the 1980s or 1990s, it was virtually impossible to live in southern Louisiana and not know someone who was employed in an oil-related enterprise. In addition, as reported in the 2000 Census, Louisiana residents were more likely to live in the state in which they were born than were residents of any other state. In contrast, in most of the coastal regions of the United States today, the situation is the opposite. Not only do these regions have few residents who are involved in oil or gas extraction but also they have high numbers of people who have moved to the coastal regions precisely because of their desire for high environmental quality. This tendency is especially likely in areas such as northern California, where there is no current base of employment directly dependent on local oil and gas development.

Finally, an additional way to understand the uniqueness of Louisiana's compatibility with offshore development is to examine the degree of adaptation that has taken place. As the various components of the human environment become adapted to a given form of development activity, there is a tendency for new skills, knowledge, tools, networks, and other resources to be built up around that activity. Three potentially problematic results, however, can also occur. First, any type of development narrows a region's options because time, resources, and human capital are devoted to a particular developmental scenario, sometimes limiting the options for alternative scenarios. We call this process developmental channelization, although others have used terms such as path dependency to denote similar patterns. Second, as part of this process, adaptations to earlier forms of development may be lost (sometimes quickly and sometimes across generations). Third, nearby communities can run the risk of overadaptation to the new development activity. Particularly if that new activity is not a sustainable one, then when it ceases or declines, communities or regions may be left in the position of being less able to survive in their environment than they would have been before the new development occurred. Thus, to a large extent coastal Louisiana

TABLE I

Factors That Led to Positive Evaluations of Offshore Oil in Louisiana[a]

Historical factors
Early historical era—"age of exuberance"
Temporal priority of development
Incremental onset and evolution of industry
Local origins and development of technology
Biophysical factors
Coastal topography
Broad coastal marshes that preclude coastal highways and population concentrations
Estuary systems that include many potential harbors
Low relief and energy levels
Marine topography
Broad, gradual slopes that increase area and decrease significance of conflicts with platforms
Silt bottoms with few outcroppings and obstacles
Social factors
Low educational levels
Extractive orientation toward biophysical environment
Favorable patterns of contact with oil industry personnel
Extensive prior adaptation to oil development

[a] Adapted from Freudenburg and Gramling (1994).

has become not just adapted to but also dependent on its offshore petroleum activities, and it is difficult to be too critical in evaluating an activity from which one has benefited, particularly if the activity is one on which one remains dependent for any hopes of comparable future prosperity. This, coupled with the industry's generally good record in terms of offshore environmental accidents, has tended to bolster the perception of offshore activity in the Gulf as involving relatively low levels of risk. Table I summarizes these factors. As a simplified but generally helpful rule of thumb, where more of these factors are present, attitudes toward offshore development can be expected to be more positive.

Glossary

biomass Organic materials such as woodchips, twigs and stems, grasses, weeds, aquatic plants and other quick-growing plants, and animal wastes that can be used to produce fuels or electricity through a process of fermentation, distillation, or incineration.

cogeneration The simultaneous production of several types of energy; a process that converts a fuel into both thermal and electrical energy.

ethanol Nontoxic alcohol produced from sugar, starch, or other carbohydrates through the process of fermentation; sometimes referred to as grain alcohol or ethyl alcohol; used as a fuel or fuel additive to improve oxygenation.

fuel cell A device that converts the energy of a fuel directly into electricity and heat without combustion but through the process of oxidation; originally developed for the space program and now largely intended for use in automobiles.

geothermal energy Energy in the form of natural heat originating from within the earth and contained in rocks, water, brines, or steam.

green power Electricity produced from renewable sources or in such a way that the process results in little or no adverse impact on the environment.

green pricing Strategies and formulas used by utility companies to recoup the costs of producing electricity from renewable sources, often by charging customers premiums or incremental amounts on their monthly utility bills; customer participation in green pricing programs is voluntary.

grid-tied photovoltaics (GPV) Photovoltaic systems designed to operate in parallel with and interconnected to the electric utility grid.

hydroelectric power or hydropower Energy produced by the force or pressure of falling water.

landfill gas A gas consisting mostly of methane that is generated as a by-product through the natural decomposition of organic material at landfill disposal sites.

methanol A toxic alcohol derived largely from natural gas or coal; sometimes referred to as the simplest alcohol, and other names include methyl alcohol, carbinol, and wood alcohol. It is used as an antifreeze, solvent, or fuel/fuel additive.

nuclear fission The process of splitting the nucleus of an atom into two parts, either spontaneously or as the result of an impact from another particle, resulting in the release of energy.

ocean energy Energy produced by the force or pressure of wave action.

photovoltaics (PV) Passive devices constructed from semiconducting materials that absorb sunlight and convert it into heat or electricity.

renewable energy Heat, electricity, or power produced from renewables or renewable sources, such as

 © 2004 Elsevier Inc. All rights reserved.

wind, the sun, subsurface steam, and water/wave action.

renewables Naturally occurring resources or materials used in energy, fuel, or electricity production that can be regenerated or replenished over time.

solar energy Energy from the sun that is converted into heat or electricity through passive collector devices.

sustainable In the context of energy resources, consumption in a manner that does not result in depletion and/or use of natural assets that are renewable; in the context of the environment, usage or treatment of Earth and its natural and physical assets in a manner that does not deplete, damage, or destroy.

wind energy Heat or electricity produced by the force or pressure of wind or air currents.

Whereas most energy streams are derived from sources that are exhaustible (e.g., fossil fuels), renewable energy is produced from sources that can be replenished over time. Faced with declining availability of some nonrenewable resources and with growing concerns about their environmental and public health impacts, society has become increasingly more attracted to renewable energy that exists in greater abundance and has minimal adverse physical effects. In response to a measurable shift in public opinion over the past two decades, many initiatives have been undertaken to expand the use of renewable energy sources and systems. The results of numerous polls and surveys indicate that citizens throughout the industrialized world now desire greater reliance on renewable and are willing to invest in their development.

1. DEFINITION OF RENEWABLE ENERGY

Renewable energy means different things to different people. Although there is little argument as to what energy is, even in its myriad forms, the term renewable energy conjures up a more diverse assortment of images.

In the simplest terms, energy is the capacity of a physical system to do work, or alternatively, to produce heat. Energy is a characteristic of the physics of a system. Renewable, on the other hand, pertains to the origin of the energy; thus, ideas and opinions about renewable energy are often confounded with information (or misinformation) about the source.

Renewable energy is energy that is derived from a supply that is constantly and naturally replenished over a relatively short time. Hence, any discussion of renewable energy is ultimately reduced to a discussion of renewable resources as they are derived from geophysical processes: sunlight, wind, falling water, sustainable biomass, wave motion, tides, and geothermics. Some entities, such as the Texas Renewable Energy Industries Association, describe all renewable energy as being directly or indirectly derived from the sun or natural movements and mechanisms of the environment. Others—private, commercial, governmental, and international—have their own definitions. One of the more visible characterizations has been provided by the U.S. Department of Energy (DOE), which segregates renewable energy into six components: bioenergy derived from biomass resources; geothermal energy derived from the earth's own heat-producing processes; hydrogen, hydropower, or hydroelectric power; ocean energy; solar energy; and wind energy.

2. POLITICAL, PHILOSOPHICAL, AND ECONOMIC PERSPECTIVES

Given the absence of a uniform definition, it is not surprising that the larger energy community is somewhat unclear about the role renewable energy plays in the broad arena of energy policy and economics, and that markets for renewable energy and related systems have yet to fully mature. In addition, because public perception is so often impacted by media coverage, or the lack of it, uncertainty and misunderstanding about renewable energy among the general public might be a perfectly legitimate response.

Renewable energy evokes many different metaphors and perceptions. Some people think of renewable energy as a nondepletable, environmentally friendly alternative to conventional fossil fuels, whereas others consider it to be an expensive, high-tech, and possibly unreliable proposition. Some feel threatened by renewable energy and view it as detrimental to current energy markets and jobs, but others (e.g., residents of California) believe it represents a sound investment for long-term economic and energy security.

For many years, renewable energy advocates have been unjustifiably associated with the more radical component of the environmental movement. Although this impression has moderated, the political and economic struggles over energy supply, demand, efficiency, and sustainability continue even today in countries throughout the world, and the role to be played by renewable energy, along with the concept of energy efficiency, is at the very heart of many of them.

One has to look no further than the ongoing conflict in the United States over drilling for oil in the Alaska National Wildlife Reserve (ANWR) to understand what is at stake with regard to jobs, markets, and the domestic economy. Hence, within the greater energy complex, the views and claims of renewable energy and energy efficiency advocates have sometimes been mistrusted—even totally dismissed—because, on the surface, they have seemed counter rather than complementary to conventional energy policy and wisdom. However, from a retrospective viewpoint, there has been a not-so-subtle shift in public and corporate attitudes toward renewable energy, particularly in the past decade. In the historical arena in which plentiful, inexpensive fossil energy was taken for granted, renewable energy was not even on the map. However, in the more contemporary worldview that is tempered by international conflict, global warming, economic uncertainty, environmental and public health concerns, and rolling electricity blackouts, renewable energy has a more prominent place at the table, even among those who are steeped in the fossil fuel tradition. As is the case for many things, it is a matter of perspective. It is the changing perspective regarding renewables within the energy community that holds such great interest from both the social and economic standpoints.

3. THE EVOLVING CONSUMERISM TOWARD RENEWABLE ENERGY

The posture of consumers is unquestionably changing. Although some politicians and corporate executives would still have the public believe that renewable energy is a bad investment, the more pragmatic and economically savvy consumers of the early 21st century are not buying the argument. It seems they are not quite as ill informed as they were once thought to be. First detected in the late 1980s, a distinctively proactive stance toward energy derived from renewable resources is now readily apparent in the results of almost all public opinion energy research. This change, which has been described as "the quiet revolution in renewable energy," has occurred at the grassroots consumer level with little fanfare and surprising determination, catching the corporate energy establishment somewhat off guard. Despite earlier technological missteps, consumers now see reliance on alternative energy sources and systems as fundamental to maintaining the social norms and economic well-being of society. Consumers seem poised to rapidly adapt their lifestyles to a wide range of alternative energy technologies, from wind turbines to fuel cell vehicles and rooftop solar electric panels.

Some of the attitudinal and behavioral change is undoubtedly due to initiatives by consumers to seek more balance in their lives, a greater degree of economic security, and more independence and control over their own futures. In addition, the post-baby-boom generation has simply been exposed to more technological innovation, and individuals in this age group have come to understand that technological expansion is a major economic force throughout the world.

4. GOVERNMENT SUPPORT FOR RENEWABLE ENERGY INITIATIVES

The change is also partly attributable to substantial government investment in research and development activities that serve not only as the catalysts for new ideas and equipment but also as incubators for fledgling industries that create jobs. Through government mandates, rebates, tax credits, and other incentives, use of renewable energy and renewable energy systems is proliferating at both the local and the national levels. In the United States, all federal agency vehicle fleets must now contain specified percentages of alternative fuel vehicles, and energy consumption at federal facilities and installations must include specified percentages from renewable sources. As an example of the results of such a proactive government stance, late in 2002 Dyess Air Force Base in Abilene, Texas, became the first U.S. facility to be fully dedicated to wind power. Programs, situations, circumstances, and events of this nature, being publicized through the media, definitely have a positive, although perhaps unquantifiable, impact on consumer awareness and behavior.

Throughout the United States and in other countries as well, government agencies have engaged in a fairly robust educational blitz aimed at promoting the development and use of renewable resources. Such educational initiatives begin at the elementary school level in an effort to establish an attitude toward renewable energy that gives rise to lifelong patronage and support. Numerous advocacy groups, such as the Colorado Renewable Energy Society, the American Council for Renewable Energy, the Clean Energy Funds Network, and Citizens for Renewable Energy in Canada, have taken up the charge and play a major role in the overall educational process. Increasingly more public and grassroots community events, such as the 2003 Renewable Energy Roundup

and Green Living Fair in Fredericksburg, Texas, and the 2004 Renewable Energy and Sustainable Living Fair in central Wisconsin, are being organized and promoted, although the total number of individuals who participate in these activities and their reasons for doing so have not been researched and are unknown.

In the United States, the federal government also provides grants directly to individual citizens and small businesses to encourage the use and development of renewable energy. The U.S. Department of Agriculture sponsors a grant program to assist farmers, ranchers, and rural small businesses in developing renewable energy systems and energy efficiency improvements. The DOE has also announced grant awards to eight Native American tribes to develop renewable energy projects on their lands.

In addition, state and regional governments have been prime marketers of information about renewables. Many, if not all, U.S. state energy offices actively promote the use of renewable energy through Internet sites and other media. The events in California during the past few years have brought renewable energy to the forefront and have impacted public opinion about energy (at least in that area of the United States) in ways that might not otherwise have been possible.

5. TRENDS IN THE DEMAND FOR RENEWABLE ENERGY AND RENEWABLE ENERGY SYSTEMS

With all this activity and an increasingly pro-renewables consumer stance, one might expect actual use of renewable energy to be skyrocketing. In some ways, this is true, but in others it is not. The U.S. Energy Information Administration (EIA) reports in its "Renewable Energy Annual" that in 2001, total renewable energy consumption (solar energy, biomass, geothermal energy, conventional hydroelectric, and wind energy) declined by more than 12%, resulting in a decrease in the share of total U.S. energy consumption to 6%, the lowest level in 12 years (Fig. 1). These percentages are somewhat misleading because much of the change is due to a sharp reduction in the use of hydropower resulting from environmental and political pressures to eliminate dams in the Pacific Northwest. Shipments of solar thermal collectors, on the other hand, surged from 8.4 million square feet in 2000 to 11.2 million square feet in 2001 (Fig. 2), whereas total renewable electric generating capacity increased by a modest 1803 MW to 96,741 MW in 2001 (Fig. 3) due largely to increased wind power generation. The latest data available on total shipments of geothermal heat pumps indicate that they declined from 41,679 in 1999 to 35,581 in 2000 (Fig. 4). A new DOE initiative pertaining to geothermal heat pumps, planned to begin in 2004, may reverse this trend.

A major reason why renewable energy consumption has not exhibited larger increases is that utility

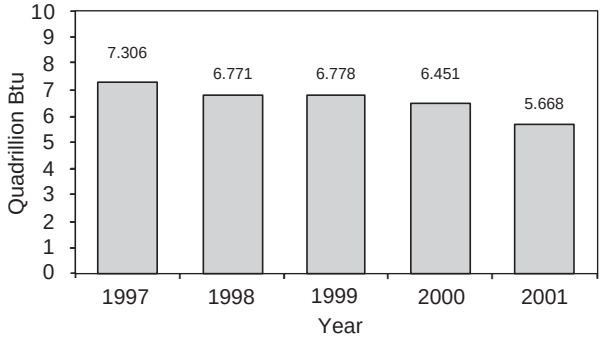

FIGURE 1 Total U.S. consumption of renewable energy, all sources, 1997–2001. Data for 2001 were preliminary at the time of reporting. Data from the U.S. Energy Information Administration (2002b).

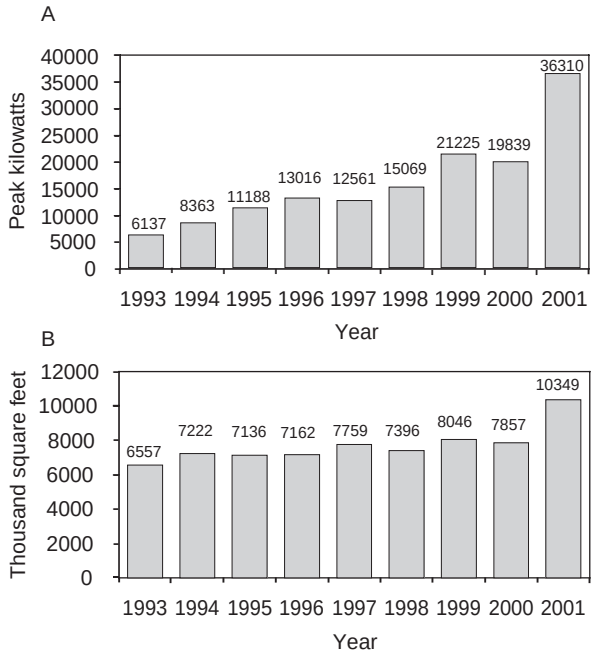

FIGURE 2 Annual total domestic shipments (U.S. states and territories, excluding shipments for space/satellite applications) of photovoltaic cells and modules (A) and solar thermal collectors (B), 1993–2001. FIGURE 4 Annual total shipments of geothermal heat pumps, 1996–2000. Data from the U.S. Energy Information Administration (2002b).

companies have been slow to incorporate renewables into their resource base, citing economic factors associated with developing infrastructure and reliable resource supplies. Another reason is that utility regulators have been slow to adopt pro-renewable energy policies, and local government agencies have been inconsistent in their pursuit of economic incentives that promote market development. Although it is true that sufficient infrastructure may not yet exist to support continuous growth in the renewable energy market, this is really a proverbial "chicken-and-egg" problem. Markets cannot develop unless investments are made, and investments cannot be made unless the market is thought to be of sufficient size to justify them.

The utilities, however, being driven by their own consumer research, are finally getting the message. Utility customers are telling their electricity suppliers that they want renewables in the resource base. During the past few years, approximately 85 utilities in the United States have begun offering electricity generated from wind and solar power to their residential and commercial customers. The DOE provides a variety of information in both written and electronic form about successful ventures of local utilities into renewable energy. As a result, two phenomena are occurring: Energy supply is becoming more diverse and less centralized, and the demand for microturbines, rooftop-mounted solar panels for water heating and electricity generation, and other decentralized power sources is intensifying, in both the residential and the commercial markets.

6. CONSUMER ATTITUDES TOWARD RENEWABLE ENERGY AND RENEWABLE ENERGY SYSTEMS

Public response to renewable energy sources and systems is commonly measured through market and opinion surveys. Many such surveys pertaining to renewable energy have been conducted during the past 20 or more years by various organizations with different agendas. The quality of such surveys is highly variable due to inconsistency in survey format, question phrasing, and selection of respondents. Attitudinal responses are also affected by respondents' knowledge about specific energy sources since respondent knowledge is often uneven. In addition, almost all the results are descriptive in nature and provide little in the way of inferences with regard to the real populations of interest. Furthermore, consumer attitudes about renewable energy can span a wide variety of topics, so the research results are not always directly comparable. Table I provides comparative information about the operational and statistical aspects of a cross section of market and opinion research efforts at the local, regional, and national levels that pertain to renewable energy. Data obtained in objective, national surveys are thought to be the most reliable and unbiased.

Despite the acknowledged difficulties with some surveys, a trend has emerged with regard to consumer attitudes toward renewable energy. Some of the most telling results have been obtained from utility market surveys, many of which have been conducted by and for individual utility companies. Two 1999 reports summarize some of the findings. The first report, prepared at the National Renewable Energy Laboratory (NREL), contains an aggregate summary of results obtained in 14 different "best practices" quantitative surveys encompassing 12 utility service territories in five western/southwestern

states (results from an Electric Power Research Institute study are also included). Drawing on the approach and research used at NREL, the second report, prepared at the Bonneville Power Administration (BPA), contains a similarly constructed summary of 17 surveys or focus group studies conducted in the Pacific Northwest.

Included in the NREL report are the results for representative questions abstracted from the 14 surveys. One such question asked the customers to indicate the extent to which they favor various energy resources. The percentages of respondents indicating that they "somewhat favor" or "strongly favor" solar energy, wind, natural gas, geothermal energy, nuclear fission, and coal were 93, 91, 83, 71, 31, and 24%, respectively, suggesting a higher degree of favorability toward renewables than more traditional energy sources. Another question from this group of surveys asked customers to indicate which energy sources their utilities should use to generate power. Of the residential customers that responded, 88% said their utilities should use renewables (solar, wind, geothermal, or landfill gas) and 85% said their utilities should use hydropower, whereas only 55, 39, and 14%, respectively, said their utilities should use natural gas, nuclear fission, and coal. In a third question, customers were asked to indicate the source from which they preferred their electricity to be generated. Of those responding, 41% said they would choose wind and solar energy as their electricity source, 35% said they would choose natural gas, 9% said they would choose nuclear fission, and only 5% said they would choose coal.

Similar results are reported in the BPA document. In a question included in the 1997 Environmental Issues and Tracking Study commissioned by Portland General Electric and summarized by BPA, customers were asked to indicate the single additional energy source they would like to see their electric company develop during the next 5–10 years. Sixty-nine percent chose solar, wind, geothermal, or hydroelectric, 11% chose cogeneration using waste heat, 9% selected natural gas-powered turbines, 2% selected fuel cells, 2% chose coal, and 7% indicated some other source or did not know. The BPA report also summarized the results from a 1997 survey commissioned by Conservation and Renewable Energy Systems, an energy and conservation consortium of public utilities in Washington State. In that study, 88 and 89% of residential and commercial customers, respectively, indicated that utilities should include renewables as one of their energy sources. Even when residential customers were told that "renewables may cost more today but might make sense in the long run," there was no change in the percentages favoring them.

These comprehensive assessments reveal a repeated and consistent pattern that strong majorities of utility customers in various regions of the United States prefer renewables to other available energy sources and favor utility use of renewable resources to produce electricity. This pattern corroborates findings in polls conducted at the national level during a period of 23 years that Farhar summarized and described in a 1996 publication for the Renewable Energy Policy Project (REPP) in Washington, DC.

Some of the most recent evidence about consumer attitudes toward renewables was obtained in a 2002 survey conducted by the Wells Fargo Public Opinion Research Program (Wells Fargo PORP) at the University of Colorado, Denver. In this case, 95% of respondents disagreed with the statement, "It really makes no difference to me how my utility generates electricity." Of these same respondents, 82% indicated that utilities should focus on renewable resources as opposed to fossil resources to generate additional electric power; and when asked which source they would most like to see developed, 82% chose a renewable one (wind, solar, or hydropower). Furthermore, 84% indicated that the state's utilities should use "somewhat more" or "a lot more" renewable energy than they currently are using, 62% indicated that the state legislature should require utilities to use more renewable energy, and 78% said they would support a legislative mandate for utilities to produce 10% of their electricity from renewables within the next 10 years. Finally, strong majorities of respondents in this study rejected the notions that (i) it is too soon for utilities to invest in renewable energy, (ii) renewable energy is not worth developing because there is not enough of it, and (iii) wind farms are ugly.

The opinions and attitudes of European consumers toward renewable energy appear to mimic those of citizens in the United States. In a 2002 survey conducted by the European Commission, 69% of respondents said they supported more research for renewable energy, whereas the percentages of respondents who said they supported more research for natural gas, oil, and coal were only 13, 6, and 5%, respectively. On the other hand, only 40% stated they believe renewable energy would be the least expensive source in 2050. Like so many surveys of its type, this research does not directly address consumer attitudes toward actual use of renewables in power generation. It does, however,

serve to highlight the tendency of consumers to favor renewables when all other things are equal.

Information on consumer acceptance of specific renewable energy technologies and systems is more limited. Perhaps the most recent and extensive study about a particular technology, grid-tied photovoltaics (GPV), was conducted at NREL in 2000. In this survey of homeowners in Colorado, 68% of respondents favored GPV being made more widely available, but there was clearly greater favorability toward than familiarity with the technology. In the same study, participants were asked to identify which electricity source—coal, hydropower, natural gas, nuclear fission, oil, or solar energy and wind—they think of most when presented with each of several descriptive statements. Table II indicates the percentage of respondents who selected solar energy and wind with respect to each of the statements, providing information on a somewhat broader spectrum of attitudes toward renewable energy than presented in the other work.

Several surveys have been conducted in the United Kingdom concerning consumer favorability toward wind energy development. In one such survey, the University of Wales surveyed public opinions on behalf of the British Broadcasting Corporation at three different sites. At all three sites, majorities of greater than 60% of participants responded in favor of wind development despite aesthetic concerns associated with equipment installation. Environmental superiority to other fuels was most often selected as the main attribute of wind energy.

Collectively, this evidence suggests that a sizable percentage of consumers are favorably disposed toward renewable energy, particularly from the environmental standpoint; consumers and utility customers want to see more renewable energy use; and markets for renewable energy systems are growing.

TABLE II

Percentages of Colorado Respondents to a Survey about Grid-Tied Photovoltaics Who Associate Wind and Solar Energy with Several Economic and Environmental Statements

Statement	Wind and solar (%)
Best for the environment	79
Safest	70
Most abundant	43
Makes the United States most self-reliant	35
Least expensive	24
Will help the most in meeting the growing demands for energy	41
Stimulates economic development the most	24
Diversifies and extends our energy mix the most	52
Improves the quality of our air the most	80
Adds the most new high-technology jobs	40
Use of this energy source will increase the most in the 21st century	60
Best for the U.S. economy	32
Most positive overall reaction	51

7. STATED WILLINGNESS TO PAY FOR ELECTRICITY DERIVED FROM RENEWABLE ENERGY

Although measuring consumer attitudes and perceptions about renewable energy is relatively straightforward, quantifying actual program participation or likely purchases of renewable energy and associated equipment is not. A consumer's proactive stance toward renewable energy does not always lead to direct or explicit actions that represent true consumption behavior. The reasons are numerous and complex, although some are more apparent than others. A full discussion is beyond the scope of this article.

One of the more obvious reasons is that the cost of producing electricity from renewable resources may be more than the cost of producing it from fossil fuels, and so the prospect of higher monthly utility bills sometimes dampens the enthusiasm of consumers despite their personal preferences. Consequently, a disparity exists between consumers' stated preferences for renewables or green pricing programs and their actual conduct/behavior when it comes time to participate or financially underwrite resource and infrastructure development.

Potential consumer actions are difficult to quantify directly. Consequently, stated "willingness to pay" is often used as a surrogate indicator of likely behavior in many avenues of consumer research. Although imperfect as a measure of actual behavior, willingness to pay is a notion that addresses the idea of potential consumer response to technological enhancements and it allows businesses, industries, and governing bodies to determine the probable extent to which consumers might embrace products and technologies in the marketplace. Willingness to pay, particularly in the context of green pricing, has been used extensively in energy market and opinion

surveys during the past decade as a proxy for consumers' actual purchase of electricity generated from renewable resources.

The 1999 NREL report described previously provides an authoritative summary of stated willingness to pay for electricity from renewable resources. As previously noted, this work encompasses the results of 14 different surveys and an Electric Power Research Institute study. In all the surveys reviewed, majorities of respondents indicate they are willing to pay at least a modest incremental monthly amount for electricity generated from renewable resources. The sizes of these majorities range from 52 to 95% without prior coaching or training regarding the economic or technological issues. The percentages are even higher when such information is made available.

Based on the similarity in the nature of the survey findings, an aggregate residential customer willingness-to-pay curve can be developed representing the incremental monthly amount that consumers would be willing to pay for electricity produced by their utility companies from renewable sources (Fig. 5). As expected, the percentage of consumers who are willing to pay more decreases sharply as the amount increases. Nonetheless, based on this analysis, approximately 70% of consumers could be expected to report a willingness to pay at least $5 more per month for electricity produced from renewable resources, and approximately 38% of consumers could be expected to report a willingness to pay at least $10 more per month. Although willingness to pay is not the same as actual purchase, these percentages are not trivial and they represent fairly solid market potential.

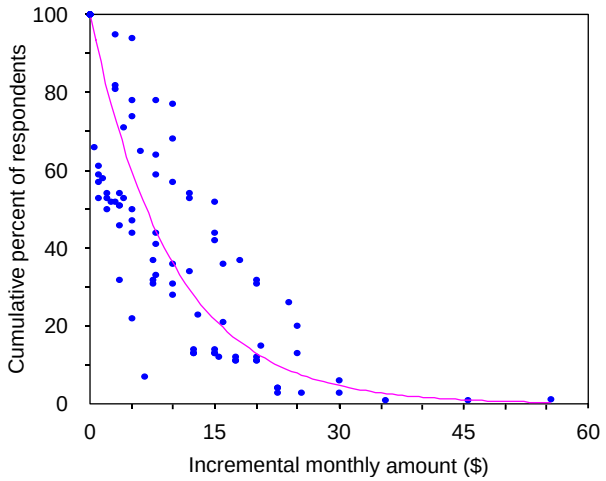

FIGURE 5 Aggregated willingness-to-pay curve for residential customers. The equation of the curve is $Y = 100e^{-104}M$, where Y is the cumulative percentage of respondents and M is dollars more per month ($R^2 = 0.76$). Source: Farhar (1999).

The results pertaining to stated willingness to pay from the utility-sponsored surveys summarized in the 1999 NREL report corroborate other survey results. Farhar's 1996 report on behalf of REPP indicates that 57–80% of the respondents in national polls state they are willing to pay more for "cleaner" electricity or electricity generated from "environmentally friendly" sources. The 2000 NREL study of Colorado homeowners pertaining to GPV indicates that 76% of respondents are willing to pay at least $1 more per month for electricity generated from renewable sources. Further corroborating evidence from polls of adults in four midwestern states is reported in a 1998 study conducted by Tarnai and Moore at Washington State University, along with information contained in the 1999 BPA report.

Some results that specifically pertain to wind power program participation are presented in a 1998 report by the Energy Center of Wisconsin. In contrast to the opinion and market research surveys described in the 1999 NREL and BPA studies, this one is more experimental in nature, the research is more controlled, and the analysis is more rigorous. Of the 761 respondents who were asked hypothetically if they would be willing to pay an additional amount on their monthly utility bill to obtain wind power, 43% said yes. Of these, 61% said they would be willing to pay at most an additional $2 per month or $24 per year. Fifty-eight percent said they would be willing to pay at most $4 more per month or $48 per year, 50% said they would be willing to pay at most $8 more per month or $96 per year, and 18% said they would be willing to pay at most $12 more per month or $144 per year. These results compare closely with those noted previously (Fig. 5).

Perhaps the most recent research in the United States on willingness to pay for renewables is found in the study conducted by Wells Fargo PORP. In this study, 55% of respondents indicate they are willing to pay an additional $10 or more on a typical monthly bill of $55 for electricity generated from renewables, whereas 18% are willing to pay nothing more. Two-thirds (67%) of the respondents indicate that any additional cost of using renewables to generate electricity should be spread across all consumers.

Current knowledge about U.S. consumers' stated willingness to pay for renewables closely parallels research findings in other industrialized countries, although more information seems to be available for

the United States. For example, in a small survey conducted on behalf of New Zealand's Energy Efficiency and Conservation Authority, more than half of the respondents indicated a willingness to pay 5% more for wind-generated electricity, and approximately 20% were willing to pay an additional 15%.

Irrespective of issues about comparability, the combined message from all these studies is that a high percentage of consumers nationwide, and perhaps even in other areas of the world, are indeed willing to pay more on a monthly basis for electricity produced from renewable sources. Of all possible indicators, this one signifies a fairly positive public response to renewable energy sources and systems in the general context of green pricing.

The finding suggests that markets for renewable energy and renewable energy systems do exist and that they can be expanded through strategic planning and implementation.

8. GAUGING ACTUAL PARTICIPATION OF CONSUMERS IN RENEWABLE ENERGY PROGRAMS

As suggested previously, engaging consumers in renewable energy participation has been the subject of much thought and investigation. However, because it is largely proprietary in nature, information about actual consumer participation in renewable energy programs and their purchases of renewable energy systems is difficult to obtain and assess. There are both operational and technical difficulties to overcome as well as definitional inconsistencies. For several years, the EIA has tracked shipments of solar PV cells/modules and solar thermal collection devices as a proxy for consumer demand (both private and commercial); as noted previously, these shipments were at an all-time high in 2001. Such equipment includes solar hot water devices. In fact, the EIA reports that in 2001, the residential sector replaced the industrial sector as the largest market for PV cells and modules. This evidence alone suggests, at least indirectly, that consumer demand for renewable energy systems is on the rise.

In addition, since April 2000, NREL staff have compiled and reported a "top ten" list of green pricing programs in the United States in each of the following categories: renewable energy sales, total number of customer participants, and customer participation rates. More than 300 utilities in 32 states offer green pricing programs. In December 2002, the number of patrons in the 10 largest programs with respect to customer participation ranged from 5644 to 72,732, for a total of 201,305 (approximately 42,000 of which are low-income customers in Los Angeles who do not pay a premium for green power). Participation rates in the programs with the 10 highest figures ranged from 3.0 to 5.8%.

Other entities throughout the world are also focusing more formally on the engagement of consumers and measurement of their participation in renewable energy programs. The National Institute for Research Advancement (NIRA) in Japan devoted an entire issue of its journal, *NIRA Policy Research*, to renewable energy development and citizen participation in the context of wind power.

Some of the most interesting and promising research concerning consumer attitudes and participation pertains to the new-home construction industry. Under the auspices of its Zero Energy Home (ZEH) program, DOE is promoting the construction of new single-family homes that combine available renewable energy technologies and energy-efficiency construction techniques to consume zero net energy from the utility grid. Both qualitative and quantitative research is currently being conducted at NREL on the consumer response to ZEH-like homes in San Diego, California. Although proprietary studies of homebuyers are relatively widespread in the building industry, this is some of the earliest work on customer response to ZEHs, particularly in a geographic locale in which volatile energy costs have been a political and economic concern.

The research involves direct interviews with purchasers of high-end homes (in excess of $500,000) in a large development in which more than 250 highly energy-efficient homes with GPV may eventually be sold. Almost all the homes will have solar water heating as well. Initial interviews with the home buyers have targeted the following issues: reasons for purchase, preferences for standard or optional systems, views on energy efficiency and solar energy features, satisfaction with utility bills, aesthetics, construction and technological problem areas, impacts on energy-related behavior, homeowner knowledge, and overall homebuyer satisfaction.

Early findings were described in a paper presented at the 2002 Summer Study conference of the American Council for an Energy Efficient Economy. Among homeowners with GPV, the availability of solar features was frequently cited as one of the top three reasons for purchase. Some of these buyers said they were looking for a hedge against rising energy

costs and some were motivated by their own environmental values. Although indicators of satisfaction can be misleading in the early stages of technology deployment, all the individuals interviewed indicated they were satisfied and that they would make the purchase again. Their feedback, although expected to be representative of highly positive and proactive early adopters, provided key insights into the motivation of consumers to become involved with renewable energy technology and the marketability of ZEHs. The realization that so many of these homes would actually be sold is further evidence of the existence of consumer demand for renewable energy and renewable energy systems.

Both GPV and solar water heating are included in the Million Solar Roofs initiative directed by DOE's Federal Energy Management Program. The objective of the Million Solar Roofs program is to encourage and support the installation of 1 million solar energy systems on residential, commercial, and public sector buildings by 2010. If successful, the program will have had a major impact on public perception and renewable energy markets in the United States.

Solar water heating is a more mature technology than GPV, having been available in several forms for more than 20 years. Studies on the market response to solar water heating have been conducted by several entities. The actual size of the installation base is difficult to reliably estimate, but anecdotal estimates for the United States range from 1 to 2 million systems. In the international arena, the International Energy Agency conducted a 5-year program begun in 1998 to enhance the market for solar domestic hot water systems in Canada, Denmark, Germany, The Netherlands, and Sweden. With the ultimate objective of 10,000 installations, this program is similar to the Million Solar Roofs initiative in the United States. Results of the project have not yet been made publicly available. Based on a March 2002 survey, the Australian Bureau of Statistics estimates that in Northern Territory, approximately 53% of households have solar hot water systems, as do approximately 16% of households in Western Australia (although this number is down from its peak of approximately 20% in 1999). Although these percentages seem robust, they represent only approximately 4% of all households in Australia.

Finally, the 1998 study by the Energy Center of Wisconsin concerning wind power program participation reports that 24% of 647 survey respondents who were asked to make an actual commitment to pay more to receive wind power agreed to do so (as previously noted, in another group of 761 individuals in the study that were asked, hypothetically, about their willingness to pay for green pricing, 43% responded affirmatively). When presented with a menu of monthly payment amounts, 47% committed to pay up to $2 more per month or $24 per year for wind power (compared to 61% of the other group who said, hypothetically, that they would be willing to pay up to $2 more per month). Thirty-five percent committed to pay up to $4 more per month (compared to 58% of the other group), 23% committed to pay up to $8 more per month (compared to 50% of the other group), and 8% committed to pay up to $24 per month (compared to 31% of the other group). A third group of 237 individuals were asked to pay for a fixed-size block of wind power of their choice every month, and surprisingly, more than one-third (37%) agreed to do so. The minimum block size was 50 kWh per month at an estimated incremental cost of $2, and the maximum block size was 600 kWh per month at an estimated incremental cost of $24. Other block sizes in multiples of 100 kWh were available at $4 per 100 kWh per month.

As expected, the percentages of respondents in the Wisconsin study who actually agreed to sign up were lower than the corresponding percentages of respondents who were asked about their hypothetical willingness to pay. This is the only publicly available research that involves a direct comparison of actual consumer behavior regarding renewables to presumed, hypothetical behavior, and it is the only publicly available work that attempts to measure the difference. Nonetheless, it seems clear that consumers throughout the world are utilizing or purchasing renewable energy systems for personal use and that the trend toward greater acceptance and deployment is a positive, increasing one.

9. PUBLIC RESPONSE TO RENEWABLES IN THE TRANSPORTATION ENERGY SECTOR

The foregoing discussion focuses on electricity and power generation, particularly as they relate to the residential and commercial energy sectors. However, attitudes toward renewable resources carry over to other energy sectors as well. With respect to transportation energy, a decade-long emphasis on the development and proliferation of alternative fuels and

alternative fuel vehicles has produced consumer responses not unlike those exhibited toward electricity and power generation. Again, only limited information is available, and it must be noted that not all alternative fuels are derived from renewable resources.

Although the rate of growth since 2000 has slowed, the total number of alternative fuel vehicles in use has increased steadily in the past decade in response to direct support, mandates, and research and development activities of government agencies throughout the world. Whereas more alternative fuel vehicles have certainly been placed in service during this time, record keeping has also improved, so the estimated annual rates of increase, particularly in the early 1990s, may not be completely accurate. The EIA estimates that in 2002 there were approximately 500,000 alternative fuel vehicles in use in the United States, of which approximately 60% were privately owned and operated. Approximately 82,000 of these were estimated to be ethanol-fueled vehicles (E85 and E95 combined; E85 is an 85/15% mixture of ethanol and gasoline). In comparison, the EIA reported only approximately 45,000 alternative fuel vehicles in 1993, of which only approximately 450 were ethanol fueled.

Of all the fuels classified by the DOE as alternative fuels, only ethanol can be specifically classified as a renewable transportation fuel. Ethanol is derived mostly from corn. Methanol might also be regarded as having been derived from a renewable resource, depending on its composition. The number of methanol-fueled vehicles in use in the United States has declined rapidly since 1997 to fewer than 6000 in 2002, whereas the number of ethanol-fueled vehicles has increased. In fact, no new methanol-fueled vehicles are being manufactured. Among all types of alternative fuel vehicles, the number of ethanol-fueled vehicles is growing at one of the fastest rates, particularly in the Midwest, where corn is plentiful (Fig. 6).

Not all alternative fuel vehicles operate exclusively on alternative fuel (alternative fuel vehicles that operate exclusively on their target fuel are referred to as dedicated vehicles; those that do not are said to be nondedicated). Ethanol vehicles, for example, can typically operate on either ethanol or gasoline (these are often referred to as flexible fuel vehicles). Information about the percentage of time that such vehicles actually operate on ethanol, especially privately operated vehicles, is sketchy.

Despite the growth in alternative fuel vehicles, the total number is still only a fraction of the entire in-use vehicle population. The EIA estimates that in the United States, alternative fuel vehicles represent only approximately 0.2% of total registered on-road vehicles. Furthermore, the amount of alternative fuel consumed annually in the transportation sector is less than 3% of total fuel consumption, and the percentage has declined since 1999. The EIA estimated U.S. alternative fuel consumption in 2001 to be 4.4 billion gasoline-equivalent gallons, of which ethanol accounted for 1.12 billion gasoline-equivalent gallons. A large percentage of ethanol is used as an additive in oxygenated gasoline formulations; thus, by default, many Americans—indeed many consumers throughout the world—are ethanol users.

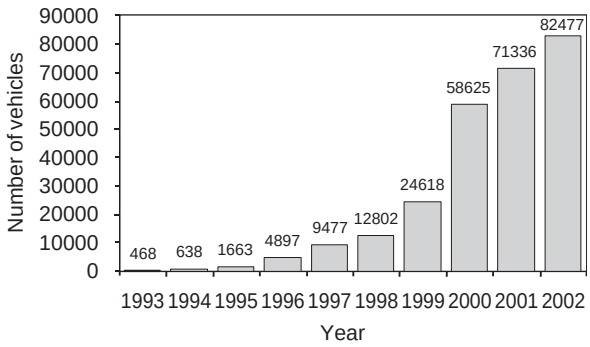

FIGURE 6 Annual numbers of ethanol-fueled vehicles (E85 and E95) combined. Totals for 2001 and 2002 are estimated. Data from the U.S. Energy Information Administration (2002b).

A number of studies have been conducted regarding market penetration of alternative fuel vehicles. For example, in 1996 the EIA reported on the markets for alternative fuel vehicles in general, whereas an earlier study conducted at the University of California at Davis focused specifically on alcohol-fueled vehicles.

Three NREL reports from the mid-1990s provided synopses about the preferences and satisfaction of drivers of alternative fuel vehicles. The first one described the results of a survey of U.S. federal fleet drivers in which respondents were asked to compare the performance of alcohol-fueled vehicles to that of other types. Approximately 90% of respondents assigned overall ratings of "very good" or "excellent" to alcohol-fueled vehicles, and similarly high percentages of drivers indicated they were leaning toward being "satisfied" or "very satisfied" with their vehicles. Approximately 87% of drivers of ethanol-fueled vehicles and approximately 67% of drivers of methanol-fueled vehicles indicated they would recommend their vehicles to someone else. A second report described the results from a corresponding survey of federal fleet managers. A high percentage of

these individuals (approximately 70%) indicated that drivers of the alcohol vehicles in their fleets were neutral toward them (a somewhat less enthusiastic response than from the drivers), but more than 80% of the fleet managers indicated they received approximately the same number of complaints from drivers of alcohol-fueled vehicles as they did from drivers of gasoline-fueled vehicles. The final report described the results of a survey of drivers of state and city government fleet vehicles. More than 80% of the drivers of alcohol-fueled vehicles assigned them overall ratings of excellent or very good, and almost all drivers said they were about the same as gasoline-fueled vehicles. Approximately 70% of the drivers of alcohol-fueled vehicles said they were very satisfied with their vehicles, and approximately the same percentage said they would recommend their vehicles to other drivers.

A number of other surveys of fleet managers have been conducted, both by commercial entities and by professional research organizations. However, many such studies have statistical and operational shortcomings, and they are not specifically concerned with alcohol-based (renewable) fuels.

Detailed information regarding the preferences and perceptions of owners/drivers of privately owned alcohol-fueled vehicles is not available, although anecdotal evidence suggests similarly high levels of satisfaction. After all, individuals are unlikely to purchase these kinds of vehicles for private or business use if they do not already have a positive attitude toward them. Likewise, no recent data concerning willingness to pay for alcohol-fueled vehicles are available.

Like the consumer information concerning heat and power generated from renewables, this collective body of evidence suggests the public response to automobiles capable of operating on renewable fuels is positive. More expansive growth seems to hinge primarily on vehicle availability in the marketplace, accessibility to adequate fuel (adequate refueling infrastructure, ease of refueling, etc.), and both vehicle and fuel price.

Fuel cell technology promises to revolutionize automotive power systems and substantially reduce the environmental impact of transportation emissions. Fuel cells also show promise as power plants for other appliances and devices such as computers. Simply stated, fuel cells are devices that produce electrical energy from a fuel using an electrochemical reaction, or the process of oxidation, rather than combustion. The function of a fuel cell is similar to that of a battery. Although various fuels can be used, hydrogen is the primary choice because the only by-products of the reaction are water, heat, and electricity. In a direct-hydrogen fuel cell vehicle, the controlled reaction between hydrogen and oxygen is believed to be more efficient than the process of internal combustion, in which the fuel (e.g., gasoline or diesel) is actually burned. Other fuels besides hydrogen can be used—particularly gasoline, diesel, ethanol, and methanol—but they all have to first be converted to hydrogen onboard in order for the fuel cell process to work. Safety concerns surrounding the transportation of hydrogen onboard private and commercial vehicles is the primary reason for considering other fuels, and there is considerable interest in renewable fuels such as ethanol and methanol because of their environmentally friendly characteristics. With support from various government agencies and other funding organizations, most of the automotive industry is engaged in fuel cell technology research. Honda and Toyota are the industry leaders; both companies have manufactured a limited number of fuel cell vehicles for sale (Toyota already has a sizable market, particularly in Japan, for its hybrid electric vehicles). Fuel cell systems for heavy vehicles and buses are also being researched by various organizations, such as Georgetown University and NREL. Although an important objective of many fuel cell vehicle research programs, there has been little investigation into public acceptance or consumer demand, and only limited information is available in the public arena. Consequently, only time will tell whether fuel cell technology can live up to its billing and supplant other power systems that are already deeply entrenched in the transportation sector.

10. FACTORS THAT MOTIVATE PUBLIC RESPONSE TO RENEWABLES

The question as to what motivates consumers to become personally involved with renewable energy is both interesting and multifaceted. The driving forces are myriad, but some of the more obvious ones are individualism and personal security, economics, environmental concern, the pursuit of a technocentric lifestyle, and even altruism. Although a direct linkage between such influences and actual purchase behavior is difficult to establish, survey data support the notion that individuals who are more favorable toward renewable energy also tend to be more sensitive to, or disposed toward, one or more of these factors.

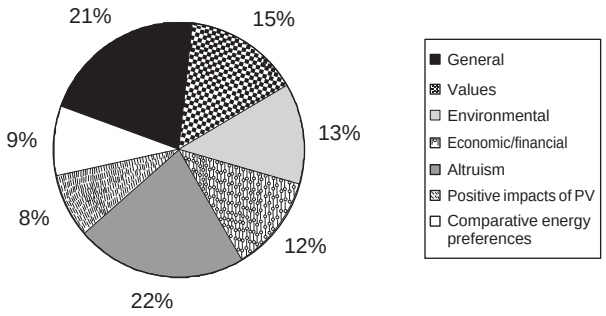

FIGURE 7 Percentages of references by participants in focused interviews to factors that motivate GPV adoption; $n = 3465$ total references by 120 participants in a purposive sample of residential energy customers in Colorado. Source: Farhar and Burhmann (1998).

A fairly extensive analysis of consumer motivation to adopt renewable energy technology is reported in the qualitative work by Farhar and Burhmann leading up to the 2000 NREL study of public response to GPV in Colorado. The percentages of all references in focused interviews to various motivating factors are summarized in Fig. 7.

The 2000 NREL study subsequently reports the percentages of respondents who indicated various perceived benefits of GPV to be important. These percentages are summarized in Table III. Taken together, the results of these two studies suggest that consumers' motivations to adopt renewable energy technology (e.g., GPV) are quite varied but perhaps more generally focused on economics and the environment.

The link between energy preferences and environmental concerns has been known for some time, but with increased emphasis on global warming and the greenhouse effect, the linkage is becoming more pronounced. National surveys conducted during the past 10 years indicate that fairly strong majorities of Americans believe there is a connection between energy usage and risk to the environment, and in the 2000 NREL study Colorado homeowners are shown to associate energy usage with environmental threat.

Although economic issues are always on the minds of consumers, they have perhaps been brought to the forefront by the recent energy shortages and price spikes in California. A 2001 brief prepared by Farhar on behalf of the Roper Center describes the results of several national polls conducted prior to the September 11, 2001, terrorist attack that indicate increasing concern among Americans about energy costs and the impact that worldwide shortages might have on them.

TABLE III

Percentages of Survey Respondents Who Indicated Several Perceived Benefits of Grid-Tied Photovoltaics (GPV) to Be Important

Perceived benefit of a GPV system	% of respondents indicating importance[a]
Result in long-term energy cost savings	86
Help reduce air pollution and acid rain in our area	84
Conserve natural resources	85
Benefit future generations	82
Reduce electricity bills right away	82
Help protect the environment	82
Increase resale value of home	79
Have electricity during a power outage	76
Help reduce global warming	75
Pay for itself over system lifetime	72
Sell excess electricity back to ultility company	71
Increase self-sufficiency	70
Increase diversity of energy sources	70
Help create jobs for Colorado	68
Good for Colorado's economy	68
Encourages others to replace gas and coal use	62
Feels good to do this	51
Increase awareness of household energy use	46
An opportunity to make a difference in community	44
Help create and expand PV market	38
A new technology to enjoy	33
Profitable for utility companies	20
First on block to have a PV system	10

Source. Farhar and Coburn (2000).

[a] On a scale of 1 to 10, with 10 being "very important," the percentage of all respondents who chose 7–10.

Research conducted at the University of Michigan prior to the catastrophic events of 2001 suggests, however, that economics may not be the sole motivating factor. In 1998, Clark et al. noted that the motivation for individuals to participate in initiatives such as green power programs is more complex, encompassing both intrinsic and extrinsic factors. Recent research concerning the motivations for corporations and other nonresidential customers to become involved in green power complements the University of Michigan findings. A 2001 report

prepared by Lawrence Berkeley National Laboratory (LBNL) in conjunction with Ed Holt & Associates indicates that altruism is the most significant factor, particularly among smaller companies and firms. Although conventional wisdom might suggest that economic gain is the principal motivating factor, this work implies otherwise.

Taken together, this body of evidence suggests that economics, environmental concerns, and national security and self-sufficiency will be the forces driving consumer demand for renewable energy and renewable energy systems in the foreseeable future. This conclusion is not surprising, particularly to those who have broad knowledge of the issues facing the energy establishment. What is surprising is the rapidity and certainty with which the interaction of these forces is changing the worldwide political, industrial, and economic landscape. The wildcard in the proliferation of renewables may be the speed with which science, engineering, business, and industry can bring products to the marketplace to capture the imagination of a public eager to try new inventions that have the potential to reduce personal uncertainty.

11. MODELING PUBLIC RESPONSE TO RENEWABLES

Surprisingly, little has been done in the way of formally modeling or predicting the public response to renewable energy and renewable energy systems. The 1998 report by the Energy Center of Wisconsin pertaining to wind power program participation purports to develop predictive models, but no such work beyond descriptive percentage distributions is actually presented. The 2000 NREL report presents the results of an extensive multivariate analysis of the survey data aimed at characterizing the Colorado market for GPV, which in context can be used to predict consumer participation. Beyond these two endeavors, little has been done to specifically predict public participation or response. On the other hand, there have been many efforts to develop economic models and market penetration models pertaining to renewable energy and renewable transportation fuels, although some of this knowledge is becoming dated. A collaborative partnership among NREL, LBNL, and Ed Holt & Associates resulted in forecasts of growth in green power markets in the United States.

The problem is that modeling and predicting public response to any technological intervention is difficult. Societal, cultural, economic, and other forces all interact to affect the responses of ordinary citizens. In addition, the identification and selection of appropriate measurements, and the collection of data in sufficient amounts and of sufficient quality, are substantial impediments to research. Finally, as previously suggested, behavior and attitudes are not necessarily directly related, and without a specific definition of what actually constitutes the public response, the ideas of modeling and prediction are necessarily reduced to purely theoretical exercises or to the reporting of mostly empirical, possibly indirect, observations.

12. CONCLUSION

Public attitudes toward renewable energy and renewable energy systems have shifted during the past 10–20 years, and they continue to evolve. The change is observable in ongoing opinion and market research conducted by government agencies, business entities, and respected research organizations throughout the world. Several factors are responsible. Most significant, perhaps, is a growing recognition that worldwide demand for energy—specifically, electricity—is surging and that traditional energy resources are limited. Recent economic and political instability, both globally and domestically, have created a milieu of uncertainty that accentuates public concern about the ability of government and industry to supply the energy necessary to meet societal needs. In addition, there is increasing evidence of global climate change, and consumers are becoming more convinced of its link to the consumption of traditional fossil fuels and more apprehensive about its impact on the environment and public health.

Nearly all the evidence of an attitude shift is empirical, and more needs to be done from an inferential and predictive standpoint. In addition, there are acknowledged issues of data quality and comparability. However, the amount of evidence has grown to the point that the positive trend toward renewables in public opinion and consumer attitudes cannot be denied. Operationalizing a favorable outlook into actual product purchases and program participation is a different matter, indeed; but here, too, there is substantial evidence that markets are developing and that consumers are increasingly acting on their convictions that renewable energy is a viable approach to sustainable economic and environmental security. As in the case of all technological ventures, price, availability of products,

accessibility to infrastructure, and reliability and performance of systems will be key to further consumer participation and expansion of markets.

Glossary

absolute risk model A model in which the increase in the rate of cancer, or other disease, is independent of the natural incidence at that age and place.

absorbed dose The amount of energy absorbed in a material. The Système International unit for absorbed dose is named after the medical physicist Professor L. H. Gray. The gray (Gy) represents an energy absorption of 1 joule per kilogram of absorbing material, i.e., 1 Gy = 1J/kg. However, an older unit, the rad, is still often used, particularly in the United States (100 rad = 1 Gy).

ALARA An acronym for "as low as reasonably achievable," a criterion for judging radiation protection; alternatively, ALAP (as low as practicable) or ALARP (as low as reasonably practicable).

assigned share See **probability of causation**.

equivalent dose (radiation weighting factor) An expression introduced to take into account the dependence of harmful biological radiation effects on the type of radiation being absorbed. The same absorbed dose delivered by different types of radiation may result in different degrees of biological damage to body tissues. The total energy deposited is not the only factor that determines the extent of the damage. The equivalent dose is therefore a measure of the risk associated with an exposure to ionizing radiation. Risks due to exposures to different radiation types can be directly compared in terms of equivalent dose. The unit of equivalent dose is the sievert (Sv), defined for a given type of radiation by the relationship $H = DW_r$, where H is the equivalent dose in sieverts, D is the absorbed dose in grays, and W_r is a numerical weighting factor. In older centimeter-gram-second (CGS) units, the term "roentgen equivalent man" (rem) is still often used (1 Sv = 100 rem).

excess relative risk (ERR) The excess (additional) risk caused by radiation, divided by natural risk (incidence).

ionizing radiation The radiation with individual quanta of high enough energy to ionize an atom.

LD_{50} The "least dose" at which 50% or more of people are affected (usually producing, but not always, death).

probability of causation The estimated probability that an event (such as cancer) was caused by a postulated action (usually radiation exposure).

radiogenic cancers Occurrence of cancers at a body site where it is known that radiation can cause an increase; most leukemias are radiogenic cancers, whereas chronic lymphocytic leukemia is not.

relative biological effectiveness (RBE) An alternative description for the weighting factor W_r.

relative risk model Extrapolation of the ratio of a risk to the risk from natural causes at a certain age and place; this model is in contrast to the absolute risk model.

Each and every one of us is exposed to natural ionizing radiation, all the time, from the sky, from the air, from the ground, and even from our own bodies. Mankind can also produce ionizing radiation. This was realized when X rays were discovered by Professor Roentgen in 1895; radioactivity was discovered by Becquerel soon thereafter, and scientists began to notice that exposure to radiation had harmful effects—radiation was noted to burn, damage, and even destroy tissue. These effects were used very soon (about 1905) for beneficial purposes, to destroy an unwanted skin tumor. Almost from the

beginning arose the dilemma: excessive radiation can be bad for you, but it can also be good for you. The focus here is on assessment of the risks and the benefits of radiation.

1. INTRODUCTION

The most important medical application of radiation is the use of X rays for diagnostic purposes. There is an enormous advantage to a physician, and hence to the patient, of knowing exactly where a bone or blood vessel lies in the body. Early on, this realization seemed to outweigh any small risk that continued use of X rays might entail. This crude risk–benefit comparison probably contributed to the fact that it was many years before people acted to reduce radiation risk. The benefit seemed so great that it was forgotten that risk could be reduced without changing the benefit. In the 1920s and 1930s, a number of pioneer radiologists suffered severe injuries, and some even died, as a result of prolonged exposure to dangerously high intensities of X rays. These early workers in the field had no means of accurately measuring the harm caused by radiation and they often used inferior measurement equipment even though better equipment was available; to establish radiation exposure, they depended on unreliable effects, such as the degree of skin reddening caused by the exposure, or on timing the exposure from a certain type of X ray machine.

Other adverse effects of radiation were noted in workers involved in several industrial or clinical uses of radiation in the first half of the 20th century. In the 1920s, watch dials were painted with a luminous paint containing an alpha particle emitter, usually from radium. Most watch factory painters sucked the paintbrush to obtain a fine point, thereby absorbing radium in their mouth, ultimately in their bones. In clinics and hospitals, physicians suffered from excess radiation when they administered large doses of radiation to cure painful diseases such as ankylosing spondylitis. X-Ray operators failed to shield themselves and the parts of the patient's body that were not under study. Radiologists would sometimes look straight at a fluorescent screen and therefore straight into the X-ray tube.

The radiation dose for a typical chest X ray was about 1 rem until about 1960; with good shielding and use of image intensifiers it can now be (and could have been 50 years before) 7 mrem. The big impetus toward understanding the health effects of radiation was the massive expansion of nuclear technology following the development of nuclear reactors, and the explosion of the atomic bombs in 1945. Since then, radiation has become inextricably linked with the atomic bomb and its adverse effects, much to the detriment of benign uses. The fact that radiation is associated with bombs leads many people to believe that radiation is uniquely dangerous. That is far from the case. For example, the largest and most important study of radiation-induced cancer comes from the study of Hiroshima and Nagasaki victims, among whom 500 or so excess cancers (more than expected from the nonexposed population) were observed. Yet that many excess lung cancers were found in a separate study unrelated to exposure from the bombs. One crucial feature of such data is that radiation does not seem to cause any medical or biological effect that cannot also occur naturally. It merely increases the probability of the effect. This fact is very important, both for understanding possible dose–response curves and for deciding what, if anything, to do about radiation at low doses. It also leads us to ask a general question: Does radiation add an additional probability of developing cancer (an absolute risk model) or does it multiply the probability that is there from natural or other causes (a relative risk model)? Although both models are discussed in most summary reports, it is noteworthy that the emphasis has changed from an absolute risk model (in 1970) to a relative risk model with an increase in calculated risk—particularly in aging population groups.

2. EFFECTS AT HIGH DOSES (>3 Sv)

When radiation is given over a short period (less than a day) at doses greater than 200 rem, the primary effect is serious destruction of blood and tissue. Two situations can be distinguished: radiation exposure of a small area of the body and exposure of a large percentage of the body surface. A recent example of the first situation arose in the republic of Georgia, of the former Soviet Union, when a soldier picked up a large strontium 90 source that had been used for a thermoelectric generator and left behind by the Soviet army. The soldier's hand was treated for a year in the hospital of the Curie Institute in Paris before the soldier fully recovered.

In the past, misuse of X rays led to many situations in which a hand or other extremity was

heavily exposed (up to 200 Sv = 20,000 rem). At this level, tissue is destroyed but can be surgically replaced. High exposures of limited quantities of tissue occur in radiotherapy. The aim in radiotherapy is to provide a large enough dose to destroy a tumor, without destroying neighboring tissue. Typical doses to the tumor are 60 Sv (= 6000 rem). If the dose is given in several fractions, the neighboring healthy tissue can recover. In contrast, a much smaller dose given to the whole body can destroy the whole organism. Ordinarily, the dose from which half of the recipients will die, the LD_{50}, is about 2.5 Sv (= 250 rem), but the LD_{50} can be extended up to about 5 Sv in aggressive treatment. Following high-dose radiation, blood transfusions to bring in healthy blood have been successful, and bone marrow transplants to replace destroyed bone marrow were tried in a few cases of heavily exposed workers after the 1986 Chernobyl nuclear accident. A couple of the Chernobyl patients improved, but an equal number were probably killed by the treatment. At 5 Sv (= 500 rem), the gut and many other body organs begin to fail. Death is not immediate but takes up to a week. One famous victim, the Canadian Dr. Louis Slotin, a scientist at the Omega Site Laboratory in Los Alamos, New Mexico, lived for a month, and actually wrote a description of the incident while he was dying, after an accident with supercritical plutonium in 1946 exposed him to ~10 Gy of gamma and neutron radiation.

3. EFFECTS AT MODERATE TO HIGH DOSES (0.3–3 Sv)

3.1 Chronic vs. Acute Effects

Daily doses lower than those required to destroy tissue, can, if repeated over a long period, cause health effects. In contrast to the acute effects from exposure over a short exposure, these chronic effects often involve whole body doses accumulated over years, of 10 Sv and more. From general biological principles, the following effects of continued exposure to even moderate doses of radiation might be expected: induction or aggravation of cancer, induction or aggravation of heart disease, induction or aggravation of other diseases, production of genetic anomalies that can be passed on to another generation, and induction of birth defects by genetic mutation. Most of the studies address only cancer induction, and the data do indeed suggest that cancer induction is the dominant effect. The data are better for cancer than for the other outcomes largely because the observed effects are greater. Several groups of radiation-induced cancer (e.g., leukemia, solid cancers, lung cancer) can be distinguished based on their different characteristics.

3.2 Chronic Radiation Sickness

Normally, any worker who receives a high radiation dose on the job is prohibited from participating further in any work that involves radiation exposure. A case history in which this practice was ignored occurred in the late 1950s, in the former Soviet Union, where there was a great push to build an atomic bomb to "balance power" with the United States. For many years, it had been rumored that workers at the Mayak nuclear reprocessing plant in the southern Urals received large radiation doses. Attempts from the western countries to discover the facts about what happened at Mayak were fruitless until 1991, when a description was published in Russian in the journal *Priroda*. The workers at Mayak had continued working even after being highly exposed, and over a 2-year period received doses up to 10 Sv (= 1000 rem). The first diagnosed effect was a drop in blood cell count and general sickness. This was called chronic radiation sickness, in contrast to acute radiation sickness, which is caused by large singular doses. Radionuclides from the Mayak chemical processing facility were dumped into neighboring Lake Karachay. In 1955 and 1956, water overtopped the reservoir and spilled into the Techa River, which drains into the Arctic Ocean. Villagers drank the water and ingested many radionuclides. For 40 years, the health of 30,000 villagers around the Techa River has been studied and chronic radiation sickness has been diagnosed. Around the Techa River, the exposures were mostly internal; the internal organ dose is used in describing leukemia incidence. In contrast, "solid" cancer diagnoses depend on external doses, which are far less easily determined. The internal Techa River exposure determination was based on detection of the "bone seeker" strontium-90; doses were fairly accurately determined by examination of radioactivity of teeth and other bones.

3.3 Leukemia

Although there have been studies of the effects of radiation on people for 100 years, the most important studies are the studies of the consequences of the Hiroshima and Nagasaki atomic bombs. The

research on the survivors has involved many good scientists, considerable effort, and considerable expense, mostly at the Radiation Effects Research Foundation in Hiroshima. The exposures occurred many decades ago, but an increase in cancers over that expected in the general population is still occurring. Therefore, the most recent research is of greatest importance. In addition, the radiation dose to which the population was exposed is uncertain. It was derived from measurements at other (similar) nuclear explosions, and based on the neutron dose by measuring long-lived radioactivity in the region.

Leukemia was the first cancer to be noticed in the atomic bomb survivors. Leukemias began to appear 5 years after the exposure and continued to appear for another 20 years, after which the incidence of leukemias (almost) ceased. Radiation induces leukemias more readily than other cancers. Therefore, leukemias are often considered to be a "marker" for radiation effects. But the variation with age is clearly in great contrast to that of the "solid" cancers, and in the elderly even an "absolute risk" model would overpredict the number.

3.4 Solid Cancers (Excluding Lung Cancer)

Solid cancers occur in tissues of the body and are not connected with blood components. They do not appear until 20 years after radiation exposure and have been noted to continue to appear for 50 years. The increase of cancer with radiation dose seems to follow a "relative risk" pattern whereby the risk, after the latent period of 20 years, is increased by a constant fraction relative to the background at that age.

3.5 Lung Cancers

Lung cancers are of particular interest because the lung is the point of entry for a major radiation exposure. In order to understand the effect on humans of alpha particle irradiation, there have been several animal studies that show an increased incidence of cancer related to radiation dose. The animal studies showed a quadratic relationship. Therefore researchers initially looked for a quadratic relationship, and not a linear relationship, in human lung cancers. Several cohorts have provided useful information.

One of the surprises of the atomic age (i.e., since 1945) was that an excess of lung cancers appeared among uranium miners. In some of the early studies, lung cancers seemed to appear only among Caucasian miners and not among Native American Indians. There was some speculation of a racial difference in sensitivity. This speculation was proved incorrect both by follow up and by observations that there were fewer tobacco smokers among the Indian miners, compared to the Caucasian miners. Most analysts have assumed that lung cancers are due to exposure to radon gas in the mines rather than to any other pollution in the mines (dust, etc.), although there is still room to question this. The main concern is that inhaled particles or radionuclides might cause lung cancer. The generally accepted effect of radon gas is that radon alpha particles and "daughter" products irradiate the lung and induce cancer. This suggests that exposures to other alpha particle emitters also should produce lung cancers.

There have been several studies of the health of persons who worked with, and possibly inhaled, plutonium. Lung cancer is the principal effect that may be caused by plutonium inhalation. Although there have been many persons working with plutonium, in Los Alamos (New Mexico), Rocky Flats (Colorado), and Hanford (Washington), safety precautions have kept exposures small except in one cohort, the workers at Mayak (the former Soviet Union) in the 1950s. Because plutonium deposits in the bone, it was possible in most cases at Mayak to make accurate estimates of exposure by looking at the deposited radioactivity in the bone, either in *vivo*, or after autopsy. The highly exposed group of Mayak workers developed lung cancer at twice the rate of the less exposed workers, whose lung cancers are assumed to be caused by cigarette smoking. The first studies found agreement with the expected quadratic variation of incidence with dose, but later studies showed that a linear relationship is more probable.

There have also been "ecological" studies of the relationship between the average lung cancer incidence in a population and the average concentration of radon gas. In the most complete of these studies, radon gas was measured in half a million U.S. households and data were compared to the average lung cancer incidence in the region. To the surprise of the author of the studies, the lung cancer rate was found to be lower in high-radon areas compared to low-radon areas. The effect is highly significant. There is argument among experts as to whether these data indeed show that inhaled radon gas is beneficial. On one side, modern epidemiologists argue that such "ecological" studies show little by themselves. All they show is that the average lung cancer incidence rate $\langle i \rangle = -k * \langle c \rangle \times \langle p \rangle$, where $\langle c \rangle$ and $\langle p \rangle$

are the average concentration and the average population density. They do not show that $c = k * a * b$. Moreover, there is, in their view, too much room for bias. In particular, the study includes both smokers and nonsmokers intermingled, and the largest cause of lung cancer is known to be cigarette smoking. On the other side, scientists note that data are data; the data do not fit the regulatory model proposed by the U.S. Environmental Agency (EPA), and that model must be incorrect or at least inadequate. The general consensus is that, at the concentration levels of concern, radon gas cannot be the major contributor to lung cancer, either for smokers or nonsmokers.

3.6 Childhood Cancers

In the period from 1940 to 1970, it was common to give an X ray to pregnant women to discover any problems with the infant fetus. This dosed the fetus with radiation approaching 0.01 Sv ($= 1$ rem). In a classic study (the Oxford study), it was found that the probability of developing childhood leukemia in the age group 0–8 years increased with the number of X rays. This effect was not observed in the Hiroshima–Nagasaki studies. It is usually accepted that these leukemias are caused by something that happened *in utero*. But there is a possibility that causality proceeds in the opposite direction. A physician noticing an abnormality leading to cancer might call for an X ray. The correlation might then merely be between the abnormality and a subsequent cancer. Childhood cancers occur up to 7 years from birth, so cancers from the Chernobyl accident should have been seen. A small effect is possible; it would not be larger than, and could be smaller than, the effect suggested by the Oxford study. It would be especially interesting to examine this more carefully by looking at all children of the women who were pregnant and who were exposed at Chernobyl or any other radiation accident.

3.7 Thyroid Cancers

In any nuclear reactor accident, one of the first determinations must be whether any radioactive iodine was released. The short-lived iodine isotope can deposit in pastures; if cows ingest contaminated pasture grass, the iodine will concentrate in their milk. If children drink the milk, the iodine will concentrate in the thyroid, resulting in a large radiation dose, up to 100,000 times normal. This happened at an accident in Windscale, U.K. in 1956, and at Chernobyl in 1986. The first preventive measure must be to break the route of contamination by stopping all consumption of milk from the affected area. This was done at Windscale, but not at Chernobyl because of a desire to maintain secrecy. Many western scientists brought this to the attention of the scientists and politicians in the former Soviet Union, but when thyroid cancers were diagnosed among children starting in 1979, it was a great surprise.

Thyroid cancers, particularly among children, are usually not fatal. They are closely linked with benign thyroid nodules, so it is hard to get a diagnosis that is consistent across many groups. Initially (in 1989 and 1991), therefore, an increase in children's thyroid cancers in the former Soviet Union was attributed to a sudden increase in attention paid to the problem by physicians. However, this was soon shown to be incorrect. By 2002, over 1500 childhood thyroid cancers were seen in Belarus, Ukraine, and Russia, with excess relative risk of over 50. Fortunately, there has been considerable attention paid to these by western physicians, and only 11 fatalities have occurred so far. Increases in childhood thyroid cancers have not been seen elsewhere. Now that many years have passed since the Chernobyl accident, an increase in adult childhood cancers might be expected. Indeed, an increase has been seen, but such increases are hard to interpret, because of the twofold effect of increased attention to the problem by physicians and the fact that it is hard to develop consistent diagnostic criteria. One Russian study claims to account for the difficulties by searching for a dose-related effect, but none was found. Nonetheless, whether adult thyroid cancers have truly increased since 1979 (when an apparent increase was observed) remains a matter of controversy.

3.8 Heart Disease and Other Chronic Outcomes

A careful examination of the Hiroshima–Nagasaki data shows an increase in several other medical outcomes. In particular, heart disease appears with a frequency of about one-third the frequency of cancer.

3.9 Genetic Effects

There is a general belief, based both on general biological principles and on animal experiments, that radiation can cause genetic defects, but no well-authenticated examples attributable to radiation have been observed in humans, even in the Japanese

atomic bomb survivors. Again, the numerical value of the dose response is controversial. However, for both cancer and genetic defects, the disagreement is over very small numbers, i.e., whether the effects around 1 mSv (= 100 mrem) are very small or very, very small—much smaller per capita compared to the cancer effects.

3.10 Growth and Development of Children

A statistically significant adverse effect of radiation has been found in the Radiation Effects Research Foundation (RERF) data on children whose parents were irradiated while they were *in utero*. Those whose parents were exposed within 1500 m of the hypocenter of the Hiroshima bomb were on average 2.25 cm shorter, 3 kg lighter, and 1.1 cm smaller in head circumference compared to those exposed further away. Although (just) statistically significant, this effect needs confirmation in other cohorts before it can be generally accepted. This has not been confirmed in any other cohort. However, although other exposed groups exist, such as those exposed near Chernobyl or at the Techa River, there has been no systematic study that either confirms or denies the relationship. Another effect that is perhaps associated with (or a consequence of) the reduction in head size was seen in the RERF data. There is a statistically significant reduction in Intelligence Quotient (IQ) among children exposed *in utero*. In other cases, there is severe mental retardation. Although these effects on children are generally believed to have a threshold, the data on reduction in IQ are also consistent with a linear relationship between reduction and dose.

4. THE EFFECTS OF DOSE RATE

The previous discussion of the cancers caused by radiation exposure implies that it is the accumulated dose that is important. This seems to be a good first approximation. But from general principles one might guess that a high radiation dose given at a low rate over a period of years might have a different (probably smaller) effect than the same dose given in a short time, although if the time period is long, on the order of a lifetime, the difference is likely to be small. Data from animal exposures to radiation show that there is a reduction in cancers (for the same total dose) at low dose rates. A dose rate reduction factor (DRRF) is usually introduced to describe this. From animal data, a DRRF of between 2 and 10 is found and can be used for radiation protection purposes. Situations of accumulated radiation doses of 0.5 Sv (= 50 rem) exist, including the Mayak and Techa River cohorts noted earlier and the population exposed to Cs-137 subsequent to the Chrenobyl accident. From the Techa River and the Mayak data it seems that the DRRF for leukemia is about 3, but with a large error band (perhaps from 2 to 6). The DRRF for solid cancers is about 1, with a much larger error band ranging up to a factor of 10.

The importance of the data from these accident situations in which large cumulative doses, but not large acute doses, were received can not be overestimated, as they are useful for predicting the effect of nuclear accidents, as distinct from nuclear explosions. However, the data are not accurate enough to be used directly, and so at the present time, the world must depend primarily on the Hiroshima-Nagasaki data with an associated DRRF.

5. EFFECTS AT LOW AND VERY LOW DOSES

5.1 Early Belief in Beneficial Effects

Soon after natural radioactivity was discovered in the 1890s, there arose a general belief that exposure to moderate levels of radiation was therapeutically beneficial. This belief was not unique to radiation exposure, and many known poisons were given for therapeutic purposes. The small amounts of arsenic in Fowler's solution cured many disorders, and arsenic was also used in larger doses to cure syphilis before other, safer antibiotics were available. Communities with mineral hot springs added "radium" to their names to attract customers. The name Radium Hot Springs appeared in many places. As late as 1980, the radioactivity level of some European mineral waters was listed in advertising as a positive feature. However, the data supporting the suggested beneficial effect are scanty. Although there were several reports of cures, it is unclear whether these cures were due to radium, to other minerals in the water, or merely to the beneficial effects of a long soak in hot water.

Some old experiments on animals suggested that moderate radiation doses led to a reduction in disease and to a prolongation of life. But these reports have not been replicated with recent protocols, nor have there been human studies with modern

epidemiological methods. It is completely consistent that radiation would cause a beneficial effect for one medical outcome and an adverse effect for another one. It seems very plausible that radiation could reduce infectious disease by destroying the germs. But in the last 100 years, infectious diseases, with the exception of autoimmune disease syndrome (AIDS), have been controlled by other methods, so that even if it is true that radiation reduces the effect of infectious disease, it may now be irrelevant. It may be relevant for AIDS, but no study has been made. Alcohol in high doses is well known to cause cancer and has a narcotic effect at still higher doses. But at low doses—up to one drink a day—alcohol reduces the risk of stroke.

Since 1945, there has been a search for some chemical that can reduce the effects of radiation. A few substances can cause excretion of undesired radionuclides. It has been suggested that the cellular molecule MDC1 (mediator of DNA damage checkpoint protein 1) acts like an emergency service in cells to detect and repair damage to DNA caused by radiation. It is too early to say whether the effect is significant.

Although it is generally assumed that radiation effects at any site or organ will follow similar dose–response relationships, this is not necessarily true. The National Toxicology Program database lists a couple of dozen chemicals that decrease the likelihood of cancer in rats or mice when applied at one site, but increase it when applied at another.

5.2 The Definition of Low Dose

The concept of what constitutes a low dose has been modified considerably over the past 50 years. In the first half of the 20th century, physicians believed that 0.01 Sv (= 1 rem) was a low dose. In 1945, a typical chest X ray administered a dose of 0.01 Sv and at least one jurisdiction (United Kingdom) went as far as to propose mandating such a X ray every year to help fight tuberculosis. Most experts now believe that this would have caused an excess number of cancers. The proposed U.K. bill died in the House of Lords because of the objections of the physicist Lord Cherwell. A mandate for a yearly chest X ray would now be more reasonable. Chest X rays are now routinely performed with a dose 150 times smaller. Also, a skin test for tuberculosis antibodies now makes a chest X ray unnecessary in most cases.

The idea that 0.01 Sv per year is a low dose has changed. In 1987, the U.S. Nuclear Regulatory Commission proposed to label "Below Regulatory Concern" a radiation dose exposure of no more than 1 mrem (0.00001 Sv) to any person. The proposal was withdrawn after some vocal public opposition. This dose is 1000 times smaller than what was medically accepted before 1945! Moreover, natural background exposures are a few hundred millirems, or 100 times this amount, and vary considerably from place to place and person to person. For scientific and political reasons, "low dose" now means doses as low as, and usually well below, background doses. But scientifically there is still no generally accepted evidence for an effect, beneficial or adverse, of a radiation dose this small for any medical outcome

5.3 Dose–Response Curves of Acute and Chronic Radiation Exposure

Acute effects seem to occur only with radiation doses above a definite threshold dose. They are sometimes called deterministic effects. When a population is exposed and the dose is below that threshold, no one is hurt; everyone is hurt when exposure is above that threshold. This threshold dose seems to be independent of gender, genetic predisposition, and of racial characteristics. Even skin effects, which might be expected to be affected by pigmentation, seem to be independent of race. There are small variations and a dose–response curve is usually drawn as in Fig. 1. The dose at which 50% of persons in a population are affected is called the LD_{50}. For whole body exposure, the LD_{50} is about 2.5 Sv (= 250 rem) and persons exposed at half this dose survive. At a dose that is one-fourth of the LD_{50}, it is generally accepted that acute effects will not occur.

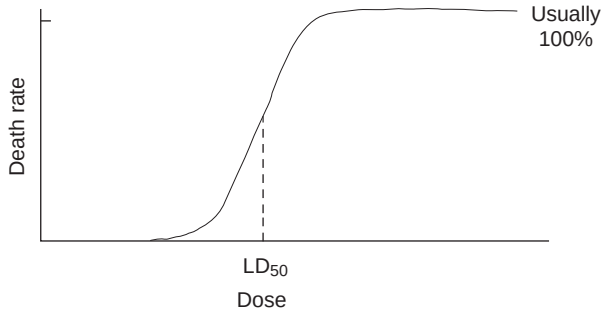

FIGURE 1 Dose–response curve, graphically representing the acute effect of a lethal dose of radiation. The LD_{50} is the dose at which 50% of persons in a population are affected. A single acute dose or an accumulated acute level of radiation over a short time causes death, whereas one-tenth the lethal dose, repeated 10 times, does not cause death.

In contrast, the chronic radiation effect of cancer seems to follow a different dose–response curve. For those dosed at the LD_{50}, cancer seems unimportant. Even of those surviving after an exposure at the LD_{50}, only about 10–20% will develop cancer. However, in contrast to acute effects, at a quarter of this dose (0.5 Sv), many persons will develop cancer. Moreover, no one has been able to determine which persons in an exposed group will develop cancer and which will not. The dose–response relationship follows a flatter curve. Various possibilities to extrapolate high doses from the data are shown in Fig. 2. These include the linear; the superlinear, in which the effect at low doses is higher than the linear; the threshold, with zero below the threshold; and one with hormesis (from the Greek, *hormaein*, to excite), which is a beneficial effect below the threshold. That a linear curve is theoretically possible was noted in 1922 by the physicist Geoffrey Crowther, who produced the first theory of radiation-induced cancer. The idea is that when a cell is ionized by radiation it will initiate a cancer. The probability of ionizing a cell in a given time is clearly proportional to the radiation intensity and hence affords a theory that cancer induction is linear with dose even at low doses. But this theory in its simplest form cannot be true. Cosmic rays and background radiation ionize millions of cells every day and yet lifetime cancer incidence is only about 30% in the U.S. population. Other effects must modify this idea drastically. Cells can be repaired; they can be excreted without leading to a cancer, and so on. Whether cancer incidence is linear with dose depends, therefore, on whether these important mechanisms vary with dose. A discussion of these

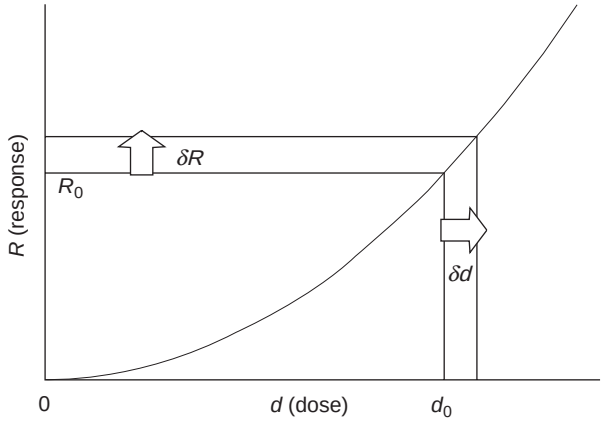

FIGURE 2 Threshold dose–response relationship($R = Ad^3$), with axes shifted to R_0 and d_0. Note that δR_0 is proportional to δd_0.

becomes very complex. Nonetheless, it is therefore generally believed that the development of cancer, whether induced by radiation or other agents, natural or anthropogenic, is basically a stochastic process.

The discussion in the preceding paragraph does not, by itself, tell us the behavior of the dose–response curve at background levels. But it raises the possibility that it is a linear dose–response, down to zero additional dose. This is the assumption that is now usually made for all cancers.

5.4 Variation of Cancer Incidence with Background Exposure

Mankind is exposed to a variety of radiation from naturally occurring sources, often called background exposures. These background exposures have been extensively measured and vary widely over the globe. The average North American or Canadian receives about 0.4 mSv (= 40 mrem) per year from internal radioactivity and cosmic rays, 0.6 mSv (= 60 mrem) per year from medical and dental diagnostics, and about 0.02 mSv per year from other miscellaneous man-made sources. Among these sources, nuclear power stations contribute less than 0.001 mSv. Collectively, background radiation exposures total about 1 mSv (= 100 mrem) per year, although persons living at high altitude have a higher radiation exposure than do those at sea level. Many studies have therefore attempted to relate health indices to altitude to deduce the effect of radiation. In many studies, cancer mortality seems to be lower in the high-altitude areas. In particular, the radiation levels in the Rocky Mountain states are higher than they are in the Gulf Coast states, yet the cancer rate is lower. This effect may be seen throughout the United States and Canada, but confounding factors may exist. Many Mormons, who do not smoke or drink alcohol or coffee, live in Utah and mountain states and seem to have half the cancer rate of their non-Mormon neighbors. Many analysts conclude that the only fact of importance from studies of geographical variation is that radiation at levels of about 2–3 mSv per year, or 0.1–0.2 Sv (10–20 rem) per lifetime, is not an important factor in developing human cancers compared to other factors.

In addition to high altitudes, there are other areas of high radiation background in the world. High levels of ambient radiation are encountered in Brazil, China, and India, for example. A population of several hundred thousand people living in coastal

areas of Kerala, South India, is exposed to natural radiation levels up to 70 mSv (=70 rem) per year, with half the population exposed to doses higher than 2.6 mSv (=260 mrem) per year. The observed incidence of cancer is about three-quarters of that in North America. This cannot be discounted as a consequence of early deaths due to other causes, because the population's life expectancy is 74 years for women and 69 years for men—only a few years less than life expectancy in North America. There has been no observation of an elevated incidence of malformations in newborns in this population. Although most experts are unwilling to accept these data as definitive evidence for a beneficial effect at low doses of radiation, these studies do show unequivocally that ordinary people who do not worry about the geographical distribution of cancer rates, which is almost everyone, should not worry about radiation at these doses.

5.5 General Argument about Effects of Low Doses

When radiation doses of concern are considerably greater than background doses, it is possible to discuss logically the effects of radiation, independently of whatever causes the background. In discussing radiation doses at levels comparable to the background, or even 100 times smaller, it is necessary to consider "introduced" and background doses together. However, very few scientists and scientific studies do this logically. The most important fact in such a discussion is that introduced radiation does not seem to induce any cancers that are not seen in the absence of radiation and are therefore also assumed to be caused in the population by "background" processes. The common idea that there is a "radiation cancer" that a physician can diagnose as distinct from any other cancer is false. The assignment of causation—that a cancer was caused by radiation—depends not on a physician's observations but on knowledge of likely exposure. Because the cancers produced by radiation and those produced by background are indistinguishable, it is likely that, at some stage in the tumor formation process, the background and radiation doses act in the same way. This is an assumption that has not been refuted, although of course it is an assumption, the validity of which must constantly be questioned. Whatever the basic biological process relating a dose to cancer, Taylor's theorem then tells us that a differential linearity results, provided that the radiation dose acts similarly to background. This argument is a general one and can apply to outcomes other than cancer. It can also apply to other cases such as respiratory problems caused by air pollution or cigarette smoking. This then makes it mandatory for any discussion of behavior related to low doses to include a discussion of what causes the natural background of cancers. It should also have implications for public policy and public perception. It is usually assumed that chronic radiation sickness and the effect on growth and development (Section 3.10) are threshold-type effects following the dose–response curve of Fig. 1. But the general argument applies to more than cancer. Either of these two medical outcomes could follow a linear dose response. In the Techa River study of chronic radiation sickness, for example, high radiation exposure was explicitly included in the definition of the disease, making it impossible to study the dose–response below that screening level.

The cancers from introduced radiation and background radiation cannot be distinguished by pathologists with typical, currently available tools. But it is possible that they can be distinguished, in principle, in which case the preceding argument would not apply. One, but only one, study suggests that the chromosome structure of an acute myelogenous leukemia (AML) occurring subsequent to, and presumably caused by, radiotherapy was appreciably different from cases of AML that occur "naturally." If this turns out to be a general result, the low-dose extrapolation arguments must be drastically reconsidered.

5.6 Epidemiological Studies of Low-Dose Behavior

There is great difficulty in measuring any effect, positive or negative, at the low radiation doses at issue. First, a study of 10,000 patients is only just enough to measure an effect, either beneficial or adverse, of 6% with a statistical significance of three standard deviations. Second, at levels of a few percent, other nonstatistical errors enter into any study. To measure reliably an increase in cancer rate of 10% would necessitate careful study of nearly 1000 patients with the disease. Another important effect is that if there is differential uncertainty in measuring the radiation dose, any structure in the dose–response curve tends to get washed out, and a threshold-type curve may appear to be linear.

The earliest studies of the survivors of the atomic bombs in Hiroshima and Nagasaki suggested (with

weak statistical significance, because they are on the edge of the natural background) a threshold at a dose of about 0.2 Sv (= 20 rem), or even hormesis. The data from the most recent follow up are better fit with linearity down to a dose of 0.05 Sv (= 5 rem). The recent analysis takes all the data together in a manner similar to a maximum likelihood analysis. It is well known that a maximum-likelihood approach can pull out of the "noise" those signals that are not clear when binned data are taken, and a Gaussian approximation is used. It is, however, admitted that there may well be nonstatistical errors that invalidate this conclusion. The authors of the recent research warn against concluding that there is any heath effect of radiation, adverse or beneficial, below 0.1 Sv (< 10 rem).

One of the first studies to suggest a threshold involved the study of bone cancers among the radium dial painters of the early 20th century. The dose to which they were exposed can be measured very reliably after diagnosis, either *in vivo* or in autopsy, because the radium stays in the bone. Two groups of dial painters have been studied, European and American. Data from the U.S. study (Fig. 3) indicated no cancers at a low dose. Linearity is statistically excluded. However, this is for alpha particle exposure and may not be generally applicable.

Workers at nuclear power plants and workers at other fuel cycle facilities have also been exposed to radiation at levels above background. A United Nations agency, the International Agency for Research on Cancer (IARC), compiled a database of 90,000 workers in the nuclear industries of the United States, Canada, and the United Kingdom. In their compilation, several workers received cumulative doses up to 0.2 Sv (= 20 rem). The data alone do not establish a clear link to any form of cancer. This is not merely a "meta-analysis" of several papers but is a combined study of those groups for which the data are deemed reliable. The additional number of leukemias seen is consistent with an extrapolation from the number at higher doses (but the lower 95th percentile of the number is close to zero). The number of additional "solid" cancers is close to zero but the upper 95th percentile is close to the linear extrapolation from higher doses. This suggests that numbers five times larger, as sometimes suggested by individual studies at a single location, are definitively excluded.

Data on workers who helped to clean up Chernobyl and live in the Russian Republic have been collected by the Medical Research Laboratory in Obninsk, Russia. There is a small, marginally

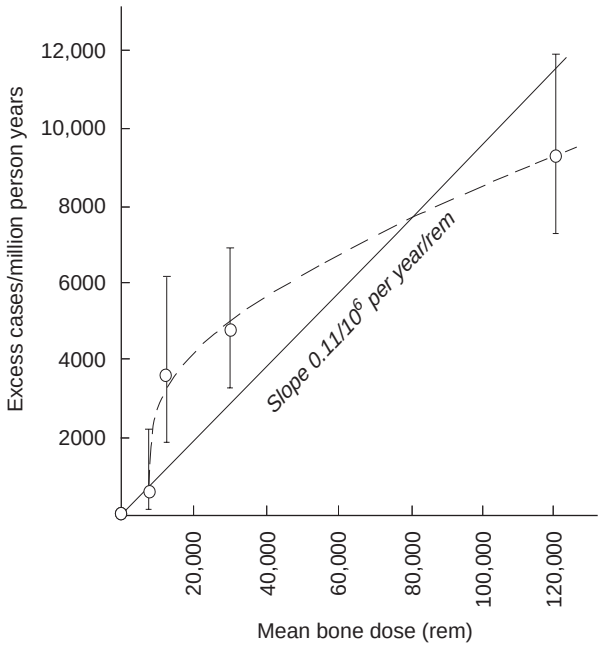

FIGURE 3 Dose–response data for a bone cancer study at Argonne National Laboratory. Study participants were exposed to radium-226 during a 20-year period (1915–1935); follow-up assessments were continued through 1971. The group included watch dial painters and some patients given radium therapeutically. Error bars include the 90% range.

significant, increase in leukemia, in agreement with the calculated linear response. Data on lung cancer among another group of cohorts, the previously discussed Mayak workers, are particularly interesting. The first studies on the Mayak workers suggested that the dose–response relationship was quadratic with dose (in qualitative agreement with animal data), and therefore a low-dose effect approaching zero seemed to make sense. But a more careful look at the data suggests that a linear dose–response relationship fits the data better. However, the doses are not low and a threshold or reduced effect at lower doses is possible.

Attempts have been made to use data on therapeutic uses of radiation to address the issue. There are few such studies with a large enough data sample. Some of these suggest that there is a dose below which there is no effect. But there are potential biases in such a study in that physicians may only look at cases in which the doses are high. There is no consensus that systematic errors are so well controlled that the studies can be used to discuss directly the shape of the dose–response curve below a total dose of 0.2 Sv (= 20 rem).

Only recently have there been studies of the effects of radon on people in residential situations. There are

two types of studies. One, an "ecological" study, compares the average lung cancer rate in a community to the average radon concentration in the houses of that community. The average lung cancer rate decreases with increasing radon concentration. It would be a logical non sequitur to derive directly from such a study the relationship of the probability of an individual person succumbing to cancer and the radon concentration to which that individual is exposed (the dose–response relationship). To make such a conclusion is sometimes called "the ecological fallacy." However, it is legitimate to compare any set of data with a theory, and if the data do not fit, the theory must be wrong. In particular, the theory esposed by the U.S. EPA, which uses a linear dose–response relationship, cannot be correct. However, the EPA error may be in not including other risk factors for lung cancer that are more important than radon. Another type of study is the "retrospective cohort" approach. There are a few such studies, in which a group of people are followed and the individual doses from radon are estimated. These are free from the ecological fallacy, but there are few data in the low-dose region, to which 90% of Americans are exposed. It is important to realize that any conclusion about the risk at low doses (that is, doses below natural background level) derived from these studies is dependent on an extrapolation, which may not be in direct disagreement with the ecological studies that use more people and are therefore statistically more significant. Most experts agree that below a radon concentration of about 20 pCi/liter, no one is sure which type of study is correct.

6. WEIGHTING FACTORS (W_r), OR RELATIVE BIOLOGICAL EFFECTIVENESS

As a first approximation, the effect of radiation on people depends only on the energy deposited per unit volume (measured in grays or rads). However, radiobiological reasoning suggests that particles traveling at speeds less than the velocity of light are relatively more effective at producing radiation effects, and a weighting factor, W_r, sometimes called the radiobiological equivalent (RBE), must be used. For high-energy X ray and gamma ray exposures, $W_r = \mathrm{RBE} = 1$. Most of the studies of effects of radiation on people are associated with ionization by particles traveling at speeds near the velocity of light, and the ionization per unit of energy loss is at a minimum. For example, the radiation from the Hiroshima and Nagasaki bombs consisted mostly of high-energy gamma rays. Data on the correct value to use for this factor for other situations are sparse. The factors are usually estimated from animal data and contain large errors. This is clear from Table I, which summarizes the latest data.

TABLE I

Approximate Radio Biological Equivalent (RBE) Factors (Simplified)

Radiation type	RBE factor
Photons	
E > 250 keV	1.0 (definition)
30 keV < E < 250 keV	1.9
E < 30 keV	2.4
Electrons	
E > 60 keV	1.0
15 keV < E < 60 keV	1.9
E < 15 keV	2.7
Neutrons	
E > 20 MeV	2.2
2 MeV < E < 20 MeV	4.4
0.1 MeV < E < 2 MeV	7.8
10 keV < E < 100 keV	3.4
E < 3.4 keV	1.7

Modified from the SENES study (see Further Reading) for probability of causation.

7. POLICY IMPLICATIONS

7.1 ALARA

The first step in discussing a sensible public policy is to summarize the data in quantitative terms. This is repeatedly done by various agencies. In the United States, the important agencies include the National Council on Radiation Protection and Measurements and the National Academy of Sciences, Committee on Biological Effects of Ionizing Radiation. In the United Kingdom, the agencies include the National Radiological Protection Board. Internationally, there is the United Nations Subcommittee for the Effects of Atomic Radiation. These organizations produce a set of predictions that, for want of a better word, is often called the "establishment" position. This establishment position assumes, for example, that the dose–response curve is linear at low doses, and provides data on the best estimate of the slope of this dose–response curve. As noted previously, this assumption remains unproved and is probably unprovable in any direct way.

The details of the establishment predictions are complex. The predictions depend on location of exposure, age at exposure, duration of exposure, rate of exposure, and gender. They concentrate almost exclusively on effects on cancer, but there are differences between the various cancer body sites. Scientists, however, tend to summarize the effects by a risk coefficient that is a sum over all fatal cancers, a weighted average over the population and for exposure to whole body irradiation. The cancer risk then is about 1/20 to 1/50 of lifetime cases per person-sievert (1/2,000 to 1/5,000 per person-rem). Alternatively stated, the dose to add 1% to the cancer incidence (which is a relative risk of 0.03) is between 0.2 and 0.5 Sv (20–50 rem). Of course, for some cancer body sites and for some ages the relative risk (RR) is much greater.

Starting in 1927, the International Commission on Radiological Protection (ICRP) noted that no threshold had been found below which adverse effects on health are known not to occur. They recommended that "no radiation exposure shall be permitted without expectation of some benefit," a view that survives today. Attempts have been made over the years to define the ICRP precautionary principle more clearly. It was first suggested that radiation exposures be kept as low as practicable (ALAP). In the early 1970s, scientists, unhappy with the vagueness of the terms, replaced ALAP with "as low as reasonably achievable" (ALARA) (economic and other factors taken into account). Europeans instead adopted "as low as reasonably practicable" (ALARP). It is unclear why anyone thought that this wording was an improvement.

In 1975, after a 2-year-long public hearing, the Atomic Energy Commission (later the Nuclear Regulatory Commission) attempted a quantitative definition of ALARA. It decided that radiation dose should be reduced if the cost per unit of integrated radiation dose (integrated over the whole population) is less than $1,000 per person-rem. (The present limit, which has been updated in response to political correctness, a change of units of radiation exposure, and inflation, is $200,000 per person-sievert.) Using a widely used establishment slope of the dose–response relationship for ionizing radiation and cancer, this corresponds to a cost of about $6,000,000 per cancer averted. It is interesting to note that the U.S. EPA has recently, and apparently independently, come up with a number of $6,100,000 as the "value of a statistical life" to be used in discussing costs to avert a cancer, for which the EPA also assumes a linear low-dose response.

On face value, this rule would suggest that an attempt to reduce exposure that costs more than $200,000 per person-sievert is overreacting to the radiation risk, and also that any such attempt should be enforced only "on the average." The reality is more complicated. In disposal of nuclear wastes, for example, this rule has not been applied and already much more money has been spent than the rule suggests. Also, it is clear that exposure to radiation of someone aged 70+ years is far less important than it is to someone aged 40 years. A 70-year-old has a shorter time to live, and the 20-year latent period for most cancers almost guarantees that he or she will not get a radiation-induced cancer.

Moreover, people have traditionally been allowed higher exposures in their work, with the obvious compensation of having a job. Thus, the National Council for Radiation Protection and Measurement (NCRPM) recommended in 1990 that the rule for occupational exposure be closer to $2,000 per person-sievert ($20 per person-rem). The radiation protection authorities are just beginning to consider such niceties, which are easily handled by standard tools of decision analysis. Despite these complexities, the application of "precautionary" policies for radiation protection has been closely tied to cost–benefit analysis, and to the conservative (but difficult-to-test) assumption that the risks from exposure at low levels is linearly proportional to the exposure.

Professional societies, unhappy with the present use of ALARA for very low doses, have emphasized the uncertainty surrounding the possible effects caused by low doses of radiation. For example, the Health Physics Society issued the following statement:

> *In accordance with current knowledge of radiation health risks, the Health Physics Society recommends against quantitative estimation of health risks below an individual dose of 5 rem (= 0.05 Sv) in one year or a lifetime dose of 10 rem (= 0.1 Sv) in addition to background radiation. Risk estimation in this dose range should be strictly qualitative, accentuating a range of hypothetical health outcomes with an emphasis on the likely possibility of zero adverse health effects. The current philosophy of radiation protection is based on the assumption that any radiation dose, no matter how small, may result in human health effects, such as cancer and hereditary genetic damage. There is substantial and convincing scientific evidence for health risks at high dose. Below 10 rem (which includes occupational and environmental exposures), risks of health effects are either too small to be observed or are nonexistent.*

7.2 Probability of Causation

When a person has cancer, society or the individual wants to know the cause and who to blame. In most

cases, the cause is, of course, not known and there may be multiple causes. It is not appropriate to calculate the "risk" of getting cancer (or indeed any other disease) when it is already known that the person has cancer, because the risk in such a situation is unity! But it is appropriate to use a different concept, the "probability of causation." Loosely, the question to ask concerns what the probability is that the cancer was caused by the particular agent of concern. The answer can be derived from the general ideas of probability using the concepts of conditional probability. The probability of causation (POC, or sometimes PC) is defined as follows:

$$\mathrm{POC} = \frac{\left(\begin{array}{c}\text{Risk of cancer from the}\\ \text{cause under study}\end{array}\right)}{\left(\begin{array}{c}\text{Risk of cancer from all causes}\\ \text{including the cause under study}\end{array}\right)}$$

There have been many theoretical criticisms of this concept and some scientists prefer the expression "assigned share." If the radiation effect is beneficial, the probability can be negative, which makes no sense. If radiation is only one of several causes, the sum of the various POCs for different possible causes can be greater than unity. But with the approximations usually used, POC makes sense. Synergistic effects are usually ignored, and the dose–response slope is linear and positive. Then the probability is positive. To evaluate this, the risk from causes other than the one under consideration is usually taken as the natural incidence of the cancer in question the assumption is then made that the population group from which the incidence data are derived is representative of the individual whose risk is evaluated in the numerator. Dividing through by the natural incidence, we derive the equation $\mathrm{POC} = \mathrm{ERR}/(1 + \mathrm{ERR})$, where ERR is the excess relative risk for the cancer in question. Of course, ERR is a function of age and gender.

In the 1950s, the United States conducted many atomic bomb tests in the atmosphere in Nevada. In some tests, U.S. army veterans were deliberately situated as observers to give them experience and ability to respond in battle without panic. In 1985, some of these veterans, and, later, residents of the states downwind of the test explosions, put pressure on Congress to give them compensation for the assumed damage. Because, as noted previously, there is no such thing as a "radiation cancer," the U.S. Congress requested the National Cancer Institute to develop a set of tables to determine the probability that a person's cancer was due to radiation exposure. These tables were published, but have since been updated into a user-operated computer program. The tables assume a linear dose–response relationship. There is disagreement on how to use the POC concept. In the United Kingdom, partial compensation is given to persons whose POC is greater than 20%. Procedures in the United States are governed by the legal maxim that "it is more likely than not" that a particular action or dose was the cause of the injury. This translates to POC $>50\%$. But few veterans would be compensated under such a rule, and it was desired politically to be generous to the veterans. An uncertainty distribution is now requested and the screening demands that only if POC is $<50\%$ with 99% certainty shall the effect be ignored.

A more logical approach would be to note that for an individual it does not matter whether a cancer developed because of bad luck in the stochastic probability or because the actual risk coefficient was on the high side of the uncertainty distribution. Then the two distributions should be combined (folded) into one. This has not been used in any situation to date.

8. PUBLIC PERCEPTION

As already noted, public perception of the effects of radiation exposure changed dramatically in the second half of the 20th century, presumably as a result of the atomic bombs in August 1945. This, combined with an unattainable desire for "zero risk," leads to considerable logical problems. For example, it has been proposed in one jurisdiction that in dismantling any building containing radioactive material, nothing with any measured radiation levels shall be placed in an ordinary landfill. If that were applied to cemeteries, it would be impossible to bury anyone, because radioactivity in a body can be easily measured. Nor could anyone be cremated, because radioactivity in the effluent would cause the crematorium to be shut down. However, zero risk is usually used to apply only to a particular action or process a particular person or group dislikes, for which a different logic applies.

Glossary

energy services The services that consumers want from the supply of electricity and other fuels: warm homes, cold beers, lighting, mobility, etc. A combination of energy supply and appliances (boilers, refrigerators, lamps, cars, etc.) provide these services.

price elasticity The ratio of the percentage change in energy use to the percentage change in energy price.

The rebound effect (or take-back effect) is the term used to describe the effect that the lower costs of energy services, due to increased energy efficiency, have on consumer behavior both individually and nationally. Simply stated, the rebound effect is the extent of the energy saving produced by an efficiency investment that is taken back by consumers in the form of higher consumption, in the form of either more hours of use or a higher quality of energy service.

1. IMPLICATIONS OF THE REBOUND EFFECT

Implications of the rebound effect are demonstrated by the following example: If a 18-W compact fluorescent bulb is replaced by a 75-W incandescent bulb, the energy saving should be 76%. However, this is seldom the case. Consumers who realize that the light now costs less per hour to run are often less concerned about switching it off; indeed, they may intentionally leave it on all night. Thus, they "take back" some of the energy savings in the form of higher levels of energy service (more hours of light). This is particularly the case when the past level of energy services, such as heating or cooling, was considered inadequate.

The rebound effect is a phenomenon based on economic theory and long-term historical studies, but as with all economic observations its magnitude is a matter of considerable dispute. Its significance for energy policy has increased during the past few decades with the claim by energy analysts in the 1970s, and later by environmentalists in the late 1980s, that increasing energy efficiency would lead to reduced national energy consumption and hence lower greenhouse gas emissions. Whether this claim is feasible depends crucially on the extent of the rebound effect: If it is small ($<100\%$) energy efficiency improvements will lead to lower energy consumption, whereas if it is large ($>100\%$) energy consumption will be higher. Note the use of the relative terms lower and higher: What exactly they are relative to has often been left unstated and has been a cause of much confusion in energy policy debates. Sometimes it refers to current energy consumption, whereas at other times it refers to a reduction in the future rate of growth in energy consumption.

The claim that increasing energy efficiency would lead to reduced national energy consumption was first challenged by Len Brookes in 1979 in his review of Leach's pioneering work, "A Low Energy Strategy for the UK," when he criticized Leach's approach to estimating national energy savings because of its

 © 2004 Elsevier Inc. All rights reserved.

failure to consider macroeconomic factors. This was followed in the early 1980s by similar criticism by Daniel Khazzoom of the work of Amory Lovins. The criticism of Brookes and Khazzoom was called the Khazzoom–Brookes (KB) postulate by the economist Harry Saunders in 1992. The KB postulate (sometimes referred to as the Jevons paradox) may be described as follows: Those energy-efficiency improvements that, on the broadest considerations, are economically justified at the microlevel lead to higher levels of energy consumption at the macrolevel than in the absence of such improvements.

The debate grew more intense in the early 1990s, spurred by global warming concerns and policy debate over the role of energy efficiency. It was conducted mostly in the pages of the academic journals *Energy Policy* and *Energy Journal* but also spread to the pages of *The New York Times* in late 1994 and the leading UK science magazine *New Scientist* in 1998. It culminated in two special issues of journals in 2000 devoted to aspects of the rebound effect—*Energy Policy* and *Energy and Environment*—to which many of the protagonists in this debate contributed. There is no dispute that the rebound effect exists; what is at the core of the conflict is its magnitude, and the two opposing positions can be summarized as follows:

1. Energy use is higher than if there had been no efficiency response—a position maintained by Len Brookes and, in some circumstances, Harry Saunders.
2. Energy use is lower than if there had been no efficiency response—a position maintained by Lee Schipper and colleagues.

Each side has supported its case with a mix of theoretical argument and empirical observations, based on historical data on energy use. A key problem in resolving the two positions is that it is not possible to perform control experiments to determine whether energy use is higher or lower than if there had been no efficiency improvements; after all, there is only one past. Attempts to estimate the overall magnitude of the rebound effect, using theoretical economic models based on neoclassical growth theory, have proved inconclusive, with the results dependent on assumptions about the elasticity of substitution of energy for other factors of production—the greater the elasticity, the greater the rebound. Another problem is that the rebound effect differs by energy end use and sector of the economy, and the response at the microeconomic level (the consumer) is different from that at the macroeconomic level (the national economy). Also, the rebound effect can vary between countries, depending on the energy costs and unmet demand for energy services; thus, it may be considerably higher in developing countries than in the United States.

However, all agree that the rebound effect is closely linked to the elasticity of substitution, which is a component of the widely measurable phenomenon of price elasticity. The higher the observed price elasticity of energy services, the greater the rebound effect. This leads to the paradoxical position that any imposition of energy or carbon taxes, in the hope of reducing energy use, would have its impact severely blunted by the rebound effect if consumers have a high price elasticity.

2. PRICE ELASTICITY EFFECTS

Rebound effects are due to the increased use of energy services caused by the reduction in their effective price due to greater efficiency (price elasticity) and can be classified into five categories:

1. Direct effects due to the desire of consumers to use more of any commodity due to its lower price
2. Income-related effects due to the fact that with lower energy price, more income is available to spend on energy
3. Product substitution effects due to the inclination to substitute energy services for other final consumption goods when energy services become less expensive than other final goods
4. Factor substitution effects due to the inclination to substitute energy for other factors of production (capital, labor, materials, time, etc.) in the production of final goods
5. Transformational effects due to long-term changes in the economy caused by changes in technology, consumer preferences, and even social institutions brought about by the substitution of energy for other factors of production.

The effect of perceived lower costs on energy use is termed price elasticity, which is the ratio of the percentage change in energy use to the percentage change in energy price. Price elasticities vary by commodity and over time, depending on the ability of consumers to respond to price changes through changes in behavior, substitution of alternatives, or technical change. It is important to distinguish price-induced efficiency gains from non-priced-induced gains. The former are caused by factor substitution and may involve costs to the economy (such as was caused by the oil price increases in the 1970s and

may result from the imposition of energy taxes). Non-priced-induced gains are due to technological improvements, and the rebound effects from them are of most concern to energy analysts.

Much evidence on the magnitude of the direct rebound effect derives from U.S. transportation studies for which there is good statistical data on miles traveled per vehicle and petrol consumption. The results indicate that the number of vehicle miles traveled will increase (or rebound) 10–30% as a result of improvement in fuel efficiency. Similar results are obtained for domestic energy services, such as space heating (Table I). However, the long-term price elasticity is considerably higher because the ability of consumers to respond to changes in prices is much greater: For private transport in Europe, the rebound (or long-term price elasticity) is estimated to be 30–50%.

Expansion of service demand can also take the form of consumer preference for higher levels of quality, comfort, and performance. For instance, the oil price increases of the 1970s stimulated R&D on more efficient car engines providing more miles per gallon of gas (petrol); when oil prices declined in the late 1980s car manufacturers offered consumers more powerful and better equipped cars (e.g., sport utility vehicles) with the same fuel costs but lower miles per gallon. Here, consumers appear to take the possible savings in the form of higher levels of performance or quality. Another area in which consumers "trade up" is substituting energy for time: faster cars and planes, labor-saving domestic appliances, fast food, and private rather than public transport.

An important impact of the effect of higher efficiency, and consequent lower cost of energy services, is on marginal consumers—those who could not previously afford the service. The appliance market, such as for air-conditioning, will expand as the cost of energy service declines, with the magnitude depending on the elasticity of service demand. This is because consumers' choice of the efficiency of an equipment depends on factor costs, and more efficient equipment will increase the demand for the service because of lower marginal costs per unit of service.

The second effect on consumers of lower energy costs is the income effect—their ability to spend the monetary savings on other goods and services in the economy, which will contribute to economic growth. What they spend this discretionary income on depends on their current income levels: Those with low incomes will use it for basic goods and those with higher incomes on luxury services. However, almost all goods and services involve some energy consumption in their production, distribution, and consumption, and their energy intensity varies markedly. Schipper argues that the income effect is very low because only 5–15% of income saved is respent on indirect energy use (with air travel at the high end).

What the monetary savings is spent on is crucial to the concept of sustainable consumption—that is, consumption that has low environmental impact (i.e., low material and energy content).

TABLE I

Estimates of the Direct Rebound Effect by End Use for the U.S. Residential Sector[a]

End use	Rebound effect (%)	No. of studies
Space heating	10–30	26
Space cooling	0–50	9
Water heating	<10–40	5
Lighting	5–12	4
Car transport	10–30	22

3. TRANSFORMATION EFFECTS

Probably the greatest effect (in the long term) of lower costs of energy services is on the direction and pace of technical change and innovation in the economy. New goods and services will be introduced to take account of the possibility of lower costs, and mass markets will be created by the continuing decline in operating costs bought about by efficiency improvements. As Len Brookes comments.

> *It is inconceivable that we should have had the high levels of economic output triggered by the industrial revolution if energy conversion had stayed where it was at the beginning of the 19th century. Energy productivity and the productivity of other factors of production fed on one another with rising energy efficiency contributing to rising productivity of other factors of production—labor and capital—and rising output contributing to rising energy efficiency by way of embodied technical progress. Without this interactive process we should not have had, in the meantime, the very large increases in energy consumption alongside large improvement in energy conversion efficiency.*

An illustration of these very large increases in energy consumption and energy efficiency due to

technical change is given here for public lighting in Great Britain for the period 1920–1995. This sector is chosen because there are good statistical series for electricity consumption, lamp efficiency, and road mileage. These statistics show an increase of more than 30-fold in electricity consumption for public lighting and 20-fold in lamp efficiency but less than 50% in road mileage. The net result of this increase in consumption and efficiency since the early 1920s is that light intensity, in terms of lumens per mile, increased more than 400 times and increased 4-fold since 1960. During the same period, energy intensity, in terms of MWh per mile, increased 25-fold, with a 250% increase since 1960 (Fig. 1).

Thus, it seems that most of the tremendous increase in lamp efficiency has been in the form of higher levels of service, both in more miles illuminated and in higher illumination levels, and not in the form of lower consumption. Interestingly, both consumption and efficiency seem to have leveled off in the 1990s, whereas during a period of rapid growth in consumption from 1960 to 1980, lamp efficiency increased by 50%.

This process of technical change is aided by manufacturers that continually seek efficiency improvements in order to lower consumer costs and create new mass markets. In conjunction with this, utilities welcome efficiency improvements to lower the cost of their product: Better to sell much at a low profit margin than little at a high margin. The massive expansion of electricity consumption in the 20th century was fueled by the continual decrease in electricity prices, bought about by a nearly 10-fold increase in generation efficiency, which spurred the development of new electrical goods and services: electric lighting in the 1900s, domestic refrigeration in the1930 s, TV in the1950 s, microwaves and videos in the1980 s, and computers and the Internet in the 1990s.

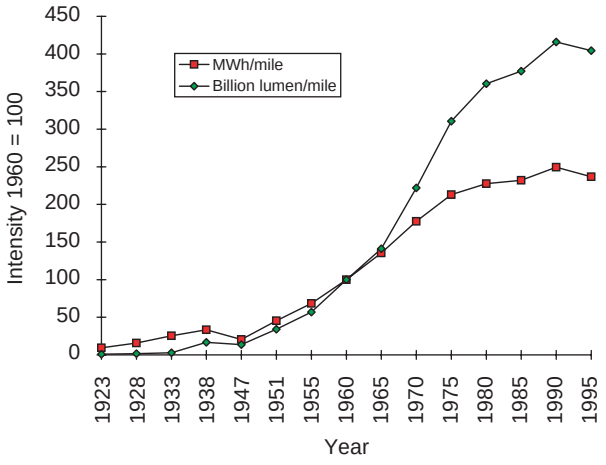

FIGURE 1 Changes in energy and light intensity for public lighting in Great Britain, 1920–1995. Reprinted from Herring, H. (1999). Does energy efficiency save energy? The debate and its consequences. *Appl. Energy* **63**, 209–226, Copyright 1999, with permission from Elsevier.

How much the improvement in energy efficiency per se stimulates economic growth is the subject of much discussion, and it is explored later.

4. THEORETICAL ARGUMENT

Key contributors in the debate over the rebound effect are economists, who seek to identify through economic theory and mathematical models the conditions under which the rebound effect may be greater than 100% (a state termed backfire). Debate by economists over the effect of efficiency improvements is long-standing, and current economists all acknowledge the work of one of the founding fathers of energy economics, Stanley Jevons, who in his classic work "The Coal Question," first published in Great Britain in1865, argued that "it is a confusion of ideas to suppose that the economical use of fuel is equivalent to diminished consumption. The very contrary is the truth."

Jevons pointed out that

> *the reduction of the consumption of coal, per ton of iron, to less than one-third of its former amount, was followed, in Scotland, by a 10-fold increase in total consumption, between the years 1830 and 1863, not to speak of the indirect effect of cheap iron in accelerating other coal-consuming branches of industry.*

Thus, Jevons laid the foundation for the idea that the rebound effect (in energy markets) could be greater than 100%, which is sometimes referred to as the Jevons paradox. The conditions under which it may occur are explored by the Austrian economist Franz Wirl and the U.S. economists Harry Saunders and Richard Howarth using extensive mathematical notion. Wirl, in his book "The Economics of Conservation Programs," argues that the extent to which more efficient appliance raises the service demand depends on elasticity of service demand:

> *The most important consequent is that (ceteris paribus) a more efficient appliance raises service demand such that actual conservation falls short of an engineering efficiency comparison. Indeed "conservation" in the sense of improving energy efficiency may raise energy demand, if demand for service is elastic.*

He demonstrates that whereas higher prices reduce unambiguously demand, the impact of efficiency is

ambiguous and an improvement in efficiency need not lower consumption. He argues, "A necessary and sufficient condition for excluding this so-called conservation paradox is that service demand is inelastic, which in turn is equivalent to the requirement that the elasticity of marginal benefit is less than -1."

He concludes that the exclusion of his conservation paradox requires a price-inelastic service demand, as for price-elastic services an efficiency improvement of 1% will lower the cost of the service by 1%, which will induce an expansion of the service of more than 1%. Hence, the expansion of service more than outweighs the conservation due to the efficiency improvement. Thus, for the rebound effect to be less than 100%, Wirl concludes that the elasticity of marginal benefit has to be less than -1 (i.e., elasticity of service demand is less than 1, which is inelastic).

Wirl observes that the rebound from efficiency improvement on electricity demand works through increasing the service demand. However, in practice some of this feedback may not lead to a physical expansion of the service demand but to upgrading, for example, cars with more features and power (larger and faster). He makes a crude assessment of this rebound effect, arguing that it is small for energy services close to saturation levels (and with low marginal costs), such as stereos or TVs, but larger for services with substantial marginal costs, such as space heating, air-conditioning, transport, and perhaps lighting. However, in the former case the absolute conservation potential is small, whereas in the latter the potential is large. This reflects the fact that consumers are more sensitive (and responsive) to end uses having a large energy cost. Thus, Wirl concludes that the rebound effect seems important for services with a significant conservation potential but negligible for services with a minor conservation potential in terms of kilowatt-hours.

Work by Saunders and Howarth, using neoclassical growth theory, seeks to identify the conditions under which backfire (rebound effect $>100\%$) occurs. The results are sensitive to the choice of production function, and for some functions they depend on the assumptions made about the elasticity of substitution between energy and other factors. The use of the Cobb–Douglas production function, with the assumption of an elasticity of substitution of 1, validates the KB postulate, although many energy analysts question its conceptual underpinnings, which rest on neoclassical economic principles. In contrast, Richard Howarth uses a Leontieff production function that assumes zero elasticity of substitution, and he argues, based on this model, that improved energy efficiency cannot give rise to increased energy use except under implausible assumptions.

Saunders lists the cases and circumstances in which the KB postulate is or is not validated. He is developing a simple economic model (or first-order tool) that will allow economists to take an arbitrary specified new efficiency technology and deploy it against an arbitrary specified production function to generate a prediction of the resulting change in fuel use, including possible rebound effects. Preliminary results show that energy efficiency technologies that enhance other factors of production may produce backfire, and that there is a marked difference in rebound between industrial sectors and between the same industries in different countries.

The impact of energy efficiency technologies in stimulating the use of other factors of production has been termed the Cashmir effect, with the observation that a technical fix to improve energy productivity can produce a bonus in materials productivity. As Ronald Sutherland comments, "Energy efficiency increases, not as a direct effort to reduce energy use, but as a result of overall productivity improvements in all inputs. In economic terms capital and energy appear to be complements not substitutes."

To resolve this issue is no easy task. Richard Howarth remarks,

> *Sorting out the empirical dimensions of the Khazzoom–Brookes hypothesis … would require detailed models that merge engineering approaches to energy efficiency, micro-engineering studies of the demand for energy services, and macroeconomic models of savings and investments. The construction of such models is an ambitious task.*

5. EMPIRICAL EVIDENCE

A number of studies have been performed to determine the impact of improved efficiency on energy use. In the United States, a major study on energy processes during the period 1880–1970 was done by Sam Schurr, whereas Lee Schipper and colleagues have done much pioneering work on energy trends for Organization for Economic Co-operation and Development countries on a sectorial level for the period 1970–1995.

However, the problem is in measuring energy efficiency because its two indicators, energy intensity (energy use per unit output) and the energy coefficient (the output elasticity of energy consumption), can give false signals. Schurr maintained that allying capital and labor inputs with new injections

of energy into economic systems can increase the productivity of both capital and labor. This results in a decrease in energy intensity due to a larger denominator in the form of higher economic output. This can deliver a false message when in fact there has been no change in the efficiency of conversion of fuel to useful heat and work. Nevertheless, it is accepted that there is a steady long-term trend in efficiency improvement in the economy due to the vintage effect. That is, the tendency for new plant and appliances to be more efficient than those they replace. Thus, it is limited by the rate of stock turnover and the rate of additions to stock, generally due to economic growth.

Schurr's empirical findings indicated that for the period 1920–1953, new technologies, often using electricity, not only increased the productivity of labor and capital but also improved energy productivity (i.e., reduced energy intensity). Energy efficiency improved at the same time that energy consumption and economic output increased. However, total output grew at a faster rate than the rate at which energy intensity declined, so total energy consumption increased. It was only in exceptional circumstances, such as the 1979 oil price hike, that energy productivity exceeded multifactor productivity, which actually declined in 1979 due to economic recession.

Other work examining U.S. energy data includes that by Bill Hogan and Dale Jorgenson, who studied time series data on energy intensity for a large number of sectors and found that there is a trend of increasing energy intensity, once price effects are carefully taken out.

The extent to which energy efficiency stimulates economic activity, and hence increased energy use, is contentious, but the effect is probably small. An examination of trends in energy intensity in International Energy Agency countries for the period 1970–1995 by Schipper and Grubb concluded that feedback effects were small in mature sectors of mature economies and only potentially large in a few cases. Their thesis is that the improvement in efficiency per se is only a small part of the reason why total energy use may have increased.

They remark that the scale of the system keeps increasing with population, household formation, and increasing incomes and sectorial output; thus, energy use must increase. However, they conclude that energy efficiency improvements, as measured by lowered energy intensities, almost always led to lower use than otherwise, and such energy efficiency improvements do restrain energy growth.

The assumption that a major part of the rebound effect will automatically manifest itself as increased output or activity levels, and thus be visible through higher energy intensities, may be incorrect. The rebound could, as Wirl points out, take the form of higher quality, performance, and comfort. A key problem in resolving the KB postulate, which is at heart a standard empirical question, is that it is not possible to run historical control experiments on society to determine whether energy use is higher or lower than if there had been no efficiency gains. This means that straightforward observation of visible macroeconomic variables, such as energy intensities, cannot provide much explanation. Instead, it may be more useful to use more sophisticated econometric tools, such as generalized technology production and cost functions, to analyze macro- or sectorial-level statistical data.

6. POLICY IMPLICATIONS

Improving energy efficiency has become, in many countries, a key part of the national strategy to deal with global warming and is founded on the belief that it would lead to reduced national energy consumption and hence lower greenhouse gas emissions. There is a long policy history of seeking national improvements in energy efficiency as a solution to environmental problems, but ultimately efficiency gains have been used to encourage economic growth and progress rather than to reduce consumption. The end result has been that economic growth has outpaced the rate of efficiency increase, and total energy consumption has increased. For instance, in the United Kingdom between 1965 and 1998, efficiency (as expressed by energy intensity, a rough proxy) doubled—a factor two improvement. However, gross domestic product increased by 147%, so total energy consumption increased by 25%. Thus, at current rates of efficiency improvement, it is feasible for there to be a factor four (or fourfold) improvement in the next century. However, as the UK Royal Commission on Environmental Protection comments,

> *There will continue to be very large gains in energy and resource efficiency but on current trends we find no reason to believe that these improvements can counteract the tendency for energy consumption to grow. Even if energy consumed per unit of output were reduced by three-quarters or factor four, half a century of economic growth at 3% a year (slightly less than the global trend for the past quarter century) would more than quadruple output, leaving overall energy consumption unchanged.*

This unequal race between energy efficiency and economic growth is well appreciated by many environmental economists and sociologists concerned with resource consumption. For instance, Mathias Wackernagel and William Rees, in their book "Our Ecological Footprint," explicitly make the point that technological efficiency may actually lead to increased net consumption of resources. They conclude

> *Ironically then, it is precisely the economic gains from improved technical efficiency that increase the rate of resource throughput. Microeconomic reality demands that these efficiency gains be used to short-term economic advantage. Far from conserving natural capital or decreasing ecological footprints, this leads to higher consumption.*

Promoting energy efficiency may not necessarily be the best way to save energy or reduce pollution. It may actually encourage energy consumption by conveying the message that consuming increasing amounts of energy is acceptable as long as energy is consumed by technologies that have been deemed efficient. Mithra Moezzi, a U.S. energy analyst, believes that changes in consumer perception and behavior are required, and that overreliance on technical solutions is mistaken. For instance, she advocates that more emphasis should be given to absolute, rather than relative, energy consumption in energy labels and standards. A larger refrigerator may be more efficient but also consumes more than a smaller one. She remarks,

> *The standards and guidelines inherent in energy policies reveal moral and technical judgments about what is "good" and what is possible. When evaluating any particular standard, guideline, or other message related to energy conservation or efficiency, it is critical to consider not only "energy saved" in a narrow sense, but what underlying messages are being conveyed and how they might affect the cultural perceptions of efficiency and consumption in short and long terms. By choosing specifications that reflect absolute rather than solely relative consumption, policies may encourage an ideological as well as practical shift in perceptions of energy use.*

Society has generally preferred technical or economic solutions, and scientists and engineers have instead emphasized the technical possibilities of a shift to less resource-intensive types of consumption (and also the development of nonfossil energy sources). One solution they advocate is the concept of service efficiency, which may be defined as providing a maximum of useful energy services to consumers using the minimum of materials and energy use. There is an extensive literature on this concept and there have been many attempts to design new types of products that deliver energy services using innovative combinations of market goods and services and household labor.

Service efficiency in itself is not a panacea for sustainable consumption because the gains are easily offset by an increase in the number and variety of products consumed. Also, as research on the cultural aspects of consumption has shown, it is necessary to understand how and why we consume. This is why innovations that are meant to be efficient and to reduce the need for resources often have the opposite effect. As F.-J. Radermacher, a German sociologist, remarked, :

> *The trap that we have fallen into again and again over the course of technical progress consists of our always using progress on top of whatever went before (the rebound effect). This effect predicts that market forces and humanity's apparently unlimited capacity for consumption will use new technology to convert more and more resources into more and more activities, functions, services, and products.*

It is often argued that information technologies such as computers will reduce material and energy consumption through substituting "virtual" for real experiences and goods. However, Finnish sociologists Heiskanen and Pantzar ask,

> *Will the information superhighway do away with the urge to travel? Will consumers actually substitute one good for another, or will they want to have it all: the television on, the newspaper on the table, and electronic news pointlessly self-scanning as the consumer of all this information dozes on the couch?*

They make the comparison with claims made in the early 1980s about the paperless office, which never happened and, in fact, office paper consumption has increased.

7. CONCLUSION

A key debate about energy efficiency concerns the extent of the rebound: To what extent does energy use increase due to efficiency improvements? Does greater efficiency lead to higher or lower energy use than there would have been without those improvements? This debate, however, is difficult to resolve, as it is with all macroeconomic arguments, since we cannot conduct such (economic) experiments on society. Thus, the rebound argument is contentious and difficult to prove either way. However, it may be possible in the long term, using good empirical research based on sound theoretical tools, to reach strong conclusions about whether it is true (or

untrue) in certain places, at certain times, or under certain conditions and thus determine its overall economy-wide impacts, but there will never be absolute scientific certainty.

Nevertheless, the school of argument that links improvements in energy efficiency with increased energy consumption—the KB postulate—has a strong claim based on the historical record dating back to the industrial revolution and the tremendous economic growth that has followed factor 10 efficiency improvements in the steam engine and other power devices. To what extent energy efficiency technologies stimulated economic growth is uncertain, and economic history, evolutionary economics, and institutional economics could shed more light on this issue than theoretical models based on neoclassical growth theory. The KB postulate may be rooted in the vast structural change in technologies, lifestyles, and social institutions that characterized the past two centuries rather than in a future world determined to reduce, or at least curtail, energy use. We need not repeat past patterns of economic growth and energy use, particularly if we practice sustainable consumption and emphasize quality of output and increased leisure time rather than quantity of output.

The rebound effect is strongly influenced by the difference in substitution potentials (elasticities) among all the factors (energy, labor, capital, and materials) and these change over time. It is very likely that energy efficiency technologies that enhance other nonenergy factors will generate substantial rebound, which will be the case in many industries. It will take some time and much research before it is known definitively whether the KB postulate is valid, and the result is unlikely to be clear-cut. It is likely that the extent of the rebound will vary depending on energy end use, industrial sectors, and even countries. Some undoubtedly will show backfire, some just modest rebound, and some may even show superconservation (i.e., a negative rebound with energy use decreasing more than the efficiency increases).

The task for energy researchers is thus to establish exactly where energy efficiency will be most effective rather than just promote energy efficiency as the solution to global warming.

3. Recycling of Metals
4. Energy Use and Recycling
5. Future of Recycling

Glossary

home scrap Scrap produced at the metal-producing plant as the result of inefficiencies or material losses in the metals-producing plant.
new scrap Scrap that is produced at a manufacturing industry using metal in its production process.
old scrap Scrap recovered from a waste stream after consumption of the metal-containing products. This is also called postconsumer scrap.
primary production The production of metals from primary resources (i.e., ore).
recycling rate The relative amount of metal recycled as a function of apparent domestic consumption of the metal. Apparent consumption is the sum of domestic production and imports minus exports of the metal.
secondary production The production of metals from recovered resources such as scrap.

Metals are used in virtually all applications and are produced in virtually all countries. The production of metals consumes approximately 7% of all the energy in the world. The most important metals are iron and steel, aluminum, copper, and a few others. Metals are produced from primary resources (ore) and from secondary sources such as scrap metal. Because of the high energy intensity and costs of metals, metal recycling is an efficient and effective way to reduce energy consumption in the metal industries. Recycling rates vary for the various metals. Energy savings vary for the various metals depending on the type of metal, amount of metal recycled, and type of scrap recycled.

1. INTRODUCTION

Metals have contributed to the technological progress of society for an extraordinary long time and are still a key material in our society. This is unlikely to change in the future. However, the source of the metals has and will change in the foreseeable future.

Historically, metals had such a high value that they were reused and recycled. However, in modern society increasingly more metals are used in a dissipative way. The use of metals has also rapidly increased throughout society. This had led to the use of lower concentrations of ores for the production of metals. For example, copper is a relatively scarce metal. At the beginning of the 20th century, copper concentrations in ore were more than 2%. Currently, copper concentrations of mined ores are approximately 0.5% or less. This means that more than four times as much ore must be processed to produce the same amount of copper. The use of lower quality resources may have led to increased costs of these materials if it were not for technological progress in mining, ore beneficiation, and metal production technology. However, with the lower concentrations found in ores used today the potential for environmental pollution has increased. It is estimated that annually more than 6.4×10^9 metric tons of ore is extracted from the earth, of which more than 90% is discarded as mine and mill wastes. With the increasing volume of ores used, the amount of energy needed to extract and process the ores has also increased dramatically. This is unsustainable from an environmental and (long-term) economic perspective.

Recycling allows recovering part of the metals entering the industrial society, reducing the need for the extraction of resources from the natural environment. Recycling will save natural resources, reduce pollution, and save energy. The energy savings depend on the energy needed to recover and upgrade the metals from the waste streams compared to the

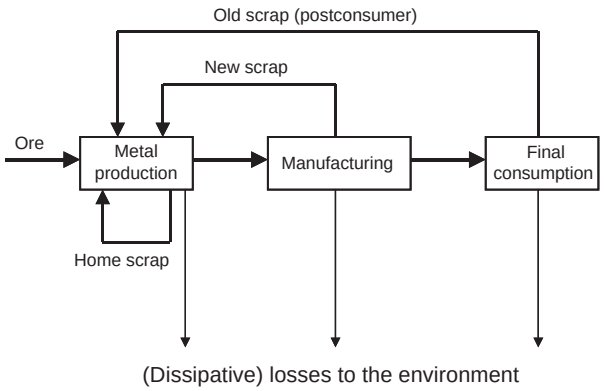

FIGURE 1 Schematic representation of scrap qualities and types.

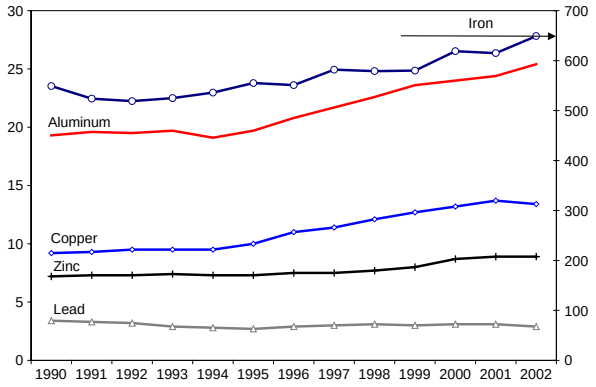

FIGURE 2 Global primary production of iron, aluminum, copper, zinc, and lead from 1990 to 2002. Iron production is depicted on the right-hand axis, whereas production of the other metals is depicted on the left-hand axis.

energy needed to extract the ores from the natural environment.

Primary production involves metals produced from ore, whereas secondary production involves recycled metals or scrap. This term is not an expression of the quality of the final product. Recycled metals can come from three streams: home scrap, new scrap, and old scrap (postconsumer) (Fig. 1). Home scrap is produced in the metal-producing plant and is the result of inefficiencies or material losses in the plant. New scrap is scrap that comes from the manufacturing industry that purchased the metal. Both for home and for new scrap, the material composition is well-known, and therefore these types of scrap demand a higher price in the global scrap market. Old scrap is scrap recovered from a waste stream after consumption of the metal-containing products. The exact composition of old scrap is not known, which may limit recycling due to contamination with other metals that may be difficult or impossible to remove in the recycling process.

Metals and scraps are typically traded on a global scale. Hence, relative prices of primary metals and scrap are determined by global developments. For example, the economic crisis in Asia in the late 1990s triggered a decline in the world prices of steel scrap because Asia is a large net importer of steel scrap.

2. PRODUCTION OF METALS

Although society uses many metals, the following metals represent the bulk of the metals used: iron (steel), aluminum, copper, lead, and zinc. This article focuses on these five metals. Figure 2 presents the global primary production of the five metals. Iron (steel) clearly dominates the metal consumption on a global scale, representing approximately 90% of all metal consumption. All ores contain the oxide of the metal. The metal oxides are reduced to metallic form to be used by society. Because the chemical reduction process is endothermic, and because many reduction processes take place at high temperatures, it requires large amounts of energy. Besides a high energy intensity, the processes used to produce primary metals are also very polluting. Pollution may be due to the concentration of the ores, the smelting process (or processes producing inputs for the smelting, such as coke making to make iron), or energy generation.

Iron is the main metal component of steel. Global steel production exceeds 900 million tonnes, whereas global iron production was 649 million tonnes in 2002. Accounting for material losses in the processes, the difference between the amount of steel and iron produced is met by recycled scrap. Steel is produced in more than 60 countries. The main iron and steel producers are China, Japan, the United States, Russia, South Korea, and Germany. Iron ore contains on average approximately 58% iron. Iron is produced in two forms: pig iron (more than 93% of global iron production) and direct reduced iron (DRI). Pig iron is produced in a blast furnace using coke in combination with injected coal or oil to reduce sintered or pelletized iron ore to pig iron. Limestone is added as a fluxing agent. Coke is produced in coke ovens. Reduction of the iron ore is the largest energy-consuming process in the production of primary steel. DRI is produced by reduction of the ores below the melting point in small-scale plants (<1 million tonnes/year) and has different properties than pig iron. DRI production is growing

and approximately 5% of the iron in the world is produced by direct reduction, of which more than 90% uses natural gas as a fuel. Steel is made by reducing the carbon content of the iron. Primary steel is produced by two processes: the open-hearth furnace (OHF; 4% of world steel production in 2002) and the basic oxygen furnace (BOF; 60% of 2002 world steel production). The OHF is still used in different configurations, mainly in Eastern Europe, India, and China. The BOF process is rapidly replacing OHF worldwide because of its greater productivity and lower capital costs. In addition, this process needs no net input of energy and can even be a net energy exporter. Hot pig iron is mixed with up to 30% recycled scrap. The process operates through the injection of oxygen. Secondary steel is produced in an electric arc furnace (34% of 2002 world steel production) using scrap. Scrap is melted and refined using a strong electric current. DRI can be used to enhance product quality. Several process variations exist and fuels can be injected to reduce electricity use. The steel is then cast and shaped into different products. Traditionally, primary steel was the steel of choice to make thin and high-quality products such as hot and cold rolled sheets. Through improved quality control of the steel manufacturing process and technological development in casting and rolling, today secondary steel is also used to produce hot and cold rolled steel.

Aluminum is one of the most abundant metals in the earth's crust. Aluminum is found as bauxite, which contains approximately 25% alumina. Hence, for every ton of aluminum approximately 8 tons of bauxite is processed. Global aluminum production was more than 25 million tonnes in 2002. Primary aluminum is produced in 43 countries. The main producers are Russia, China, the United States, Canada, Australia, and Brazil. Bauxite is first concentrated in the Bayer process to produce pure aluminum oxide, or alumina. The Bayer process uses fuels and electricity. The alumina is then processed using the Hall–Heroult process. Used for more than 100 years, the Hall–Heroult process is an electrolysis process. The alumina is dissolved in molten cryolite and electrolyzed using carbon anodes. This is a very energy-intensive process, using large amounts of electricity (generally 13 or 14 MWh/tonne of aluminum). The production of carbon electrodes from tar pitch also consumes a considerable amount of energy. Because of the high electricity intensity, aluminum production is increasingly more concentrated in countries and areas with low electricity costs. Secondary aluminum is made by melting and refining aluminum scrap. Because the scrap quality is often difficult to determine and to control, primary aluminum is typically used for high-quality applications such as thin sheet and foil, whereas secondary aluminum is mainly used for castings. Aluminum recycling rates vary for different countries depending on the primary aluminum products used. In the United States, approximately 3 million tonnes of aluminum scrap has been recovered, of which 60% came from new scrap and 40% from old scrap.

Copper has been the material of choice for electrical applications. However, competition from aluminum has reduced the role of copper in this market. Still, copper remains the third most important metal. Global primary copper production in 2002 was 13.4 million tonnes. Primary copper production is concentrated in less than 40 countries. The leading primary producers are Chile, Japan, China, and the United States. Copper ores that are currently mined have a very low concentration, typically less than 0.5%. This means that for every ton of copper more than 200 tons of ore is mined, transported, and processed. At the mine site, the ore is crushed and ground to concentrate the copper. The copper is extracted from the ore through leaching and other processes. The concentrate contains approximately 25% copper. The extracted copper oxide is then reduced in smelters at high temperatures to produce blister or anode copper. Different smelting processes are used throughout the world. The blister copper is further refined electrolytically. The smelting and refining process is highly energy-intensive. Secondary copper is produced by mixing some recovered scrap in the smelter, and it is then further refined. In 2001, only 12% of all copper was produced from secondary copper.

Zinc and lead are often found in the same ores. However, primary production is often separated. Zinc is the fourth most consumed metal in the world. Global primary production is estimated at approximately 9 million tonnes in 2002. Primary zinc is produced in 35 countries. The main producing countries are China, Canada, Australia, Japan, and the United States. Zinc is used for many applications and a relatively large portion of zinc consumption is for dissipative uses such as galvanizing steel and for chemicals. Zinc is mined from a variety of ores in coproduction with other metals. The zinc is leached from the ore and concentrated. The concentrate is often shipped to the zinc smelter. The zinc is smelted and refined in a electrolysis process using more than 4 MWh/tonne of zinc. Secondary zinc is often melted

and refined at separate plants and can also be recycled by primary zinc plants in the electrolysis process. Often, the secondary smelters produce zinc-based chemicals. In 2001, approximately 30% of the world zinc production was from secondary materials, including brass, die casting scrap, flue dust, galvanizing residues, and zinc sheet.

Lead is used for many applications, but the main market is lead–acid batteries (used in the automotive industry). Batteries represent approximately 90% of the market for lead. Lead production has remained stabile for the past decade at approximately 3 million tonnes/year. Although demand for lead–acid batteries has increased, many other uses for lead have declined (e.g., as an additive in gasoline and paint) due to environmental and health concerns related to the dissipative use of lead. Lead is found in ores with cometals such as zinc. The lead ore is most often concentrated at or near the mine. Primary lead production is concentrated in 30 countries, with the largest producers being China, Australia, Canada, the United States, the United Kingdom, and Germany. The lead concentrate is smelted at high temperatures in a blast furnace. The product of the blast furnace is refined into the final lead metal. Lead is most often processed in secondary lead smelters. Most of the recycled lead is from old scrap recovered by specialized lead-recovery companies.

3. RECYCLING OF METALS

Recycling and recovery rates vary for the different metals. The recovery rate is defined as the amount of metal that is recovered after use, whereas the recycling rate is determined by the amount of metal actually recycled. These rates can be expressed as a function of apparent domestic consumption, domestic production, or the amount of discarded metal. Different researchers and countries use different system boundaries and definitions for both of these terms. Hence, it is difficult to easily compare the recycling rates between different countries and studies. Therefore, the following discussion focuses on available data for the United States collected and analyzed by the U.S. Geological Survey (USGS). The USGS expresses recycling rates as a function of apparent domestic consumption of the metal. Apparent consumption is the sum of domestic production and imports deducting exports of metal. The USGS includes both new and old scrap in the definition of recycled metals.

Globally, more than 370 million tonnes of iron and steel scrap is recycled by the iron and steel industry. In the United States, 71 million tonnes of steel scrap is recycled, compared to an apparent consumption of 119 million tonnes in 2001. The recycling rate is estimated to be 60%. Figure 3 presents the recycling rates for the major metals in the United States. Because steel production dominates the production of metals, the recycled amount of steel also dwarfs the volumes of other metals recycled. However, as Fig. 3 demonstrates, the relative recycling rate is also high compared to that of other metals. Only lead has a higher recycling rate. Unfortunately, no data are available on the contribution of old and new scrap for iron and steel. Because most steel is used in durable products (e.g., appliances, automobiles, and construction) as well as packaging, it is relatively easy to recover and recycle. Recycling rates of iron and steel vary by the metal market. It is estimated that 65% of all the steel in an automobile produced in the United States is recycled steel. However, the recycling rate of packaging cans is probably lower because not all communities have systems in place to collect and separate the steel cans. Note that tin can also be recovered from packaging cans in specialized detinning plants. After recovery of the tin, the steel is recycled in a steel plant.

Aluminum is recovered in almost all market segments in which aluminum is used. However, most secondary smelters focus on production of aluminum die casting for the automotive and appliance industry. There are no data available for the global amount of aluminum recycled. In 2001, almost 3 million tons of scrap was recovered in the United

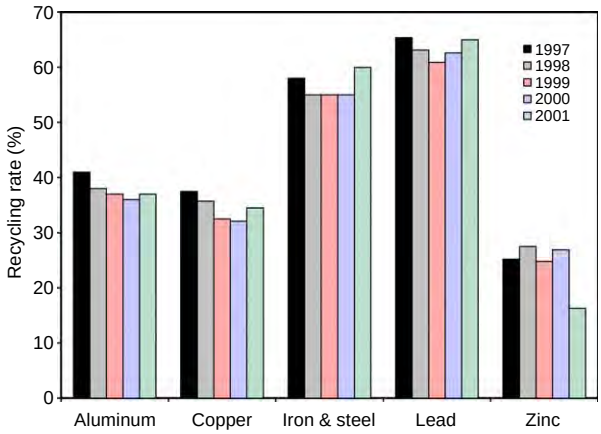

FIGURE 3 Recycling rates for selected metals in the United States for the period 1997–2001. Recycling rate is expressed as the amount of recycled metal as a share of total apparent consumption in the United States. From the U.S. Geological Survey.

States, representing a recycling rate of 37% (Fig. 3). Approximately 60% of the recycled scrap is from new (manufacturing) scrap and 40% from old scrap. In the United States, the major source of aluminum scrap is the aluminum beverage can, representing almost half of all old scrap. In 2001, 55.6 billion aluminum cans were recycled, which is equivalent to a recycling rate of 55% when compared to the manufacture of cans. Figure 4 depicts the relative shares of new and old scrap for the metals discussed in this article.

Global copper recycling was estimated to be 37% of the world copper consumption in 1997. In the United States, the total amount of recycled copper was estimated to be slightly more than 1.1 million tonnes in 2001. The recycling rate is relatively low (34.5%; Fig. 3) due to the dissipative use of copper as well as decreasing world market prices for copper. The recycling of copper concentrates on new scrap, whereas the recovery from old scrap has decreased in the past 5 years. Most copper is recovered from alloys and is mostly used by brass mills. New copper scrap represents more than 70% of all recycled copper.

Lead recycling demonstrates different dynamics than most other metals because most of the lead is recovered from postconsumer wastes (i.e., old scrap). This is due to the reduced dissipative use of lead and the concentration of lead consumption for automotive lead–acid batteries. In most industrialized countries, efficient and effective collection networks exist to recover the old batteries that are recycled by dedicated recycling companies. In the United States, approximately 96% of all recycled lead is from batteries and only 4% is recovered from new scrap (Fig. 4). In 2001, 1.1 million tonnes of lead was recycled, whereas the total apparent consumption was 1.7 million tonnes. With a recycling rate of 65% (Fig. 3), lead is currently the most recycled metal in the United States.

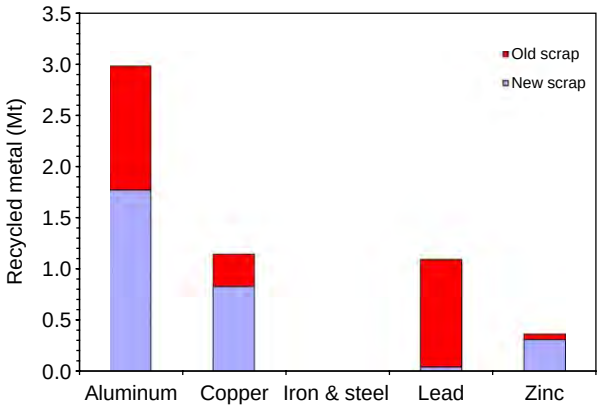

FIGURE 4 Recycled metal flows in the United States for 2001, subdivided into old (postconsumer) and new scrap. From the U.S. Geological Survey.

Zinc use is dominated by dissipative uses such as galvanizing steel products. Hence, the recycling of postconsumer wastes of zinc is very limited. Zinc can be recovered from the waste of steel recycling. Zinc is recovered from the dust of electric arc furnaces (secondary steel production) and may be recovered from the sludge from primary steel-making plants. New technological developments aim at stripping zinc from steel. Hence, zinc recycling concentrates on the use of new scrap. This limits the net recycling rate of zinc. The declining recycling of old scrap in the United States has led to a reduced recycling rate of 16% (compared to as high as 28% in 1998), of which 86% is from new scrap (Fig. 4). Worldwide, approximately 30% of all zinc is produced from secondary materials.

This discussion of the five metals has highlighted the differences in recycling rates and the impact of the dominant uses on the recycling rates. However, it also shows that relatively large shares of (postconsumer) metal wastes are not recovered. This demonstrates the potential for future increases in recovery and recycling rates, which will be especially important because the production of home and new scrap will likely decrease due to improved material efficiencies of metal production and processing.

4. ENERGY USE AND RECYCLING

Metal production comprises approximately 7% of global energy use, making the sector one of the largest energy-consuming industries. Energy consumption is dominated by the production of iron and steel. An estimated 4% of world energy use is consumed in the production of iron and steel. Table I summarizes the estimated energy intensities for selected metals. The energy consumption data include the energy used in mining of the ores. It is important to note that there are relatively large differences in the energy intensity and efficiency of industrial processes in different countries and for plants within a country. Differences in energy use for metal production in various countries are due to differences in the raw material used (i.e., ore and scrap), the mix of products produced, material losses in the production process, and the energy efficiency of the production facilities. These four factors also contribute to continuous changes in energy intensity.

TABLE I

Energy Intensities of Primary and Secondary Metal Production[a]

Metal	Primary production (million metric tons)	Energy intensity, primary production (GJ/tonne)	Energy intensity, secondary production (GJ/tonne)	Energy savings of recycling (%)
Iron and steel	649	26	12	54
Aluminum	25.4	213	11	95
Copper	13.4	91	13–37	60–85

[a] Values are approximate and will vary by product and production location. Energy intensity is expressed as primary energy. Electricity is converted to fuels used to generate the power.

It has been estimated that the energy intensity in the U.S. iron and steel industry during the period 1980–1991 changed mainly due to improved energy and material efficiency and a change toward more recycling. However, in China, during the same period only energy efficiency improvement contributed to the change in energy intensity because it has less domestic scrap available. Good statistical information on energy use does not exist for all metal industries or countries.

Table I provides estimates for the energy intensity of primary and secondary metal production. The high energy use and energy intensity make this sector an important candidate for energy conservation policy. In metals production, energy can be saved through (i) improving energy efficiency of the production process, (ii) improving material quality and material efficiency, (iii) reuse of metal-containing products, and (iv) recycling.

Table I also provides estimates for the relative energy savings of recycling metals. The data demonstrate that the largest energy savings can be achieved in the recycling of aluminum. Energy savings in aluminum recycling is estimated to be 95%. For steel, the energy savings exceeds 50% of the energy inputs of primary steelmaking. These data demonstrate the importance of recycling strategies in an integrated energy and environmental policy framework.

Increased recycling will reduce the energy intensity of metal production. The net reduction in overall energy use in a country or the world will also depend on the growth in the demand for metals and other materials. Globally, there is strong growth in the consumption of all metals, which will likely offset the energy savings of recycling. However, without recycling the total energy needs for the increased mining and primary production would be much higher than currently expected.

Several countries have started to develop integrated energy policies that account for the potential energy savings of increased recycling and material efficiency efforts. Other countries have started to account for the energy savings as part of the rationale for recycling programs. Several studies have shown the benefits of sustained recycling programs and efforts to reduce future energy use and CO_2 emissions, highlighting the importance of integration of recycling in energy policies.

The energy consumption data in Table I exclude the energy needed to collect, recover, and transport the metals. Although considerable amounts of energy can be used to collect and recover postconsumer and old scrap, these are generally small compared to the energy savings. The efficiency and effectiveness of postconsumer programs will vary depending on the type of collection system operated, sustained lifetime, geography of the area served, as well as cultural characteristics. Based on the energy used in collecting and energy savings of recycling, an "energy optimal" recycling strategy can be designed. Such a strategy may well result in different optimal recycling rates based on the regional characteristics (Fig. 5). This optimum will change with changes in technology performance. A study of aluminum recycling in Germany showed that the current recycling rate of 59% could be improved to 79% to optimize energy savings from the recycling scheme using currently available technology.

Technology development will affect the energy consumption of primary and secondary production. New energy-efficient technologies are being developed that can substantially reduce the energy consumption in steelmaking through integration of different production steps (e.g., casting and shaping of steel products) and new designs of processes (e.g., electric arc furnaces with scrap preheating). For aluminum, new developments aim to reduce the

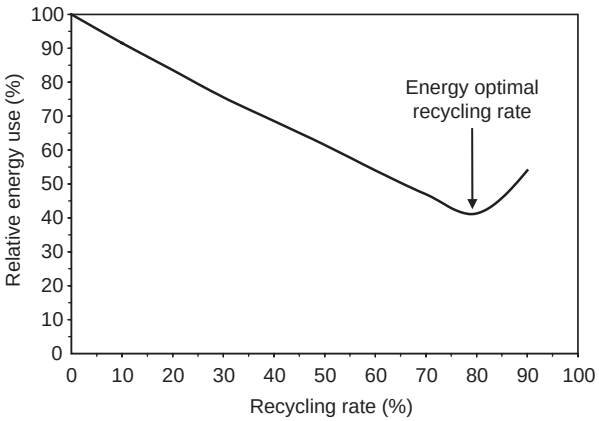

FIGURE 5 Schematic representation of energy use as a function of the recycling rate. The vertical axis depicts the amount of energy used for the production of a given volume of metal relative to the amount of energy needed to produce the primary metal (0% recycling is 100% of the primary energy use). Energy use includes the energy needed for collection, recovery, transport, and recycling of scrap.

electricity consumption of primary aluminum smelting through new electrode development and, in the long term, the development of totally new smelting processes to break through the thermodynamic barrier of the Hall–Heroult process. Secondary aluminum production is also improved through more efficient furnaces and improved yield of secondary melting furnaces. Similar developments are found for the other metals. New developments in metal recovery and separation technology will increase the recovery efficiency, improve quality control, and reduce energy intensity.

5. FUTURE OF RECYCLING

The future of metal recycling will be shaped by different driving forces. The main driving forces are depletion of high-quality ores, technology innovation, the availability of secondary resources, the costs of energy, and a drive toward more sustainable industry practices as part of sustainable development.

Depletion of high-quality ores has driven metal producers to extract ores with increasingly lower metal concentrations. Copper is an excellent example of the depletion of high-quality ore, such that ores currently exploited have concentrations less than 0.5%, whereas it was 2% at the beginning of the 20th century. This had led to exploitation of high-quality ore reserves at remote locations. Decreasing ore quality may not apply to all metals. For example, iron ore and bauxite reserves are abundant and are found in many locations. However, there is competition to use the highest quality ore first. Also, geopolitical factors may play a role in the sourcing of raw materials and hence the costs of primary production. This process will increase the costs of primary metals and make recycling more attractive.

On the other hand, the increasing costs of ore extraction are also driven by technology innovation. Innovation and the introduction of new technology in the metals extracting and primary metals industry have reduced the cost of metal production over time. Therefore, although current copper ore contains on average only one-fourth of the copper that the ore contained a century ago, copper is now cheaper. Continued innovation in the metals industry will drive down the costs of primary production. However, the same applies to secondary metal produc-tion technology. Innovative processes are decreasing the costs of metal recovery and recycling while simultaneously improving the quality of the secondary metals. The rapid growth of the secondary steel industry in the 1990s in the United States is an example of how innovative technology and low resource (scrap) costs gave secondary steel producers a competitive edge over primary (integrated) steel producers. Within a decade, the secondary steel industry expanded to provide almost half of the steel production in the United States.

As previously discussed, the sources of scrap vary for the different metals. Most secondary metal producers prefer new scrap because the exact composition of the metal is known, enabling the production of high-quality secondary metals. However, due to innovations improving the energy efficiency of metal production and processing, the amount of new scrap will further decline in the future. Hence, future recycling efforts will focus more on old (postconsumer) scrap. Costs, quality, and availability will become more important factors with regard to secondary production. Innovative technologies may alleviate some of the quality and costs problems, whereas policies aimed at the reduction of dissipative use of metals and improved scrap recovery efficiency are needed to contribute to sustainable secondary metal production.

The high energy intensity of primary metals production makes this type of production much more vulnerable to energy price changes and supply disruptions. Already, primary production of the most energy-intensive metals such as aluminum takes places in countries with low-cost energy sources. The changing energy markets in the United States have contributed to the closing of primary aluminum smelters in the

northwest. The increased importance of climate change in energy policy worldwide will affect the costs and opportunity to use fossil energy. The primary metals industry will be affected more intensively by these changers than the secondary producers.

Finally, a drive toward sustainable development of our industrial society will affect the metals industry. Climate change is just one of the challenges for sustainable development because primary metals production is also a source of many other environmental pollutants. Historically, primary metal producers were major sources of acidic air pollution (from copper, nickel, and other metal smelters) and metal dust emissions. Primary metal production also results in large volumes of solid and fluid wastes (e.g., red mud from bauxite processing and sludge containing arsenic from metal leaching processes). A drive toward sustainable business practices will drive innovation but will also support further recycling efforts as well as material substitution and product changes. This will lead to an increased importance of metal recycling.

It is difficult to assess the contribution of the different drivers to the future of the metals industry. However, it is clear that metal recycling will play a more important role in the future, leading to further reductions in energy intensity in metal production.

Glossary

chemical pulp Pulp obtained by digestion of wood with solutions of various chemicals. Chemical pulps are used to make shipping containers, paper bags, printing and writing papers, and other products requiring strength.

corrugated container A box manufactured from containerboard, layers of linerboard, and one layer of medium. The layers are combined and corrugations pressed into the medium.

de-inking A process in which most of the ink, filler, and other extraneous material are removed from recovered paper, resulting in a pulp that can be used in the manufacture of new paper.

direct energy Fuel or electric energy consumed during a process.

indirect energy Energy required to produce a material or chemical input to a process.

kraft paper Paper made from wood pulp by a modified sulfate pulping process. Its natural unbleached color is brown, but it can be bleached to white. It is used as a wrapping paper or converted into bags, envelopes, or coated paper.

kraft (sulfate) pulp A strong papermaking fiber produced by the kraft chemical process in which the active cooking agent is a mixture of sodium hydroxide and sodium sulfide. The term kraft is derived from a German word meaning strong.

mechanical pulp Wood pulp manufactured by mechanical processes. The resulting paper is opaque and has good printing properties, but it is weak and discolors easily when exposed to light due to residual lignin. Uses include newsprint, specialty papers, tissue, toweling, paperboard, and wallboard.

newsprint A lightweight paper, made mainly from mechanical wood pulp, engineered to be bright and opaque for the good print contrast needed by newspapers.

paper The name for all kinds of matted or felted sheets of fiber (usually vegetable, but sometimes mineral, animal, or synthetic) formed on a fine screen from a water suspension.

primary fiber Pulp made from trees or other vegetable matter rather than recovered materials. Also called virgin fiber.

pulp Fibrous material prepared from wood, cotton, grasses, etc. by chemical or mechanical processes for use in making paper or cellulose products.

pulp substitutes A combination of paper and paperboard trimmings from paper mills and converting plants.

recycled or secondary fiber Cellulose fiber reclaimed from waste material and reused, sometimes with a minor portion of virgin material, to produce new paper.

After paper products have served their intended uses, there are several alternative paths for material disposition. These include (generally, but not necessarily, in order of decreasing energy saved) reuse, recycling to the same product, recycling to a lower valued product, combustion for energy recovery, incineration without energy recovery, and landfill. The best option depends on the decision criterion selected.

1. INTRODUCTION

After paper products have served their intended uses, there are several alternative paths for material disposition. These include (generally, but not necessarily, in order of decreasing energy saved) reuse, recycling to the same product, recycling to a lower valued product, combustion for energy recovery, incineration without energy recovery, and landfill. Solid-waste management is an important issue in the United States, and the priorities are a subject of

 © 2004 Elsevier Inc. All rights reserved.

debate. According to the U.S. Environmental Protection Agency (EPA), "Recycling (including composting) is the preferred waste management option to further reduce potential risks to human health and the environment, divert waste from landfills and combustors, conserve energy, and slow the depletion of nonrenewable natural resources." Combustion for energy recovery is generally not counted toward material recovery goals, probably because it is viewed as a form of disposal and is therefore assumed to waste resources and have negative environmental effects. However, cocombustion in coal-fired plants or combustion in appropriately pollution-controlled waste-to-energy (WTE) plants is safe, avoids landfill costs, and can displace fossil fuels. In some cases, more fossil fuels can be displaced by combustion than by recycling. This article evaluates alternative product life cycles and discusses trade-offs among possible goals. For instance, office paper recycling conserves trees but may require greater fossil fuel input than virgin paper production. Technical and institutional barriers could arise as recycling rates increase. The main areas of concern are energy and materials use and landfill volume, but key economic and environmental factors are also identified.

2. PRODUCTION AND RECYCLING STATISTICS

In the period from 1990 to 2000, production of paper and paperboard in the United States increased from 80.5 to 96.4 million tons. This represents a 6% per capita increase, from 644 to 683 pounds per person per year, despite predictions that increased use of electronic communications would move us toward a "paperless society." Since most paper products have very short use times, postconsumer paper waste generated during the same period tracked production closely, increasing from 72.7 to 86.7 million tons. Paper and paperboard have accounted for approximately 37% by mass [and approximately an equal percentage of volume because they have close to the average municipal solid waste (MSW) density] of MSW during the period, according to EPA statistics.

This discarded material represents a valuable resource and a costly liability to discard, and efforts to utilize it have increased. The percentage of postconsumer material recovered from 1990 to 2000 doubled from 20.2 to 39.4%. Note that the paper industry reports higher recovery numbers because it includes in-house scrap, such as pulp substitutes, and materials such as unsold magazines that are recycled immediately without actually being used, as well as postconsumer material. More paper is recovered from MSW streams than all other materials combined. Corrugated boxes (recovered at a rate of 71%) account for 54% of all paper recovered, and newspapers (with a 58% recovery rate) account for another 22% of recovered paper. Office papers (of which 54% are recovered) account for another 10%; no other category contributes as much as 5%. Therefore, energy and materials implications of paper recycling are of special interest.

A significant quantity of wastepaper is exported. Some is mixed waste, sent to low-labor-cost countries where it can be economically sorted by hand, but higher grade materials are also included. Export of high-grade wastes could adversely affect recycled fiber quality and has implications for energy use. Similarly, imports have energy use implications. In general, imports of finished products displace domestic resources, but they worsen the trade balance. The costs and benefits of imports and exports of finished products and scrap must both be considered.

3. PRIMARY PAPER PRODUCTION

More than 48% of the raw material fiber used for papermaking in the United States in 2002 was recovered or reclaimed, with recovered paper contributing 37.7% and wood residues 10.6%. The total has been more or less constant, with the percentage of recovered paper increasing and that of wood residues declining recently due to their increased use in oriented strand board and composite panels. Primary fibers are a renewable, domestic resource, much of which is currently supplied by tree plantations. Short-rotation forestry can be used to further increase the productivity of these plantations. Therefore, use of primary fibers need not mean cutting old-growth natural forests, with the implied loss of habitat, wilderness, and recreation land. However, monoculture may have environmental implications of its own, as does recycling; these should be taken into account during decision making about paper production and recycling policy.

For purposes of this article, virgin paper can be classified into two main types that have different chemical compositions and physical properties. In reality, the industry produces a large variety of products, but these two classes cover most of them.

The two types are distinguished by the processes used to make the pulp: chemical or mechanical. Kraft pulp (the most common type of chemical pulp) and thermomechanical pulp (TMP), plus recycled fiber (chemical or mechanical), are the largest inputs to U.S. papermaking (85% of total pulp input), and their use is growing. This article focuses on these types. The energy and materials inputs to production of the different types of pulp differ, although both start with wood as the basic raw material. Papers made from different types of pulp are often kept separate in recycling because of the differences in material properties, but the secondary processing sequences are similar.

Most discussions of energy use in papermaking are confusing because of a failure to define exactly what is meant by energy. It is important to keep track of the form in which energy is used. The major inputs to a paper mill are wood, purchased energy in the form of electricity and fossil fuels, and water. Some components of the wood are used as a raw material and some as by-product fuel. What the industry generally reports is the process energy use at the mill, which is the sum of the purchased energy and the process by-product energy (part of the energy originally in the wood) that is used. It is more useful to define total energy input to include the entire energy content of the wood as well as the purchased fossil fuels and electricity because the wood input could otherwise have been used as a fuel. Some of this energy is not used up; it is still available from combustion of the final product. (The difference between the total energy input and the residual energy content of the product is equal to the process energy as tracked by the industry.) Total energy input, purchased and process energy, and the net nonwood energy consumption for typical paper production and recycling are shown in Table I for discarding, burning, and recycling 1 ton of printing and writing paper ("office" paper) and newsprint (representing typical products from chemical and mechanical pulps). The table shows that total energy input is reduced by recycling, but that nonwood energy use is actually increased by recycling of office paper. Recycling office paper may actually require more fossil fuel purchases than producing it from virgin materials because the recycling process does not generate by-product fuels and must therefore use purchased energy.

Caution is in order regarding energy consumption in paper mills. The numbers cited are representative of typical U.S. industry practice for specific grades and can be used to provide an understanding of the factors involved in recycling decisions. However, actual paper mill energy use varies widely, depending on many factors, including the age of the equipment, the product and its degree of bleaching, the geographical location, and the season. For instance, recycling of paperboard requires less energy than recycling of office paper and may therefore be preferable to combustion. It is hoped that the American Forest and Paper Association will publish actual industry data that will allow more accurate analysis. In addition, different mills use different mixes of purchased and self-generated electricity, affecting both the fuel mix and the primary fuel usage for generating electricity. Also, the fuel mix for electricity generation varies from utility to utility, affecting the actual primary energy usage from electricity purchases (or the fuel displaced if electricity is sold back to the grid). Table I was prepared using the U.S. average generation mix, but decisions for specific areas should employ actual local utility data.

Energy and resources used for papermaking in other areas of the world could be quite different from those used in the United States. Therefore, the conclusions of this article may not necessarily be applicable to other regions. For example, in Europe, where wood resources are more limited, clay fillers are used more extensively in the production of newsprint to produce a lighter weight, less wood- and energy-intensive product. Nonwood plant fiber pulp is used extensively in China, whereas very little is used in the United States and Europe. Nonwood plants are fast growing and produce a different fiber than slower growing trees. Many nonwood fibers are short like hardwood fibers, but others are much longer and must be shortened mechanically or chemically to optimize their papermaking value. Process energy requirements differ with fiber characteristics.

3.1 Chemical Pulping

Chemical pulping separates wood chips into their components of cellulose, hemicellulose, and lignin and retains the cellulose fibers while rejecting most of the rest; therefore, the yields are less than 50%. However, much of the material removed is used for process fuel, so energy purchases are low. The two main types of chemical pulp are kraft (sulfate) and sulfite, indicating the types of chemicals used. Most printing and writing papers, packaging, and paperboard are made from kraft pulp because of its superior strength and economics. Sulfite pulp has a relatively small and declining market share and will not be discussed further. The total direct process

TABLE I

Energy Required to Supply 1 Ton of Paper to Consumers[a]

Path	Wood[b] (dry tons)	Heat of combustion of wood (10^6 Btu)	Purchased fuel (10^6 Btu)	Purchased electricity (kWh)	Process energy[c] (10^6 Btu)	Energy recovered (10^6 Btu)	Energy displaced (10^6 Btu)	Net total energy input (10^6 Btu)	Nonwood energy input (10^6 Btu)
Wood to kraft[d] to landfill	2.2	37.4	9.5	495	36.5	0	0	52.1	14.7

Source. Gaines and Stodolsky (1993).

[a] Abbreviations used: WTE, waste to energy; ONP, old newsprint.

[b] Wood for kraft paper includes bark, which is used as by-product fuel. Newsprint input excludes bark, generally used elsewhere in integrated mills.

[c] Electricity converted at 10,500 Btu/kWh; values are lower if some of the electricity is cogenerated.

[d] Kraft refers to printing and writing grades; other paper or board types would have slightly different energy requirements.

energy requirement reported by the industry for pulping and making of printing and writing papers averages approximately 26×10^6 Btu/ton, but the energy required varies greatly with the product and with the degree of energy recovery included, ranging from a high of approximately $30–35 \times 10^6$ Btu/ton for kraft board to a low of $10–12 \times 10^6$ Btu/ton for recycled tissue. Process energy use is generally higher for products requiring extensive bleaching. Using paper that has undergone less bleaching could reduce fuel purchases more than recycling. There is a public misconception that virgin paper is white and recycled paper is brown. However, it is the degree of bleaching that determines brightness, so virgin paper can be brown and recycled paper can be white. Reducing bleaching also reduces environmental impacts. The primary purchased energy requirement for kraft paper, over half of which is bleached, is typically approximately 15×10^6 Btu/ton.

3.2 Mechanical Pulping

Products made from mechanically produced fibers include newsprint, high-bulk news (pocket books), coated publication paper, and chipboard. Newsprint is generally made from TMP, although some other mechanical pulps are still used, and some kraft pulp may be added to increase strength. The energy required to make 1 ton of newsprint (both direct and indirect energy) is all purchased (no process by-product energy) and ranges between 27.6 and 39.4×10^6 Btu/ton. This range primarily results from variation in pulping energy and electrical power-generation efficiency. It is assumed that all steam needed by the process comes from the waste heat generated in the TMP process. Therefore, these estimates include electrical power only. The mid-range estimate is 33.5×10^6 Btu/ton, which is calculated on the basis of typical pulping energy and 50% in-plant power generation.

4. USE OF RECOVERED PAPER

4.1 Paper Recycling

Wastepaper is pulped mechanically and possibly de-inked before bleaching and papermaking. These upgrading processes, used to recycle printing and writing papers, remove ink and any coatings or fillers that were used in the paper. They are reasonably energy-intensive, using approximately 2×10^6 Btu/ton (excluding energy embodied in chemicals). However, they are essential for upgrading of recycled material for utilization in high-grade products, such as printing and writing paper. High-grade recycled products therefore may have higher energy requirements than shown in this analysis and yield lower energy savings. Segregated wastepaper streams such as paperboard, newsprint, or corrugated generally do not require de-inking.

For de-inked fiber of modest quality, the yield is typically approximately 67%. This means that each ton of wastepaper yields 0.67 tons of fiber

and 0.33 tons (dry basis) of sludge, which is sent to the landfill. Sludge is difficult to dewater and at best only approximately 50% solidifies, resulting in a mass to the landfill of 0.66 tons. Thus, for every ton of de-inked fiber, 1 ton of sludge goes to the landfill or is available for combustion. Although the Office of Technology Assessment classified this sludge as noncombustible, it can be gasified or dried with stack gas and then burned. The sludge has a heating value of approximately 14×10^6 Btu/ton (dry basis) from the fiber and ink content. There was previously concern about toxic metals from printing inks in the sludge (or in the ash from sludge or MSW combustion); however, the inks that contained these materials have been phased out in the United States.

The production of secondary paper results in fiber loss. Therefore, virgin fiber is needed to maintain a constant supply of paper to the consumer. Very little newspaper is reported to be rejected at the materials recovery facility, but 15–22% of the fiber input to the mill is lost in the recycling process because of fiber breakage. There is no way to avoid this loss. Thus, the recovery rate for collected material is 78–85%. The energy needed to produce the primary pulp that makes up for the loss must be included in the energy needed to recycle. Direct energy purchases by a modern secondary newsprint mill are typically approximately 16×10^6 Btu/ton of recycled paper product; the total primary energy needed, including transportation and embodied energy in chemicals, is approximately 20.8×10^6 Btu/ton. The energy needed to supply newsprint to the consumer, assuming 22% fiber loss, is thus 23.6×10^6 Btu/ton ($0.78 \times 20.8 \times 10^6$ Btu/ton for the recycled material plus $0.22 \times 33.5 \times 10^6$ Btu/ton for the makeup material).

For recycled paper products, all of the energy is generally purchased, although some mills do generate some of their own energy by combustion of sludge. This can reduce energy purchases by as much as a factor of two. Technically, if paper is recycled within an integrated mill, some of the energy used may have been generated as a by-product of other processes within the mill. However, it cannot be credited to the recycling process and should still be considered as imported or purchased.

Recycling processes may also differ by region. Most European and Japanese mills started using flotation technology for de-inking before U.S. mills did so. However, at least one major U.S. mill still uses washing to de-ink the recovered fiber. The flotation process became dominant in Europe mainly because of effluent regulations (washing utilizes more water) and the higher recovery yields of fines and fillers (the high levels of clay fillers in European paper necessitate high levels of recovery to maximize yield).

4.2 Fiber Energy Recovery: Use of Wastepaper as Fuel

Energy can also be saved by burning waste newsprint or kraft paper (instead of recycling it) and recovering energy as electrical power or steam. This option should be called fiber energy recovery and is not a type of disposal. It should not be confused with incineration, in which wastes are burned but no energy is recovered. Approximately 10% of old newsprint (ONP) in the United States is removed from the waste stream and utilized for fiber energy recovery. The energy generated (normally electrical power) displaces energy produced from fossil and nuclear fuels at central-station power plants. When 1 ton of paper is burned in a WTE plant, 11.3×10^6 Btu of energy is displaced. If paper (news or kraft) is pelletized (either alone or as part of mixed waste) for cocombustion in coal-fired power plants, the generation efficiency of electricity produced from the waste is that of the power plant, rather than the lower efficiency of the WTE plant, and more energy is displaced. In cocombustion, each ton of paper displaces 16.8×10^6 Btu of coal. In addition, combustion can be accomplished in an environmentally sound manner; emissions of sulfur oxides (SO_x) are actually reduced by cocombustion of waste pellets, so more costly pollution controls can be avoided.

Wastepaper can be burned in either existing woodwaste- or coal-fired boilers or in new, efficient boilers designed to burn recovered fiber/wastepaper. Depending on the type of boiler, it may be necessary to pelletize the paper fuel to ensure clean and complete combustion. The energy produced can displace fossil fuel use in pulp and paper mills, cement kilns, and other industrial or commercial facilities. If electricity is cogenerated, any excess power generated can be sold back to the grid, thereby displacing additional fossil fuels. Although total energy use may not be reduced by this strategy, renewable biomass energy is substituted for fossil fuels, and the result is a reduction in emissions of CO_2 as well as SO_x, NO_x, and volatile organic compounds. In addition, the volume of solid waste is reduced. Pelletization of mixed waste paper (MWP) requires the addition of moisture; one manufacturer supplies this via paper recycling sludge, which is otherwise a disposal problem.

This technology has been used in at least one large paper mill; the boiler technology is commercially available. The boilers should be no more costly than those firing fossil fuels, although retrofits and pelletizing equipment could be needed and add to total costs. An economic factor that could hinder use of this technology is the extremely volatile price of wastepaper. This is, in turn, related to the varied mandates for recycled content in paper. Recognition of fiber energy recovery as an acceptable form of recycling could help reduce this barrier. One potential drawback to combustion for energy recovery is that it could result in competition with paper recycling mills for feedstock. This could drive up the price of recovered paper and jeopardize the economic viability of both industries.

A key institutional and economic factor is whether the paper to be burned is classified as a solid waste. If it is so defined, more stringent emission requirements may apply to the boiler in some states, and additional, costly pollution control measures may be required, negatively impacting the process economics. Requirement of additional controls is inappropriate because combustion of wastepaper actually reduces boiler emissions; therefore, either used paper should be classified as fiber fuel (with less stringent regulations) and not as a solid waste or facilities switching to it should be exempted from equipment installations specified in waste-combustion new source performance standards (NSPS) or from the "Best Available Control Technology" review on fuel switching if they can demonstrate that they have reduced their emissions to levels at or below those of the NSPS.

Compared to production of recycled office paper using fossil fuel, production of virgin office using wastepaper as the fuel would reduce CO_2 emissions by approximately 2 tons per ton of paper, in addition to reducing fossil fuel use. The result is that paper is produced with zero or negative net CO_2 impact. This is because biomass is a renewable resource. It is assumed that trees cut down to produce paper will be replanted and again sequester the CO_2, so there is no net CO_2 impact on the environment. The sulfur content of paper is much lower than that of the coal or oil it displaces; SO_x emissions may be reduced by more than expected by simply displacing coal or oil with paper because of reactions with compounds in the paper. NO_x emissions are also reduced, as is the quantity of solid waste generated.

Chesapeake Paper Products Company (no longer in business) estimated energy use and emissions for a boiler that would have burned recovered fiber at its pulp and paper mill in West Point, Virginia, as well as for an efficient new mill. In both cases, combustion of recovered fiber would have reduced emissions and fossil fuel use. Georgia Pacific Corporation cofired wastepaper pellets with low-sulfur coal in a water-tube stoker boiler at its mill in Jarratt, Virginia. It compared steady-state operation of the boiler with 100% coal feed to that with 30% coal and 70% wastepaper pellets (by weight); measured emissions of CO_2, CO, SO_2, NO_x, and hydrocarbons; and analyzed the ash. Results were very favorable.

In addition, feasibility studies were completed of combustion of MWP at three facilities in Washington State: a paper mill, a hospital, and a cement kiln. Shredded MWP could be fired in a cement kiln without the need to pelletize it, with no additional controls required because of the nature of the existing process. Hospitals and paper mills would require additional pollution controls if the paper were classed as a waste. Economics were found to be favorable if disposal costs were avoided. MWP was obtained from recycling brokers for proximate and ultimate analysis, and it was found to have acceptable fuel characteristics, but insufficient funding was available for test burns. However, data from a test burn of 50% coal/50% pellets at the University of Wisconsin showed reductions in emissions of SO_2, NO_x, and metals compared to 100% coal. Additional feasibility studies with favorable results were carried out in Canada, Oregon, and Wisconsin. A small college in Iowa has used pellets to supply much of its steam.

4.3 Effects of Recycling

The maximum purchased energy that could be saved by recycling newspapers in the United States, assuming a constant supply to the consumer, is 150×10^{12} Btu/year or the equivalent of approximately 8 million tons of coal annually ($[33.5 \times 10^6$ Btu/ton-23.6×10^6 Btu/ton$] \times 15.0 \times 10^6$ tons). The savings at current levels of recycling are lower. Similar energy savings could be achieved by burning ONP and recovering energy that would displace fossil fuels in electricity generation. However, if newspaper is recycled, the trees that would have been used for replacement newspaper are also saved. Therefore, because trees are a valuable resource, recycling of newspaper makes sense and should be encouraged. The purchased energy difference between recycling and WTE options for newspaper is

small, but the total energy input, including wood, is reduced by recycling of newsprint.

However, the situation for office paper is very different. In a modern kraft mill, paper can be made from wood with little purchased energy because of the use of by-product fuels, whereas recycling requires significant energy purchases because no fuel by-products are produced when wastepaper is pulped. Therefore, a decision to recycle office paper is a decision to use fossil fuels in place of wood. Recycling paper does keep it out of landfills, but so does combustion in a WTE or power plant, and energy recovery displaces additional fossil fuel. Combustion of paper in MSW (excluding newsprint) could displace more than 650×10^{12} Btu/year of fossil and nuclear fuels ($[60 \times 10^6$ tons$] \times [15.6 \times 10^6$ Btu/ton$] \times [0.7$, the relative efficiency of WTE plants to utilities]). This is equivalent to approximately 30 million tons of coal annually or approximately 3% of U.S. annual coal consumption.

The best option for paper depends on the objective. In the case of office paper, there is a choice. To save fossil energy and reduce landfill volume, burn wastepaper. To save trees, recycle paper. Therefore, it may be inappropriate for waste management planners and policymakers to exclude combustion for energy recovery from the acceptable waste disposition alternatives, as proposed U.S. legislation did very explicitly. Combustion for energy recovery (as opposed to incineration) as an appropriate option to recycling has been accepted in Europe, however, with The Netherlands adopting a 40% goal and Sweden 60%.

Significant energy conservation could be achieved by reuse of some paper products, such as corrugated boxes. Newspapers could also be reused. There are bins located in subway stations for collection of newspapers. The message on the bins is "Read, Ride, Recycle." They could also include "Reuse" in their list. Newspapers left by early commuters could be read by those arriving later. One possible mechanism would be to hire some of the people already soliciting money to reassemble and sell complete used papers at a reduced price. This would benefit the worker and the environment to a much greater extent than would recycling the paper after one use.

Another factor to be considered in decisions regarding paper production and disposition is emission of CO_2 to the environment, which is of concern because of possible global warming. Growing trees respire (take in) CO_2 at a rate that varies with their age. The new trees in the plantations that replace the ones cut for fiber take in more CO_2 than do the old forests. A study for Electric Power Research Institute (EPRI) estimated the effects on CO_2 emissions of various materials options for paper production and disposition. This study concluded that producing paper from plantation trees and burning the wastepaper for energy recovery is preferable, from the standpoint of greenhouse gas emissions, to all other options, including recycling. Thus, the same option for disposition of office paper is chosen if greenhouse gas reduction is the objective as when fossil fuel use and old-growth forest cutting are to be minimized.

Because a large amount of wastepaper is exported, the energy implications of used paper exports are considered briefly. For most categories of paper, U.S. consumption exceeds production, so net exports of waste imply an increase in primary production for domestic use. The balance of trade is better served by exporting higher value-added finished products. Export of old newsprint without importing newsprint increases domestic energy use and cutting of trees and does not serve the goal of energy conservation. Although export does avoid landfill, so would combustion or recycling, which would recover the embodied energy domestically. For office paper, an increase in primary production over secondary production implies greater wood use but smaller fossil fuel purchases. Therefore, if domestic energy conservation is the primary goal, it may be appropriate to encourage exports of waste office paper but not of old newspaper.

5. CONCLUSION

The most beneficial product life-cycle depends on the goals to be achieved. Trade-offs may have to be made, as in the case of kraft paper, in which trees and fossil fuels are traded off in the recycling decision. Therefore, the objectives of decision makers must be well defined before appropriate recommendations can be made. The optimal mix of reuse, recycling, and combustion for the United States may not necessarily correspond to the optimal mix for Europe and other areas of the world. Reuse is often overlooked but may be the best option when possible.

Technical and institutional barriers to increased recycling rates must be considered before mandating high recovery levels. High rates mean either separation of mixed waste, with its attendant technical difficulties, or development of improved source-separation procedures. The success of source-separation programs depends on the willingness of the

public to cooperate. Such incentives as bottle deposits have had some success; the limits of public cooperation need to be explored. In general, the cleanest, most easily recognizable waste products are recovered first. As recovery rates rise due to government mandates, economic pressures, or possibly public awareness, the quality of the material recovered will decline, and the energy and costs required to produce an acceptable product will rise. Eventually, a break-even point will be reached, at which the benefits of recycling are outweighed by the cost. This break-even point depends on the material and on the measures of cost being used.

Recycling of newspaper saves trees (a material and an energy resource) and fossil fuels, whereas combustion only displaces fossil fuels; recycling is preferable. Production of paper from chemical pulps, on the other hand, depends primarily on wood inputs for production but on fossil fuels for recycling, and the product can be burned to displace fossil fuels. More energy could be recovered by combustion of office paper than by recycling. In addition, kraft paper represents approximately 70% of the volume of material discarded, so it must be kept out of landfills. Combustion and recycling prevent paper from filling up landfills. A life cycle for office paper that included virgin production from dedicated plantations (to save old-growth forests and their value for recreation and wildlife habitat) and product combustion for energy recovery would minimize fossil fuel use as well as landfill volume. This is, in essence, substitution of biomass for fossil fuels. On the other hand, a life cycle including recycling minimizes the use of trees. The best answer depends on the grade of paper, the location, the fuel mix for the plants and the electricity supply, and the details of the process design. All of the alternatives must be evaluated objectively before decisions are made.

Acknowledgments

I thank the many helpful people in the paper industry who provided real-world feedback on the information in this article, enabling important updates and clarifications. Thanks especially to Benjamin A. Thorp at Georgia Pacific, who provided information, references, and personal contacts. Those who provided particularly useful input include Tom Brown at Caraustar, Jim Ramp at SP Newsprint, and Dedric Bergstrom at Glatfelter.

Glossary

air conditioner System composed of a refrigeration machine, heat exchangers, air ducts, filters, fans, and/or a humidifier that supplies air at specified parameters (temperature, humidity, and purity).

air-conditioning The simultaneous control of the temperature, humidity, and cleanliness of the air in a space as required either by the thermal comfort of persons that live or work in the respective space or by specified technological prescriptions.

Carnot cycle Thermodynamic cycle having theoretically the highest efficiency; used as a criterion in evaluating the effectiveness of a real cycle.

coefficient of performance Thermodynamic efficiency of a refrigeration cycle, expressed as the ratio between the heat removed from the low-temperature body and the external work consumed in order to remove that heat and to transfer it to the high-temperature body (surroundings).

cryogenics The deep-refrigeration domain involving temperatures less than 120 K.

refrigerant Substance in the fluid state that transfers to the surroundings the heat removed from the cooled space.

refrigeration The creation and maintenance within a medium of a temperature lower than that of the surroundings.

refrigeration system Complex aggregate of interrelated machines, heat transfer equipment, and control devices that together accomplish the refrigeration task.

The second law of thermodynamics, as stated by Clausius, asserts that heat can be transferred from a body of low temperature to a body of higher temperature only if external work is expended. The high-temperature body is called cooled medium (space) and the fluid that carries the removed heat and transfers it to the surroundings is called refrigerant. To be able to accomplish these tasks, the refrigerant must perform a sequence of thermodynamic processes the effect of which is the refrigeration of the cooled medium. The temperature domains of refrigeration correspond to air-conditioning (approximately 5°C), industrial refrigeration (0 to −150°C), and cryogenics (−150 to −273°C).

1. INTRODUCTION, APPLICATIONS, AND HISTORICAL BACKGROUND

The applications of refrigeration cover almost all domains of human activity: the food industry (processing, storage, and transportation of aliments), air-conditioning, ice manufacture, chemical industry (removal of the heat of reaction or of the heat of mixing, salts separation from solutions, and gases liquefaction), civil engineering and mining (freezing of moisture in unstable water-bearing soils), the manufacturing industry (heat treatments and metal cutting), the pharmaceutical industry, biomedical applications (blood and tissue storage and hypothermia in surgery), and fundamental research (atomic and nuclear physics).

In 1755, William Cullen obtained ice by evaporating water under low pressure. In 1805, Oliver Evans described theoretically the operation of the refrigerant's vapor compressor. J. Leslie developed the first absorption refrigeration system using the water–H_2SO_4 solution in 1810. In 1823, Michael Faraday published the first classical work on gases liquefaction and liquefied SO_2, H_2S, CO_2, and NH_3. Sadi Carnot described the refrigeration cycle in 1824. The first patent on a mechanically driven refrigeration system belongs to Jacob Perkins (1834, London), who proposed ether as a refrigerant. In 1844, John Gorrie, an American physician, constructed the first compression refrigeration machine using air as refrigerant. The first viable commercial system was put into operation in 1857 (James Harrison and D.E. Siebe) using ethyl as a refrigerant. The first absorption refrigeration machine was patented by Ferdinand Carré in 1859 and was designed to use the water–ammonia solution. At the beginning, these machines were used to produce ice. More than 600 absorption refrigeration machines had been sold in the United States by 1876. A. C. Kirk patented the reversed Stirling air refrigeration cycle in 1861. Carl von Linde (Germany) developed the first air liquefaction machine in 1895, and in 1908 Kammerlingh Onnes (Holland) liquefied helium. The first primitive version of a household refrigerator dates from 1898. In 1910, Maurice Leblanc (France) constructed the first steam jet refrigeration machine. Migley, Henne, and McNary (United States) used chlorofluorocarbons (CFCs) for the first time as refrigerants in 1930, and in 1933 the adiabatic demagnetization of paramagnetic salts (theoretically developed in 1926 by Debye and Giauque) was applied by W. F. Giauque and D. P. MacDougall to obtain temperatures of approximately 0.7 K. The lithium bromide–water solution was utilized after 1940 in industrial applications of the absorption refrigeration cycle (the Carrier and Trane systems). Small refrigeration machines that work on the basis of the reversed thermoelectric effect have been in use since 1958 to cool electronic components. In the 1980s, the adiabatic demagnetization of the nuclear spin system of copper allowed a temperature of 10^{-8} K to be reached.

The applications of refrigeration in the area of food processing and preservation have given impetus to the economic development of the meat-, fruits-, and vegetables-producing countries (usually located in the warm climate zone), allowing them to export these goods long distances. The evolution of the perishable foodstuff refrigeration techniques was consequently strongly related to the development of these countries. In 1873, Charles Tellier presented to the Academy of Sciences a note regarding fresh meat refrigeration. In 1875, the ship Paraguay, equipped according to Carré's specifications, transported refrigerated meat at -30°C from Buenos Aires to Le Havre, France. In 1876, Tellier uses for the first time an absorption refrigeration system to preserve meat, fruits, and vegetables on the ship Le Frigorifique during its journey from Rouen, France, to Buenos Aires. In 1882, Argentina used for the first time refrigeration systems in slaughterhouses.

Refrigerated fruits were marketed for the first time in the United States in 1910. In approximately 1930, refrigerated vegetables were marketed for the first time. Refrigeration trucks have been in use in the United States, Italy, and Great Britain since 1933. In 1938, the Hoveman quick refrigeration method (direct contact under vacuum of the foods contained in latex sacks) was developed.

2. BASIC PRINCIPLES OF REFRIGERATION

The refrigerant passes through the refrigeration system by continuously removing heat from the cooled medium and rejecting this heat to the surroundings (atmospheric air). To accomplish its task, the refrigerant must be in a fluid state. Due to the fact that the latent heat of vaporization–condensation is much higher than the sensible heat, the change of state of the refrigerant is preferred in order to maximize the transferred heat (the refrigeration effect). Consequently, in most refrigeration systems the cooling effect is achieved by the evaporation of a liquid, a process that extracts the amount of heat necessary to vaporize the fluid. By using a fluid that boils at a low temperature, heat is removed from the respective body (space) by cooling it. The greater the removed heat (latent heat of vaporization), the more intense the cooling effect. The refrigeration processes that occur in such a manner that the refrigerant undergoes a single time the heat removal from the cooled medium are called open-cycle processes. Some examples of open-cycle processes are (1) Water evaporation in atmospheric air: water cools the air by removing from it an amount of heat equal to the latent heat of evaporation, and (2) Endothermic mixtures: by using substances that require heat to mix, the formation of the mixture removes the heat from the space that

contains the mixture. Such endothermic mixtures contain different percentages of water and salts such as sodium chloride, ammonium chloride, calcium chloride, and ammonium carbonate.

Refrigeration processes that occur when the refrigerant, after undergoing a sequence of physical transformations, regains its initial state and repeats the same sequence of transformations a number of times are called closed-cycle processes. The basic refrigeration techniques (vapor–compression refrigeration, absorption refrigeration, and steam jet refrigeration) are examples of closed-cycle processes.

2.1 Methods of Refrigeration

Thermodynamic methods

- Open-cycle processes (evaporation of a liquid and refrigerant mixtures)
- Closed-cycle processes (mechanical vapor–compression, absorption refrigeration, steam jet refrigeration, and expansion of a compressed gas in centrifugal field of forces)

Electrical and magnetic techniques

- Reversed thermoelectric effect
- Adiabatic demagnetization of a paramagnetic salt

Methods used in cryogenics

- Gas throttling (the Joule–Thomson effect)
- Expansion of a gas with work output
- Reversed Stirling cycle
- Linde method
- Claude method
- Diffusion pump method.

The refrigeration capacity has been defined as the heat rate necessary to freeze a short ton (907 kg) of ice in 24 h. One ton of refrigeration = 12,000 Btu/h = 3.51 kW.

3. REVERSED THERMODYNAMIC CYCLES

Thermodynamic cycles allow the reciprocal conversion in a continuous manner of thermal energy into other kinds of energy. A work-supplying cycle is referred to as the power cycle (Fig. 1). Such cycles are traced clockwise and they remove heat from the hot reservoir, supply work, and reject heat to the cold reservoir. A reversed cycle is traced counterclockwise and consumes external work in order to cool the cold reservoir by transferring heat to the high-temperature reservoir (Fig. 1).

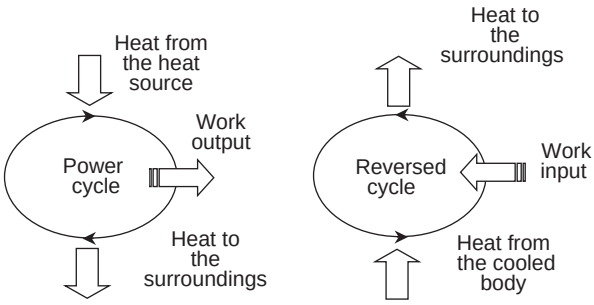

FIGURE 1 Power and reversed cycles.

Reversed cycles are used either to extract heat from bodies colder than the surroundings (cooling effect), referred to as refrigeration cycles, or to heat spaces by extracting heat from low-temperature sources (heating effect), called heat pump cycles.

The efficiency of a cycle is evaluated by the coefficient of performance (COP). In general, the effectiveness of a cycle is the ratio of the desired effect to the energy expended to obtain this effect. In the case of power cycles, the desired effect is the net work transfer, and the expended energy is the heat extracted from the high-temperature reservoir. For the reversed cycles, the desired effect depends on the purpose of the cycle, whereas the energy expense is the same, namely the external work input:

$$\mathrm{COP} = \frac{\text{desired (useful) effect}}{\text{work input}}.$$

If the purpose is the refrigeration of a space, then the desired outcome is the refrigeration effect (i.e., the heat removed from the low-temperature body):

$$(\mathrm{COP})_{\mathrm{refrig}} = \frac{\text{refrigerating effect}}{\text{work input}}.$$

The actual COP of the refrigeration systems is on the order of 3.

On the other hand, if the purpose of the cycle is to heat a space, the heating effect (the heat rejected to the high-temperature body) represents the required result:

$$(\mathrm{COP})_{\text{heat pump}} = \frac{\text{heating effect}}{\text{work input}};\ (\mathrm{COP})_{\text{heat pump}} = 4-5.$$

The reversed Carnot cycle is the reversible (ideal) cycle that has the thermodynamically highest possible COP and is composed of two isothermal and two isentropic (adiabatic) processes. Figure 2 shows the Carnot refrigeration (a–b–c–d–a) and the Carnot heat pump (1–2–3–4–1) cycles traced in the temperature–entropy plot. The processes that compose

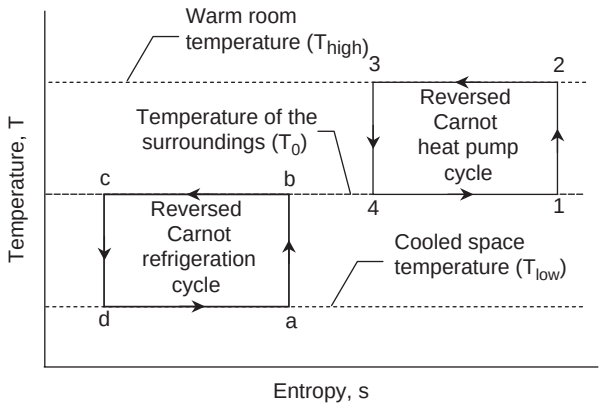

FIGURE 2 Reversed Carnot cycles.

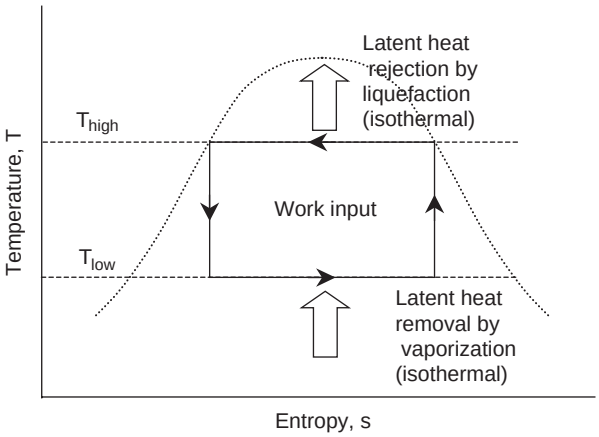

FIGURE 3 Reversed Carnot refrigeration cycle with liquefaction and vaporization of the refrigerant.

the Carnot refrigeration cycle are the adiabatic (isentropic) compression a–b from T_{low} to T_0, the isothermal heat rejection b–c to the surroundings at T_0, the adiabatic (isentropic) expansion c–d from T_0 to T_{low}, and the isothermal heat removal d–a from the cooled space at T_{low}. The COP of such a cycle is

$$(\text{COP})_{\text{refrig}}^{\text{Carnot}} = \frac{1}{(T_0/T_{\text{low}}) - 1}$$

The Carnot heat pump cycle consists of the adiabatic (isentropic) compression 1–2 from T_0 to T_{high}, the isothermal heat rejection 2–3 to the warm room at T_{high}, the adiabatic (isentropic) expansion 3–4 from T_{high} to T_0, and the isothermal heat removal 4–1 from the surroundings at T_0. The COP of a Carnot heat pump cycle can be expressed as

$$(\text{COP})_{\text{heat pump}}^{\text{Carnot}} = \frac{1}{1 - (T_0/T_{\text{high}})}$$

Perfect isothermal processes cannot be obtained with gases as working fluids since such processes require either infinitely low rates of expansion or compression to maintain the temperature rigorously constant at a finite heat transfer rate or infinitely high rates of heat transfer at finite rates of expansion or compression. The only way to obtain the isothermal processes of a reversed Carnot cycle is to use a fluid as refrigerant that liquefies from the gas state by ejecting its latent heat of vaporization at the higher temperature and that vaporizes at the lower temperature of the cycle by removing from the cooled space an amount of heat equal to the latent heat of vaporization. This cycle is represented in Fig. 3.

There are two major drawbacks to the reversed Carnot cycle with phase-change refrigerant:

1. The adiabatic compression between T_{low} and T_{high} occurs in the liquid–vapor region, which is why it is called wet compression. Due to the presence of the liquid phase, the liquid droplets may damage the compressor blades (erosion and pitting).

Solution: The compression should occur in the superheated vapor region.

2. The expansion involves a low-quality liquid–vapor mixture and therefore the turbine's efficiency is extremely low. Although this process provides work for the compressor, the price to be paid in terms of efficiency and difficult operation conditions does not justify the presence of the expander–turbine. The advantage of the net work production is surpassed by the losses.

Solution: The expansion process in the turbine is sacrificed in favor of a more thermodynamically effective process: throttling. The expander is replaced by a throttling valve, which destroys the potential energy of pressure and reduces the refrigerant's pressure from p_{high} to p_{low} but makes the system more reliable and simple.

The result is the so-called vapor–compression refrigeration cycle.

4. THE AIR–STANDARD REFRIGERATION CYCLE

The adiabatic expansion of a gas is accompanied by a significant decrease in temperature. Therefore, this phenomenon can be used in refrigeration cycles. When refrigerant leakage may occur in the cooled space occupied by living beings, or when air-conditioning is required (such as in the case of aircraft), air is the recommended working fluid. Other advantages result from the fact that air is available in unlimited quantities and involves no

manufacturing costs. Due to the low COP of the gas refrigeration systems, their use is recommended only when very well justified.

The air–standard refrigeration cycle is the reversed Brayton cycle. The direct Brayton cycle is the basic cycle of operation of gas turbine power systems.

4.1 Reversed Brayton Cycle

The cycle is composed of two isentropic processes (compression and expansion), an isobaric heat rejection to the surroundings, and an isobaric heat removal from the cooled space.

The reversed Brayton cycle requires relative high pressure ratios and large volumetric flow rates to achieve modest refrigeration capacities. For usual applications, vapor–compression or absorption refrigeration systems are more suitable from the standpoint of refrigeration capacity per system size. However, by modifying the scheme gas refrigeration systems can be used to liquefy air. Use of a regenerative heat exchanger, which cools the air below the temperature of the surroundings, leads to an important temperature decrease after the expansion, which means that the cooling effect is much more intense.

Figure 4 shows the scheme of the system and the temperature-entropy plot of the cycle. The processes that comprise the cycle are the adiabatic compression (1–2) of the air from p_{low} to p_{high} (in the compressor), the isobaric heat rejection (2–3) to the surroundings, the adiabatic expansion (3–4) of the air from p_{high} to p_{low} (in the turbine), and the isobaric heat removal (4–1) from the cooled space. The turbine supplies a fraction of the necessary work input for the compressor.

The functions of the environmental control system of the aircraft are to adjust the cabin temperature, pressure, and humidity; cool avionics; defog the windshield; and supply conditioned air to various systems and subsystems. The heat that is removed from the previously mentioned parts of the aircraft is transferred to the ambient air and to the vehicle's fuel supply. Figure 5 shows the schematic of the air refrigeration system for aircraft cooling and the cycle's *T–s* (temperature-entropy) diagram.

Atmospheric air is absorbed by the compressor, and it heats up and rejects heat to the surroundings. The cooled air expands in the turbine and its temperature decreases under the prescribed cabin temperature. The cooled air leaving the expander is mixed with the warm cabin air, and the result is refreshed air with the imposed temperature. In addition, a fraction of the cooling air is directed to the avionics and other systems that require cooling. The dashed line in Fig. 5 represents a fictitious process necessary to close the cycle.

The COP of the cycle strongly depends on the pressure ratio p_{high}/p_{low}: The lower the ratio, the higher the COP. Consequently, the compression ratio is limited to the values in the range 3–5. On the other hand, this fact leads to a decrease of the refrigeration effect (the heat extracted from the cooled body). To increase this amount of heat, regeneration is required: The air leaving the cooled space cools the air that leaves the heat transfer surface of the hot end of the refrigeration system. The air leaving the cooled space (state 1) is cold enough to cool the stream of air that has rejected heat to the ambient (state 3). Consequently, a regenerative heat exchanger is placed before the expander in order to achieve this supplementary cooling.

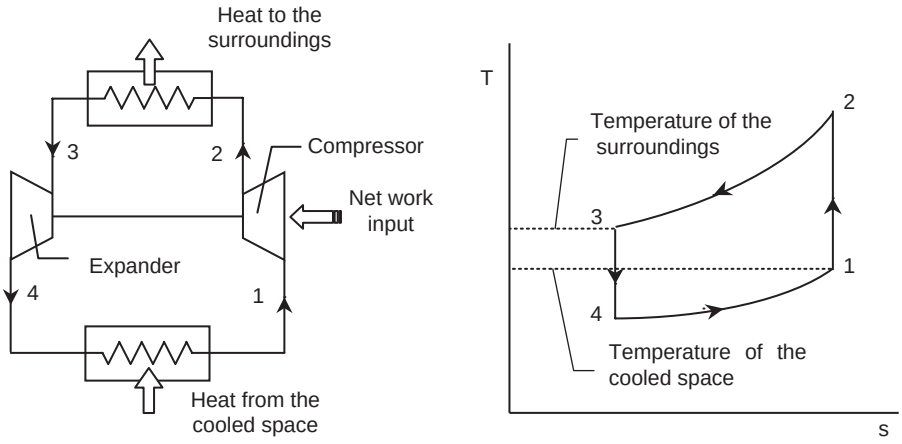

FIGURE 4 Scheme of the typical reversed Brayton refrigeration system and the temperature–entropy diagram of the cycle.

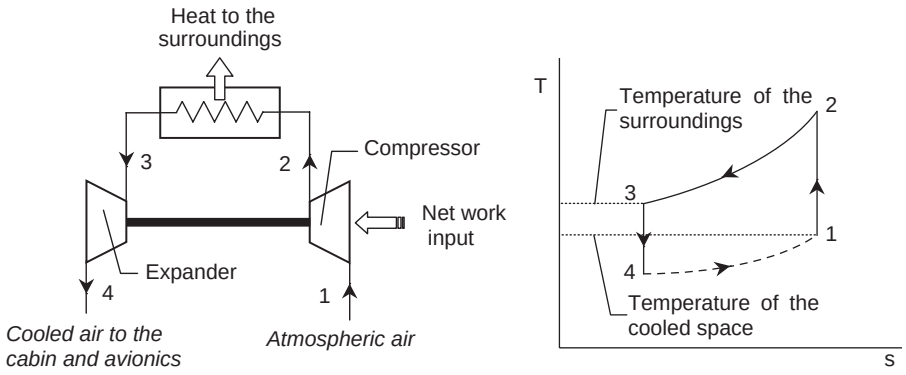

FIGURE 5 Open-cycle arrangement of the reversed Brayton refrigeration system for aircraft cooling.

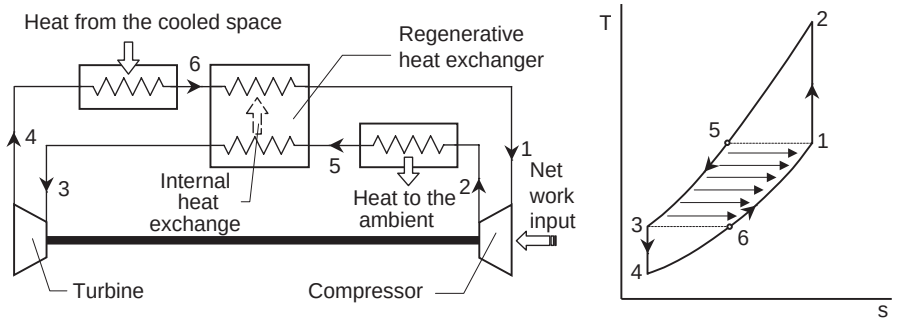

FIGURE 6 The air cycle with heat regeneration.

Figure 6 shows the reversed Brayton refrigeration system with heat regeneration. The processes are basically the same as for the reversed Brayton cycle. In addition, an internal heat exchange occurs in the regenerative heat exchanger: The air that rejected heat to the surroundings undergoes a supplementary cooling (process 5–3) by rejecting heat to the air that leaves the cooled space (process 6–1).

In order to reduce the work required by the system and thus to increase the COP, compression may be divided into two stages with intercooling. The pressure ratio for the two compression stages (compressors) must be the same so as to minimize the work input.

4.2 Bootstrap System

When using ram air as a heat sink to reject the generated heat within an aircraft, the corresponding takeoff gross weight (TOGW) penalty can be defined as the sum of the ram air circuit equipment weight and the additional fuel. Optimizing the aircraft performance means minimizing the ram air circuit TOGW penalty, and consequently the most light-weight and simple systems are required. This is the case for air–standard refrigeration systems. Due to severe weight limitations, most of the aircraft cooling systems use the open-loop bootstrap configuration.

Open-loop bootstrap systems use bleed air from the aircraft's engine compressor. This stream is compressed by the bootstrap compressor, cooled by the ram air, and passes through a turbine that drives the bootstrap compressor. The temperature of this stream after passing through the turbine is lower than the temperature of the load and thus cooling is performed and heat is rejected overboard together with the air.

Figure 7 shows a schematic of an open-loop bootstrap system with heat regeneration. Air is compressed in the aircraft engine compressor from the ambient pressure to the combustor pressure. In the lower stages of the engine compressor, a fraction (called bleed air) is extracted at an intermediate pressure and is sent to the bootstrap compressor, where its pressure and temperature are increased. Next, the air stream passes through the regenerative cross-flow heat exchanger, where it undergoes a preliminary cooling by rejecting heat to the "used" air that leaves the cabin. In the ram air heat exchanger, the ram air coming from the surroundings cools the air. In the bootstrap turbine, air is expanded to the cabin pressure and to a temperature lower than

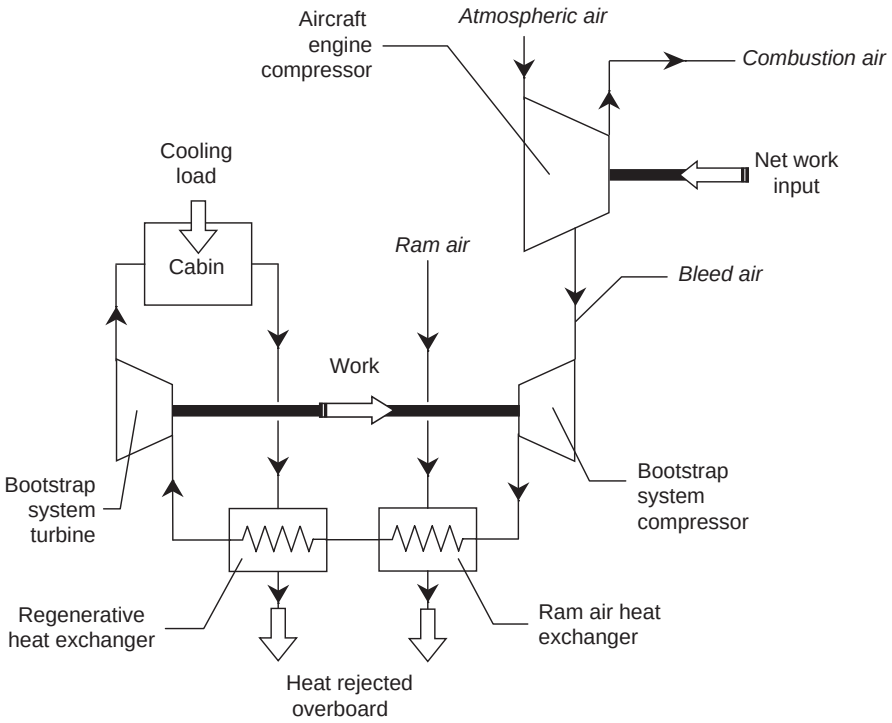

FIGURE 7 Open-loop bootstrap system for an aircraft.

the imposed cabin temperature. By flowing through the cabin and the aircraft systems, it removes the cooling load and afterward is sent to the regenerative heat exchanger to cool the incoming air. Finally, the used air is thrown overboard, as is the ram air. In the open-loop bootstrap system, the power supplied by the bootstrap turbine equals the shaft work rate absorbed by the bootstrap compressor.

5. VAPOR–COMPRESSION REFRIGERATION CYCLES

As discussed previously, the major drawbacks of the reversed Carnot cycle with vaporization and liquefaction make the Carnot refrigeration machine inappropriate for practical applications. By replacing the turbine (expander) with a throttling device and moving the compression into the superheated vapor domain, these shortcomings are eliminated and the result is the vapor–compression refrigeration (VCR) cycle.

5.1 Basic Vapor–Compression Refrigeration Cycle

The four basic components of a VCR system (Fig. 8) are discussed here. The compressor increases the refrigerant's pressure from p_{low} to p_{high} (the isentropic process 1–2 in Fig. 8) and consequently its temperature becomes higher than that of the high-temperature region. In the condenser, the refrigerant rejects to the surroundings (or to a cooling medium) its latent heat of condensation and liquefies (the isobaric process 2–3). The expansion (or throttling) valve reduces the refrigerant's pressure (the isenthalpic process 3–4) from p_{high} to p_{low}, which is characterized by a boiling point below the temperature of the cooled space. In the evaporator, the refrigerant boils by removing heat from the refrigerated space (the isobaric process 4–1) and turns into superheated vapor that is sucked by the compressor. This process is repeated (Fig. 8).

The condenser and the evaporator are heat exchangers and the expansion valve is a capillary tube or a short-tube orifice. The throttling process occurs at constant enthalpy, which is why it is called isenthalpic. In modern refrigeration systems, an active throttling device that senses the temperature in the evaporator replaces the capillary tube and adjusts the pressure drop in order to control the cooling effect.

The expansion of the high-pressure liquid in the expansion valve results in a low-quality, two-phase fluid. The COP of the vapor–compression

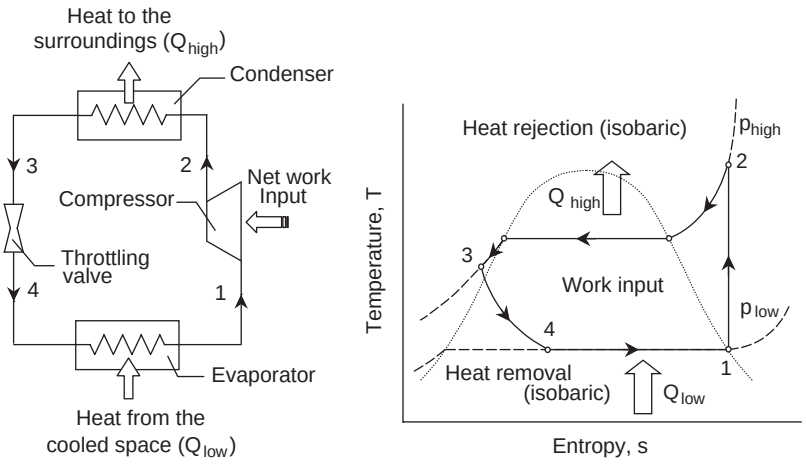

FIGURE 8 Scheme of the basic vapor compression refrigeration system and the cycle representation in the temperature–entropy diagram.

refrigeration system is given by

$$\text{COP} = \frac{h_3 - h_1}{h_2 - h_1}$$

where h is the specific enthalpy.

Irreversibilities inevitably occur in actual processes, and therefore the actual performance of the vapor–compression refrigeration system is less effective than that of the ideal cycle. Such an irreversible process is the nonisentropic compression in the compressor, which results in larger work input and an additional vapor superheating that increases h_2 and thus decreases the COP. Another effect that reduces the COP (h_3 decreases) is the slight liquid supercooling after the condensation due to the variation in temperature of the surroundings.

The lowest cooling temperature of the system is determined by the pressure ratio of the compressor and by the characteristics of the refrigerant. In a simple cycle, typical cooling temperatures vary from -50 to 2°C. Reciprocating compressors operate with pressure ratios up to 9:1. Outside the previously mentioned temperature range, either the compressor performance becomes unacceptably poor or the risk of excessive heating endangers lubrication, bearings, etc. By staged compression, the inferior temperature limit is lowered to -100°C. There are limitations regarding the refrigerant's characteristics: the high specific volume at low temperatures, which necessitates large size equipment; the too small specific volume of the condensed liquid; and the too high condensing pressure. In this case, the solution is to use cascaded systems with two or more refrigerants, each of which operates in a separate cycle. The advantage of this approach is the possibility to choose for each cycle the best refrigerant from the standpoint of properties, which ensures the best possible operation. With cascaded systems, the lowest temperature that can be obtained is approximately -150°C.

Although centrifugal compressors may operate with pressure ratios up to 18:1, due to the low efficiency caused by the high temperature at the end of compression, the practically acceptable pressure ratio is the same as that for reciprocating compressors. To increase the efficiency, interstage cooling is used in the so-called economizers. In such equipment, relatively cool gas is mixed with the hot gas resulting from the compression process.

5.2 Refrigerants

More than 30 refrigerants are known, of which 10 are the most used. Refrigeration involves a large variety of applications and parameters. Consequently, one refrigerant cannot meet all the requirements. This is why there are different refrigerants.

5.2.1 Requirements

The general criteria to be met by a refrigerant candidate are

- High latent heat of vaporization in order to minimize the amount of refrigerant used
- Freezing point below the operating temperature at the cold end of the system
- Condenser pressure sufficiently low to avoid too high mechanical stresses in the components of the refrigeration system

- Evaporator pressure above the atmospheric pressure in order to eliminate the risk of leakage of air and moisture into the refrigeration system
- Critical parameters (temperature and pressure) well above the operating ones
- Low specific volume in the suction section of the compressor; large specific volume requires a larger size compressor and high cross section areas of the low-pressure piping
- Low manufacturing cost
- Good heat transfer properties (thermal conductivity, specific heat, and viscosity)
- Nonflammable, nontoxic, noncorrosive, and nonexplosive.

The toxicity of refrigerants, combined with their flammability, is rated by a class system. Class A designates refrigerants that are nontoxic at concentrations less than 400 parts per million (ppm) and class B refers to refrigerants that are toxic at less than 400 ppm in the air. Odorless toxic refrigerants should contain a warning agent (e.g., acrolein, which is an irritant to eyes). The flammability is evaluated by numbers ranging from 1 to 3 (1, nonflammable; 2, moderately flammable; 3, highly flammable). For instance, a refrigerant rated A2 indicates that it is nontoxic at less than 400 ppm and moderately flammable. Ammonia is rated B2.

5.2.2 Classification

The refrigerants are classified as showed in Table I. Almost half of the vapor–compression refrigeration systems use ammonia as refrigerant. Other working fluids usually referred to as halocarbons or halogenated hydrocarbons are the CFCs and the hydrochlorofluorocarbons (HCFCs), which are generally

TABLE I

Classification and Physical Properties of the Refrigerants

Class	Chemical name	Chemical formula	Number designation	Normal boiling point (°C)	Critical temperature (°C)	Critical pressure (bar)
Inorganic compounds	Water	H_2O	—	100	374	221.29
	Ammonia	NH_4	R-717	−33.35	132.4	113
	Carbon dioxide	CO_2	R-744	−78.5	31	73.3
	Sulfur dioxide	SO_2	R-764	−10.01	157.5	78.8
Hydrocarbons	Methane	CH_4	R-50	−161.5	−82.5	44.4
	Ethylene	C_2H_4	R-1150	−103.5	9.5	51.2
	Ethane	C_2H_6	R-170	−88.6	32.2	48.9
	Propylene	C_2H_6	R-1270	−47.7	91.4	46
	Propane	C_3H_8	R-290	−42.3	96.8	42.6
	Isobutane	C_4H_{10}	R-600	−11.7	113.7	36.7
Chlorofluorocarbons	Tetrachloromethane	CCl_4	R-10	76.7	283.14	45.6
	Trichlorofluoromethane	CCl_3F	R-11	23.7	214.1	34.1
	Dichlorodifluoromethane	CCl_2F_2	R-12	−29.8	112	41.15
	Chlorotrifluoromethane	$CClF_3$	R-13	−81.5	28.8	38.6
	Tetrafluoromethane	CF_4	R-14	−128	−45.5	37.5
	1,1,2-Trichlorotrifluoroethane	CCl_2FCClF_2	R-113	47.7	214.1	34.1
	1,2-Dichlorotetrafluoroethane	$CClF_2CClF_2$	R-114	3.5	145.7	32.8
	Monochloropentafluoroethane	$CClF_2CF_3$	R-115	−38	80	32.4
Hydrochlorofluorocarbons	Dichloromonofluoromethane	$CHCl_2F$	R-21	8.9	178.5	51.66
	Chlorodifluoromethane	$CHClF_2$	R-22	−40.8	96	49.36
	Dichloromethane	CH_2Cl_2	R-30	39.2	235.4	59.7
	Chloromethane	CH_3Cl	R-40	−24	143	66.8
	Chlorodifluoroethane	CH_3CClF_2	R-142	−9.25	136.45	41.5
	Trifluoroethane	CH_3CF_3	R-143	−47.6	73.1	37.8
	Difluoroethane	CH_3CHF_2	R-152	−25	113.5	44.9
Azeoltropes mixture	R-22, R-115	—	R-502	−45.6	90	42.6

nonflammable and nontoxic. CFCs and HCFCs have proven to be harmful to the ozone layer and contribute to the greenhouse effect responsible for global warming. For this reason, national and international regulations have restricted their use, recommending their substitution with other fluids that are not harmful.

Hydrocarbons such as propane and butane are cheap and suitable as refrigerants, except they are flammable. However, careful handling, a good system design, and the avoidance of leakage by appropriate safety measures reduce or eliminate the risks of explosion.

Mixtures of two or more refrigerants are also used. They are of two types: zeotropic mixtures, which exhibit a saturation temperature range (called temperature glide) at constant pressure, and azeotropic mixtures, which behave like a single component, evaporating or condensing at a fixed temperature at constant pressure (Table I).

5.2.3 Environmental Problems, Regulations, and Substitution Agents

In 1986, world production of CFCs was 950,000 tons. The highest CFC quantities are used in air-conditioning (house and automotive); in the United States and Japan, 40 and 25%, respectively, of R-12 production in 1986 were directed to this area of applications. Automobile production in 1990 was 40 million pieces (40% air-conditioned).

In 1974, Rowland and Molina discovered that CFCs destroy the ozone layer, which acts like a shield for life on Earth against the cosmic ultraviolet (UV) rays. In 1985, a 40% depletion of the ozone layer was observed. The mechanism of the phenomenon, which takes place in the stratosphere, consists of the reaction (triggered by UV radiation) of a molecule of CFC with ozone (O_3), the result of which is the liberation of an atom of chlorine, which combines with ozone to form oxygen and a molecule chlorine–oxygen. This molecule may react with a free atom of oxygen, resulting in molecular oxygen and a free chlorine atom, which again reacts with ozone and the process is repeated.

The ozone-depletion potential (ODP) of a refrigerant defines the potential damage caused by the refrigerant molecule to the ozone in the stratosphere and is evaluated based on the estimated life of the refrigerant in the atmosphere. It seems that ozone depletion is proportional to the squared concentration of chlorine in the atmosphere. This concentration is approximately 3 parts per billion in volume, and it is estimated that it will double by 2020. The life span in the upper atmosphere is 120 years for R-12, 90 years for R-113, and 65 years for R-11. CFC molecules are nontoxic and chemically stable (inert) in the lower atmosphere and in the troposphere (up to 10 km in altitude). They become chemically active in the stratosphere, where they are decomposed by the cosmic UV radiation and are destroying the ozone layer.

Another harmful effect of the CFCs and HCFCs relates to the fact that they are opaque to the infrared radiation emitted by the earth as a result of its exposure to the sun's thermal radiation. As a result, infrared thermal radiation is confined in the system Earth–atmosphere and thermal energy is accumulated instead of being emitted, leading to global warming. The previously described mechanism constitutes the greenhouse effect (the glass covering a greenhouse acts in a similar manner by heating the space of the greenhouse).

The intensity of this phenomenon associated with a CFC or HCFC is evaluated by means of the halocarbon global warming potential (HGWP). For instance, a molecule of R-12 has the same effect as 5000 molecules of CO_2.

CFCs exhibit the highest ODP and HGWP. HCFCs are less stable and therefore their ODP and HGWP are correspondingly lower. Hydrofluorocarbons (HFCs) have zero ODP since fluorine does not react with ozone, but some of them are characterized by equal or larger HGWP than that of the HCFCs. Hydrocarbons have zero ODP and HGWP. Figs. 9 and 10 illustrate the relative ODP and HGWP of some of the most popular CFCs.

Due to their harmful effects, regulations have been issued by governments in order to ban or to reduce the use and production of these substances. In the

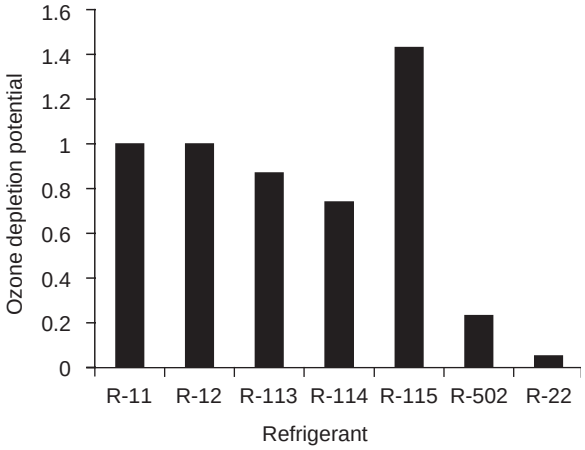

FIGURE 9 The relative ozone-depletion potential of some of the most used CFCs (normalized with respect to R-11).

late 1970s, the United States and Canada prohibited the use of CFCs as aerosols. In 1987, the Montreal Protocol was signed by 43 countries, which agreed to freeze the CFCs production at the 1990 level and to gradually decrease production by 20% by 1994 and by 50% by 1999. In the United States, the production of CFCs was to cease by 1996 and that of HCFCs is scheduled to cease by 2020. The European Community, after amendments made in London in 1990 and introduced in the Copenhagen Protocol in 1992, decided to eliminate the use of CFCs by 1995. The most promising substitution agents seem to be the HCFCs and the HFCs. Unfortunately, by increasing the amount of hydrogen in the molecule, the flammability increases, whereas by increasing the amount of fluorine, the HGWP increases. Therefore, the Copenhagen Protocol states that the HCFCs should play only a transitory role by 2030. After this deadline, only HFCs will be accepted.

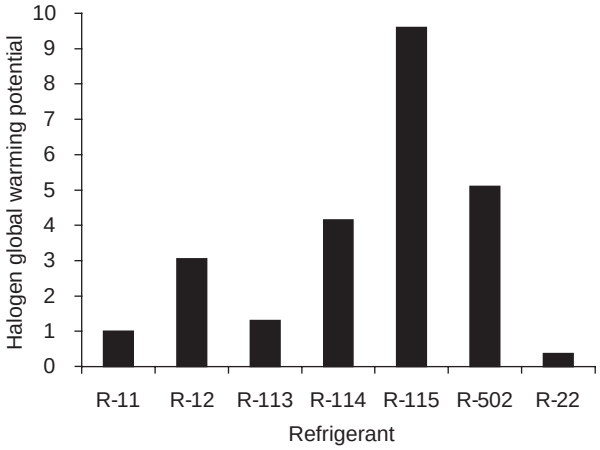

FIGURE 10 The relative halogen global warming potential of some of the most used CFCs (normalized with respect to R-11).

The refrigerants to be replaced are R-10–R-12 and R-113–R-115. Proposed substitution agents (all of them HFCs and HCFCs) are R-141b, R-123, R-22, R-125, R-143, and R-124:

R-123 ($CHCl_2CF_3$) replaces R-11 and R-113: ODP = 0.5 and HGWP = 0.1.
R-141b (CH_3CCl_2F) replaces R-11 and R-113: ODP = 0.08 and HGWP = 0.092.
R-134a (CH_2FCF_3) replaces R-12: ODP = 0 and HGWP = 0.285.
R-290 (propane) replaces R-12: ODP = 0 and HGWP = 0.

An overview of the substitution solutions that are considered is presented in Table II.

TABLE II

Substitution Substances for the CFCs[a]

	Transition refrigerants			Chlorine-free alternatives for medium and long term

5.3 Variations of the Vapor–Compression Refrigeration System

Some solutions will improve the performance or the flexibility of the vapor–compression refrigeration systems. The most used are presented here.

5.3.1 Multiple Evaporators

These systems operate at more than one evaporator temperature. The stream of liquid refrigerant coming from the condenser is divided and each fraction is throttled at a different pressure, which determines the evaporation temperature. The higher pressure fractions, after turning into vapor in the corresponding evaporators, pass through valves in which they expand in order to match the lowest pressure and to allow mixing. Such systems are used to cool different temperature loads.

5.3.2 Multistage Compression

The reason why such systems are used is to minimize the compressor work input by means of intercooling (gas cooling) between the compression stages. Vapor coming from the evaporator is compressed adiabatically by the first-stage compressor (Fig. 11). The heated vapor that results from the compression process mixes in the gas cooler with the relatively cool vapor coming from the condenser at $p_{intermediate}$. The mixture is compressed in the second stage up to the condenser pressure, p_{high}. After rejecting heat, the vapor stream (whose temperature is lower than the temperature after the first compression stage) is divided into two streams: the main one, which goes to the main expansion valve and to the evaporator, and the secondary one, which is directed to the gas cooler. Since its pressure p_{high} exceeds $p_{intermediate}$, a throttling valve is necessary to reduce it to $p_{intermediate}$ (Fig. 11).

5.3.3 Cascaded Systems

In multistage systems, the pressure ratio p_{high}/p_{low} cannot be increased above a certain limit, which is imposed by the refrigerant's triple and critical points (p_{low} must be higher than p_{triple} and p_{high} must be less than $p_{critical}$). These limits impose a pressure range that is different for each refrigerant. Moreover, an evaporator pressure below 0.1 bar is not recommended due to the bulky compressor cylinders required for the high specific volume of the refrigerant at such a low pressure and to the special safety measures that have to be considered in order to prevent air from leaking into the installation. Therefore, for a three-stage vapor–compression refrigeration system, the highest acceptable value for the overall pressure ratio is 100–110. The temperature gap corresponding to this value is approximately 100–120°C; consequently, the minimum refrigeration temperature to be achieved is approximately

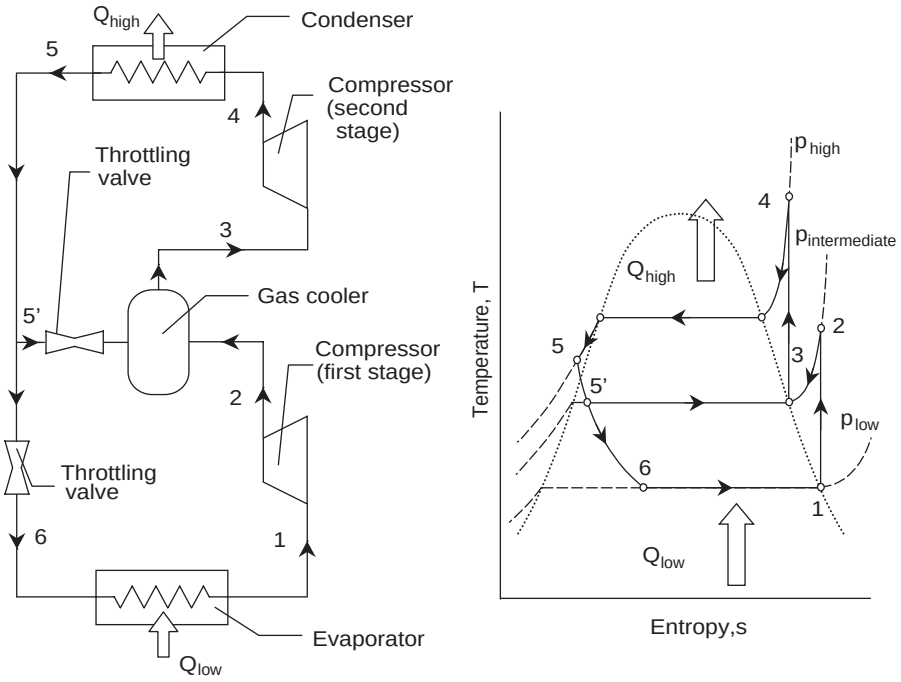

FIGURE 11 Scheme and cycle representation of a two-stage vapor-compression refrigeration system.

−70 to −80°C, considering that the condensation temperature varies from 30 to 40°C. When a single system has reached its limits, to achieve a more effective refrigeration effect, a chain of refrigeration systems using different refrigerants is necessary. Such a configuration is referred to as a cascaded system. Each of the components of a cascaded system may be single stage or multistage. With such configurations, temperatures of approximately −200°C are achievable. For instance, by cascading four systems—ammonia for the range 30 to −33°C, followed by ethylene (−28 to −104°C), methane (−99 to −160°C), and nitrogen—a temperature of −196°C can be obtained. The components in a cascade system are linked by heat exchangers, which operate as an evaporator for the "upper" component and as a condenser for the following system in the sequence.

6. ABSORPTION REFRIGERATION SYSTEMS

The idea of using an absorption fluid as a refrigerant carrier derived from the drawback of VCR systems that the gas compression requires a high work input. A pump that requires practically no work to increase the pressure in the refrigeration system replaces the complicated and work-consuming compressor.

There are two major advantages of absorption refrigeration systems (ARSs) compared with VCRs: No CFCs or HCFCs are used as refrigerants, and they use heat from different sources, such as combustion, industrial processes, waste heat (an economical solution for recovery), or solar heat.

6.1 Principles of Absorption Refrigeration

The cost of the energy supplied to the compressor represents the cost of operating a VCR system. This is why a great deal of effort has been dedicated to designing work-reducing techniques. Whatever the work-saving methods involved, as long as a gas must be compressed, a large amount of input work is required. On the other hand, increasing a liquid's pressure involves practically no work since liquids are almost incompressible. The idea of compressing a liquid in order to save work led to the development of absorption cycles. The price to be paid results from the fact that in order to accomplish the cycle, the refrigerant has to be absorbed by the liquid before compression and must be released after. The absorption process at constant pressure involves a heat exchange: When the liquid (absorbent) absorbs the refrigerant, it releases heat (absorption heat) that has to be removed because the increase in temperature results in a decrease in the solubility of the refrigerant. When the solution containing the absorbed refrigerant must liberate it, heat input from an exterior source is necessary. Therefore, heat represents the primary energy used by ARSs.

The solution poor in refrigerant is called weak solution, whereas the solution rich in refrigerant is referred to as strong solution. An ARS is composed of a generator, in which heat is added to the strong solution to release refrigerant vapor; a condenser, throttling valve, and evaporator, which perform the same functions as for VCR systems; a pump that increases the pressure of the solution; and an absorber, in which the weak solution coming from the generator absorbs the refrigerant vapor by rejecting the absorption heat to a cooling medium (usually water). Fig. 12A shows the scheme of an ARS. There are two paths:

The refrigerant path: The high-pressure vapor leaves the generator (state 1), condenses in the condenser by rejecting heat to the surroundings, and leaves it in state 2. Its pressure is reduced in the first throttling valve (state 3) and it evaporates at low pressure in the evaporator by removing heat from the cooled space. State 4 corresponds to saturated low-pressure vapor. The vapor is absorbed in the absorber by the weak solution.

The solution path: The pressure of the strong solution (state a) is increased by the pump (state b). The absorption occurs in the absorber and is facilitated by the heat removal performed by the water that flows through the cooling coil. The strong solution enters the generator, where heat is added in order to perform the separation process of the vapor from the solution. The high-pressure vapor leaves the generator, and the weak solution that results from the separation process (state c) is throttled in the second throttling valve to the absorber pressure (state d).

To save energy, a regenerative heat exchanger (also called economizer) may be placed on the solution path (Fig. 12B). The weak solution that leaves the generator still contains enough thermal energy to preheat the weak solution entering the generator. Moreover, the process of solution enrichment occurring in the absorber generates heat that must be removed. Precooling of the weak solution can improve this process. The strong solution

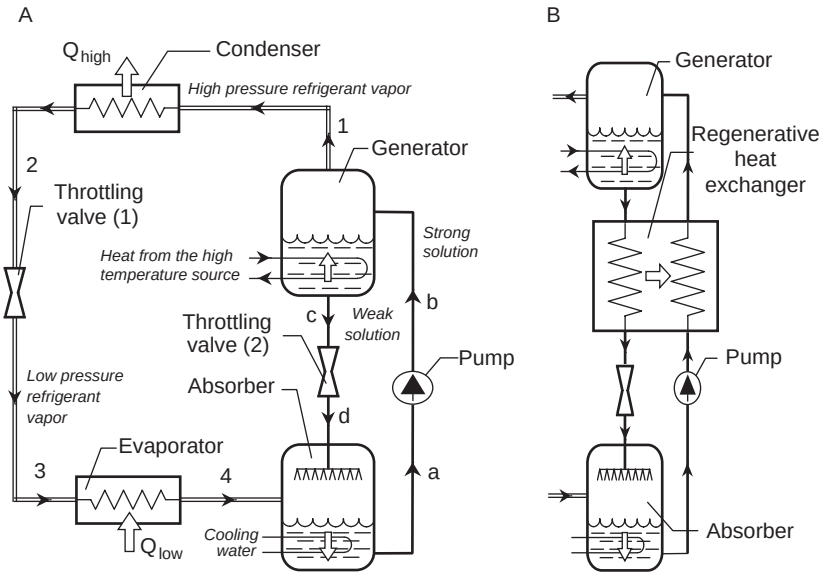

FIGURE 12 Scheme of an absorption refrigeration system: (A) without heat regeneration; (B) with heat regeneration (only the solution path is schematized).

preheating before the generator saves energy by "returning" heat to the separation process that occurs in the generator.

The COP of the ARS is

$$\mathrm{COP} = \frac{Q_{\mathrm{low}}}{Q_{\mathrm{high}} + W_{\mathrm{p}}},$$

where Q_{low} is the heat removed from the low-temperature body, Q_{high} is the heat rejected to the surroundings (the high-temperature body), and W_{p} is the work input of the solution pump.

Supposing that the heat transfer processes are isothermal and reversible and that the pump work input is negligible, the previous expression of the COP becomes

$$\mathrm{COP} = \frac{T_{\mathrm{high}} - T_{\mathrm{A}}}{T_{\mathrm{high}}} \times \frac{T_{\mathrm{low}}}{T_{\mathrm{A}} - T_{\mathrm{low}}},$$

where T_{low} and T_{high} are the temperatures of the cooled space, respectively, of the surroundings, and T_{A} is the temperature of the heat removal in the absorber. Note that this equation represents the upper limit of the COP (under ideal conditions). Due to the irreversibilities, the actual COP is less than this maximum value. In terms of actual COP, ARSs are generally poor compared with VCRs. For instance, the COP of a lithium bromide–water system is approximately 0.6, which can be improved by different techniques but with increased capital costs.

Most ARSs use the pairs water–ammonia and lithium bromide (LiBr)–water. They can be coupled with vapor–compression refrigeration systems and are used especially in the chemical industry and in air-conditioning. Their main advantage is the simultaneous refrigeration and warm water supply. The most common pairs used in ARSs are presented in Table III.

TABLE III

Absorbent–Refrigerant Pairs Used in Absorption Refrigeration Systems

Absorption Medium	Refrigerant
Water	Ammonia
Water	Methyl-amine
Lithium chloride or bromide	Water
Paraffin oil	Toluene or Pentane
Sulfuric acid	Water
Dimethyl ether or tetraethylene glycol	Methylene chloride
Sodium or potassium hydrate	Water

6.2 Water–Ammonia System

This system is used especially for small refrigerators with gas or electric heating. There are three major differences with respect to the LiBr–water systems:

1. The water–ammonia systems operate at high pressures (4–5 bar), whereas the LiBr–water machines operate at 0.04–0.08 bar.

2. Whereas LiBr is not volatile, water releases vapor during the distillation process, and therefore a rectifier is required before the condenser to separate water vapor from ammonia vapor.

3. The cooling medium for the water–ammonia system is air, whereas for the LiBr–water machines water is used as coolant.

6.2.1 Platten–Munters (Servel) System

This is a water–ammonia ARS used especially for household refrigerators and has no moving parts (pumps). The main feature of this system is the presence of an inert gas (hydrogen) that has two main functions: (i) It plays the role of an equalizing medium for the pressures in the system and thus it eliminates the necessity of a pump between the absorber and the generator, and (ii) it acts as a carrier for the refrigerant.

The pressure is the same in the entire system, namely the condenser pressure. Ammonia has different partial pressures in different regions of the machine. The ammonia vapor that leaves the generator and the rectifier chases the hydrogen from the condenser. After the condenser, liquid ammonia directly enters the evaporator, without any throttling. Here, ammonia evaporates and its vapor diffuses among the hydrogen molecules. The evaporation occurs due to the difference between the partial pressure of the refrigerant vapor in the close vicinity of the free surface of the liquid and the partial pressure of the refrigerant vapor in the hydrogen–ammonia mixture. This mixture is heavier than pure hydrogen. It moves downward and leaves the evaporator entering the absorber, where the weak solution absorbs the ammonia vapor from the mixture, which becomes lighter and returns to the evaporator. The strong solution leaving the absorber passes through a coil, in which a fraction of it releases vapor that "pumps" the solution to the generator by the thermosyphon effect. The heating of the generator is performed either electrically or with combustion gases. The separation process occurs in the generator and the weak solution returns to the absorber by gravity. The ammonia vapor enters the condenser and the cycle is repeated.

6.3 Lithium Bromide–Water System

The refrigeration systems belonging to this family can be classified from the standpoint of the origin of the heat source in indirect-fired systems, which use steam or hot liquid; direct-fired systems with heat from combustion gases; and heat-recovery systems, which use waste heat. Alternative heat sources, such as solar or geothermal energy, are also used.

The absorbent (LiBr) acts as a refrigerant carrier from the low-pressure region to the high-pressure region of the machine. For water chilling, the COP of a LiBr–water ARS varies in the range 0.65–0.7. Heat input temperatures for single-stage machines are usually 95°C, whereas for two-stage ones they are approximately 150°C.

ARSs that use this pair usually serve as water chillers for air-conditioning applications. Water is chilled to approximately 5°C. The condenser temperature is 40–45°C, whereas the evaporator temperature is 4–7°C. Temperatures below the water's triple point are not reachable since water (the refrigerant) freezes.

Low-power units used in unitary air conditioners are natural gas fired. Very high-power units with a refrigeration capacity of up to 6 MW use 1.5–2 bar of steam as a heat source and are cooled with water at 26–30°C.

6.3.1 Carrier Absorption Refrigeration System

ARSs operate at two pressure levels, p_{high} and p_{low}. The pressure is p_{high} in the generator and condenser and p_{low} in the evaporator and absorber. Therefore, the components operating at the same pressure level may be grouped in the same vessel. The Carrier system uses this arrangement, as shown in Fig. 13.

The LiBr–water solution boils in the generator by removing heat from the high-temperature heat source (steam, hot water, solar heat, or waste heat). Only water vapor is released. The vapor enters the condenser, where it condenses by rejecting the latent heat of evaporation to the cooling water that flows through a coil. The resulting liquid refrigerant passes through a throttling valve, where its pressure is reduced and it turns into a liquid–vapor mixture, which enters the evaporator. Here, the mixture evaporates by removing heat from the cooled agent (chilled water). To improve the process, the liquid fraction of refrigerant is recirculated by a refrigerant pump and sprayed onto the heat transfer surface of the cooling coil. The vapor passes to the absorber, where it is put into contact with the sprayed weak solution and is absorbed. The strong solution that results is pumped and flows through the economizer, where it removes heat from the downstream flowing weak solution and enters the generator. The process is then repeated.

The coolant (water) first flows through the absorber, where it removes the absorption heat from

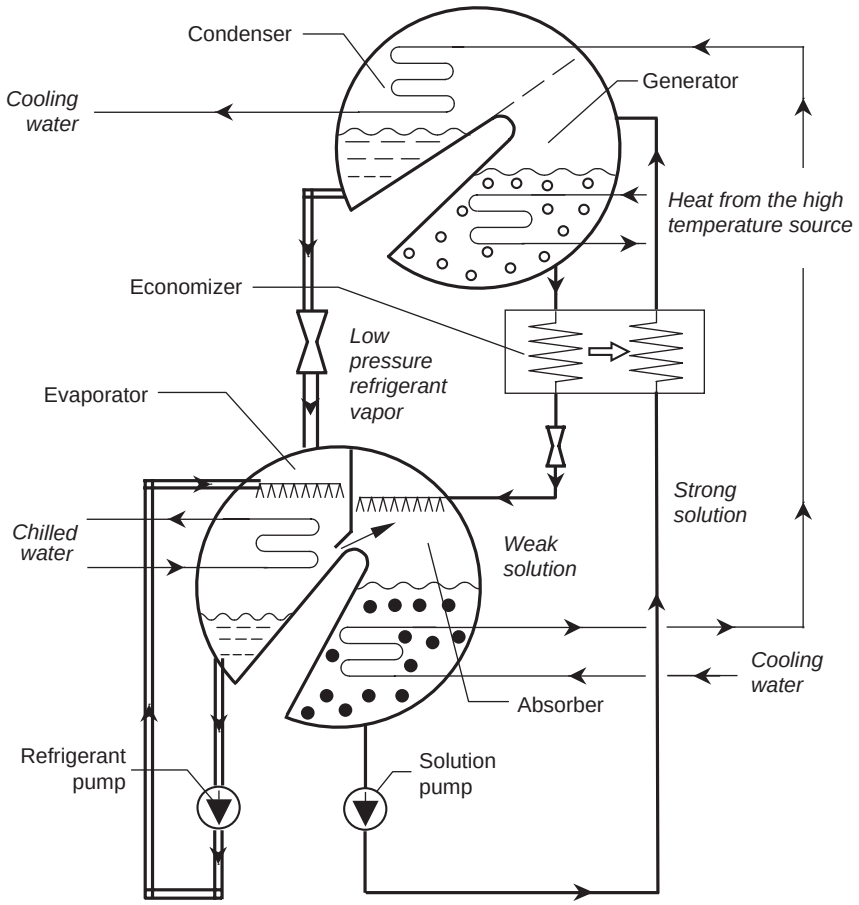

FIGURE 13 Scheme of the Carrier absorption refrigeration system.

the solution, and subsequently goes to the condenser, where it is heated by the condensing refrigerant.

In contrast to the Carrier system, which uses two vessels, in the Trane system a single vessel contains all the components of the absorption refrigeration machine. A comparison between the water–ammonia and the LiBr–water systems is provided in Table IV.

7. STEAM JET REFRIGERATION

The specific feature of the steam jet refrigeration (SJR) is the use of water as refrigerant. From the thermodynamic standpoint, water is a very good refrigerant since it has a high latent heat of evaporation and it is cheap, nontoxic, nonflammable, and available in unlimited quantities. On the other hand, water exhibits two important shortcomings: very low saturation pressures and very high specific volumes at usual temperatures. For these reasons, the use of water as refrigerant is limited to temperatures in the range 8–11°C and very rarely below 4°C. To obtain an evaporator temperature of 7°C, p_{low} must be approximately 1 kPa. Consequently, very large specific volumes (on the order of 129 m^3/kg) are involved in the compression process, and only centrifugal compressors are able to manipulate them. Another option is to use steam ejectors, which represent an economically convenient solution when steam is available and is not produced just for this purpose.

SJR is actually VCR with the mechanical compressor replaced by an ejector (or jet compressor). Although much less efficient than centrifugal compressors, jet compressors are simple (no moving parts) and inexpensive. The condenser operates at subatmospheric pressure and air leakage into the condenser is to be expected. For this reason, a secondary ejector driven by a fraction of the steam main stream removes the noncondensable gases. The high-pressure steam used to compress the low-pressure steam coming from the evaporator must also condense; therefore, the heat transfer surface area of the condenser must be large enough to

TABLE IV

Comparison between the Water–Ammonia and Lithium Bromide–Water systems

Criterion	Water–ammonia	Lithium bromide–water
Saturation temperatures difference	Relatively low	Very large
Refrigerant vapor purity	Poor	Very high
	The vapor released in the generator is a mixture of water and ammonia vapor and therefore a rectifier is required.	The vapor in the generator is pure water vapor. No rectifier is required.
Absorption rate	High	Low
	No recirculation is needed.	LiBr slowly absorbs water and therefore a recirculation of the weak solution in the absorber is necessary.
Toxicity	High	Relatively low
Corrosion	Noncorrosive toward ferrous metals	Corrodes nonferrous metals
	Ammonia corrodes copper and its alloys.	
Heat supply shutoff	Accepted	Not accepted
	The cooling of the solution due to the lack of heat input does not result in crystallization, which occurs at temperatures far below the ambient temperature.	The strong solution crystallizes at ambient temperature. In such situations, the installation has to be emptied and the solution is stored in heated reservoirs.

achieve this task. As a consequence, the size of the condenser must be three or four times the size of a VCR condenser.

The capacities of SJR systems are in the range 35–3500 kW. Typical applications of such systems are foods drying, concentration of fruit juices, and dehydration of chemicals. Direct vaporization is used in order to cool the substance; therefore, no heat exchanger or indirect cooling process are required, making SJR more suitable than VCR.

SJR systems are simple, require low capital costs and a low operating cost if using waste steam, reliable (safe) due to the lack of moving parts, and use an inexpensive refrigerant (water). On the other hand, they require a high consumption of steam and cooling water for the condenser, are difficult to operate under conditions of variable load, and have a limited area of applications compared with the other refrigeration systems. Their only worthwhile application is cooling by evaporation in drying processes.

A SJR system is presented in Fig. 14. The liquid water entering the evaporator evaporates at constant pressure by removing heat from the cooled body. The vacuum generated in the ejector by the high-pressure steam sucks the resulting vapor. The compression effect is accomplished in the jet compressor's diffuser section by the conversion of the kinetic energy of the jet into potential energy of pressure. The high-pressure vapor condenses in the condenser and the resulting liquid is divided into two streams: One fraction is pumped into the steam boiler, where it turns into steam, and the other passes through the throttling valve and evaporates in the evaporator by removing heat.

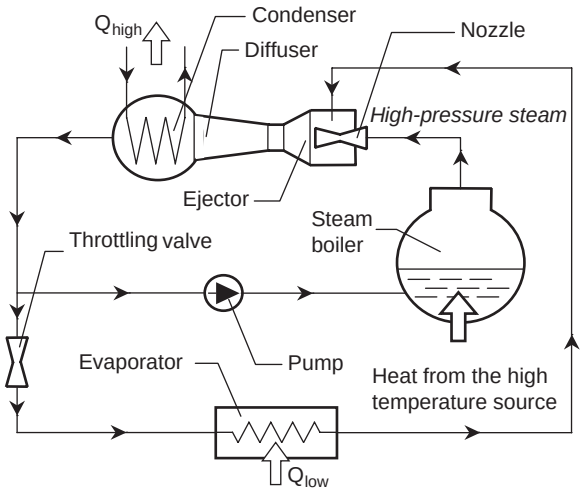

FIGURE 14 Steam jet refrigeration system.

Adjustment of the refrigeration power can be performed by varying the number of ejectors working at the same time (gross tuning) and by means of the steam flow rate per ejector (fine-tuning).

8. OTHER METHODS OF REFRIGERATION

Other refrigeration techniques are used, but only within a narrow area of applications: electronic components cooling, air liquefaction, refrigeration of small spaces, and aerospace.

8.1 Reversed Stirling Cycle (Philips Machine)

The power Stirling cycle was patented in 1816. The reversed cycle was applied in refrigeration after World War II by the Philips Company. Basically, the cycle is composed of two isothermal and two isometric (constant-volume) processes.

An interesting attribute of the Stirling cycle is that it occurs in a closed system: The working fluid is contained in the machine and there is no exchange of substance between the exterior and the refrigeration system. Another beneficial consequence is the possibility to choose the optimal fluid (from the thermodynamic standpoint) since cost is of no importance in this case due to the small quantity of refrigerant required. Moreover, because under ideal conditions all heat transfer processes between the system and the heat source and sink occur isothermally, the cycle's efficiency equals the Carnot efficiency. Obviously, under actual conditions, the Stirling's cycle efficiency is less than the ideal one due to the irreversibilities that inherently occur in every process.

The main feature of the cycle is heat regeneration, namely the internal flow of heat, which is first stored in a structure called a regenerator and is discharged later to the gas circulating through this unit. The regenerator consists of a heat-storage material (ceramic mesh, wire, or metallic gauze) through which the gas is forced back and forth during the isochoric processes. The gas rejects heat to storage medium (cooling) or removes heat from it (heating). In this manner, heat is "lent" to the storage mass of the regenerator during the isochoric gas cooling and is taken back later from it during the isochoric gas heating.

The machine (Fig. 15) is of the reciprocating type and consists of a cylinder with two pistons (A and B) and a regenerator (R). By means of a sophisticated mechanical system, the two pistons perform interrelated motions that allow the processes that comprise the cycle to occur.

The principle of the cycle operation is schematized in Fig. 15 in correspondence with the *T–s* plot of the processes. The first process is the isothermal compression (1–2), which occurs as piston B is moved to the left while the coolant removes the heat that is generated as a consequence of the compression work and thus the temperature T_{high} of the gas remains constant. During this time, piston A is held in position. The following process (2–3) is performed by moving both pistons at the same rate to the left. The volume of gas remains constant and the evolution is isochoric (isometric). The gas is forced

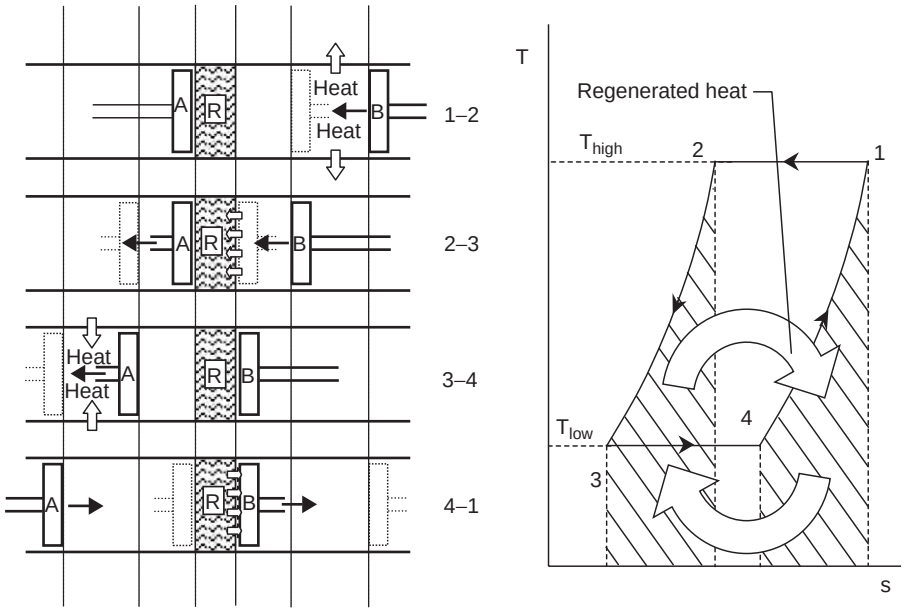

FIGURE 15 Schematic representation of the reversed Stirling cycle operation.

through the regenerator and rejects heat to the storage medium, which is colder as a result of the previous passage of gas. Isothermal expansion (3–4) follows, which is performed by blocking piston B and moving piston A to the right while heat is removed from the cooled space at T_{low} = constant. The last process of the cycle is isochoric gas heating (4–1). Both pistons move at the same rate to the right and the volume of gas is constant. By passing through the regenerator R, the cold gas removes the heat that has been stored during the previous isometric process and regains the temperature from the beginning of the cycle (T_{low}).

The Philips machine is used for temperatures in the range 223–13 K (−50 to −260°C). Most of its applications are in cryogenics. The actual machine, designed by Köhler and Jonkers, differs from the previously discussed scheme from the standpoint of the pistons' movement, which is continuous (the pistons of the ideal machine move intermittently). Helium and hydrogen are the usual working fluids. For temperatures higher than −130°C, air may also be used. The most usual applications are in the area of scientific research, gas liquefying, etc. The Philips refrigeration machine is characterized by very low losses and therefore its efficiency in the temperature range −150 to −90°C is approximately 0.4. A machine with a relatively small size (cylinder inner diameter = 70 mm and piston stroke = 50 mm) can liquefy approximately 5 kg of air per hour, with the necessary power input being approximately 6 kW.

8.2 Open-Cycle Systems

8.2.1 Gas Expansion in a Field of Centrifugal Forces (Ranque Effect)

The French physicist Ranque observed this phenomenon for the first time in 1933, which is why it is referred to as the Ranque effect. The vortex tube device of a cylindrical tube is equipped with a tangential nozzle and a cone, as in Fig. 16. As the gas expands in the nozzle, a very intense circular current develops, characterized by a strong radial velocity gradient. The compression of the gas close to the tube wall heats the gas, whereas the circulation becomes longitudinal near the tube's axis. As a result, a separation of streams occurs: The hot one leaves the tube at the right end and the cold one is collected at the exit orifice from the left end. The axial position of the cone controls the flow rate and thus the temperatures of the two streams. Turbulence and viscosity are the source of the phenomenon: The kinetic energy of the gas particles has important variations, and thus the gas is compressed and expanded adiabatically, performing a refrigeration cycle that pumps heat to the peripheral regions of the gas by cooling the regions situated on the tube axis (Fig. 16).

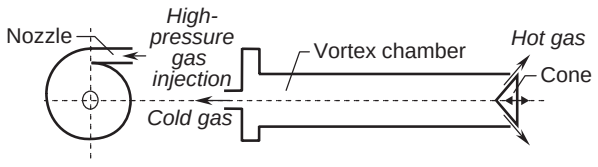

FIGURE 16 The vortex (Ranque) tube.

The parameters that influence the performance of the vortex device are the tube's geometry (length and diameter), the diameter of the cold gas escape orifice, the nozzle's section area and type, the temperature and pressure of the compressed gas, and its physical properties. For instance, for an air pressure of 11 bar at an inlet volumetric flow rate of 30.5 m^3/h, by using a tube with a certain geometry one can obtain a fraction equal to 0.2 from the total flow rate at −41°C.

8.2.2 Reversed Thermoelectric (Peltier) Effect

The direct thermoelectric effect was discovered in 1821 by the German physicist Thomas J. Seebeck. It consists of the apparition of an electromotive force as the junctions of two wires made of different electrical conductors (the ensemble is called thermocouple) are placed in mediums with different temperatures.

The reversed thermoelectric effect was discovered in 1834 by the French physicist Jean-Charles Anastase Peltier. By connecting a thermocouple to a direct current (DC) source, one junction heats and the other cools. By inverting the current's direction, the cold and hot junctions switch functions.

The apparition of a temperature difference between two junctions involving different metallic conductors when connected to a DC source is referred to as the Peltier effect. The explanation resides in the fact that different electrical conductors exhibit different energy levels of their conduction electrons. When forced to pass from the high-energy region to the low-energy region under the influence of an electric field, the electrons reject their excess energy as heat. This phenomenon occurs at the boundary between the two conductors, which are put into contact by welding. The opposite process takes place at the other junction: Low-energy electrons absorb from the surroundings the necessary energy to pass to the high-energy region, and this phenomenon manifests as heat removal from the environment.

The cooling effect is poor in conductors, whereas in semiconductors its intensity is important. The maximum cooling efficiency is reached when one of the semiconductors is of the n type and the other is of the p type. Typical p-type semiconductors used for this purpose are alloys of Sb_2Te_3 and Bi_2Te_3, and n-type semiconductors are alloys of Bi_2Te_3 and Bi_2Se_3. With such couples, temperature differences of up to 60°C have been obtained. By connecting more thermoelectric couples in series (battery arrangement: the cold end of one of them cools the hot end of the other), the temperature gap can be increased.

Thermoelectric refrigeration batteries are used in low-power as well as high-power applications. For small systems, optimization aims to get the highest power possible by sacrificing efficiency. High-power systems are designed to achieve the highest performance in terms of efficiency. Other potential applications of thermoelectric refrigeration systems are small air-conditioning systems, household refrigerators, and aerospace.

The cooling effect is reduced by heat generation at the passage of the electric current through a conducting body (the Joule–Lenz effect) and by the conduction heat transfer between the two junctions.

The advantages of thermoelectric refrigeration systems result from the fact that they require no refrigerant, have no moving parts, are simple, the refrigeration power can be as small as necessary, the refrigeration element has a very small size (applications in surgery, electronics, and dentistry), and the refrigeration temperature can be easily controlled by varying the current's intensity. On the other hand, they have poor shock resistance and are expensive.

9. CRYOGENICS

The term cryogenics derives from the Greek *kryos*, for icy cold. The upper limit that characterizes the cryogenic region of the temperature scale is subjective. If the delimitation criterion takes into consideration practical reasons, then this upper limit can be established at a higher than usually declared value (120 K) in order to include natural gas liquefaction. The cryogenics region of the temperature scale 0–120 K can be divided into subregions according to the criteria of the cryogenic method and refrigerant as follows:

- 63–120 K: The industrial cryogenics domain. The cryogenic methods are based on thermodynamic state-change processes of the usual refrigeration type, as described previously.
- 1–60 K: Thermodynamic methods combined with additional vacuum processes that characterize the domain of liquefaction of hydrogen, helium, neon, nitrogen; also of industrial importance.
- 0.3–1 K: The domain of laboratory cryogenics.
- <1 K: The cryogenics domain of advanced scientific research. The methods used are of the magnetic type. Temperatures on the order of 10^{-8} K have been obtained. The third law of thermodynamics (Nernst, 1906) states that absolute zero cannot be reached whatever method used.

Cryogenics is most important in industrial applications: liquefaction, gas separation, and superconductivity. Cryogenics is also on the cutting edge of scientific research: nuclear and elementary particles physics, physics of the solid, cryobiology, and cryosurgery.

9.1 Cryogenic Cycles and Methods

Some of the previously described refrigeration techniques are also applicable to the cryogenic temperatures' domain. In gas-expansion processes, the gas, after being compressed and rejecting heat, expands in an expansion machine. Compared with throttling, this method has a higher cooling intensity, expressed as the temperature drop per pressure drop (degrees/bar). In the cryogenic cycles without the refrigerant's phase change, the latter remains gaseous as it undergoes the processes that comprise the cycle. Usually, these cycles correspond to low- and medium-power refrigeration systems (also known as gas refrigeration machines) and are used in laboratory applications. The most used is the Philips machine, whose cycle (the reversed Stirling cycle) was previously described. By using helium as refrigerant, such machines can reach 77 K in a single stage and 12 K in two stages.

In the following sections, specific cryogenic methods are presented. Some of the most used cryogenic agents are shown in Table V along with some important physical properties.

9.1.1 Joule–Thomson Effect

By being throttled, the gas undergoes a pressure reduction and under certain conditions its temperature decreases. The phenomenon is called the Joule–Thomson effect and is accompanied by a temperature change of the gas. If the process occurs within a temperature and pressure range that ensures that the

TABLE V

Main Cryogenic Agents and Important Physical Properties

Cryogen	Normal boiling point (K)	Critical temperature (K)	Critical pressure (kPa)	Triple point temperature (K)	Triple point pressure (kPa)
Helium	4.22	5.28	227		
Hydrogen	20.39	33.28	1296	14.0	7.2
Nitrogen	77.33	126.17	3385	63.22	12.55
Carbon monoxide	82.11	132.9	3502	68.11	15.38
Argon	87.28	151.2	4861	83.78	
Oxygen	90.22	154.8	5081	54.39	0.14
Methane	111.72	190.61	4619	90.67	11.65
Krypton	119.83	209.4	5488	116.0	73.22

effect is positive (the gas temperature decreases as its pressure is reduced), then throttling results in gas cooling and can be successfully used to liquefy gases. The following requirements must be met:

1. The gases involved must have very low saturation temperatures and pressures.
2. In order to bring the gas into a state characterized by a positive Joule–Thomson effect, a foregoing preparation is necessary: the gas has to be precooled in auxiliary classical refrigeration systems.
3. To obtain very low temperatures, very high pressure drops are necessary.

For instance, for hydrogen, the pressure value before throttling must equal 110 bars after a precooling below 190 K (approximately −83°C) to obtain a positive Joule–Thomson effect.

9.1.2 Linde Method

Basically, the configuration of the cryogenic system is that of a classical VCR machine. The specific features of the cryogenic system are the aftercooler that replaces the condenser and the counterflow heat exchanger placed between the aftercooler and the throttling valve. In the aftercooler, the gas is brought to the ambient temperature. The function of the counterflow heat exchanger is to perform a supplementary cooling of the high-pressure gas that leaves the aftercooler. The coolant is cold gas collected from the separation vessel placed after the throttling valve. A low-quality liquid vapor mixture results after the throttling process. The mixture enters a separation vessel, where the liquid phase is gravitationally collected at the bottom and withdrawn, whereas the vapor occupies the space above the liquid. The vapor (which is at the saturation temperature) is circulated through the counterflow heat exchanger and removes heat from the stream of high-pressure gas coming from the aftercooler. This supplementary cooling significantly increases the liquefaction efficiency.

Adding a second throttling and a precooling of the compressed gas after the compressor can improve the basic configuration described previously. Such improvements reduce the necessary power input of the cryogenic system.

9.1.3 Claude Method

This technique uses an expander and is an improved variation of the Linde method. By expanding a gas in a machine, the work output combined with the pressure decrease leads to a stronger cooling than that of the simple pressure destruction by throttling. Consequently, after being cooled in the aftercooler, the gas undergoes a primary cooling in a counterflow heat exchanger by rejecting heat to a stream of cold gas coming from the second-stage counterflow heat exchanger. After this primary cooling, the gas stream is divided: A fraction enters the second-stage heat exchanger, whereas the remainder expands in the expander, resulting in a colder gas, which is returned to the main coolant flow path that enters the second-stage heat exchanger. The vapor collected at the upper end of the separation vessel is directed to the final counterflow heat exchanger, where it cools the gas stream that leaves the second-stage heat exchanger. By cascading several Linde and Claude cryogenic systems operating with different refrigerants, one can obtain liquefaction of helium and an additional cooling in helium down to 0.7 K.

9.1.4 Diffusion Pump Method

This device is used to liquefy helium and is based on the active coal's property of adsorbing or desorbing

helium. Active coal has a very porous structure, which allows it to adsorb gases in large amounts. The quantity of gas adsorbed increases as temperature decreases and as pressure increases. As a consequence, a gas is adsorbed at low temperature. By heating the adsorbent, the gas is released. This property allows the adsorbers to operate in adsorption–desorption cycles. The adsorption process is exothermic (i.e., it releases heat), whereas the desorption is endothermic, requiring heat in order to occur. These phenomena are used to liquefy helium in cryogenic systems in which the compressor has been replaced by a diffusion pump.

The active coal is saturated with helium at normal or higher pressure and the heat of adsorption is evacuated by cooling. The system (coal + adsorbed helium) is then thermally insulated and undergoes a process of desorption by creating vacuum in the space that confines it. As a result, the temperature decreases, and the refrigeration effect occurs. Using such a technique, a temperature of 2 K has been obtained in liquid helium.

9.1.5 Thermomagnetic Effect

A substance that is not a magnet in the absence of a magnetic field is called paramagnetic. Only few substances are paramagnetic: the crystalline hydrates of some rare minerals (e.g., $Gd_2SO_4 \cdot 8H_2O$) or the salts of the metals from the platinum or aluminum groups.

When subjected to an exterior magnetic field, the microscopic dipole magnetic moments of the paramagnetic material oppose this action and consequently the magnetic field performs work to change their orientation. At the macroscopic level, this phenomenon manifests as heating of the substance. If one removes this heat with a coolant, the magnetization process will be isothermal. Switching off the magnetic field, the substance undergoes a demagnetization process and the energy stored in the substance as a consequence of its opposition to the action of the field is transferred to the magnetic dipoles to regain their chaotic orientation. If the substance is thermally insulated, the result is an intense cooling. The phenomenon is called the thermomagnetic effect and the method is referred to as adiabatic demagnetization of paramagnetic substances.

A second phenomenon occurs during the magnetization–demagnetization cycle of the paramagnetic body. The internal energy of a substance depends not only on the kinetic and potential energies of the molecules but also on the magnetization. As magnetization increases, more order is transferred to the system by orienting the elemental magnets along the magnetic field lines and thus the chaotic movements of the molecules are limited. The number of degrees of liberty of the thermal motion is correspondingly reduced. By this action, an internal magnetic field develops, called the internal Lorentz field. The internal energy of the body decreases as a consequence of magnetization. During the adiabatic demagnetization phase, not only does the magnetization work have to be redistributed to the molecules to regain their initial chaotic orientation but also the amount of internal energy corresponding to the degrees of liberty lost during the magnetization process has to be redistributed. An additional temperature decrease occurs due to this internal energy redistribution process.

By using the adiabatic demagnetization of paramagnetic salts, temperatures in the range 0.3–10^{-3} K can be obtained and maintained for a short time.

To obtain temperatures less than 10^{-3} K, the adiabatic demagnetization of the nuclear state of a paramagnetic salt has been used. The phenomenon is basically the same as in the case of the atomic paramagnetism. Using adiabatic demagnetization of the nuclear spin system of copper, a temperature of 10^{-8} K was attained in the 1980s.

9.2 Applications

9.2.1 Air Separation

Air components such as oxygen, nitrogen, and argon are used in different applications. Nitrogen is used in metallurgy (as inert atmosphere), electronics, chemical processes, and deep refrigeration.

Oxygen is used in metallurgy, welding, chemical industry, and medical applications. Argon is used as inert atmosphere in electric bulbs and welding.

Dry air is a mixture of three major gases (in moles, 78.03% nitrogen, 20.99% oxygen, and 0.934% argon) and other components, such as carbon dioxide, rare gases, hydrogen, and helium (all less than 0.05%). Air liquefaction constituted the first application of the Linde method in 1895. Before being processed, air is dried up and carbon dioxide is removed since water vapor and CO_2 freeze during air liquefaction, endangering the operation of the air-separation unit. The separation of the three main components is based on the distillation process. A two-staged distillation column operating at two pressure levels separates oxygen and nitrogen, whereas argon is distilled in a separated column. A typical air-separation plant supplies liquid and

gaseous oxygen, which are collected at the lower end of the low-pressure stage of the column, and liquid and gaseous nitrogen, which are extracted from the medium- and high-pressure regions of the second-stage column. A turbine expander supplies the refrigeration effect necessary for the air separation. Less important refrigeration is obtained by means of the Joule–Thomson effect.

Total air-separation plants provide oxygen, nitrogen, argon, and rare gases (He, Ne, Kr, and Xe).

9.2.2 Liquefaction of Natural Gas

Two reasons justify the liquefaction of natural gas. First, the demand is not constant, exhibiting a peak in midwinter. To meet this increased demand, the distribution piping should be designed accordingly, which involves high capital costs. It is more economical to design the distribution grid according to a medium demand, to store liquefied gas in large storage tanks, and to vaporize and add it to the network when necessary. Second, the oil/gas field is usually far away from the users or in a location that does not economically or technically justify a pipeline for collecting the extracted gas (e.g., offshore extraction platforms). In such cases, gas is liquefied and transported to a facility near the user area, where it is vaporized and injected into the distribution network.

The refrigeration effect necessary for liquefaction is achieved by a variety of methods. In some cases, methane is used as a refrigerant in intermediate refrigeration.

9.2.3 Helium Liquefaction

Helium was the last of the gases to be liquefied in 1908 by Kammerlingh Onnes. Helium is used in welding, aerospace, superconductivity, inert atmosphere applications, medicine, and advanced scientific research. Helium's concentration in air is well below the economically acceptable level. However, it is present in much higher concentrations (up to 15%) in natural gases. Helium's liquefaction requires special cryogenic techniques since its saturation temperature is the lowest among all substances (Table V). Due to the fact that at room temperature helium has a negative Joule–Thomson effect (it heats when throttled), previous precooling below the inversion temperature (the temperature above which the Joule–Thomson effect changes slope) is necessary. This is performed by means of a Claude process, which brings the gas to 20 K at 3000kPa. Liquefaction is then accomplished by means of an expansion valve.

9.2.4 Superconductivity

Helium has two stable isotopes, He_I (atomic mass = 3) and He_{II} (atomic mass = 4), which are present in different concentrations. Its normal boiling point is 4.23 K, and below this temperature it is a colorless lightweight liquid with a very low viscosity. The separation of the two isotopes can be done at temperatures lower than 2.17 K, which is the threshold below which He_I is in a normal state, whereas He_{II} is in the superfluid state. Helium is the only substance that can maintain its liquid state at near absolute zero and has no triple point. Solid helium can be obtained only under high-pressure conditions (at $T < 1.0$ K, the pressure must be higher than 2500 kPa to obtain solid He_{II} or higher than 3000 kPa for He_I). The higher the temperature, the higher the pressure: For instance, at $T \approx 60$K, the solidification pressure is approximately 10^6 kPa.

Superfluidity is a special property of liquid He_{II} at $T < 2.17$ K. The liquid's unusual behavior consists of the fact that its flow velocity through capillary tubes depends only on the temperature and the tube diameter, and not on the pressure drop and the tube length. The flow occurs without friction, with the viscosity of the liquid becoming extremely low. The phenomenon was discovered in 1932 by the Russian physicist P. L. Kapitsa, who called it superfluidity. At 5.072 kPa and $T = 2.174$ K, helium's thermal conductivity exhibits a radical change: It suddenly becomes 3×10^6 times higher than the thermal conductivity of other liquids at the same temperature (liquid helium included) or 1000 higher than copper's conductivity at ambient temperature.

In normal electrical conductors, the resistance decreases as temperature decreases. In 1911, by studying the electrical behavior of a mercury sample in liquid helium, the Dutch physicist Kammerlingh Onnes discovered that the sample's electrical resistance disappeared suddenly. It was the first time that the phenomenon called superconductivity was noticed. Further research on this phenomenon was performed and it was found that it occurs in a wide range of metals and alloys. Practically, the resistance equals zero. This fact has been verified by immersing a metal ring in liquid helium and injecting an electric current. The current can run through the ring undiminished for months.

Superconductivity is used mainly in magnet applications (plasma physics and electrical machines). An interesting application may be the use of superconductive magnets for magnetic levitation in high-speed railroads (500 km/h).

Other potential applications are in the field of electric energy transport. Power plants are situated as close as possible to the fuel source, which is generally far away from users. Consequently, the energy has to be transported through metallic cables. Due to the losses caused by the metal's electrical resistance, economic limitations dictate that the transported power at 1.5×10^6 V be less than 10^6 kW. The use of superconductive cables may be economically acceptable for energy transport at distances on the order of 200 km for AC and 50–800 km for DC. In the case of very high-power superconductive energy transport, the economy may be approximately 5 or 6 MWh/km.

For obvious economic reasons, the research in the field focuses on different alloys and semiconductor combinations in order to develop substances that reach the superconductive state at the highest possible temperatures, preferably 100 K (liquid nitrogen).

10. AIR-CONDITIONING

The following are the most important developments in the evolution of air-conditioning and air-conditioning systems:

At the end of the 19th century:

- Founding of the scientific hygiene (Max von Pettenkofer, Germany)
- Research on air exchange, hygrometry, and air moisture
- The use of electric motors for air fans in large buildings; air filtration
- By 1890, air humidification with steam and later by water spraying; beginnings of air-conditioning.

20th century:

- By 1900, the first air-conditioning systems with preheater, humidifier, and reheater (United States); W. H. Carrier (1876–1950), father of air-conditioning
- The first temperature and humidity control systems (pneumatic and electrical)
- By 1920, the upsurge of air-conditioning; central air-conditioning systems for comfort (theaters, office buildings, and conference halls) and industry, especially for hygroscopic materials processing (tobacco, paper, and textiles)
- By 1930, the first unitary systems that include all the components; the use of freons for the refrigeration side; room air conditioners

TABLE VI

The Standard Dry Air Composition

Component	Volume fraction
Oxygen	0.2095
Nitrogen	0.7809
Argon	0.0093
Carbon dioxide	0.0003

After 1945, very rapid development of air-conditioning systems: dual-path systems, air-and-water systems with induction devices, and fan–coil units.

10.1 Basic Principles

The standard dry air composition as established in 1949 by the International Joint Committee on Psychrometric Data is presented in Table VI. The water vapor content of the air may vary from zero (dry air) to a maximum (saturated air) that depends on the temperature at a certain atmospheric pressure.

The humidity ratio W of the air is the ratio of the mass of water vapor (m_v) to the mass of dry air (m_a):

$$W = \frac{m_v}{m_a}\left[\frac{\text{kg water vapor}}{\text{kg dry air}}\right].$$

The relative humidity ϕ is the ratio of the mass of water vapor (m_v) contained in the air to the mass of water vapor at saturation (m_s) at the same temperature:

$$\phi = \frac{m_v}{m_s}.$$

The relative humidity varies in the range 0–1 (0, dry air; 1, saturated air).

The dew point temperature is the temperature below which water vapor condensation occurs if the air is cooled at constant humidity ratio. The dew point temperature can also be the air saturation temperature at the same pressure and humidity ratio as the considered mixture.

Due to the moisture present in the air, the heating and cooling processes undergone by the air are accompanied by changes in its relative humidity and/or humidity ratio. Consequently, the design of air processing to meet certain requirements regarding its temperature and moisture must take into consideration the heat and mass transfer associated with these state changes. Moreover, in certain cases (such as cooling below the dew point temperature at constant humidity ratio), water vapor condensation will result and liquid water will leave the air.

10.1.1 Human Comfort

The main parameters that define the air quality in a space are temperature, humidity, air purity (involving dust, microorganisms, and odors), thermal radiation, and air motion.

The factors that influence the subjective sensation of comfort in a space are of extreme variety and depend on sex, age, the nature of the human activity in that space, etc. A 100% satisfaction regarding comfort is an unrealistic objective due to the previously mentioned considerations. This is why the American Society of Heating, Refrigerating and Air Conditioning Engineers Comfort Standard 55 defines an environment as thermally acceptable if at least 80% of the occupants consider it acceptable from the thermal standpoint.

The normal temperature of the human body is approximately 36.9°C and is maintained at this constant value by physiological mechanisms. If the temperature and humidity of the environment allow these mechanisms to accomplish their duty, then the subjective perception of comfort is obtained.

There are basically two ways by which the human body maintains its temperature at a quasi-constant level:

1. Metabolism, which increases or decreases the rate of internal heat production as the body temperature decreases or increases, and which depends on the level of effort that characterizes the human activity.
2. Control of the heat transfer between the body and the environment: If the external temperature is low, the body's heat losses are reduced by reducing the intensity of blood circulation (vascular constriction at the skin level). If the exterior temperature is too high, blood vessels that irrigate the skin dilate, allowing a higher blood flow and consequently a higher rate of heat rejection. This cooling mechanism is combined with the heat rejection by means of the latent heat of evaporation of the sweat.

The heat release of the human body can vary from 75 (sleep) to 700 W (sustained hard work), in accordance with the degree of effort of the activity. The corresponding limits of the humidity release by perspiration are 0.05 and 0.45 kg/h, respectively.

The relative humidity of the air is not directly perceived as such, but it contributes to the general sensation of comfort by encouraging or hampering sweating. This is why a higher temperature is endurable when air is dry, whereas moderate temperatures seem intolerable if the relative humidity approaches 100%.

In all cases, the air motion is of great importance since it intensifies the convection heat transfer of the body. An air velocity of approximately 0.25 m/s is acceptable from the standpoint of thermal comfort. Another factor that determines the thermal comfort is thermal radiation, which becomes important if there are surfaces in the environment whose temperatures are different from the air temperature.

These factors act in strong correlation with each other, which is why their influence must always be considered in an overall manner. For example, Figs. 17 and 18 present the combined action of air temperature and relative humidity and air temperature and velocity, respectively, in defining the comfort domain.

The air-conditioning systems are classified according to the following criteria:

Application: Comfort and technological
Air pressure: High and low (classical)

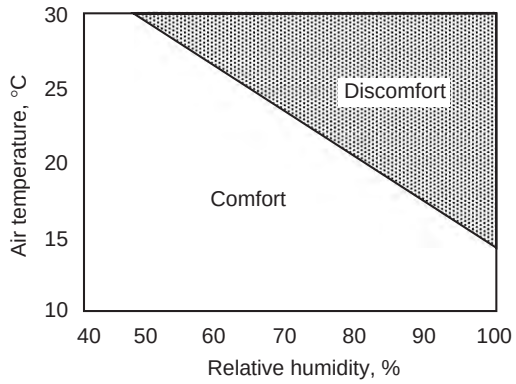

FIGURE 17 The comfort and discomfort domains resulting from the combined action of the air temperature and relative humidity.

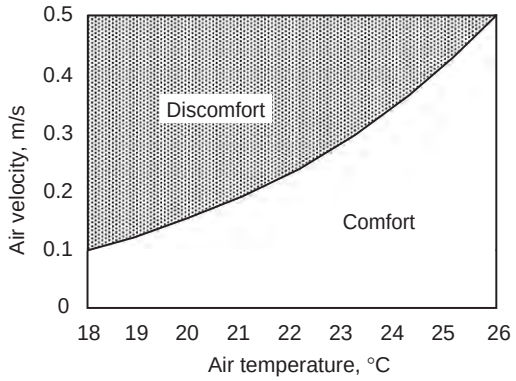

FIGURE 18 The combined action of air velocity and temperature in defining the comfort and discomfort domains.

Flow rate: Constant and variable
Heat transfer agent: All air, air and water, or all water.

The design of an air-conditioning system must consider many variables that determine the air parameters, such as solar radiation, air infiltration, heat gains due to conduction and convection from boundaries and internal objects, and latent heat and humidity gains caused by water-containing objects. All these heat and moisture sources determine the cooling load, which must be equal to the heat rate that has to be removed from the space by the air-conditioning equipment. This requirement is rarely met since the cooling load is almost permanently variable as a consequence of the ever-changing conditions (season, solar radiation, ambient temperature, wind, occupancy of the space, daily and weekly work cycle, variable operation of the heat and moisture-generating equipment, etc.). Therefore, it is recommended that the air-conditioning system should be designed for a peak cooling load and it will be operated intermittently at loads less than the peak (design) value.

The indoor design conditions are 25°C and 50% relative humidity. The necessity of a good match with the cooling load has determined the design of packed refrigeration systems of different refrigeration powers, which are delivered ready to be integrated in the air-conditioning systems:

- VCR systems equipped with reciprocating compressors: power range, 11.6–464 kW
- VCR systems with centrifugal compressors: power range, 348–2320 kW
- Lithium bromide–water absorption refrigeration systems: power range, 116–5800 kW
- Steam jet refrigeration systems: power range, 10–6000 kW.

10.2 Temperature and Humidity Requirements for Different Activities

The function of air-conditioning systems is to control the temperature and humidity of a space in order to either meet the comfort requirements of the personnel in that space or create the microclimate in an industrial space. The thermal comfort conditions for a space impose a temperature within the range 20–25°C, and the relative humidity must be in the range 35–65%. Many industrial processes involve technological prescriptions that impose special temperature and/or humidity values for the air, in some cases in very narrow ranges. Table VII illustrates these requirements for some of the most common domains.

TABLE VII

Temperature and Relative Humidity Requirements for Some Activities

Domain	Activity	Temperature (°C)	Relative humidity (%)
Libraries	Book storage	18–25	40–50
Museums	Painting galleries	18–24	40–55
Beverages	Brewing	10–15	80–85
Rubber	Vulcanization	26–28	25–30
	Surgical material	24–33	25–30
Chocolate	Packaging	18	55
Mechanical	Precision assembly	20–24	40–50
Pharmaceuticals	Manufacturing	21–27	10–50
Tobacco	Tobacco storage	32	85–88
	Cigarette manufacturing	21–24	55–65
	Packaging	23	65
Textiles	Cotton spinning	24–27	50–65
	Wool spinning	24–27	60–80

10.3 Basic Central Air-Conditioning

This is a single-zone air-conditioning system and supplies a constant or variable air volume at low, medium, or high pressure. Usually, the system is located outside the air-conditioned area.

The typical components of air-conditioning equipment are air filters; a refrigeration unit; cooling coils; heating coils using steam, hot water, or electricity; an air humidification unit; air ducts; water pipes; fans; and control equipment.

Usually, central systems supply to an entire building both warm air for heating during the cold season and cold air for cooling in the warm season. The outdoor air undergoes a series of heating and cooling processes combined with humidification and/or drying, with a resulting stream of processed air that meets the comfort requirements. Only the air-conditioning subsystems that comprise the general system are discussed further.

The air-handling components of such systems can be arranged in various configurations according to the specific requirements of the space to be air-conditioned. The air-conditioning system must be easy to maintain and must accomplish its task in the simplest configuration possible. The central systems

may be classified as all-air systems, air-and-water systems, and all-water systems.

10.3.1 All-Air Systems

These systems supply only air to the conditioned space and process it in order to offset the maximum cooling load from the building. For spaces in the building whose cooling load is less than the maximum one, a reheat of the air can be provided by adequate heating equipment.

A typical all-air system is shown in Fig. 19. All-air systems are of two types: single-path and dual-path. In single-path systems, a single stream of air flows through the heating and cooling coils that are arranged in series. In dual-path systems, the heating and cooling coils are placed on separate paths and the processed air stream results by blending the heated and cooled steams.

All-air systems are used in buildings that have several spaces that each require a separate control of the air's temperature and humidity, such as hospitals, office buildings, hotels, and stores. All-air systems are used wherever a close temperature and humidity control is required (e.g., hospital operating rooms, computer rooms, and textile and tobacco industries).

10.3.2 Air-and-Water Systems

These air-conditioning systems were developed and implemented after World War II due to the need to reduce the space required for the air ducts in buildings. Their typical use is in high-rise structures. A central unit processes the minimum amount of fresh air at 14–16°C, called primary air, and distributes it under a relatively high pressure to the rooms and spaces to be air-conditioned. Due to the higher pressure, the air velocity through the ducts is high, and therefore the flow section area of the ducts is small, as is the space required. As a result, higher power fans are required. Water (called secondary water) is also processed in the central unit. Primary air and secondary water are distributed to terminal units in the conditioned spaces throughout the building. The room terminal may be an induction unit or a fan–coil unit. The primary air supplied by the central air-conditioning system is mixed in the room terminal units with the return (secondary) air and distributed in the rooms. The advantage of this system is that the temperature can be adjusted in each room. However, this configuration complicates the piping because each room or space must have its own heating and cooling pipes (water is the heat transfer agent), and consequently the costs are higher.

The induction unit uses the ejection effect produced by the high-pressure primary air that flows through nozzles and sucks the interior (return) air, which is forced through heat exchangers that cool or heat it as required. The induction units are usually installed under a window or in an overhead location. They have some advantages, such as individual room temperature adjustment, less space required, easy maintenance (no moving parts), long life span, and smaller size of the central unit due to the small volume of primary air to be processed. On the other

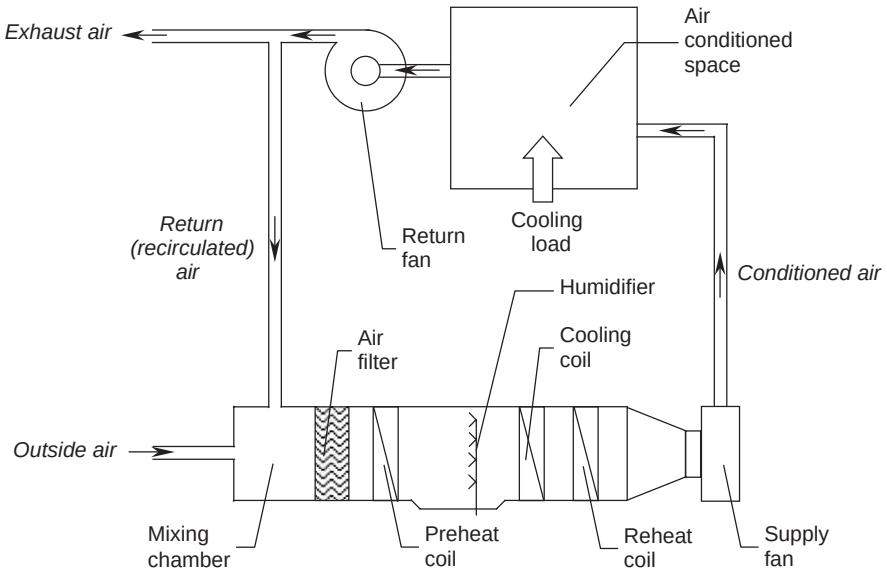

FIGURE 19 Scheme of an all-air central air-conditioning system.

hand, fouling of the secondary air side of the cooling or heating coils is possible and high energy consumption is necessary.

The typical components of a fan–coil unit are a filter, finned-tube coils, and a fan. Hot or cold water circulates through the coils. The main drawback is the noise produced by the fan. Some configurations contain an additional electric heater, which is used during the season transition to avoid changeover problems.

The air-and-water systems are used when no accurate control of the humidity is required (schools, office buildings, hotels, hospitals, etc.).

In all-water systems, the only cooling agent is water, which flows through finned coils, and individual fans blow air across the coils. These systems are recommended for their flexibility, but only air cooling and dehumidification are possible, unless a central humidifier is provided. The typical room terminal unit in this case is the fan–coil unit.

10.4 Unitary Air Conditioners

Unitary systems (also called multiple-packaged unit systems) are intended to match the air quality criteria for separate (individual) spaces. Their design allows a large variety of configurations and placements. The arrangement may be single or split, placement may be wall mounted or suspended from ceilings, cooling may be done with an evaporative condenser, they may be water or air cooled, etc. The main advantage of the unitary systems is flexibility. They operate more economically than central systems in large spaces, in which the placement of the units can cover the local cooling loads in a very effective manner.

Unitary systems (cooling capacity, 2.5–400 kW) are suitable when low initial cost, lower performance, and simple installation are required. Typical applications are office buildings, motels, and stores.

They are manufactured in different configurations in order to meet the multitude of possible requirements and applications. Each system consists of filters, heating and cooling coils, fans, one or more refrigeration compressors, and control equipment. Sometimes, multipackaged units for perimeter rooms are used in combination with central air-conditioning to increase flexibility.

Outdoor unitary systems are intended to cool or heat an entire building and consist of unitary systems, air ducts, and temperature and humidity control equipment. Usually, they are mounted on the roof, but in certain situations they can be mounted on the ground level.

Indoor unitary air-conditioning systems are located in the service areas of the building, close to the conditioned space, and are composed of an indoor unit with a water- or an air-cooled condenser, air ducts, and temperature and humidity control equipment.

The split configuration consists of two units connected by the refrigerant pipes:

1. The exterior unit (usually mounted in a console on the external face of the wall, on the ground, or on the roof), which contains the compressor, a fan, and the condenser
2. The interior unit, which consists of the evaporator, the reheat coil, the humidifier, and the fan

The advantages of unitary air conditioners are as follows:

- Simple temperature control by the room occupant
- One room can be heated or cooled independently from other rooms in the building
- Malfunction affects only one room
- Low initial cost
- Space economy
- Individual energy metering possible
- Immediately available.

Disadvantages include:

- Limited performance options and air distribution control
- No possibility of humidity control
- Higher energy consumption due to the usually lower efficiency

10.5 Room Air Conditioners

Room air conditioners (cooling capacity, 1.2–10.5 kW) are intended for air cooling, humidifying, and cleaning and are designed for mounting in windows, as consoles, or through special openings in walls. They have low installation costs and a relatively low price, are reliable and easy to maintain, and no or a minimum number of air ducts are required.

The window-mounted air-cooling unit (Fig. 20) only cools the air, without controlling its relative humidity. The refrigeration power of such units varies from 1 to 8 kW. The condenser is air cooled and the fan blows the air through the evaporator and the condenser. Window-mounted room air conditioners are usually used when low cost, simplicity of

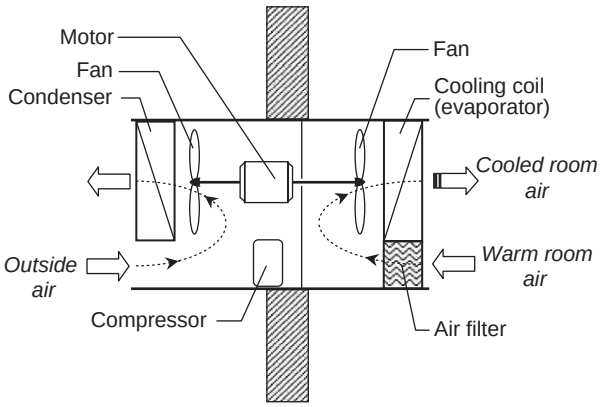

FIGURE 20 Typical window-mounted room air conditioner.

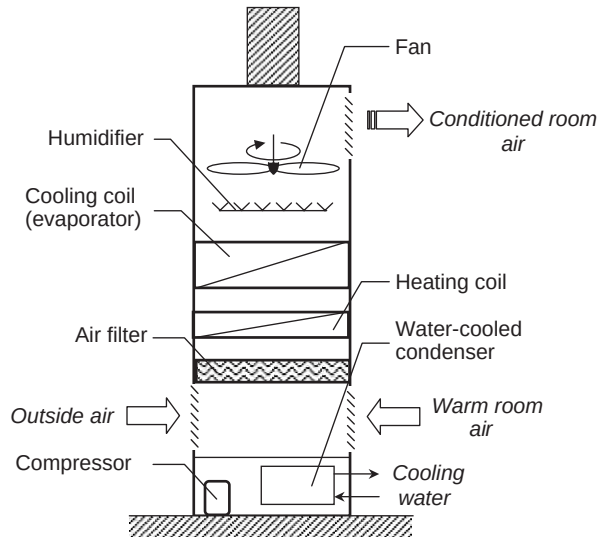

FIGURE 21 Typical through-the-wall room air-conditioning unit.

operation, and maintenance are primary criteria in selecting a candidate system (motels, low-cost apartments, and hotels), as auxiliaries to central systems, or as a backup for certain spaces when the basic system is down.

Through-the-wall mounted air conditioners (Fig. 21) contain a complete air-cooling and air-handling system packaged in one unit. They are used in buildings that require several temperature control zones (office buildings, hotels, and schools) and because less space is required compared with a central system, installation is relatively simple, and initial costs are generally lower than those of a central system. However, their noise level generally limits their applications.

1. Remote Sensing Technology
2. Oil Exploration
3. Environmental Applications

Glossary

anticline An arch in sedimentary strata. Oil may occur in the crest of anticlines.
electromagnetic spectrum The continuous sequence of electromagnetic energy arranged according to wavelength or frequency.
Landsat The unmanned Earth-orbiting satellites operated by NASA that acquire repeated remote sensing images.
radar Acronym for radio detection and ranging. Radar is an active form of remote sensing that records wavelengths from millimeters to centimeters.

Remote sensing is defined as the science of acquiring, processing, and interpreting images from satellites and aircraft that record the interaction between matter and electromagnetic energy. Remote sensing images of the earth are acquired in three wavelength intervals, or regions, of the electromagnetic spectrum. The visible region ranges from 0.4 to 0.7 μm and is divided into the blue, green, and red bands. The infrared (IR) region ranges from 0.7 to 30 μm and is divided into the reflected IR and thermal IR portions. The reflected IR portion ranges from 0.7 to 3.0 μm; the energy is predominantly reflected sunlight at wavelengths longer than visible light. The Landsat and other satellite systems acquire valuable images in the visible and reflected IR regions. The thermal IR portion ranges from 3.0 to 15.0 μm; the energy is radiant, or heat, energy. Thermal IR images have considerable potential for oil exploration in arid and semiarid terrains; however, the method has been underutilized in recent years largely because suitable images are lacking.

Visible, reflected IR, and thermal IR images are acquired in the passive mode by remote sensing systems that simply record the available energy that is reflected or radiated from the earth. The microwave region ranges from 0.1 to 30 cm; images are primarily acquired in the active mode called radar. An aircraft or satellite radar antenna transmits short bursts of microwave energy toward Earth. The energy interacts with materials and is returned to the antenna system, which records the information for later display as an image. Remote sensing is a rapidly evolving science with new imaging systems deployed on an irregular schedule by various nations and private concerns. The World Wide Web is a primary source of information about this dynamic science. Table I lists representative Web sites, many of which are linked to additional sites.

1. REMOTE SENSING TECHNOLOGY

The major application of remote sensing to energy is for oil exploration and, to a lesser extent, assessing the environmental impact of oil-related operations. The two most widely and successfully used systems are Landsat and radar.

1.1 Landsat Thematic Mapper Images

Landsat is an unmanned NASA satellite that orbits the earth in a sun-synchronous pattern at an altitude of 705 km.The satellite orbits over almost the entire earth in 16 days. If an area is cloudy during one overflight, suitable images may be acquired during subsequent 16-day cycles. Beginning in 1982, the

 © 2004 Elsevier Inc. All rights reserved.

second-generation Landsats 4 and 5 carried the thematic mapper (TM), which is a multispectral scanner that records images in seven separate wavelength intervals, or bands, for each scene. Bands 1–3 record blue, green, and red light. Bands 4, 5, and 7 record reflected IR energy. Band 6 records thermal IR energy, but it is rarely used for exploration. Table II lists the bands and their characteristics. Figure 1 shows reflectance spectra of vegetation and common sedimentary rocks together with wavelengths recorded by TM bands. The spectra of the different rocks are very similar in the visible bands but have major differences in the reflected IR bands; therefore, bands 4, 5, and 7 are especially useful for mapping different rock types.

Spatial resolution of the visible and reflected bands is 30 m. The current Landsat 7 carries the enhanced thematic mapper with an additional band 8 (0.52–0.90 μm), which has a spatial resolution of 15 m and can be convolved with the other bands during computer processing to improve their apparent spatial resolution.

Figure 2 is a subscene from a TM band 4 image of central Wyoming. The subscene displays less than 0.5% of the area covered by the full scene (170×185 km). Figure 3 shows the major features in the image and is generalized from a detailed geologic map that was interpreted for the full scene. The image includes four anticlines, two of which (Gebo and Little Sand Draw) are oil fields. These fields were discovered prior to the launch of Landsat, but this example demonstrates the value of the images for oil exploration.

Any three TM bands may be merged in any combination of blue, green, and red to produce color composite images that are far superior to panchromatic images, such as Fig. 2. TM images of the world are available at modest prices from the U.S. Geological Survey EROS Data Center in Sioux Falls, South Dakota (Table I). The images are distributed in digital format and must be computer processed to produce images. A variety of commercial desktop computers and software are available for this purpose.

Multispectral scanners, such as TM, record up to approximately 10 bands of data with wavelength intervals on the order of 0.10 μm. Hyperspectral scanners are a special form of multispectral scanners

that record many tens of bands with wavelength intervals on the order of 0.01 μm. The Web sites for the Jet Propulsion Laboratory (JPL), U.S. Geological Survey Spectroscopy Laboratory, and EROS Data Center (Table I) describe the major hyperspectral systems. Hyperspectral images have had limited applications to oil exploration.

In addition to Landsat, a number of other Earth-orbiting remote sensing satellites have been launched and others are planned. The Web site of the American Society for Photogrammetry and Remote Sensing (Table I) summarizes the characteristics of these satellites.

1.2 Radar Images

Radar is an active form of remote sensing that is shown diagrammatically in Fig. 4. Pulses of microwave energy, at wavelengths of a few centimeters to a few tens of centimeters, are directed to the terrain from a fixed antenna carried on an aircraft or satellite. Energy is directed downward toward the side of the ground track. Each radar pulse "illuminates" a narrow strip, or scan line, of terrain normal to the track. The depression angle is measured between the horizon and the center of the pulse of radar energy. Figure 4 shows a single scan line. The incident energy interacts with the terrain and portions are returned to the radar system, which records the data. Three characteristics of terrain determine the intensity of the radar return:

1. Dielectric constant, which is largely a function of moisture content.
2. Surface roughness at a scale of centimeters. Smooth surfaces, such as calm water, have dark signatures. Rough surfaces, such as forests and coarse gravel, have bright signatures.
3. Topography at a scale of meters to kilometers. Figure 4 shows that slopes facing toward the radar antenna have bright signatures called highlights. Slopes facing away from the antenna have dark signatures called shadows.

Radar images have two major advantages over visible and reflected IR images, such as Landsat. Because radar is an active system that provides its own source of energy, images can be acquired day or night and through clouds, rain, and fog. Aircraft radar images are typically acquired with a low depression angle of 20° or less (Fig. 4), which causes strong highlights and shadows from topographic features that may express geologic features. Spatial resolution of modern synthetic aperture radar (SAR) images ranges from meters to tens of meters, even at satellite altitudes. Topographic maps are produced from repeated images using the process called interferometeric SAR (IFSAR), which is described on the JPL Shuttle Imaging Radar Web site (Table I).

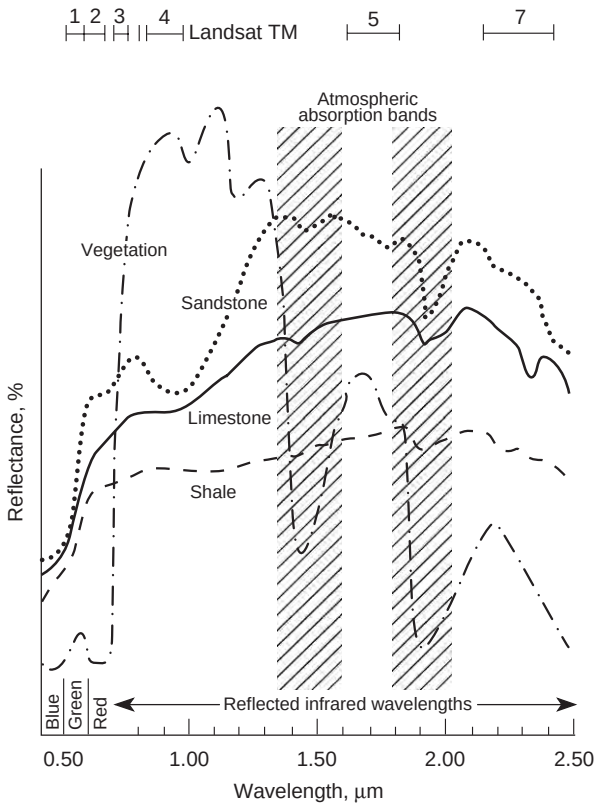

FIGURE 1 Reflectance spectra of vegetation and sedimentary rocks. Positions of TM bands are shown. Note that rock spectra have more distinguishing characteristics in the reflected IR region than in the visible region. Atmospheric absorption bands are caused by water vapor in the atmosphere, which prevents image acquisition. From Sabins (1997, Fig. 3-1).

FIGURE 2 Landsat TM band 4 (0.76–0.90 μm) image of subscene in central Wyoming. This subscene (190 km^2) is taken from a TM scene that covers 31,450 km^2. From Sabins (1997, Fig. 3-7D).

Figure 5 is a radar image along the south flank of the Papuan Fold and Thrust Belt in Papua New Guinea (PNG). Figure 6 is a generalized geologic map interpreted from the image. The terrain consists of northwest-trending anticlines and faults that form topographic ridges and scarps. Radar illumination was toward the north, which forms bright highlights on southwest-facing slopes and dark shadows on northeast-facing slopes.

The Web sites for the EROS Data Center and JPL provide examples and information on aircraft and satellite radar images acquired by U.S. government agencies. The Radarsat Web site provides access to satellite radar images acquired by Canada.

1.3 Digital Image Processing

Except for conventional aerial photographs, all remote sensing images are recorded in digital format and are computer processed to produce images for interpretation. The three functional categories of image processing are

1. Image restoration, which compensates for data errors, noise, and geometric distortions introduced during the scanning, recording, and playback operations.
2. Image enhancement, which alters the visual impact that the image has on the interpreter in a manner that improves the information content.
3. Information extraction, which utilizes the decision-making capability of the computer to recognize and classify pixels on the basis of their digital signatures.

The Purdue University Web site (Table I) provides image processing software.

2. OIL EXPLORATION

The major energy application of remote sensing is for oil exploration. In the early stages of an exploration

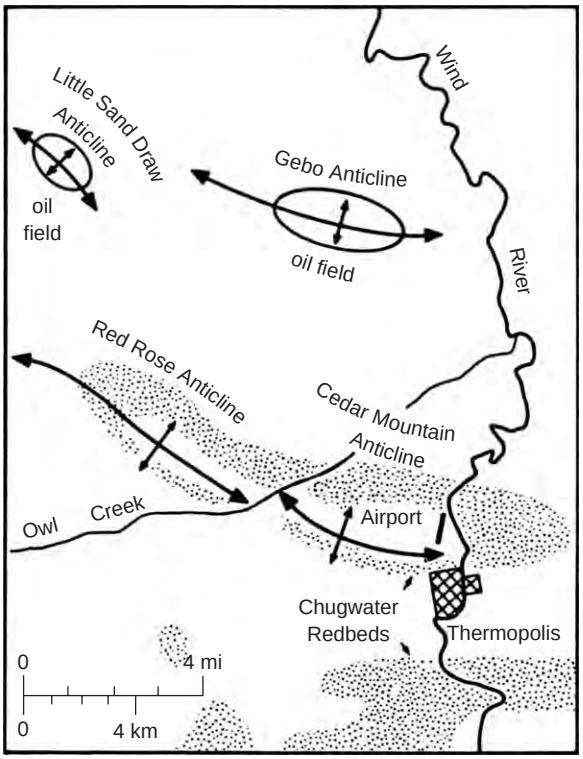

FIGURE 3 Map showing major features in Wyoming subscene. From Sabins (1997, Fig. 3-7H).

project, images are used to outline sedimentary basins and potential drilling prospects. Geologic fieldwork and geophysical surveys are used to verify and refine the prospects prior to drilling exploratory wells. In 1978, the Chevron Corporation (now ChevronTexaco) utilized images from an early version of Landsat to help discover the first oil fields in the Sudan. Remote sensing has subsequently played a key role in major discoveries in PNG and the Central Arabian Arch. The PNG project area is a tropical rain forest with complex geology, whereas the Arabian project is a desert with relatively simple geology. These two case histories illustrate the successful application of different remote sensing technologies in widely different geologic and environmental settings.

2.1 Papua New Guinea Project

In 1984, the Chevron Corporation explored two petroleum prospecting licenses (PPLs) in the eastern portion of the island of New Guinea, which is part of the nation of PNG. The PPLs cover an area of 14,400 km^2 that spans the boundary between the Fly–Strickland Lowlands in the southwest and the Papuan Fold and Thrust belt in the northeast. Oil

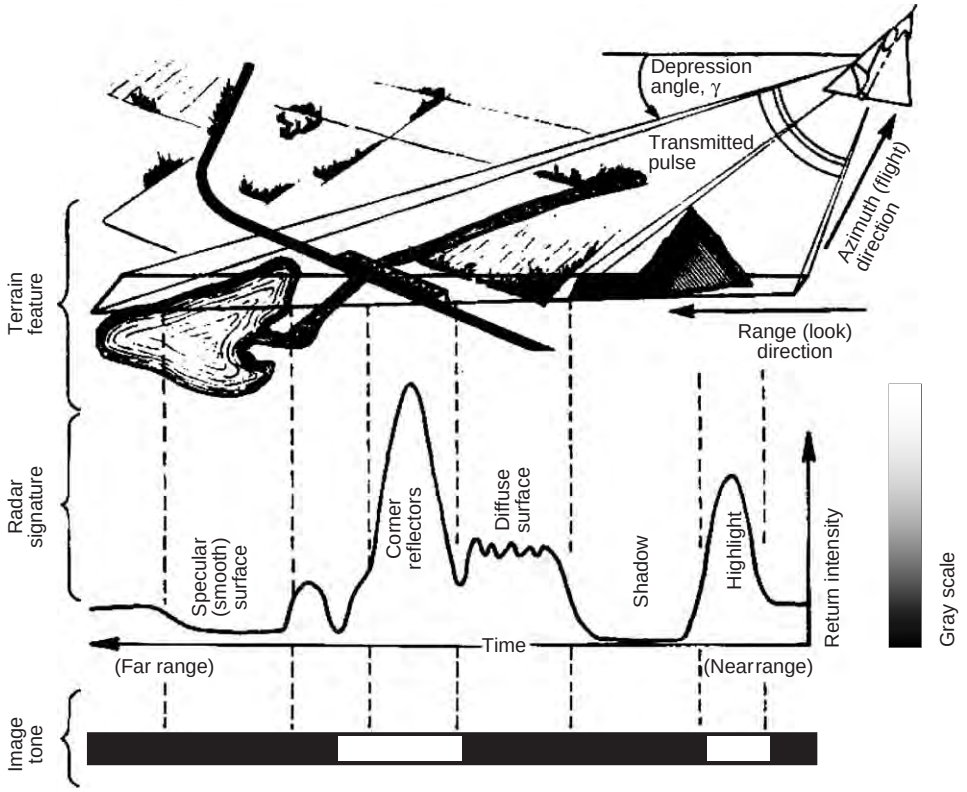

FIGURE 4 Terrain returns and image signatures for a pulse of radar energy. From Sabins (1997, Fig. 6-3).

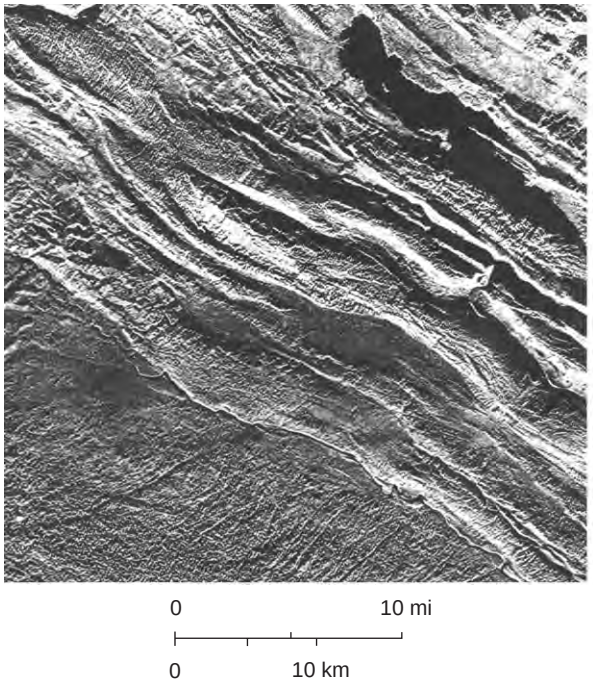

FIGURE 5 Aircraft radar image of the Lake Kutubu area of Papua New Guinea. From Sabins (1997, Fig. 10-8).

companies have explored and drilled the region for many years because of the numerous surface seeps of oil and gas and hydrocarbon shows in exploratory wells. When this project began, 144 wells had been drilled in PNG, but no commercial oil fields had been discovered. This remote area has a canopy of tropical rain forest and a hot, humid climate with persistent cloud cover and heavy rainfall. The terrain is dominated by steep ridges and deep river channels. Much of the region is underlain by limestone that weathers into steep pinnacles and pits, called karst topography, that cannot be traversed by vehicles. Reliable seismic data were unobtainable because of the rugged terrain and the weathering effects caused by pervasive subsurface solution cavities.

At the beginning of the project, Chevron decided to rely on radar images and limited fieldwork. A contract radar survey aircraft covered the area with a series of parallel image strips that were compiled into mosaics and interpreted to produce geologic maps. Based on these maps, the first well was drilled on a promising structure. The well was dry but had encouraging shows of oil. Exploration then shifted southeast to the region of Lake Kutubu. Figure 5 is

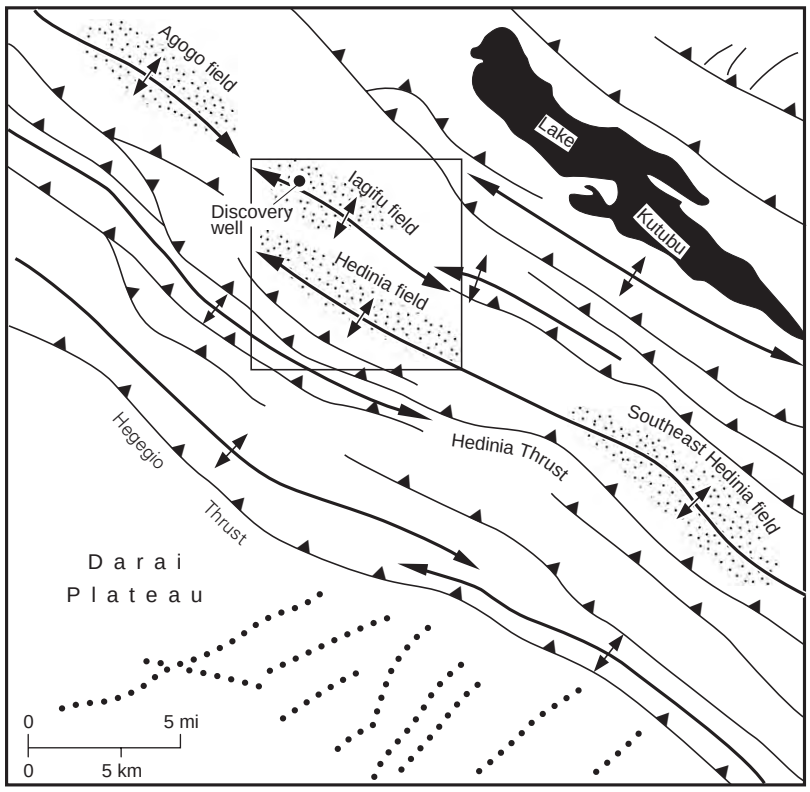

FIGURE 6 Geologic interpretation of radar image of the Lake Kutubu area of Papua New Guinea. From Sabins (1997, Fig. 10-9).

the radar image and Fig. 6 is the interpretation map for the area. Based on the radar interpretation and limited fieldwork, the first commercial oil discovery in PNG was made in March 1986 on the Iagifu Anticline at the location shown in Fig. 6. Subsequently, Chevron has discovered several additional commercial fields. A number of promising structures remain to be drilled in the region.

2.2 Central Arabian Arch Project

For a number of years, the Arabian American Oil Company (Aramco) was restricted to explore only within the "Retained Areas" of existing production that are located along the Arabian Gulf. Once the giant fields were drilled, no new fields were discovered through 1986. At that time, the government directed the company, now called Saudi Aramco and owned by the government, to explore the vast region of the Kingdom with oil potential that lies outside the Retained Areas. In early 1988, Saudi Aramco asked the Chevron Remote Sensing Research Group to conduct a remote sensing analysis of this region. The initial phase of the study covered the Central Arabian Arch, an area of approximately 200,000 km^2. The two objectives of the project were to map the regional geology and identify surface features that may be the expression of oil prospects.

The climate, topography, and geology of Saudi Arabia are the opposite of those in PNG. The arid climate and lack of vegetation are ideal for using Landsat images. The geologic structure is simple and uniform, in contrast to the complex faulting and folding in PNG.

Landat TM bands 2, 4, and 7 were combined in blue, green, and red to produce color images that were interpreted to produce regional geologic maps at a scale of 1:250,000 (1 in. = 4 miles). Aside from the sand seas, bedrock is well exposed. Geologic structure consists of regional dips of approximately 1° to the northeast or east on opposite flanks of the Central Arabian Arch. Distinctive color signatures on the images enabled the interpreters to divide several formations of sedimentary rocks into two or more mappable subdivisions, which proved valuable for identifying oil prospects.

Identifying potential drilling prospects was challenging because the geologic structure is dominated by broad uniform dipslopes that extend for several hundred kilometers along the strike and several tens of kilometers in the downdip direction. Unlike PNG, there are no obvious folds. Within the Retained Areas, oil fields are trapped in gentle anticlines formed above high-angle faults that offset the underlying rocks. The anticlines grade upward into flattening of the regional dip to form subtle structural terraces at the surface. We used this information to develop a three-dimensional geologic model for recognizing potential oil prospects on the images. A number of prospects were interpreted and were checked by geologists in the field. Saudi Aramco then followed up with seismic surveys of the most promising prospects.

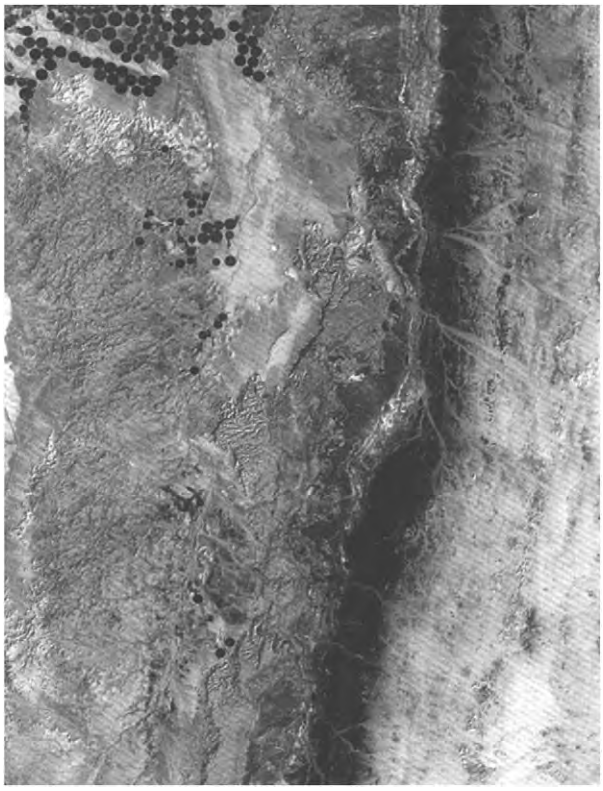

FIGURE 7 Landsat TM image of the Raghib prospect, Central Arabian Arch. From Sabins (1997, Plate 20-D).

Figure 7 is the TM image of the Raghib prospect located 110 km southeast of Riyadh. This black-and-white version lacks much of the information shown in the original color image that was used for our interpretation. Figure 8 is the geologic interpretation map. Jurassic and Cretaceous strata dip 1° east. Arcuate scarps form the downdip margin of an anomalous topographic depression that is mantled by windblown sand. Figure 9 is a subsurface structure map from a seismic survey that defines a northwest-trending anticline that is 35 km long and 10 km wide. The axis of the anticline is annotated on the Landsat interpretation map (Fig. 8). The topographic depression on the image coincides with the

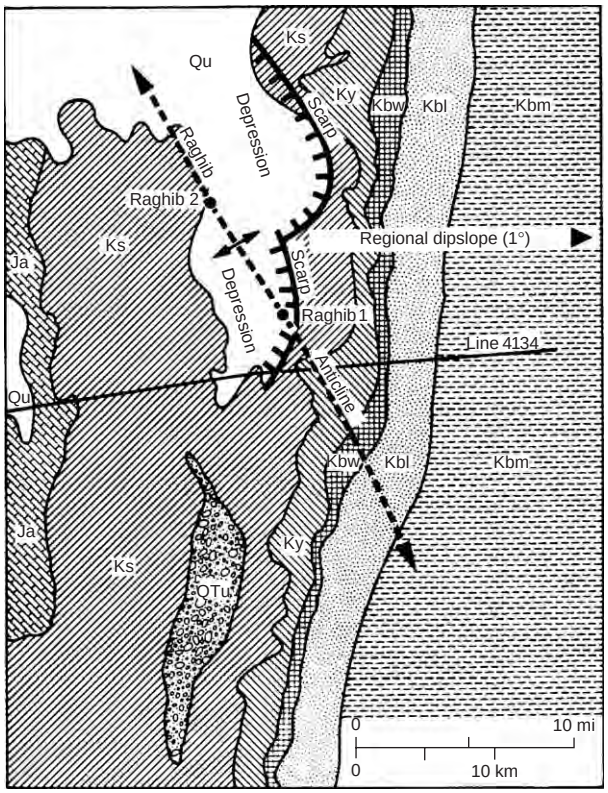

FIGURE 8 Geologic interpretation of the Raghib prospect. Raghib 1 is the discovery well and Raghib 2 is the confirmation well for the Raghib oil field. The patterns and symbols designate geologic formations. From Sabins (1997, Fig. 10-20).

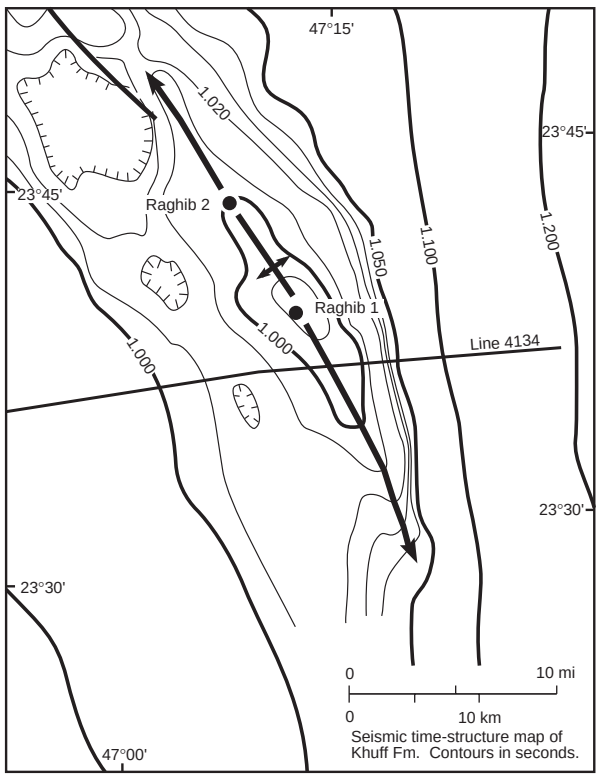

FIGURE 9 Seismic structure map of the Raghib oil field. The area coincides with the image (Fig. 7) and geologic map (Fig. 8). Contours are drawn on top of the Khuff Limestone (Permian age) and delineate a closed anticline that coincides with the surface feature. From Sabins (1997, Fig. 10-21).

crest of the subsurface anticline. In late 1989, Saudi Aramco drilled the Raghib 1 exploratory well located on the crest of the subsurface anticline (Fig. 8) and discovered a new oil field. A number of prospects remain to be explored.

2.3 Operational Applications

In addition to defining prospects, images are a valuable asset to field operations in regions that lack reliable maps. The cost and effectiveness of seismic surveys can be improved by information on topography and trafficability of the survey area. In the Sudan, Landsat images provided the only reliable base maps. The images were also digitally processed to map the different terrains, such as rivers, marshes, uplands, and papyrus swamps, that required different vehicles for the seismic surveys. In the rugged terrain of Yemen, topographic maps were compiled from satellite images and used to lay out the optimum pattern of seismic survey lines. In older oil fields, well sites and pipelines may be mapped inaccurately but can be correctly located with high-resolution satellite images. The cost is much less than that of a conventional survey on the ground.

2.4 Direct Detection of Oil

In PNG, Saudi Arabia, and elsewhere, remote sensing is used to recognize the surface expression of the subsurface structures (folds, faults, and domes) in which oil is trapped. Oil is not detected. In a number of oil deposits, some oil leaks to the surface to form oil seeps. During the early days of the oil industry, exploratory wells were commonly located at seeps. In a few fields the leaking oil has interacted chemically with the surface rocks to alter their mineralogy and color. Some investigators have attempted to identify seeps and altered rocks as an exploration method called direct detection. To date, the results of this method have been inconclusive.

3. ENVIRONMENTAL APPLICATIONS

Offshore oil spills are predominantly caused by tanker accidents and, to a lesser extent, drilling and production activities. Remote sensing images are used to detect spills and to monitor and direct cleanup operations. Table III lists the interactions between oil and electromagnetic energy at wavelength regions ranging from ultraviolet (UV) to radar. Figure 10 shows these interactions diagrammatically. The following sections describe the detection of oil spills on remote sensing images acquired in the various spectral regions. In offshore areas, oil may leak from deposits beneath the seafloor and form slicks on the water. Remote sensing of these natural slicks has been used to aid offshore exploration.

3.1 Ultraviolet Images

The UV spectral region spans wavelengths from 0.03 to 0.40 μm. Wavelengths shorter than 0.30 μm are absorbed by the atmosphere; therefore, only wavelengths from 0.30 to 0.40 μm are used in remote sensing of the earth. Figure 10A shows that incoming UV radiation from the sun stimulates oil to fluorescence at wavelengths from 0.30 to 0.45 μm (long-wavelength UV to visible blue). UV images are the most sensitive remote sensing method for monitoring oil spills and can detect films as thin as 0.15 μm. Daylight and very clear atmosphere are essential to acquire UV images. UV energy is strongly scattered by the atmosphere, but useable images can be acquired from altitudes below 1000 m. Cameras and scanners are passive systems that operate in daytime to record fluorescence stimulated by the sun. Active UV systems have been developed for aircraft use. A laser irradiates the water with UV energy that stimulates any oil to fluoresce. The fluorescence is recorded as a spectrum or as an image. The spectrum can be compared with a reference library of spectra to identify the oil in the spill. These active systems can acquire images both day and night but must operate at low altitudes under clear conditions.

3.2 Visible and Reflected Infrared Images

The visible spectral region spans wavelengths from 0.40 to 0.70 μm and is detectable by the eye. The reflected IR region extends from 0.40 to 3.00 μm, which is beyond the sensitivity range of the eye. The interaction between oil and electromagnetic energy in the visible and reflected IR regions is determined by the absorption and reflection of sunlight (Fig. 10B). Various types of aerial photographs record visible wavelengths and the shortest IR wavelengths (0.70–0.90 μm). Landsat TM records three visible and three reflected IR bands in digital format that is suitable for computer processing. During the invasion of Kuwait in January 1991, Iraqi forces deliberately released 4–6 million barrels of crude oil into the Arabian Gulf, where it covered approximately 1200 km^2 of water and 500 km of the Saudi Arabian coastline. This spill is the largest on record; for comparison, the 1989 Exxon Valdez spill in Alaska (<300,000 barrels) was an order of magnitude smaller. Repeated TM images tracked the extent and movement of the Kuwait spill.

3.3 Thermal IR Images

The thermal IR region spans wavelengths from 3.0 to 14.0 μm (Table III) and consists of energy radiated, or emitted, from materials. Figure 10C shows the interaction of thermal IR energy with oil and water. Both liquids have the same kinetic temperature of 18°C because they are in direct contact. Remote sensing systems, however, record radiant temperature. Radiant temperature differs from kinetic temperature because of the property called emissiv-

TABLE III

Remote Sensing Interactions and Systems for Detecting Oil on Water[a]

Remote sensing region	Wavelength	Oil property detected	Oil signature	Water signature
Ultraviolet	0.3–0.4 μm	Fluorescence stimulated by sunlight or laser	Bright	Dark
Visible and reflected infrared	0.4–3.0 μm	Solar reflectance	Brown, black	Blue, green
Thermal infrared	3.0–14.0 μm	Radiant temperature, controlled by emissivity	Dark (cool)	Bright (warm)
Radar	3.0–25 cm	Dampening of capillary waves	Dark (smooth)	Bright (rough)

[a] From Sabins (1997), Table 3–4.

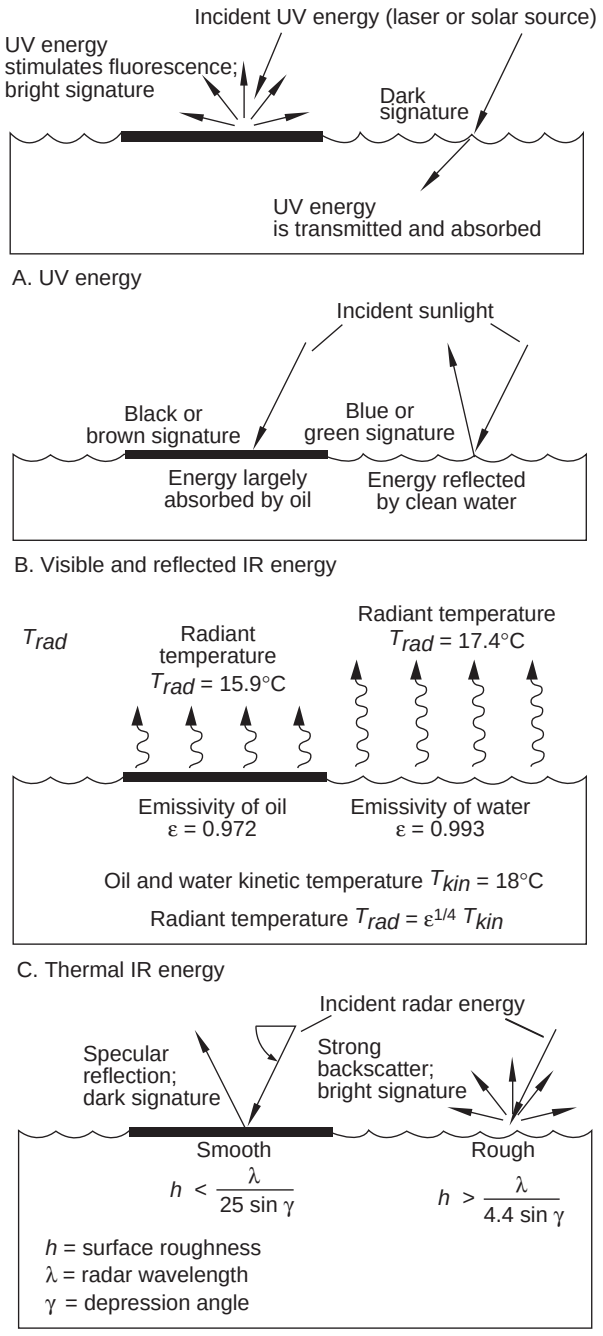

FIGURE 10 Interaction mechanism between water and oil spills. From Sabins (1997, Fig. 9-30).

ity, which expresses the ability of a material to emit radiant energy. Figure 10C shows emissivity values for oil (0.972) and water (0.993) and the equation for calculating radiant temperature. Substituting these values into the equation (for a kinetic temperature of 18°C) results in a radiant temperature of 17.4°C for water and 15.9°C for oil. The difference of 1.6°C in radiant temperature between oil and water is readily measured by thermal IR systems, which are typically sensitive to temperature differences of 0.1°C. Thermal IR images acquired from aircraft and satellites record oil slicks with cool signatures that are distinct from the warmer signatures of clean water.

3.4 Radar Images

The interaction between the surface and incident radar energy is very sensitive to variations in roughness of the surface, measured in millimeters and centimeters. Rough surfaces scatter large amounts of energy back to the antenna and have bright signatures. Smooth surfaces reflect the energy away from the antenna and have dark signatures. In Fig. 10D, clean water has characteristic ripples and capillary wavelets that cause a bright radar signature. An oil spill dampens the waves and causes a smooth surface, or slick, with a dark radar signature.

Glossary

city An urbanised area managed and represented by one or several local governments, culturally and communally understood as a city, with specific administrative and political boundaries.

city region The general urbanized, ecological, and economical area constituting and surrounding one or several urban nuclei, all or any of which may be defined as a city.

climate-stable practice A city's climate-stable practice is a practical commitment to lower greenhouse gas emissions by a target date such as the year 2050 to an amount that is proportionally in keeping with the globally sustainable level.

carbon-dioxide-equivalent (CO_2-e) Expresses the presence of all effective greenhouse gases as an amount that would be required in CO_2 to achieve the same effect.

greenhouse gas (GHG) Human activity effected gases that trigger global warming are carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), chlorofluorocarbons, especially CFC-11, HCFC-22, and CF_4. In this article their emission levels are expressed as CO_2-e.

solar In its wider definition connotes all aspects of energy sources, which can be traced to the action of the sun. These include solar thermal, photovoltaic, biomass, bio energy, wind and wave energy, and, strictly speaking, also fossil fuels. In the pure sense, solar describes renewable forms of energy that neither create greenhouse gas emissions nor nondegradable or toxic waste.

urban(ized) area A builtup space of higher density and production and consumption functions that is distinct from rural or undisturbed natural areas.

Cities are intensive centers of social activity and the central feature in the economical technology of civilizations. Cities directly express the energy resource framework and infrastructure available at any given time in history. Global acceleration in city formation and urban growth can be ascribed to a number of technological innovations, none more profound in their impact than the rise and spread of fossil fuel resources, products, systems, and tools. The resulting massive threats—CO_2 emissions–induced climate change and the inevitably approaching plateau in worldwide fossil fuel production—raise the vexing issue of cities' overwhelming dependence on oil and other hydrocarbon energy sources as well as the question of how and when a postfossil fuel urban era can commence and whether this necessary historical transformation can take place in a stable manner.

1. ENERGY TECHNOLOGY AND MODERN URBANIZATION

The age of industrialization came into full force through the modern exploration and use of fossil fuels. As one of its most striking phenomena, the rapid expansion of cities throughout the late 19th and the 20th centuries was a direct outcome of the fossil fuel economy as well. The development and operation of cities and urbanized areas presently absorbs roughly three-quarters of the world's fossil fuel production, including intra- and interurban transport. This indicates cities' massive role in the worldwide carbon consumption and emission regime: fossil fuels, prime source of anthropogenic CO_2 emissions, supply 85% of total global commercial energy use—and their consumption is increasing at a rapid rate.

Yet economic regions, nations, and cities worldwide are under great pressure to find alternative

sources. Cities will have to be powered differently within the lifetime, prompted by a historical coincidence of carbon emissions–induced climate change, the great likelihood of an impending plateau in fossil fuel production—while energy demand continues to rise dramatically, prompting steep price rises—and mounting environmental damage due to the use of oil and coal. The use of renewable and distributed micropower systems is already on the rise, but the speed of change is seen as too low by many to meet global goals in time to avert serious crises. Combined with large-scale facility efficiency and energy conservation programs, the introduction of renewable energy generation technologies in cities offers one set of profound opportunities as well as challenges, and the reform of transport systems, settlement patterns, and land-use practices provides another.

Cities, towns, and other urban communities are regarded as settings for coordinated efforts aimed at global renewable energy technology introduction and carbon emissions reduction programs. However, substantial organizational and cultural barriers militate against immediate, wider change. Among these loom large the subsidiary regard in which cities are held in the traditional hierarchical frames of the international arrangements that deal with global issues. Another challenge is the energy-blind nature of contemporary physical planning, typically very short planning horizons and political uncertainties that prevail on the local level. In terms of policy development, measurement techniques, and planning reality, an extraordinary gulf exists between the global nature of greenhouse gas impacts and fuel depletion prospects and the local reality that represents both final impact and original source of globally experienced change.

Due to their fundamental fossil fuel reliance, most capital outlays in new buildings, infrastructure, and other urban facilities risk early obsolescence: urban areas, infrastructure systems, and individual buildings and other facilities that are based on fossil fuel construction, maintenance, and operation are likely to be rendered dysfunctional well before the end of their life. All basic urban communication infrastructures, both traditional (such as roads, rail, air, and seaports) and advanced (such as telecommunications), have been nurtured in a world of near-absolute fossil fuel dependency. Indeed, the Internet, a vital global and largely urban network of networks, relies largely on fossil fuel operated hardware, conduit-based webs, and wireless communication systems. If global communications are to be sustained reliably beyond the middle of the 21st century, they must be powered by distributed, ubiquitous, and redundant renewable power supply systems. The required technology arrays with the concomitant policy and action frameworks do in principle exist to bring about manageable postfossil fuel urban environments.

2. HISTORICAL PERSPECTIVES

2.1 The Rise of the Fossil City

Modern cities have grown on a rich fossil fuel supply base, and especially dependent are the largest, most rapidly growing urban agglomerations. The very logic of their global rise and regional spread is founded on the availability of powerful, centralized, and inexpensive fuels—coal, petroleum, and natural gas—yielding fossil urban structures and patterns based on fossil transport, fossil construction machinery, and fossil industrial systems and manufacturing processes. Intensive economies and labor markets are clustered around the centralized and networked city regions, anchored by heavy investments in infrastructure: power, transport, and communications. This has boosted the primacy of cities over—and ultimately detachment from—agrarian hinterlands.

The new cities of the 19th and 20th centuries—and the very cultures they engendered—were a product of the rising combustion economy. The sheer size of London exploded when coal-fired power made this a technological possibility. Historian Lewis Mumford called the phenomenal urban transformations taking place in industrializing countries between 1820 and 1900 “Coketown” or “Paleotechnic Paradise.” Pre- and post—World War I modern city innovations in the Soviet Union, the United States, Europe, and across Asia were brought to life by the electrifying jolt of the new energy technologies. In the 1940s and 1950s, industrial and government-led transport policies revolutionized urban America away from rail-based modes to technologies promoting petroleum, automobile, and tire consumption. The rising car dependency in most cities, combined with the spread of electrified suburban households under expanding power grids, constitutes one of the most vexing challenges of managing urban environments worldwide today.

Fossil fuel–powered industrial transformations that underpinned broad urban structure change were celebrated by the leaders of the great modern design

movements, from the beginning of the 20th century: Italian futurism, constructivism in the early Soviet Union, De Stijl in the Netherlands, the Bauhaus in Germany, the declarations of the International Modern Architecture Congresses (CIAM—Les Congrès Internationaux de l'Architecture Moderne, 1928–1956) and the International Style that spread from the United States throughout the industrialized world.

The fossil machine age is an outgrowth of earlier stages of the Industrial Revolution when water power was a main driver of textile mill operations. Boosted by the industrial application of coal and electricity, it gave rise to Frederick Winslow Taylor (1856–1915) and Henry Ford's (1863–1947) ideas about the mechanization of manufacturing, as noted by Gideon in 1948. In their wake, the increasingly urban and automated global production-consumption systems of the advanced industrial age boosted global power use at an exponential rate.

But industrialization as powered by electricity, coal-fired steam engines, and petroleum combustion motors also meant the rapid growth of cities, driving the search for innovation in urban form. A plethora of utopian premonitions spread as a result, as revolutionary as the technological changes that triggered them. Peter Kropotkin's (1842–1921) and other anarcho-syndicalist influences on ideas about ideal communities were a direct outgrowth of this era; so were Sir Ebenezer Howard's (1850–1928) concepts and the rise of the Garden City movement. The genesis of the Regional Plan Association of New York and its seminal plan of 1929 were of this lineage, as was Frank Lloyd Wright's (1869–1959) Broadacre City (first described in his 1932 work *The Disappearing City*). Ludwig Hilbersheimer's (1885–1967) mass housing concepts and General Motors' Futurama pavilion at the 1933 "Century of Progress" World Exposition in Chicago boldly anticipated the great car-friendly cities to come. Brasilia, Canberra, and all of the British New Towns are fossil technology plans come to life.

The urban environmental phenomenon of the modern suburb followed. Early ex-urban subdivisions sprung up as aspiring new communities along the tracks of electric tramways, such as the famed streetcar suburbs of many North American, European, and Australian cities such as Brookline, Newton, or Jamaica Plain in Boston, or Balmain, Rozelle, or Mosman in Sydney. Soon thereafter the combustion-engine driven vehicle created a new urban reality altogether: the new car suburbs expanding along motorways. Mass media–driven promotion of a new fossil fuel–based lifestyle spawned the automobile and petrochemical product–based industrial civilization after World War II. This new vision became expressed in a new set of urban form aspirations. Many of these early premonitions proved to be very much practical concepts: already very early in the 20th century the great electric inventions of the telephone and the elevator opened the door to skyscraper cities, first as utopian visions and later as pervasive reality.

Modern carbon-based energy civilization is epitomized in its great landmarks with the seminal work of migrant Bauhaus architects such as Walter Gropius and Mies van der Rohe. Swiss architectural pioneer Le Corbusier's ideas about the radical modernization of cities are widely regarded the most influential of these, boldly calling for the razing of prefossil cities, as exemplified by his *tabula rasa* concepts: the Parisian Plan Voisin; La Ville Radieuse; the famed lone pilot project for a mass housing block, Unite d'Habitation; and in some realized urban projects such as in the Alsatian town of St. Di*é*. His plan for Chandigarh, the joint capital of the Punjab and Haryana states established in 1953, stands out among the league of pioneering fossil fuel based urban innovations. This simple yet revolutionary doctrine was soon implemented in cities in the United States, the United Kingdom, and countries around the world. It brought urban destruction and blight through wholesale urban renewal projects in what were identified as inner-city slum areas: the neighborhoods of the poor and disenfranchised and the prefossil relics they inhabited.

The postwar years in Europe saw powerful expansion plans realized, taking advantage of the spreading webs of electrification that crisscrossed former farmlands. The Greater London strategy, the European satellite city concepts, and the Stockholm and Copenhagen finger plans gave bold plan form to a wider, worldwide turn to life in cities, driven by structural shifts and opportunities brought about by the rise of the fossil fuel economy and its promises.

Yet the new vision of renewed and more orderly, healthier, and socially more equitable cities did not escape the environmental reality of advanced industrialization. With the burning of fossil fuel arrived sulfur dioxide, nitrous oxide, and a host of other toxic gases as well as carcinogenic airborne combustion particles, creating the smog and air pollution crises of the 1960s and 1970s. With the exception of the greenhouse gases themselves, these have largely been conquered as hazards in the industrialized world while still plaguing large cities of the developing world.

Mounting calls for more densely concentrated and public transport-based forms of urban development since the 1970s were early signs of a declining stage of the fossil-fuel economy when savings in energy conservation and fuel efficiency began to be identified as the cheapest, fastest, and most immediately useful means to reduce emissions. Denser cities were shown to be more fuel-efficient, while car-dependent, low-density urban structures incapable of sustaining public transport have come to be understood as a major hindrance to achieving sustainable urban life.

It is widely understood, however, that efficiency and conservation measures are not sufficient to halt the global rise in CO_2 emissions in the long term. Massive substitutions of conventional energy technologies conveyance with renewable systems of energy supply and use have long been accepted as essential. For these new technologies to be in place in time to be of significant use, they need to be widely introduced as soon as possible. In this sense, transit-oriented development and attempts at re-creating preindustrial urban patterns such as neo-traditional design and other approaches are important interim measures.

Both nature and form of buildings were changed by the development and spread of the revolutionary new fuels and the industrialized manufacturing processes they engendered. Urban environments and architecture changed radically in the new fossil age, breaking with all earlier traditions. The Modern Movement stylistically refined mass applications in electricity, power machinery, air conditioning, industrial steel products, advancing glass technology, mass produced curtain walls, prefabricated building systems, and a number of other highly energy-intensive technologies. The new thinking about buildings, highlighted by the International Style, applied to aesthetically refined, ornament-free, skeletal, industrialized, and largely corporate structures. It became the new global aesthetic of the possible as the advanced fossil age dawned in cities around the world. Buildings became disconnected from their climatic and cultural context due to the end of local resource dependency. An interest in vernacular form and regionalism emerged as a counter-reaction and an attempt to recapture the local language of form: the regional building traditions that had been lost in industrializing change. This movement remained a stylistic artifice since it failed to address the fundamental dynamics of design and development under conditions of unsustainable energy resource practice.

2.2 Local Measures: Fossil Fuel Conservation versus Replacement

As a reaction to these historical perspectives, the building industry has witnessed a certain rise in design responses to regional climatic conditions, as part of a powerful efficiency and conservation push since the 1970s. More recently, the zero-emissions house and office building has become a design concept as part of strategies to introduce renewable energy as an increasing contributor to managing urban energy supplies. In its pure form it is to function without primary fossil or nuclear energy supply input and has been the focus of worldwide research and development efforts for several decades. Also addressed is the question of how to reduce the large amount of fossil energy that is embodied in the building materials themselves, the services contributing to their making, and the energy implications of the very form and design of neighborhoods and cities. The energy household of cities is expressed by the sum total of all goods and services consumed in a given location: hence location-based emissions reduction measures are a primary target of urban energy reform.

The urban transport question, too, has opened up a powerful energy dimension, with two countervailing fundamental positions emerging. The energy conservation strategy points to the massive sprawl and wastefulness engendered by modern car-based cities, with the least dense consuming the highest amount of gasoline per capita. The public transit oriented development and urban consolidation or compact city policies of the 1980s resulted from these observations. The other argument is based on a general conviction that the age of individual transport is inevitably going to stay. It sees the future of personal transport to lie in biofuel and hydrogen combustion or fuel cell–powered vehicles. In this scenario the advocates of denser, more complex urban settings serving cultural and social objectives would lose out, since it paints the prospect of a solar-hydrogen energy revolution that could also accelerate urban sprawl.

2.3 Global Aspects

Global urbanization as a product of the fossil-fuel economy is expressed in the ready availability of inexpensive fossil power for all urban infrastructures, telecommunications, and freight and human transport systems on surface, sea, and air. These bundles of infrastructure at once link cities globally and bypass their regions. As a consequence, globalized urban systems are inherently more vulnerable to the

decline of global fossil fuel supplies than those that rely more on their local and regional human and land resources.

The deployment of renewable energy technologies on a large and especially urban scale has the potential of bringing about a time of differentiated globalization, marked by a distinction between local supplies of food and elementary goods on the one hand and the global trade in services on the other. This condition as brought about by nonfossil production modes would be characterized by a rise of regional economies in support of urban centers, based on regional resources such as productive land for food, biomass, and wind energy production. New ways of reknitting central cities with their regional economies and related spatial structures are already being pursued by a number of communities. These are based on older principles of rural urban support economies, boosting the primary sectors of agriculture and forestry. Cities around the world have started to make concrete links between their renewable energy needs and potential regional resources capable of meeting that need. This movement is also beginning to help spawn new indigenous manufacturing and advanced industry sectors in renewable energy production, supply, and services.

In urban industrial terms, initiatives fall into two categories: new technology development and the accelerated market uptake of applications. Technology push and supply from the 1970s through the 1990s were limited to a number of limited-scale industry efforts and pockets of largely government-sponsored research and development projects. This history is often marked by a mismatch with market demand, especially given the powerful subsidies granted to the fossil energy sector. Yet the international and domestic policy and pricing environment of the early 2000s promises to change fast, heralding massive urban technological and practice changes and a natural integration of technology development and markets.

While a few local urban systems may seem relatively safe from a terminal fossil fuel shock through their reliance on coal, hydroelectric, nuclear or bioenergetic power, no currently utilized alternative energy source alone can keep operational the vast majority of cities. Also, the interconnectedness of the global system makes implausible the survivability of regional pockets of self-sufficiency. The only viable option to secure the continuity of urban civilization in this century is a system-wide turn to a broad portfolio of renewable energy sources based on an overwhelming availability of solar, wind, wave, hydrogen-based, and other renewable forms of energy generation, combined with massive conservation and efficiency innovations.

3. INNOVATION IN URBAN RENEWABLE ENERGY TECHNOLOGY

Most contemporary fuel sources are due to expire well within the 21st century as widely available and predominantly peacefully contested sources, and much of this reality will become globally pervasive within these next decades. Even conservative industry, national, and international governmental sources estimate that oil will expire by 2050—the depletion of the more easily accessible supply sources is likely to take place already in the 2020–2030 time frame. Given rising use rate scenarios, natural gas is likely to evaporate as a commercially available source by 2040. The oldest and most problematic source of fossil fuel supply, coal, is expected to expire as a globally available source before 2100—provided no large-scale efforts of energy fuel substitution are pursued to stretch its deposits.

Uranium supplies are also estimated to reach depletion levels by the mid-2030s, even if the daunting cost, security, safety, disposal, and public acceptance dilemmas did not weigh so profoundly against their use. Significant growth rates in uranium usage are not anticipated, given the risks involved and a waning willingness among many governments to pursue nuclear fission further. Nuclear fusion, more than half a century after its arrival as a great modern dream, still struggles with enormous conceptual and technical flaws, and the problems associated with huge financial, environmental, and political costs. These include the spectre of broad public resistance to a new generation of nuclear super-reactors.

This outlook is as troubling as it is underemphasized in its public significance. Fossil fuels are the lifeblood of modern economies and the foundation of the petrochemical, transport, and industrial production systems. Hence they also sustain the spatial centers of global civilization: cities and city regions. The paradox is perplexing but can be explained by the daunting magnitude of the problem. While the modern city in its history, form, and growth dynamics is inconceivable without these fuels, a persuasive agenda to deal with the prospects equitably, humanely, and positively still eludes global and local planners alike.

Yet the most optimistic plans about the powering of urban areas describe entire cities as net renewable energy producers. This idea requires a rethinking of

urban-regional alliances as well as an adoption of increasingly firm industry promotion practices. The Australian city of Melbourne, as an example, is in the process of investing in renewable energy producers with the dual aim to reduce its fossil fuel dependency and to promote the development of more advanced industries capable of competing nationally as well as internationally.

In a technologically advanced renewable economy energy supplies no longer exclusively depend on large, centralized supply models but can unfold in a more diverse and differentiated manner, in keeping with the principles of convergence, blurring the conventional distinctions between different technologies and production and consumption. Traditional energy users become net energy generators, for instance, through solar systems or zero-emission, renewable-source based hydrogen fuel cells in vehicles capable of powering homes and external machinery.

Systems convergence dynamics also point to a merger of information technology, telecommunications, and energy systems. While some electric utilities already lease their grids for information transmission purposes, emerging technology goes much further: future energy systems are ubiquitous and pervasive, and networked into virtual power plants. Ubiquitous energy management connotes the hopeful notion that in a renewable-energy based economy a myriad of small and medium-scale providers of energy services could replace the system of large-scale centralized ones. In an urban system this could operate both at the high end described and at low levels of technological sophistication.

Possible high-technology directions contain features derived from information technology and telecommunications mergers, or the blending of these new technologies with energy production and consumption modes residing everywhere, in applications that range from personal equipment to cars and facilities. At the lower end of the scale, in a distributed yet low-cost and low-maintenance environment, small hydropower and solar systems are seen to be capable of leveraging access to the global information network for small remote communities in developing nations.

4. THE URBAN RENEWABLE ENERGY PORTFOLIO

A number of renewable energy technologies and related approaches and systems is available to supplement and even supplant conventional fuel sources in cities. As a main distinguishing feature when compared to more conventional systems (fossil, nuclear, large hydro, municipal waste incineration), they all vary greatly in scope, style, and systems features, and their economic and physical attributes varies too, including their visual attractiveness. Together, they present an urban power paradigm shift, in the move from the large and passively sourced supply networks to a much wider and dynamic array, or portfolio of systems, many of which are in the control of individual users.

Because the legislative, practical, and financial energy supply structure in a number of countries is not traditionally geared to cope with such simple systems as decentralized small cogeneration plants or grid-feeding domestic solar photovoltaic or solar thermal power plants, significant challenges lie ahead, waiting to be overcome. Fortunately, numerous urban applications are in place, largely in Europe and the United States, ready to be used as best-practice examples.

Buildings, facilities, infrastructures, and even cultural expectations associated with the city are intrinsically linked to and based on the industrial paradigm engendered by fossil fuels. Energy efficiency and conservation have an extraordinarily powerful role to play in reducing the historical dependency of cities on massive fossil fuel input. Ambient temperature stabilizing landscape corridors, native garden-based suburbs, vegetation-covered roofs and walls, natively landscaped atriums, urban agriculture, and better water management all contribute to reducing urban energy input requirements, in this case for cooling.

In supplementation of efficiency and conservation measures, the available power-generation techniques in cities include those shown in the Table I. Many sources listed under Bio/waste are not strictly renewable or environmentally sustainable in their use, especially those relying on waste incineration. They are nevertheless included because many countries do account for them in their renewable, sustainable, new, or alternative energy statistics, as does the International Energy Agency (IEA). Unfortunately, these de facto nonrenewable and carbon emitting sources represent the lion's share of many statistically declared sustainable energy components. New, more efficient fossil fuels systems such as advanced coal and gas applications are excluded altogether.

5. CLIMATE STABILITY IN URBAN DEVELOPMENT

Worldwide, municipal policies are marked by a slow but steady growth in commitment to planned urban

TABLE I

Renewable Power-Generation Techniques and Applications Relevant to Urban Systems

Solar	Photovoltaics (PV)	PV panel and array systems	Building/infrastructure

energy practice. As global agreements promise to become firmer under mounting pressures to resolve the greenhouse challenge, and as nations and regional policy units such as the European Union begin to establish clearer greenhouse, energy, and environment frameworks, local institutional pressure mounts to arrive at unprecedented arrangements in urban emissions and energy practice.

As cities are increasingly seen as global emissions performers, distributed energy managers and potential credit trading entities, a new science and engineering practice is on the rise that interprets cities and city regions as power systems, resource flow units, and point-of-emission locations. The best-known urban environmental and community planning models are based on relative improvement targets and selective means of accounting for greenhouse gas (GHG) emissions, setting the stage for the phasing in of renewable energy systems on an urban scale.

A number of place-based emissions allocation techniques and action approaches are in use. These

include the United States Environmental Protection Agency's support made available to states in compiling GHG inventories, in producing action plans, and in staging demonstration projects. They also include the emissions approximation system developed for the Cities for Climate Protection (CCP) program operated by the International Council for Local Environmental Initiatives (ICLEI). Another accounting approach based on the behavior of large geographical units—one degree of longitude by one degree of latitude—is a program called Global Change in Local Places developed by the Association of American Geographers. There is the potential to apply aspects of the Advanced Local Energy Planning approach developed under the International Energy Agency's (IEA) Building and Community Systems program, or the physical model of the economy developed by the Australian Commonwealth Science, Industry and Research Organization. Another ambitious model is a total-flow, end-consumption, and value-based accounting system advanced at the University of Sydney. It also aims to compare, evaluate, and advance a range of methods.

While most GHG emission sources and mitigation efforts are inherently local, their effects and most easy modes of measurement operate globally. However, the identification of globally diffused GHG levels carries little practical local meaning. For cities to become active and integral participants of any global action program, they need to opt for one or the other GHG accounting or allocation method that reliably links local practice to global aims. A persuasive argument holds that only systems reliably measuring contributions to climate stability are valid and more specifically approaches that embrace a 3.3-ton of a 1990 carbon dioxide-equivalent target by 2050. This target is based on a fundamental equity calculation: that on a per capita basis each person has only an annual 3.3 ton emissions allowance, if oceans and forests are to neutralize excessive carbon emissions. In contrast, Australia and the United States approach 30 tons per annum per person, while most developing countries, including India and China, lie well below this sustainable 3.3 t/p/a level.

An ideal method has not yet been found, and in pursuing it, cities need to apply certain performance criteria. To be informative, universally acceptable and suitable as a basis for coordinated climate stable practice such model would need to be comprehensive, precise, and accurate. To be useful it also has to be pragmatic, affordable, and easily replicable across a large number of communities or geographic units. Another challenge lies in avoiding a new information poverty barrier. It could develop were local carbon trading to be introduced as based on highly sophisticated and expensive forms of data gathering—poorer nations have less capacity to cope with the technical challenges involved in measuring emissions performance, let alone reliably monitor its progress over time.

The single most widely promoted method is that of ICLEI's CCP program. It is introduced by participating local governments as the first of CCP's five steps to better GHG performance: namely the arrival at an energy and emissions inventory, forecast, reduction target, target achievement plan, and active implementation program to achieve measurable GHG reductions. At these relatively early days of the CCP program measurable success in reaching significant implementation goals has been elusive, while the other milestones have been reached to lesser and varying degrees. It is hoped that in future rounds of development, in association with other methods and given a better understanding of the key barriers to success, a breakthrough in implementation can be achieved. The very imperfections of the method and its omission of significant emission sources makes the CCP system attractive in practical terms but perceived as scientifically ambiguous in globally credible accounting contexts, and of limited efficacy for local improvement monitoring over time, when absolute performance is to be measured.

There are a number of obstacles on the path to a transformed urban energy practice, although none is insurmountable in principle. The most formidable is the fact that local governance structures are not usually geared to end-state or long-range planning, hence the adoption of long-term accounting methods is often resisted. The effective allocation of incentives and accountabilities is difficult too. Notwithstanding the efforts described earlier, there is the persistent question of how to convincingly disentangle resource flows in a local government area not only for carbon accounting but also for scenario modeling purposes, and how to identify agency accountabilities for savings and reduction.

Despite these challenges, the very consideration of broad energy and greenhouse action programs opens up new dimensions for government. It can provide a new development perspective and drive regional realignments, the formation of state initiatives and industrial alliances. It can mean a new sense of empowerment and the opportunity for economic strengthening as well as engender competitive advantages of a more promotional nature.

Governments discover that energy responses can be scaled well to local development paths and growth options. In newly industrializing countries with interest in maintaining considerable levels of autonomy such as China and India, there is a good fit with local traditions and climatic and economic conditions. Local industry can get stimulated while environmental policies find a practical agenda. Comprehensive renewable energy practice on the local level directly reinforces broad quality-of-life aims, as well as healthy water, clean food, and sustained biodiversity levels.

Besides the aim of responsibility devolution in pursuit of global greenhouse objectives, another government reform agenda item is being satisfied as well: better accountability in public service. Outcome-geared reform and strengthening of local governance in delivering on performance commitments could well be a direct outcome of an indexed and measurable sustainable energy practice. Local consensus, too, is expected to be forthcoming more easily as agendas become more clearly understood and made visible in tangible improvements.

6. URBAN RENEWABLE ENERGY POLICY AND PRACTICE EXAMPLES

In the absence of useful and established patterns of practice, a search is under way for new means of reconciling local government's sectorial concerns, technological opportunities, and shifts in energy markets with global environmental imperatives. There are several hopeful initiatives, focusing squarely on comprehensive local action in urban and regional conversion to a renewable energy supply base.

6.1 Urban Programs: Barcelona's Solar Ordinance

An increasing number of cities search for paths to energy sustainability. One of the most progressive of these is Barcelona. The city has calculated its very favorable solar energy supply potential and in 2000 introduced a regulatory system requiring households and industrial users to provide at least 60% of their hot water requirement utilizing solar systems. The scheme is focused, specific, and practical and based on a precise accounting of domestic energy production and utilization profiles.

6.2 Professional Practice: The European Charter for Solar Energy in Architecture and City Planning

The charter, signed by 30 eminent architects and developed by these under the leadership of German architect Thomas Herzog, was released in 1996, at the Fourth European Conference Solar Energy in Architecture and City Planning, chaired by then minister for construction Klaus Töpfer and parliamentarian Hermann Scheer. The charter was advanced in historical contradistinction to the fossil-age Charter of Athens, referred to earlier. It is comprehensive in attempting to deal with most physical planning challenges in an energy-conscious manner. The charter focuses on the role of planners, the building site, the design and construction process, buildings in use, and the city as a sustainable planning challenge.

6.3 Regional Policy: The Eurosolar Guide to State Politicians—A State Program for Renewable Energy

The renewable energy technology and policy organization Eurosolar has in 2001 issued a blueprint program, for the use by regional politicians in the implementation of renewable energy. It has ten focal areas or considerations: (1) the role model played by state government, (2) the role of state energy agencies, (3) the strengthening of municipal power companies and the placement of energy supply into community hands, (4) research and education, (5) renewable energy in regional development, (6) strengthening of agriculture, (7) the orientation of land-use planning and building toward renewable energy, (8) transport and traffic systems, (9) investment and finance, and (10) state government awards for the exemplary use of renewable energy.

6.4 City Guidance: The World Council for Renewable Energy's Solar City Program

The Solar City approach originally emerged from a new generation of International Energy Agency (IEA) research and development work to pursue citywide applications as integral to the main planning agenda. It is now adopted by the World Council for Renewable Energy (WCRE) as a basic policy and planning basis for cities. It recommends that renewable energy technologies and other means of greenhouse gas

emissions reduction and absorption should be applied in a coherent spatial and social context, as well as within a finite and community-wide time frame.

For application by local institutions, the focus is on the energy supply and technology side, within a comprehensive town planning and design strategy that includes institutional arrangements. The goal is to develop energy technology applications and emissions accounting systems along with performance targets linked to urban development and reform initiatives. Also important are strategies that are based on a consideration of urban-rural linkages and value land use and transport investment choices with a view to their contribution to long-range energy and resource self-sufficiency goals.

The Solar City planning approach presents five areas of focus to cities and city-regions, to be advanced simultaneously. This recommended program constitutes a well-rounded framework for transforming any city's energy regime in a systematic and comprehensive manner.

6.4.1 Solar City Strategies

It is recommended to identify local planning and development approaches that are conducive to the introduction of renewable energy technologies, within a broadly energy-conscious community development approach. To be addressed are strategy, planning tools, organizational arrangements, legislation and standards, incentive structures, public information, and exemplary municipal practice.

By introducing improved ways of adopting renewable energy technologies, a municipal program is to be designed to contribute to climate-stable practice in the building and property development industry, land-use planning, and infrastructure development. It should be framed in ways that help strengthen local governments' efforts to build enlightened community performance and household preferences.

Cities and towns can pursue renewable energy programs through the following methods:

- Direct legislation and standards
- The provision of incentives and disincentives
- Corporate capital asset practice, power purchasing, and pricing
- Institutional reform and improved strategic and general planning practices
- Community action, industry alliances, information, and education

Guidance provided to participating cities is to investigate each of these in detail and develop advanced means of building improved urban practice approaches.

6.4.2 Setting Targets

The aim is to introduce, enhance, and evaluate suitable approaches that help explain the role of renewable energy technologies in the broader urban energy context. It is important to include both renewable energy technology implementation targets as well as absolute climate-stable carbon dioxide-equivalent emissions measures aiming at a specific future date.

Planning methods based on energy technology introduction and emissions accounting methods may deploy backcasting approaches. This involves the development of alternative urban development growth and technology transformation scenarios, then establishing milestones for technology innovation and emissions to determine workable reduction rates over time.

6.4.3 Urban Renewable Energy Technology, Systems, and Industry Development

The aim is to work with cities in advancing renewable energy technologies and systems and to help promote the renewable energy industry in a way that allows it to serve as model for the rest of the national urban system. The emphasis is therefore on market-led approaches of technology system development and deployment, through pricing, investment, electricity purchasing policies, information, model action, and other means.

It is recommended that optional paths are developed, evaluated, and implemented, suitable for the informed and broad introduction of renewable energy technology portfolios and the use by city governments, municipal utilities, businesses, industries, and households. Special emphasis is to be placed on microgeneration and distributed low-energy production in buildings, facilities, and urban infrastructures. Emerging and potentially competing solar and other renewable energy systems and related urban services are to be assessed for their systematic introduction in ways that are meaningful to cities' development agendas—physical planning, sustainability objectives, organization, services—and their value in targeted emissions reductions.

Outcomes are expected to include technology, systems, and industry development options, suitable for selective and targeted implementation in general and specific action plans—answering the following questions: What can city governments in collaboration with industry and constituent urban

communities do to advance the direct use of renewable energy sources? How can these be useful to residential neighborhoods, industry, and transport? How can they support the generation of electricity in quantity, through solar, wind, biomass, geothermal, and sustainable hydroelectric power? And how can cities as organizations contribute to the development and deployment of industrial and residential application, such as stand-alone power generators, heat pumps, photovoltaics, solar hot water production, or solar cooling?

6.4.4 Understanding Best Practice

The recommendation is to make accessible and apply useful lessons from related initiatives domestically and worldwide. This is to be achieved by studying successful practice in integrated urban energy planning, management, and projects. The activities include an identification of scope and criteria for evaluation, information gathering and documentation, study and evaluation, analysis and description, case study development, and communication and dissemination. The scope encompasses technologies, management practices, and growth strategies. Several main categories of case studies are to be differentiated: comparable cities, urban precincts, and settlement projects but also development policies and programs.

6.4.5 Learning from Action

This important final recommendation is to creatively reflect on program experience derived from the application of such programs. This will help develop a shared understanding of the barriers to community, institutional, industrial, and technological change, with a view toward the planned phasing in of solar and other renewable energy sources on an urban and regional scale.

This structured approach will not only be useful to any city engaged in a renewable energy implementation program, but also be of value in the application of lessons and methods across the national urban system.

Glossary

biomass All organic substances that can be used for energy production, including industrial, commercial, and agricultural wood and plant residues; municipal organic waste; animal manure; and crops directly produced for energy purposes. Biomass is available as solids (wood, straw), liquids (biofuels), and gases (biogases).

EU-15 The 15-member European Union countries (Western Europe is used as a synonym for the EU-15 extended by Switzerland, Norway, and Iceland).

final energy The energy used by consumers in final form: electricity, heating fuels, and transportation fuels.

geothermal energy Natural underground heat used for heating purposes either directly or by means of heat pumps (near-surface heat and hot underground water) and for electricity generation (heat extraction from hot rock).

German Renewable Energy Resources Act An act passed in March 2000 that obliges grid operators to buy electricity generated from renewable energy sources at a given price (feed-in model). The price, which depends on the technology and the year the power-generating installations were built, decreases for installations built subsequent to implementation of the act. The overall costs are passed on equally to all final consumers of the electricity.

greenhouse gases Airborne gases contributing to climate change, including water vapor, carbon dioxide, methane, nitrous oxide, and synthetic, volatile chemicals (e.g., tetrachloro- and tetrafluoromethane, sulfur hexafluoride, and hydrofluoroalkanes). The most important contribution to climate change comes from carbon dioxide.

primary energy The energy directly embodied in natural resources, including fossil fuels (coal, lignite, crude oil, and natural gas), nuclear energy (in the form of heat produced during fission), and renewable energy sources.

renewable energy sources All natural energy flows that are inexhaustible (i.e., renewable) from an anthropogenic point of view: solar radiation; hydropower; wind, geothermal, wave, and tidal energy; and biomass.

1. INTRODUCTION

There are various and somewhat complementary reasons to foster the growth of renewable energy sources (RESs) in Europe. A major incentive for RES policies in the past two decades has been to reduce the environmental impact of energy use both locally (e.g., pollutant emission reduction) and globally (e.g., greenhouse gas reduction). In some countries, concerns about the safety of nuclear power generation have motivated the search for RESs. Another motivation for replacing foreign fossil and nuclear fuels with domestic RESs relates to security issues and Europe's growing dependency on foreign energy sources. In 1999, half of the energy demand of countries in the 15-member European Union (EU-15) was met by imported energy, and this share is expected to increase to 70% within the next two to three decades. In particular, the dependence on oil could reach 90% by 2020. Further motivating studies on developing RESs are the social and economic benefits, such as the creation of jobs, the creation of new industries with good export prospects, and the positive structural effects on regional economies. The characteristics of RES development lead to public benefits in all of these areas. Additionally, the growing integration of Europe

 © 2004 Elsevier Inc. All rights reserved.

continues to highlight the importance of the future development of RESs.

Currently, individual national goals and political measures substantially determine the actual growth of RES industries. In addition to national goals for RES development, the EU Parliament and the EU Commission have defined broader goals for the contribution of RESs by 2010. Other European long-term energy scenarios, from 2030 to 2050, also deal with RESs, and some call for future energy systems based on significantly high contributions from RESs. In addition, the EU affects the promotion of national RES programs within a legal framework. The Commission is anxious to coordinate national promotion efforts, which currently vary greatly.

Markets for RESs are increasingly being established throughout Europe; the dynamically growing wind power industry has been particularly active in this regard. It is foreseeable that a uniform strategy will be developed within this decade for further promoting and implementing mid- and long-term goals for RES technologies in Europe. This process, which was an essential point on the agenda of the Johannesburg World Summit for Sustainable Development in 2002, is presently supported by a growing awareness of the importance of increasing the development of RES technology worldwide. In summary, there is every indication that Western Europe will strengthen its position as the world's leading region in utilization and commercialization of RESs in the next few years.

2. PRESENT USE OF RENEWABLE ENERGY SOURCES IN EUROPE

2.1 Energy Sources

In Europe, modern RES technologies were explored thoroughly for the first time after the oil embargo/price crisis of 1973. Notably, market introduction of renewable energy technology started in about 1985, but the RES industry has become vital only during the past decade. Accordingly, relevant statistical RES data have been systematically compiled only over the past decade, although reliable and consistent statistical RES data, collected since 1989, exist for all 15 countries of the European Union and for Western Europe (defined here as the EU-15 plus Switzerland, Norway, and Iceland). Earlier data from various European countries are fragmentary, inconsistent, and less reliable. Most energy source data are available up to 2001; the country-specific data have been compiled up to 1999/2000. Only a few eastern European countries have provided RES data, and their RES contributions today are still very small.

Of renewable energy sources presently utilized in Europe, as well as in other continents, two dominate: hydropower and firewood (for traditional heating purposes). Both resources were the main basis of human energy supply before industrialization, and even with the emergence of fossil and nuclear energies, both have retained importance. In 1970, hydropower met 30% of European electricity demand; by 2000, this had decreased to 17%. The current degree of exploitation of hydropower and firewood today is considered high, thus the contribution of these two energy sources cannot be increased considerably in the future. Primary energy production from RESs in Europe has risen continuously since 1990 (Fig. 1). Within the past decade, production increased by 40%, accounting for 6.4% of total primary energy production in 2001. The current RES production of 3850 PJ/year (a petajoule is 1000 trillion, or 10^{15}, joules) is provided mainly by biomass (62%) and by hydropower (31%). Geothermal energy (4%) and wind energy (3%) contribute far less. The usable final energy production from RESs amounts to 3350 PJ/year, corresponding to 8.5% of the total final energy consumption in the EU-15 countries. Vehicle fuels contribute only 30 PJ/year; usable RES heat (1880 PJ/year) meets 9.5% of total heat demand, and RES electricity (1460 PJ/year $\approx$ 406 TWh/year; 1 terawatt-hour = 1×10^{15} kWh) comprises 15% of total electricity generation (Fig. 2). About 80% of this electricity comes from hydropower. The use of biomass (10%) occurs predominantly in wood-fueled power plants (60%), although biogas and sewage gas (10%) and municipal waste (30%) also contribute significantly. The contribution of wind energy has grown considerably, to 6.6%, and geothermal energy contributes 1.2%; solar electricity presently contributes an insignificant amount (0.1%). The dominance of biomass in heat production is notable. Individual firewood heating contributes about 60%, and another 20% comes from wood- and waste-fired district heating systems; industrial wood-fired heating systems contribute 18% and biogas contributes 2%. Solar and geothermal energy contribute only small amounts to heating (about 1% each).

2.2 Use Different Countries

Renewable energy sources contribute to the energy supply in individual EU member states in quite

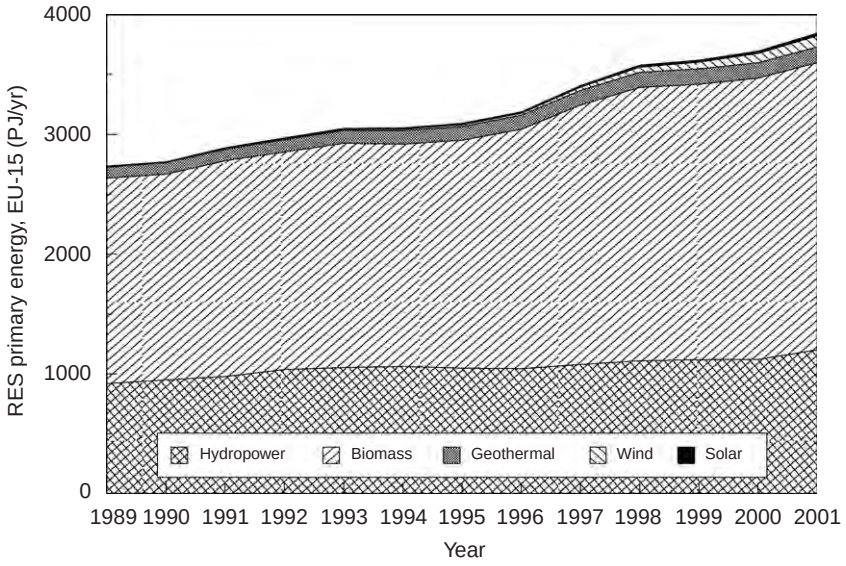

FIGURE 1 Primary energy production using different renewable energy sources since 1989 in the member countries of the European Union.

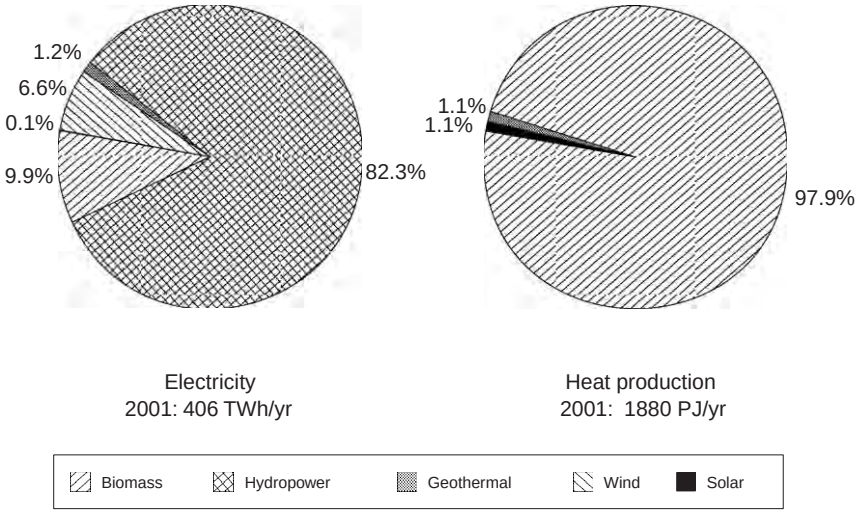

FIGURE 2 Contributions of renewable energy sources to final energy production in the EU-15 for the year 2001.

different proportions (Figs. 3 and 4). This is to be expected because the actual RES contribution is determined by a number of different parameters:

- Country-specific potential for each type of RES.
- Existence of other low-cost and abundant domestic energy resources (e.g., coal, natural gas).
- Structural boundary conditions, such as population density, structure of settlements, ratio of rural to urban areas, extension of electricity grids, and district heating networks.
- Economic conditions, such as national energy prices and taxes.
- Level of economic wealth and of total and per capita energy consumption.
- Conditions of energy policy, such as incentives and instruments to promote RES technology and national energy goals.

Renewable energy resources contribute to meeting a relatively high proportion of energy requirements in countries with large land areas, correspondingly low population density, and abundant hydropower.

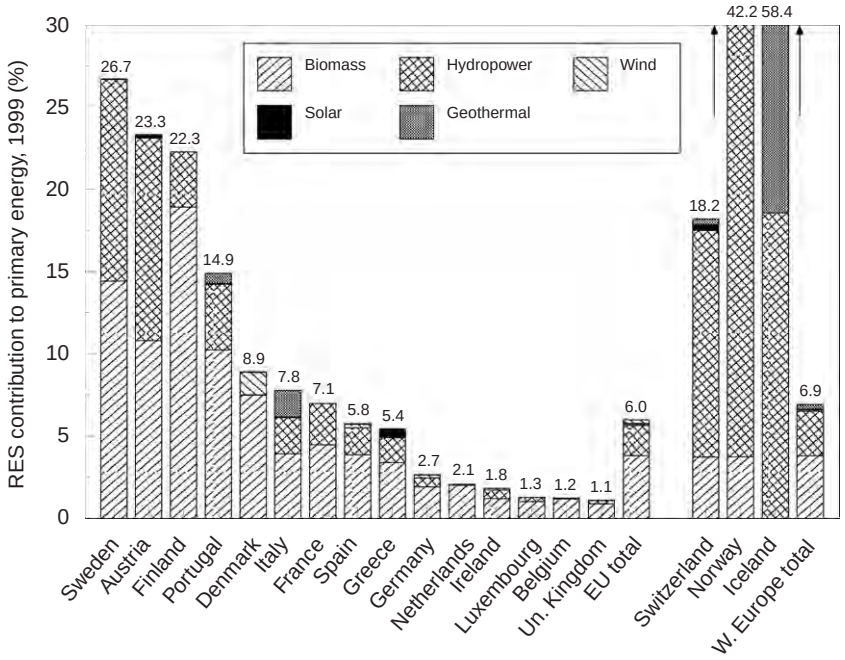

FIGURE 3 Contributions of renewable energy sources to primary energy consumption in the EU member countries and Switzerland, Norway, and Iceland in 1999.

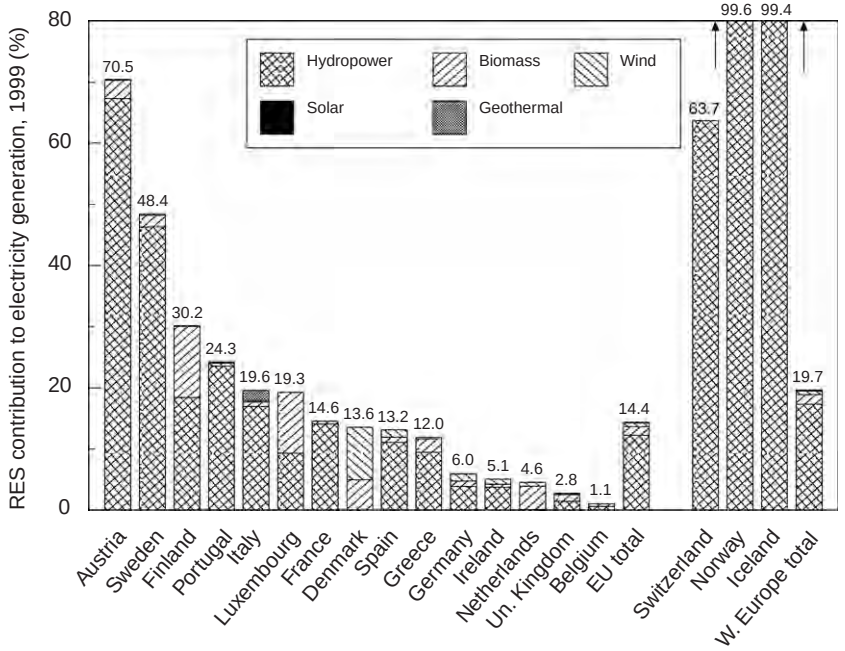

FIGURE 4 Contributions of renewable energy sources to electricity generation in the EU member countries and Switzerland, Norway, and Iceland in 1999.

Sweden, Finland, and Austria fit this profile, with RESs contributing more than 20% to primary energy consumption and electricity generation. In densely populated countries, RESs contribute less than 10%—2.7% in Germany, 2.1% in The Netherlands, and only 1.1% in the United Kingdom. On the other hand, there are strong disparities among countries with similar RES potentials and comparable

infrastructures. For example, in densely populated Denmark, RESs contribute 9% to primary energy consumption and 14% to electricity generation, showing the importance of well-defined political goals and ambitious promotion measures. Such goals and measures, however, primarily affect development of the "new" RES technologies (wind energy in Denmark). RES market development has seen little progress in the United Kingdom.

The contribution of hydropower and geothermal energy increases considerably with the inclusion of Switzerland, Norway, and Iceland, which are geographically, economically, and culturally part of Western Europe (Figs. 3 and 4). RESs in Norway and Iceland provide about 50% of the primary consumption and 100% of the electricity; in Switzerland, these values are 18 and 64%, respectively. Thus RESs accounted for 7% of primary energy consumption and 20% of electricity generation in 1999 in Western Europe. The estimated increase for 2001 is 0.5%. The five countries with the highest amount of RES primary energy are France, Italy, Sweden, Norway, and Germany, which together account for 62% of total RES primary energy production. The highest amount of RES electricity is generated in Norway, followed by France, Sweden, Italy, and Austria; these five countries account for 68% of total RES electricity production.

2.3 Technologies

The development of the "new" wind and solar technologies is of great importance for the future contribution of RESs to energy supply. Although the present wind and solar technology contribution of 0.4% to total primary energy consumption is still very small, the growth of these industries has been considerable in the past 6 to 8 years. Today they provide 10 times the energy of 10 years ago. Wind energy shows the most remarkable growth dynamics; its contribution is now reaching energetically relevant dimensions (Fig. 5). Since 1992, the average growth rate has been 35%/year. At the end of 2001, the installed capacity in Western Europe reached 17,250 MW, about 70% of the total global wind power; 1% of the Western European electricity demand is generated in this way. With 8750 MW, Germany alone accounts for 50% of the installed capacity; Spain, with 3300 MW, follows and is rapidly increasing wind installations. Spain has surpassed the pioneering wind country, Denmark, where growth decreased strongly because of a recent change in energy policy priorities. Yet, with 9%, Denmark still has the highest share of wind power for total electricity generation.

Photovoltaics also showed similar high growth rates in the past 8 years (Fig. 6), but with an installed power of 300 MW in Western Europe (280 MW in EU-15), the contribution of photovoltaics to electricity generation (0.01%) is still negligible. Even more noticeable than in the case of wind energy, the growth rate of photovoltaics is dominated by development in Germany, which accounts for 60% of the total installed power in Europe. This is the result of the very favorable conditions set up within the framework of the German Renewable Energy Resources Act and the additional "100,000 PV-installations" program. Considerable growth in photovoltaics has also occurred in The Netherlands, which has reached

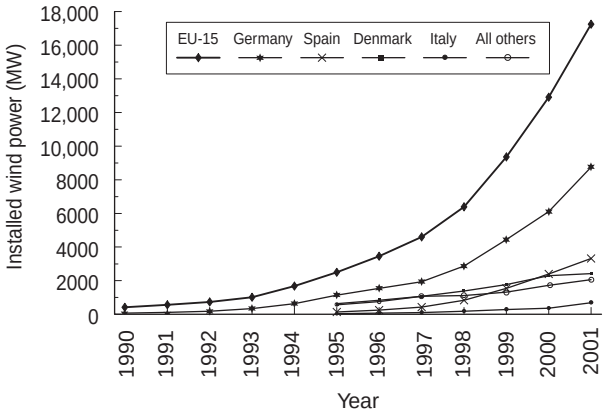

FIGURE 5 Growth of installed wind power output in selected EU member countries and the EU-15 from 1990 to 2001.

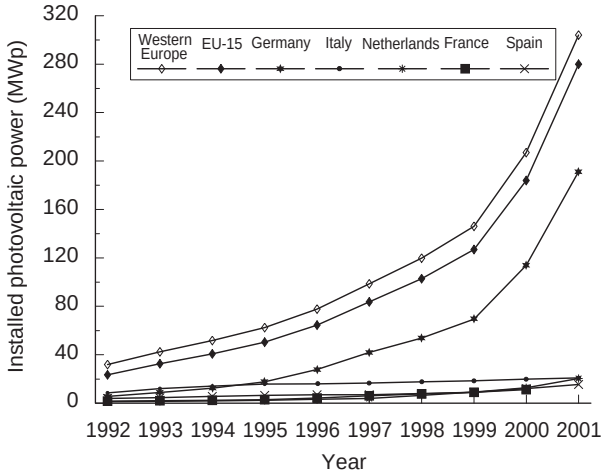

FIGURE 6 Growth of installed photovoltaic power output in selected EU member countries, the EU-15, and Western Europe from 1992 to 2001.

the power level attained by Italy (20 MW). Nevertheless, related to population, Switzerland has the highest density of photovoltaic installations, with 2 W per capita.

There has also been a solid increase in installed solar-thermal collector area, but growth has not occurred as rapidly as has growth of wind power or photovoltaics. In Western Europe, an area of $12.8 \times 10^6\,m^2$ (EU-15 $= 11.9 \times 10^6\,m^2$) supplies 0.01% of the total heat demand (Fig. 7). In Germany, Austria, and Switzerland, where climatic conditions are far less favorable than in southern European countries, the installed solar-thermal collector area is surprisingly high, primarily due to favorable incentives and promotions. In addition, nature conservation and resource protection rank much higher in public opinion in these countries, driving favorable development policy. The reverse of this, public disinterest, may be the reason that, excluding Greece, the contribution of solar-thermal collectors is currently very low in southern European countries, despite the high technical potential. In Greece, solar collectors for water heating are cost competitive against electrical water heaters.

A discussion of promising RES technologies is not complete without mentioning improved biomass conversion technologies such as advanced gasification combined with internal combustion engines, Stirling engines, or fuel cells. These technologies have future potential to convert the abundant supply of biomass more efficiently into electricity and heat than is the case today. Also, improved technologies for digestion of agricultural and municipal waste residues will be of growing importance.

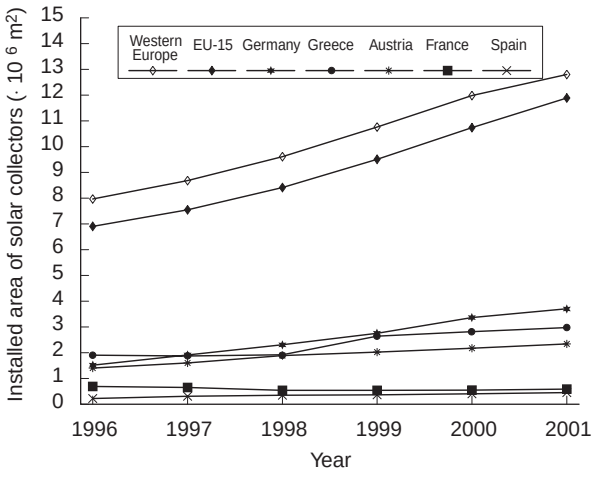

FIGURE 7 Growth of solar-thermal collector area in selected EU member countries, the EU-15, and Western Europe.

3. POLICIES TO FOSTER RENEWABLE ENERGIES IN EUROPE

An important guideline for a well-coordinated RES policy strategy involves setting definite targets, within specific time frames, for RESs to share in meeting the needs of total energy supply. Certainty in policy is a positive signal to potential investors, and attracting private investments is particularly crucial for RES; an accelerated deployment of RES technologies requires considerable funds, usually in excess of funding specified in public budgets. Different approaches are needed to support deployment of RES programs. A comprehensive strategy with a variety of different instruments, rather than a single instrument, is required to address RES development for a range of applications. Moreover, RES policies must address noneconomic barriers, research and development needs, and the cost gap between RES providers and conventional energy providers. Overcoming the renewable/conventional cost gap is a central building block of any RES policy. For this purpose, energy or emission taxes on conventional energy providers can be raised, reflecting the external costs of such fuels. The costs of a RES to the user can be reduced by providing grants, soft loans, or tax benefits. The cost gap can also be overcome by implementing the renewable portfolio standard, i.e., creating a demand for RESs through obliging electricity suppliers to generate a certain percentage of power from renewable sources and offering homeowners and businesses incentives to purchase renewable power. The voluntary purchase of "green" electricity (electricity from RESs), although widely discussed, has not met expectations in Europe so far, and can only supplement, but not substitute for, public support policies.

Establishing RESs via political and regulatory structures is a further important element for a successful RES policy. The present energy supply system and the political and regulatory framework conditions have evolved in a mutual adaptation process. Certain characteristics of RESs, such as their decentralized, dispersed nature, are disadvantaged in many cases by the present regulatory framework . A successful RES policy needs to address such noneconomic barriers for RES. This includes fair access to the electricity grid, adapted building permit procedures for wind power plants, and consideration of solar-thermal collectors in building codes. Workmen, tradesmen, and engineers need to be educated comprehensively about RES technologies and their applications. Schools and universities

need to incorporate RES studies in their curricula. Last but not least, there is an ongoing demand for research and development to exploit the cost reduction potential through technical progress.

Energy policy happens on different levels within the EU, with its institutions, the European Parliament, the European Commission, and the European Council. The promotion of renewable energy sources at every level of the European Union is gaining more and more importance. On the one hand, the general framework conditions for European energy markets are very much targeted toward creating a common market for energy, with equal conditions for all market players across the EU. As an example, the EU issued a directive, "Common Rules for the Internal Market in Electricity," which has created fairer access to the electricity grid for independent power producers using RESs and green electricity suppliers. The European Community Guidelines on State Aid for Environmental Protection allow member states to grant operating support to new RES power plants of up to 5¢/kWh, referring to external costs of conventionally fueled power plants. The European Union is also an active player in promoting RESs directly. In 1997, the European Commission issued a White Paper, "Energy for the Future: Renewable Sources of Energy," setting a goal of doubling the share of RESs for primary energy supply by 2010 and describing scenarios and policy strategies to reach this goal. As a follow-up, a "Campaign to Take-Off" was launched in 1998. The EU's own financial means allocated to this campaign have been rather limited, with $74 million (U.S. dollars) allocated over 5 years compared to the total required investment of $20 billion (U.S.). Another European directive ("On the Promotion of Electricity Produced from RES in the Internal Electricity Market") has set goals for the EU member states regarding the share of RESs for electricity production by 2010. Although the directive failed to establish a common European instrument to foster RESs for electricity generation, it has created some momentum to establish support policies on the national level, as seen recently in the United Kingdom and in Sweden. A political review of all national RES policies is scheduled for the end of 2005, with the goal of creating a basis for a common European support instrument for electricity from RESs.

National support mechanisms remain the most important means to foster development of RES technologies. For example, national minimum price standards (also referred to as fixed feed-in tariffs) have, in particular, promoted wind power in Denmark, Germany, and Spain. Favorable conditions have been created for biomass-fueled district heating in Sweden by imposing high taxes on conventional energy providers and a via CO_2 tax refund. Soft loans and direct investment grants have caused the demand for solar collectors to soar in Germany. Examples of regional and municipal RES policies include the solar ordinance in Barcelona, requiring real estate developers to install solar water heaters, and the green power purchase policy in some Dutch municipalities.

Generally, RES policies have been focused on the electricity sector rather than on transport or heating, mainly because there is a long tradition of state intervention in the electricity sector. Minimum price standards, bidding schemes, and renewable portfolio standards, also referred to as RES quotas or green certificates, have been the major way to support electricity generation from RESs on the national level. Minimum price standards require the grid operator or the default electricity supplier to purchase electricity from RES generators at fixed premium prices. It should be noted that a minimum price standard not only regulates the price, but also regulates grid access and power purchase. Within bidding schemes, RES capacity is publicly tendered periodically and power purchase contracts are awarded to the winning bids. With renewable portfolio standards, electricity suppliers are obliged to generate a certain share of their electricity supply with RESs. The engaged parties comply with the obligation by presenting tradable "green certificates," certifying the generation of a certain amount of electricity. Thus, these certificates have an economic value, generating extra income for RES electricity producers.

Countries with minimum price standards (e.g., Germany since 1991, France since 2001, Spain since 2000, and Denmark until 2000) have seen the largest growth of RES electricity. This particularly applies to wind power. At the same time, a viable RES manufacturing industry has been established in these countries. To organize political support and create local acceptance, it has been proved successful to spread ownership among many, preferably local, people. Even though it is not appropriate to attribute the success in RES deployment solely to a single policy instrument, it is clear that a well-designed minimum price standard together with supplementing policies (such as simplified building permit procedures) seems to be the most effective way to support the introduction of RES electricity. Nevertheless, as indicated by experiences in different countries, proper design of a very specific

support policy is even more crucial than the type of policy.

England and Wales introduced a bidding scheme called Non-Fossil-Fuel Obligation (NFFO) in 1990. In five bidding rounds, between 1990 and 1998, developers of RES plants could bid in different technology slots (e.g., wind power, waste to power, hydropower). The winners with the lowest bid generation costs were awarded with a 15-year power purchase agreement. The bid prices ranged between 45% (hydropower) and 70% (wind power) between the first and the last bidding rounds. Due to different conditions in the bidding procedures and the awarded power purchase agreements, the bids were not directly comparable to each other. Moreover, the large wind project put forward in the last bid round in 1998 has not been commissioned at the low average bid price of 4.5¢/kWh. Apparently, the bid prices were not economically feasible. Although the United Kingdom has the largest wind power potential in Europe, the NFFO failed to foster wind-generated and other RES electricity, perhaps due to inherent weaknesses of the NFFO and also to a lack of appropriate building permit procedures. The wind project has been abandoned.

Renewable portfolio standards have been discussed widely and have been introduced in Austria, Belgium, Italy, Sweden, and the United Kingdom. Although such mechanisms are promising in theory, practical experience has been limited and rather mixed in Europe. Larger providers are more likely than small generators to take the risk of selling electricity and certificates under uncertain conditions. Instead of a wide range of different RES technologies, only the most cost-effective technology will likely be supported at a given time. Long-term contracts rather than spot markets will govern transactions between RES providers and the obliged parties, thus undermining competition. Actually, the different designs of the national renewable portfolio standards hinder rather than enable the free trade of certificates between different countries.

Increasing prices for conventional fuels have been an effective method to deploy biomass and other RES technologies in the heating sector in Northern Europe. Widespread district heating grids support the application of RES technologies in these countries. Household solar collectors have been successfully promoted by tax benefits and direct investment grants. Building regulations allowing only a certain maximum fossil-based heat demand for new building are another effective way to promote RESs. Austria has been extremely successful in deploying solar collectors via grass-roots do-it-yourself construction groups. In some countries, the RES use in the transportation sector is supported by exempting biomass-based car fuels from taxes; this has led to a growth of demand in Germany since 2001.

An overview of promotional systems for RES technology and use in the EU-15 is given in Table I. It is apparent that most countries are using either the feed-in tariff model (minimum price standards) or the certificate trading model (the quota model). Bidding schemes, originally introduced in the United Kingdom, are used only in Ireland. The feed-in tariff model has turned out to be the most successful instrument in terms of installed RES capacity, but an increasing number of countries are considering the certificate trading model as the future winner. Possibly a mixture of both will be used in the future, because green certificates also can be combined with feed-in models.

4. POTENTIALS, COSTS, AND ENVIRONMENTAL CHARACTERISTICS OF REPRESENTATIVE TECHNOLOGIES

4.1 Technical Potentials

To provide energy for mankind, ambient energy, in terms of annual increases in biomass and the radiation, wind, water, and geothermal flows, has to be transformed into usable forms of energy such as electricity, process heat, or fuels by means of technical installations and processes. Determination of the potential energy and productive capacity of an energy technology requires consideration of a great number of physical, technical, and structural restrictions. To achieve a realistic, practical picture of the possible applications of a renewable energy source, it is necessary to add further boundary conditions, mainly economic and ecologic. In view of the huge amounts of ambient energy flows—e.g., the solar radiation reaching Earth's surface during 3 hours corresponds physically to the total annual global energy consumption—to meet future energy demands, it is sufficient to produce energy carriers only in per million shares (in maximum percent shares).

Numerous analyses of current RES technologies provide a detailed and sophisticated insight into the extent and structure of the technical potentials of RESs. Table II presents these data for Western Europe. The values are explicitly downsized according to infrastructure specifications and ecological restrictions. The comments in the table point out the most important assumptions in this respect. It can be assumed, therefore, that these potentials can be tapped completely as soon as they become economically viable. Compared with present energy costs, the majority of these technical potentials cannot be exploited without public subsidies. The total RES potential for electricity generation is almost double the present electricity generation of Western Europe and the total RES potential for heat production meets 75% of the present heat demand. Altogether, based on these calculated RES technical potentials, 62% of the present primary energy consumption could be met. The different RES technologies are exploited very unequally. Hydropower potential is exploited to a large extent, if the construction of new plants on nonregulated rivers is excluded. Biomass residue utilization also already takes place to a large extent. All other RES technologies are currently exploited to a very small degree. The potentials of RESs are 10 times the present amount of energy that is provided from RESs in Western Europe.

In the long-term, if markets for RES technologies are established, far more renewable energy sources can be made accessible. The following examples of potential market development are from the point of view of Western Europe:

- An extended application of offshore wind converters on European coasts, with an additional electricity generation potential of about 2000 TWh/year.
- Cultivation of energy crops on unused agricultural areas in connection with the planned enlargement of the EU to Eastern European countries, adding an additional 30 million ha (i.e., 3500 PJ/year primary energy equivalent).
- Further exploitation of geothermal resources, yielding additional electricity generation of up to 1700 TWh/year.
- Import of electricity from solar-thermal power plants in North Africa to Western European countries by means of an European–Mediterranean electricity grid, allowing, in principle, the additional mobilization of some 10,000 TWh/year of electricity.

It is obvious that these additional RES potentials are available mainly as electricity. There is no sense in further exploiting RES heat potentials, because heat supply at low temperature (up to 150°C) has to be adjusted to the demand for space heating, warm water, and low-temperature process heat. In contrast, surplus RES electricity can be transformed by electrolysis to hydrogen, which can be used as a fuel for transportation as well as for high-temperature process heat in industry. The above-mentioned additional technical RES potentials add up to more than 80,000 PJ/year of primary energy. Thus, even an increasing energy demand in Western Europe can, in principle, be met in the long term solely by RESs.

4.1.1 Concentrating Solar-Thermal Power Plants: A Representative Innovative RES Technology with Large Potential

Concentrating solar-thermal power plants (CSPs) are able to supply very large amounts of electricity and process heat in the earth's sunbelt. Like any conventional power plant, their integration into the grid does not require new measures for backup capacities. On the contrary, CSPs allow for a smooth transition from today's fossil-based power technology to a future energy economy based essentially on renewables. The history of the solar electricity generating

TABLE II

Technical Potentials of Renewable Energy Sources in Western Europe

Renewable source	Electricity generation (TWh/yr)[a]	Heat production (PJ/yr)[b]	Primary energy (PJ/yr)[b]	Used in 2001 (%)	Comments
Hydropower	640		2270	79	New plants only on regulated rivers; includes reactivation and modernization of existing plants
Wind energy	1580		5680	1.8	Restricted potentials onshore (630 TWh/yr); offshore = 950 TWh/yr; acceptance is high and ecological interaction is as low as possible
Photovoltaics	585		2105	0.03	The assumed 2300-km^2 module area = 25% of suitable roofs and 100% of suitable facades (1000 km^2)
Biomass residues	185	2350	3350	52	Residues from forestry, agriculture, and the organic fraction of municipal waste; for energy crops, the present excess agricultural area in the EU-15 (9 million ha) is assumed; 50% use in cogeneration plants, 50% direct heat production, no fuel production assumed
Energy crops and short-rotation forestry	85	1050	1500		
Thermal collectors		6570	7300	0.2	The assumed 4000-km^2 collector area = 75% of suitable roofs; contains also large collector fields with seasonal heat storage
Geothermal energy	350	5000	9155	1.4	Only known resources (lowest value of a variety of estimates)
Solar thermal power plants	2000		7200	0	Suitable sites for 100 to 200-MW solar thermal power plants in Southern Europe (Spain, Italy, and Greece, including Mediterranean islands)
Total RES potential	5415	14,970	38,560	12	
Consumption, 2001	2800	20,000	62,500		
Share of RES potential (%)	193	75	62

systems (SEGSs) in California shows impressive results. Steam cycle plants with up to 80 MW capacity using parabolic trough collectors have been in commercial operation for more than 15 years. Nine plants with a total of 354 MW of installed power are feeding the California electric grid with 800 GWh/year. The plants have a proved maximum efficiency of 21% for the conversion of direct solar

radiation into grid electricity. Considerable cost reductions have been achieved, with electricity costs ranging today between 10 and 15¢kWh in solar-only mode. Advanced technologies, mass production, economies of scale, and improved operation will allow reductions in solar electricity costs to a competitive level within the next 10 to 15 years, or as soon as a worldwide capacity of 5000 MW is achieved. Hybrid solar and fossil fuel plants, making use of special financial schemes, can already deliver competitively priced electricity in favorable locations.

In sunbelt countries, CSP is able to reduce the consumption of fossil energy resources and the need for energy imports, enabling diversification with a resource that is very accessible. Moreover, process heat from combined generation can be used for seawater desalination, helping to address the challenge of a growing water scarcity in many arid regions. In the medium term, large electricity grids such as the Euro-Mediterranean Power Pool via high-voltage direct current transmission will allow for intercontinental transport of RES electricity (Fig. 8), thus connecting sites with large renewable electricity resources in Europe (wind, hydro, geothermal) and North Africa (solar). This concept may be of outstanding importance for the energy future of Europeans, because it can help to stabilize political and economic relations between the countries of an enlarging European Union, as well as between the EU and the North African countries. Furthermore, it can help by contributing to a considerable reduction of the growing dependence on Middle East oil and gas resources. Primarily, CSP, in combination with other powerful RES technologies, will effectively reduce the risk of conflicts related to energy and water scarcity and to climate change.

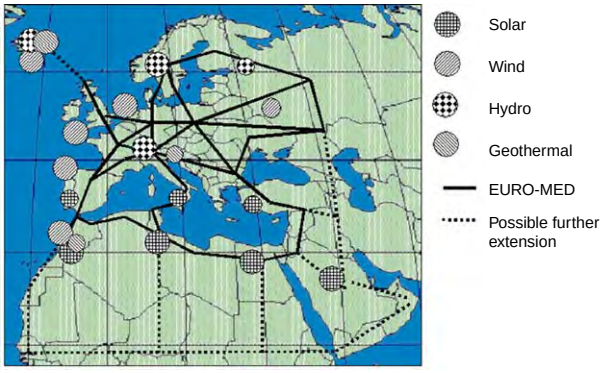

FIGURE 8 Planned extension of European high-voltage electricity grids to a European–Mediterranean (EURO-MED) pool and possible further extension in order to use renewable energy sources widely.

4.2 Costs of RES Technologies

In order to evaluate the chances of a significant commercial RES utilization in the medium term, the costs of energy production, compared to conventional energy supply, are of outstanding importance. The outcome defines which of the RES technologies are economically exploitable under the existing circumstances, and what measures are required to achieve cost competitiveness in a given time frame. It can be assumed that the cost differences between RESs and conventional energies will decrease because of further technical development and growing production rates of RES technologies, and because of an increase in prices of conventional energy sources in the medium term. Thus, a growing share of the technical RES potentials can be exploited economically in the long term. By promoting investments in RESs for a certain time or by influencing the price of energy through taxes or comparable instruments, this process can be accelerated. If future shortages of oil and natural gas or CO_2 sequestration from coal will substantially raise energy price levels, RES providers can offer even lower prices, compared to energy from fossil sources.

A survey of energy generation costs of typical RES technologies in Western European countries, representing the present status and the likely achievable cost reductions in the future, shows a very large spread (Figs. 9 and 10). This results from the great variety of energy sources and their regional differences, the broad spectrum of conversion technologies, the very large range of capacity (from about 1 kW to some 100 MW), as well as different prices for biofuels and for credits in the case of cogeneration plants.

Excluding photovoltaics, for which actual costs are typically 70¢/kWh in Central Europe and 40¢/kWh in Southern Europe, the representative cost of RESs under Western European conditions ranges from 2.5 to 15¢/kWh (Fig. 9). Only a few RES technologies generate competitive electricity today, e.g., older depreciated hydropower plants or cogeneration plants using cheap biomass residues. For that reason, these sources are already widely exploited. A large percentage of RES technologies offer electricity in the range of 7–8¢/kWh, including wind plants in coastal regions, hybrid solar-thermal power plants, and biogas and biomass gasification plants in cogeneration mode. Hence, these RES technologies require further financial subsidies for some time. If market growth of RESs takes place on a large scale, the electricity generation costs of most RES technologies will decline to 4–5¢/kWh. The newest fossil power

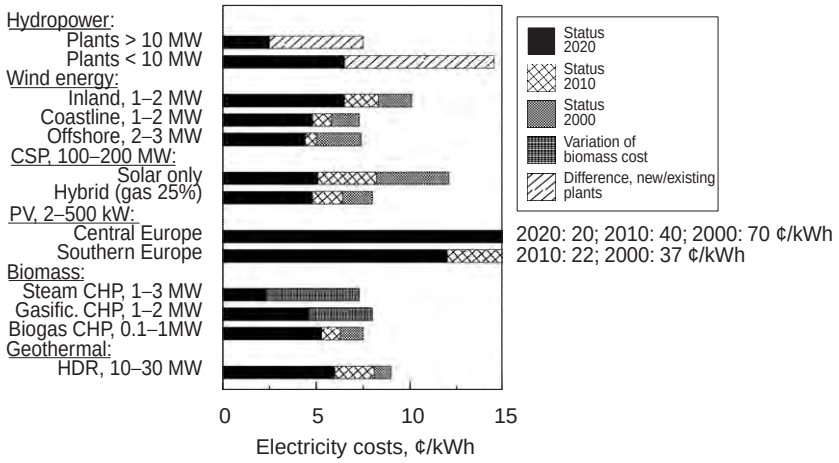

FIGURE 9 Survey of current electricity generation costs (total length of bars) of representative renewable energy source technologies and possible cost reduction until 2010 and 2020 (CSP, concentrating solar power; PV, photovoltaics; CHP, combined heat power; HDR, hot dry rock).

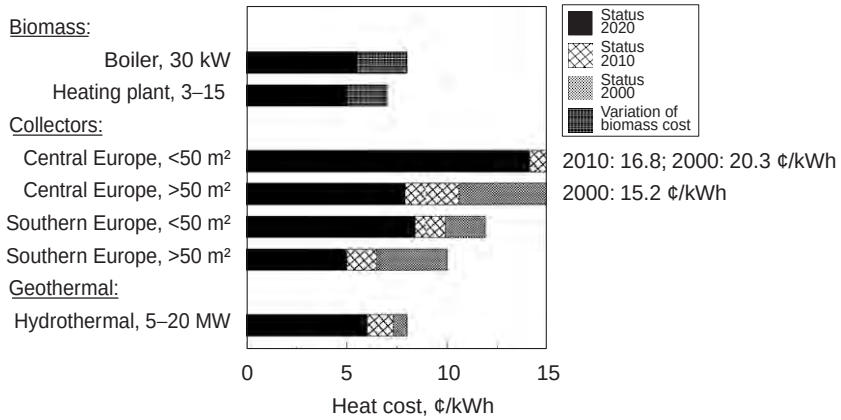

FIGURE 10 Survey of current heat production costs (total length of bars) of representative renewable energy source technologies and possible cost reduction until 2010 and 2020.

plants may generate power within the same cost range because of increasing fuel prices or, in the case of coal, because of costly measures for CO_2 separation. Under such conditions, the many RES technologies could be competitive economically. Photovoltaics, however, at 13¢/kWh in Southern Europe and 20¢/kWh in Central Europe, will still be too expensive to be used to a large extent for general electricity supply. The cost of biomass technologies will strongly depend on the price of the available biomass. Cost reductions by means of technological development or mass production will be small, because of stricter emission standards. If biofuels are to be used to a larger extent, the cost of electricity will not likely decline below a level of about 7–8¢/kWh. Therefore, it has been proposed to use biofuels preferably for the production of transportation fuels, although this will be more expensive than using gasoline or diesel in the foreseeable future. Because of relatively high taxes on fossil fuels in Western Europe, biofuels, with production costs of about 2.5–3¢/MJ, are competitive, if they are not taxed. This approach has been pursued in Germany since 2001 and has resulted in a substantial increase in sales.

Costs of RES technologies for heat production can be assessed similarly. RESs can provide heat with stand-alone systems (e.g., wood-fired boilers, small solar-thermal collectors) and by means of district heating networks. District heating networks are of outstanding importance for RESs to achieve a breakthrough in the heat market. In most cases, only district heating needs support the use of RESs, e.g., geothermal heat plants, large solar collector fields for space heating, and biomass-fired cogeneration plants.

Costs of heat distribution in typical Western European settlements are in the range of 23¢/kWh. Medium-sized heating plants and large collector fields require lower specific investments compared to small boilers or small collectors. Heating costs for the end user of both configurations are therefore comparable (Fig. 10). RES heating costs show large differences. Water heated by typical solar collectors costs about 20¢/kWh in Central Europe; larger collector fields are able to reduce the costs to 15¢/kWh, but this is still four times the price of warm water from an oil- or gas-fired boiler (actual cost of 5–6.5¢/kWh. Only biomass heating is competitive today, if wood is available at a very low cost. Warm water solar collectors in Southern Europe are less expensive (10–12¢/kWh), making them competitive with electrical boilers. Future collector systems will be able to reduce heat costs considerably. Particularly. large collector fields, covering 100 to more than 1000 m^2, will allow future costs to be about 7¢/kWh. The direct use of geothermal energy will result in future costs of about 6¢/kWh. In view of the likelihood of rising prices of fuel oil and natural gas in the future, biomass plants, geothermal units, and solar collector systems will be able to supply end users with competitive thermal energy.

4.3 Environmental Characteristics of Selected RES Technologies

The environmental problems arising from the use of fossil and nuclear energy sources are well acknowledged today; these include global climate change, acidification of ecosystems, risks from nuclear accidents, problems with long-term storage of radioactive waste, and public health effects from air pollution. Because RES technologies largely rely on natural energy and material flow cycles, they offer significant promise in reducing the environmental impact of energy use. Although for most of the RESs the energy conversion process is practically emission free, there may be environmental impacts from the development of RES technologies. The following environmental characterizations of current RES technologies for electricity generation, and their comparison against a modern natural gas-fired combined cycle (CC) power plant, are thus based on a life cycle perspective, taking into account emissions from all of the upstream and downstream processes related to energy conversion (Fig. 11).

It is obvious that for most of the RES technologies, consumption of nonrenewable energy resources and

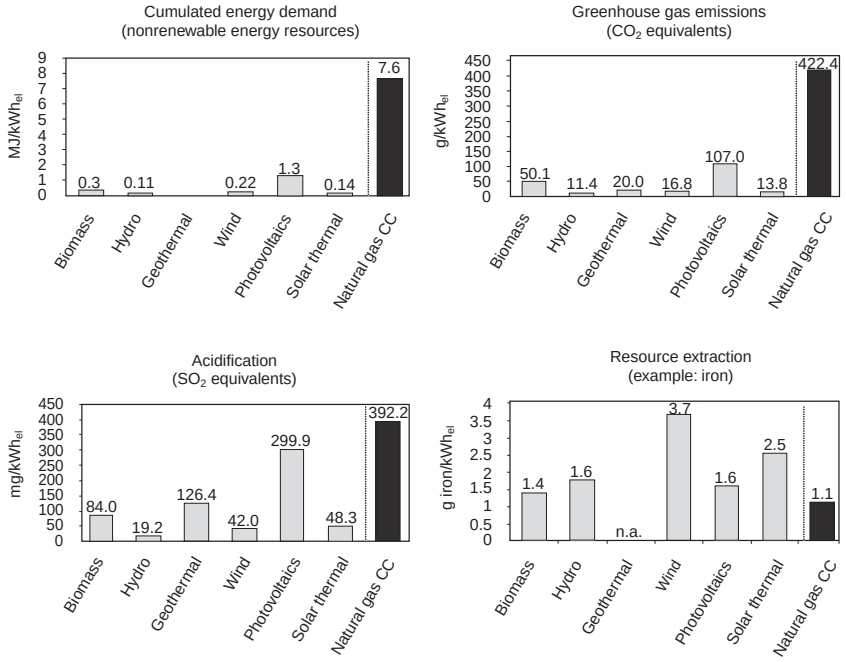

FIGURE 11 Environmental characteristics (cumulated energy demand, greenhouse gas emissions, acidification, and resource extraction) of renewable energy source technologies for electricity generation. Biomass (forest residuals), 20-MW steam turbine; hydro, 3-MW run-of-river plant; geothermal, 900-kW organic Rankine cycle cogeneration plant; wind, 1.5-MW onshore plant; photovoltaic, 3-kW p-type Si roof application (Central Europe); solar thermal, 80-MW parabolic trough (Southern Europe); natural gas CC (combined cycle), 58% efficiency.

greenhouse gas emissions are more than an order of magnitude lower than for the highly efficient gas-fired power plant; the difference is even considerably larger compared to less efficient coal-fired power plants. This fact underlines the important role of RESs in climate protection. Electricity generation from hydropower, wind, and solar-thermal power plants ranks particularly high in this regard. For geothermal energy, the combined production of heat and electricity is required to achieve similar values. The harvesting and processing of biomass fuels requires substantial combustion of fossil fuels, thus biomass electricity generation ranks slightly worse than the processes not requiring combustion. Despite significant improvements in recent years, the manufacturing of photovoltaic cells still requires a quite high material and energy input, leading to relatively high life cycle emissions, which, in the case of SO_2, are even in the same order of magnitude as emissions from gas-fired power plants. The example of iron ore indicates that for the RES technologies, the demand for nonenergy resources is higher, compared to the fossil option, a fact that is sometimes considered a critical drawback of renewable energy sources. However, the expected increase in recycling rates, which in most cases goes along with a further reduction of environmental impacts, compared to the extraction of primary raw materials, will eventually lead to a significant reduction of primary resource consumption.

The dominant environmental impacts of RES technologies are related to emissions from energy conversion in upstream processes, such as component manufacturing or transportation. The data thus primarily characterize the resource efficiency of the underlying economy rather than the performance of a specific energy conversion technology. Changes in the national energy mix, for instance, have a direct impact on the life cycle emissions of RES technologies. The evaluation of emerging technologies should thus be based on conditions that are representative for the time of their market entry, rather than associating them with the environmental load from technologies that they are expected to replace. Figure 12 illustrates the large potential for reduction of life cycle CO_2 emissions from a photovoltaic roof application due to key technological developments (use of solar-grade silicon, increase in recycling rates, and electricity generation with a high share of RESs).

Environmental impacts from energy generation include public health effects, yield losses of crops, and material damage, posing on society a significant economic burden that is not reflected in current energy prices (external costs). "Getting prices right" means imposing a surcharge on the energy price that accounts for environmental damages from power plant emissions. Although quantification of environmental impacts and the subsequent monetary valuation are extremely complex and a matter of

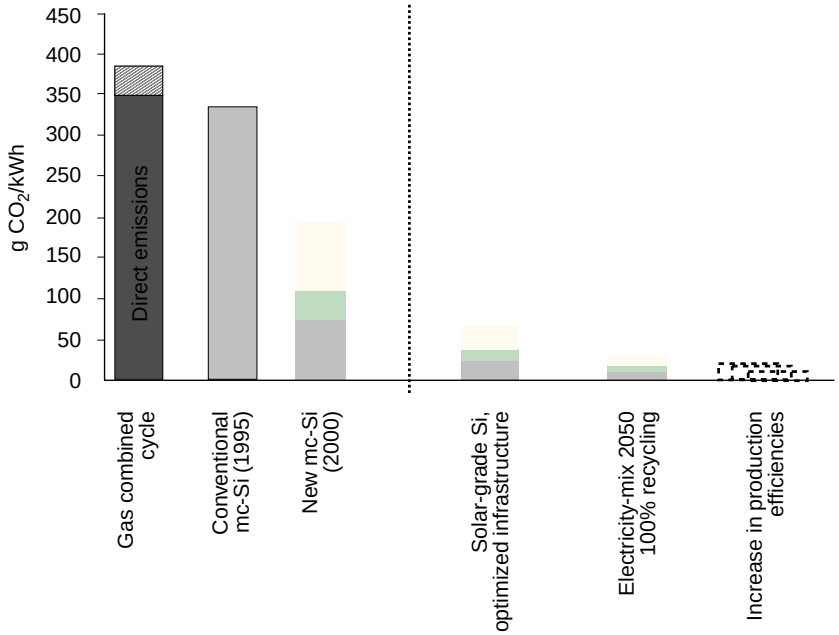

FIGURE 12 Life cycle emissions of CO_2 from a 3-kW p-type Si roof application as a function of technological development and change in the energy mix of an economy. mc-Si, Multicrystalline silicon.

many uncertainties, the European Commission, based on a thorough research effort, decided to allow member states to grant operating aid of up to 5¢/kWh, on the basis of external costs avoided, to new plants producing renewable energy. This measure for internalizing environmental damage costs underlines the environmental advantages of RESs and helps to further increase the competitiveness of RES technologies based on environmental considerations.

5. PROSPECTS OF RESs IN EUROPE

In Europe, several goals have been set to increase the use of renewable energy sources:

- In December 1997, the European Commission adopted the White Paper for a community strategy and action plan, "Energy for the Future: Renewable Sources of Energy". The objective is to increase RESs to an amount equal to 12% of the EU gross inland energy consumption by 2010. In 2001, this action plan was supplemented by a directive of the European Parliament on the promotion of electricity from RESs. The target is to increase the share of RES electricity generation to 22% of total consumption in 2010. The directive contains specific targets for the individual share of RES electricity per EU member state.
- In 1999, the European Commission started a Campaign for Take-Off with the intention to start the implementation strategy set out in the White Paper with specific goals for the period 1999–2003. In 2001, an additional draft directive on biofuels was proposed. The aim was to increase the consumption of biofuels to 2% of the consumption of diesel and gasoline in 2005.

In fact, RES production and use have accelerated clearly since 1995. Between 1990 and 1995, the average growth rate of RES primary energy production in the EU-15 was 2.2%/year; in the following 5-year period, it rose to 3.6%/year and the current growth rate amounts to 4%/year. The average growth rate of the past decade was 2.9%/year. However, the targets defined in the White Paper demand an average growth rate of 7.3%/year until 2010, 2.5 times the value of the past decade (Fig. 13); a somewhat lower increase is necessary for electricity generation (Fig. 14).

A recent investigation, having monitored the progress of RES goals, indicates that the White Paper targets will not be reached with the present

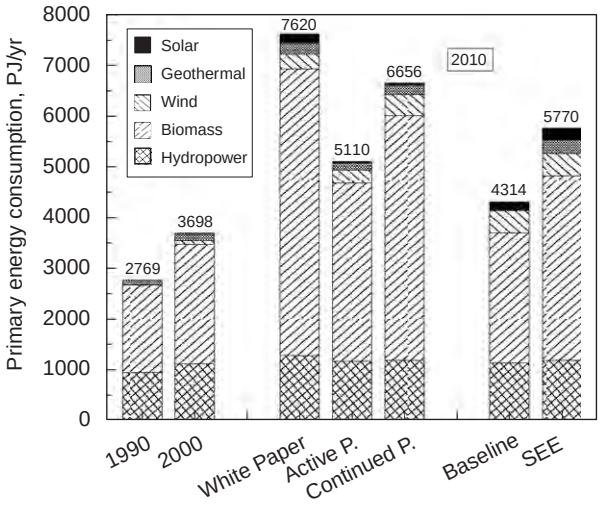

FIGURE 13 Contributions of renewable energy sources to primary energy consumption in the EU-15 in the past (1990, 2000) and to meet the goal for 2010 (from the EU Commission 1997 White Paper), and possible contributions in 2010 for different scenarios [active/continued P (active/continued policy); SEE, solar energy economy].

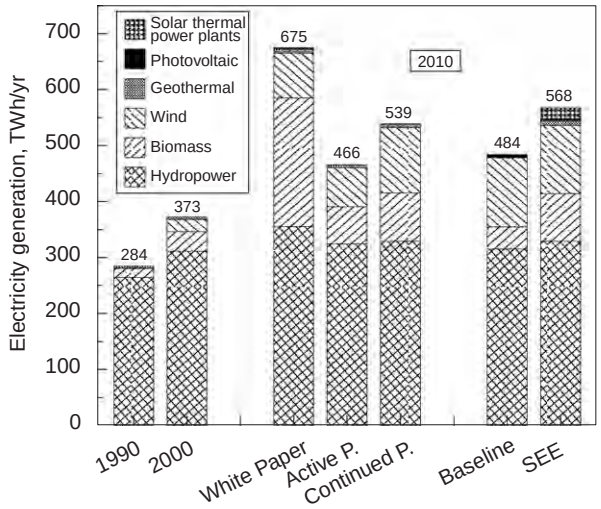

FIGURE 14 Contributions of renewable energy sources to electricity generation in the EU-15 in the past (1990, 2000) and to the goal for 2010 (from the EU Commission 1997 White Paper), and possible contributions in 2010 for different scenarios [active/continued P (active/continued policy); SEE, solar energy economy].

policy instruments and measures. The data on active policies (Figs. 13 and 14) for the year 2010 point out that only an estimated two-thirds of the target values will be achieved in time. All approved policy instruments that have passed in the parliaments of the different EU member states before September 1,

2001 have been considered. Assuming that currently existing incentives will be active in a foreseeable time (continued policy; Figs. 13 and 14), probably 80–85% of the target value will be achieved. Only the target value for wind energy will clearly be exceeded, with 60 GW of installed power in 2010 (White Paper goal: 40 GW); all other RESs will remain below the original objectives. The most severe discrepancies are expected with objectives for photovoltaics (only 20% achievement) and biomass electricity generation (35% achievement).

Substantial structural changes in an energy supply system always require long time periods. Therefore, it is of crucial importance to take into account long-term considerations concerning the transformation of the EU's energy supply structure in order to describe the prospects of RESs appropriately. The November 2000 Green Paper of the EU-Commission, "Towards a European Strategy for the Security of Energy Supply," is based on a projection of the European energy system up to 2030. Hence it can be used as a guideline for investigating the future role of RESs in Europe. The reference scenario baseline uses a business-as-usual development of the demographic and macroeconomic assumptions and is based on the EU energy policies currently in place. The gross domestic product of the EU will be 80% higher in 2030; population will rise only modestly, by 12 million people, until 2010 and will be stable thereafter, with 384 million people. Price increases for energy are assumed to be moderate until 2030, as exemplified by the crude oil price of $30/bbl (U.S.) in 2030. Policy decisions on nuclear energy remain unchanged throughout the projection period. This results in a decrease of the contribution of nuclear energy to half of the present value until 2030. These basic conditions lead to an increase in primary energy demand of 11%, to a growing dependence on energy imports from the present 49% up to 70%, and (because of growing coal consumption) to an increase in CO_2 emissions of 22%, compared to the 1990 reference value of 3068 Mt/year. Apparently, these assumptions also include a weak growth of RESs. Until 2010, RES growth roughly corresponds to the data derived from "active policy" (Figs. 13 and 14). Considering the current dynamics of wind energy growth, only the electricity generation is somewhat higher (baseline, Fig. 14), but the growth of the primary energy contribution of biomass is estimated to be clearly below the value in active policy data (baseline, Fig. 13).

Against this background, it has become clear that the targets of the White Paper for the RES contribution in 2010 cannot be met in time if only the present energy policy instruments (described in Section III) are taken into consideration. Also, after 2010, the growth of RESs will not gain substantial momentum. Hence the European energy policy has to undertake further supportive activities in the next few years to accelerate the market penetration of RES technologies. From a current point of view, the solar energy economy (SEE) scenario (Figs. 13 and 14) gives a realistic assessment of the RES contributions that can be mobilized within the next 8 years. With the strategy "continued policy" as a starting point, it is assumed that the existing energy policy instruments of the EU member states as well as current incentives will be strengthened and coordinated until 2005 in order to effect accelerated growth of RESs before 2010. In this way, almost all goals of the White Paper can be reached until 2010, except for the very high rate of biomass electricity generation assumed in the White Paper for 2010 (230 TWh/year compared to 35 TWh/year in 2000) and the somewhat lower growth rate of solar-thermal collectors. As a complement, electricity generation by concentrating solar-thermal power plants in Southern European countries is added in the SEE scenario; this has not been considered in any other scenario up to now. It is assumed that CSPs will generate 20 TWh/year electricity in 2010, corresponding to 5000 MW of installed power. This takes into consideration the legally mandated improved conditions in the Spanish electricity feed, which allows economically feasible operation of CSP plants by means of a guaranteed payment of 16¢/kWh. Several projects are in preparation now. In the SEE scenario, total electricity generation by RESs will equal 568 TWh/year in 2010, a share of 20% (Fig. 14). The contribution to gross primary energy demand increases to 5770 PJ/year, which is equivalent to 9.5% (Fig. 13).

The long-term development potential of RESs and their significance for a future energy supply system depend decisively on the status and the growth dynamics that have been reached by 2010. Comparing different long-term scenarios for the energy supply of the EU, this is quite obvious. It is noteworthy that the already discussed reference scenario "baseline" shows only a small growth of RESs over several decades (Figs. 15 and 16). The share of RESs for electricity generation obtains the 2010 target of the White Paper in 2030, and the growth in the heat and fuel market almost stagnates, so that the RES contribution to gross primary energy consumption rises only marginally. Extrapolating this scenario to 2050, RESs will fulfill at best a share

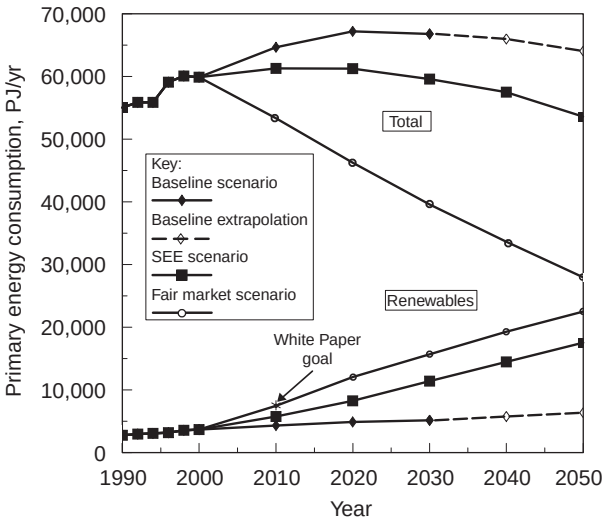

FIGURE 15 Future primary energy consumption in the EU-15 until 2050 and possible contributions of renewable energy sources for different scenarios. SEE, Solar energy economy.

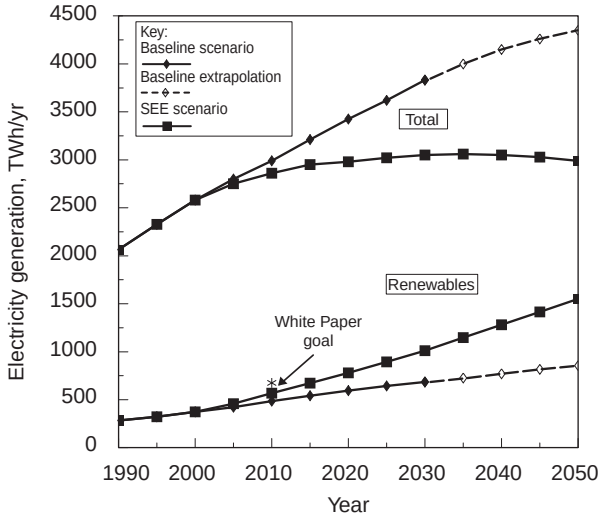

FIGURE 16 Future electricity generation in the EU-15 until 2050 and possible contributions of renewable energy sources for different scenarios. SEE, Solar energy economy.

of 10% of primary energy consumption (6400 PJ/year) and would remain a nearly negligible energy source. Such business-as-usual development would offer no chance for RESs to contribute significantly to climate change mitigation or prolongation of oil and gas resources.

A totally different perspective is offered by the fair market scenario (Fig. 15) that was developed by a consortium of five research teams from Germany, France, Belgium, and Denmark in 1997. The main approach of this scenario is the inclusion of externalities of energy consumption in energy prices to determine market behavior. Once the magnitude of external costs has been fixed, e.g., by a political consensus on taxation, the market can act on prices as usual. Adding the known externalities to market prices of energy leads to considerably strong increases and results in price levels that are twice to three times as high as the energy prices used in the baseline scenario. In parallel, learning curves have been used to calculate the decreasing future cost of RES technologies. With these conditions, a strong market growth of RESs as well as of energy-saving technologies can be expected. The transformation of the energy system will be determined mainly by structural limits, e.g., the decommissioning of power plants and boilers for heating, the reconstruction of buildings, the construction of new production sites for RES technologies, or necessary changes of infrastructure for new fuels. These very favorable conditions for RES technologies result in average growth rates for all technologies of 4.5%/year during the next three decades, starting with about 7%/year in the next 10 years. Growth is assumed to continue until 2050, with slowly declining rates, resulting in a RES contribution of 22,400 PJ/year in 2050 to primary energy consumption (Fig. 15), which corresponds to six times the present value. Energy demand declines simultaneously because many energy-saving technologies are cost-effective at the assumed prices. The fair market scenario shows that, in 2050, the demand for energy services in the EU-15 can be met by half of the present energy production. Therefore, RESs are able to contribute 80% of the remaining primary energy consumption. As a result, CO_2 emissions are negligible compared to the present value, and the dependency on external energy resources is diminished to 15% of the actual imports of crude oil and natural gas. This scenario describes a development of the European energy system that could occur under very favorable political conditions. It would considerably reduce the deficits of the current energy system with respect to sustainability. In fact, this scenario is rather unlikely from the present point of view, but it shows, in principle, the unused potentials of RESs and rational approach of modern economies.

The third scenario, SEE, tries to balance the challenges of reaching sustainability in energy supply and the well-known slowness in removing the numerous barriers and restraints, which are opposed to accelerated structural changes in the European energy system. The SEE scenario outlines the chances

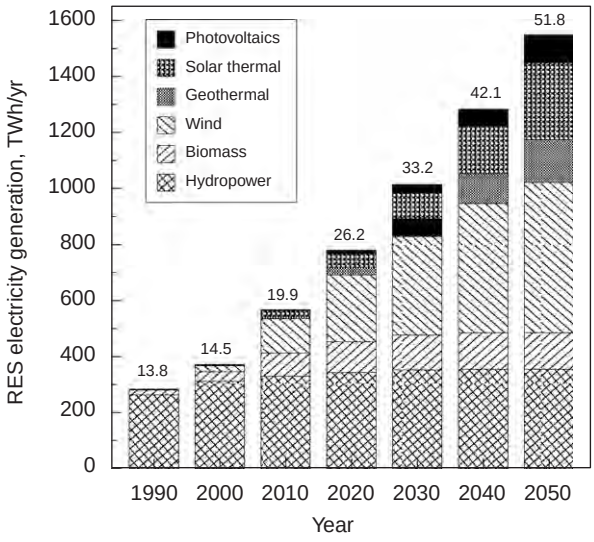

FIGURE 17 Growth of renewable energy source electricity generation in the solar energy economy scenario in the EU-15 until 2050, by individual sources. Numbers over bars indicate the percentage of total generation.

for a more independent, secure, and environmentally sound energy system in Europe with "careful optimism." This includes an efficient and quick advancement and coordination of support mechanisms for RESs (and for energy conservation) in the EU, but, on the other hand, no excessive demands by society and economy. Starting from the interim values for 2010 shown in Figs. 13 and 14, the contribution of RESs grows continuously and meets in 2050 one-third of total primary energy consumption (17,500 PJ/year). Also, reinforcement of energy conservation measures has an impact, resulting in a total energy productivity in 2050 of twice the present value. In particular, it is assumed that the steady growth in electricity demand will be slowed down by adequate energy conservation efforts. In combination with increasing RES electricity generation, about 50% of electricity demand in 2050 can be met by RESs (Fig. 16). RES contributions to the heat and fuel market are growing somewhat more slowly.

To achieve an economically attractive growth of RES production and use, a well-balanced and well-timed mobilization of all RES technologies is of paramount importance. This mobilization depends on the technical potentials of the technologies, their actual costs, their cost reduction potentials, and their technological maturity. In Fig. 17, this is demonstrated with the RES electricity generation of the SEE scenario. Until 2010, cost-effective hydropower, biomass power plants, and wind energy converters are the main contributors to RES growth. Hydropower and biomass will then reach their limits (biomass is increasingly used for fuel production). After 2010, the continuously growing use of wind energy is complemented by electricity from solar-thermal power plants and from geothermal energy. Relevant contributions from photovoltaics will not emerge until 2030 because of relatively high costs. The activities within the SEE scenario correspond widely to the minimum level of technically feasible changes. CO_2 emissions in 2050 are reduced to 2100 Mt/year, or 67% of the current value. This is only a first approach to an effective CO_2 abatement policy. Also, the dependency on imports of crude oil and natural gas, at 65% of the present value, is still too high. Altogether, the scenario represents the minimum requirements for European energy policy, if a relevant role of RESs in future energy supply is one of the substantial goals.

Glossary

biomass Biological material (in a given area).
capacity The rating of a generator, transmission, or system.
desalination Salt removal from brackish or seawater.
geothermal Pertaining to the heat of the earth's subsurface.
photovoltaic (PV) A device converting sunlight into electricity.
resources Estimated total quantity such as minerals in the ground.

Renewable energies (REs) are those naturally occurring nondepleting energies that are derived directly and indirectly from the sun, such as biomass, geothermal, hydropower, ocean currents, solar radiation, tidal wave, and wind energy. These can be harnessed through renewable energy technologies (RETs), such as photovoltaic, solar water heaters, wind and water turbines, and solar passive design. RETs deliver energy services such as mechanical work, heating, cooling, lighting, crop drying, telecommunication, transport, water pumping, desalination, and water treatment. REs are contrasted with finite nonreplenishing fossil fuels such as coal, petroleum, and uranium. REs and RETs are closely linked to new technologies such as fuel cells and the hydrogen economy as well as to energy efficiency. Africa relies heavily on traditional renewable energy in the form of fuelwood (70–80%) for pest control, water heating, space heating, food preparation, and beer brewing for the men. Beer brewing requires 25–50% of energy in villages. Women and children collect the fuelwood over ever-increasing distances, following the frontiers of desertification. The current and future impact of RE in southern Africa is a major building block toward sustainable development.

1. IMPACT OF RENEWABLE ENERGY IN SOUTHERN AFRICA

Solar cooking and solar water heaters (SWHs) can eliminate the need for collecting fuelwood and inhaling unhealthy smoke. This contributes to social sustainability because women and children who currently spend excessive time and energy collecting wood have time for education. Education and training contribute to improved work opportunities and a lower fertility rate, thereby advancing economic sustainability. The reduced population and renewable energy technologies (RETs) eliminate deforestation and desertification, thereby fostering environmental sustainability.

Solar passive buildings in urban and rural areas can totally obviate the need for artificial space

heating and cooling by kerosene, which often is a cause of death by fires or accidental swallowing. It also eliminates the use of expensive imported electricity and its environmental impact where this is generated by coal, nuclear, or hydropower schemes larger than 10 MW.

Modern RETs contribute to energy supply diversity, minimizing cost exposure to imported fossil fuels. Most African countries are importers of petroleum.

REs have a much lower cradle-to-grave life cycle impact on the environment than conventional fossil fuels. The environmental costs (social costs) of conventional energies are those costs caused by the generator of energy but paid for or carried by the local, regional, or global community, including 2 billion people who have no access to modern energies.

REs can be generated locally, feeding the electrical grid and reducing network losses. This is significant in southern Africa because power generation is centralized and power is transmitted over large distances.

Distributed RE generation also democratizes power, making it less likely that politicians can manipulate energy. Localized RETs enhance ownership of local communities that receive the local benefits and revenues. RETs are a new technology creating new export potential.

RETs create many more jobs than conventional energies. Job creation is a major instrument in poverty alleviation. The European Union plans to create 900,000 new jobs by 2020. Southern Africa may create approximately 1 million new work opportunities.

Shell International foresees that REs will provide more than 50% of the world's energy. By employing modern RETs, southern Africa's RE share may be 20% by 2020 and 50% by 2050.

2. THE SOUTHERN AFRICAN DEVELOPMENT COMMUNITY

This section discusses salient characteristic communalities under the headings Natural/Physical, Institutional/Political, Social, Economic, and RE Technological. The ensuing country-specific sections are structured in the same manner to simplify cross-referencing. Although every effort was made to collate recent and credible information, such as that supplied by Dr. P. Ashton (personal communication, 2003), it should be borne in mind that statistics for the Third World generally tend to be dated and unreliable.

2.1 Natural/Physical

The Southern African Development Community (SADC) is a group of 14 countries consisting of Angola, Botswana, the Democratic Republic of Congo (DRC), Lesotho, Malawi, Mauritius, Mozambique, Namibia, Seychelles, South Africa, Swaziland, Tanzania, Zambia, and Zimbabwe.

The country with the largest area is the war-torn DRC (2,345,410 km^2), which also has the largest population (52,046 million). The SADC countries extend over sub-Saharan Africa from 5° north to 34° south latitude, from the equatorial tropics over the arid Horse Latitudes to the Mediterranean climate zone of the Cape of Good Hope. Although the Southern Hemisphere receives intensive sunshine during summer (perihelion), temperatures are tempered by altitude and cloud cover. 59% of the world's most intense winter sunshine (more than 6 kWh/m^2/day) falls on southern Africa (for comparison, London receives 1 kWh/m^2/day). The climate is characterized by steady hot and humid conditions in the Congo Basin and major temperature and humidity changes in the remaining inland zones, which are not tempered by the sea. Snow only occurs in the eastern and southern mountain ranges. The warm, low-altitude areas are malaria infested.

2.2 Institutional/Political

The forerunner of SADC was founded to destabilize South Africa during the Apartheid era. Today, SADC includes South Africa and has the aim of regional cooperation and economic development. South Africa's dominant technoeconomic power understandably makes for very unequal partners.

The New Partnership for African Development (NEPAD) proposed by South Africa's president Thabo Mbeki offers a promise that African rulers will in the future govern their countries according to rule of law in return for $64 billion in foreign investments and donations. However, potential international long-term investors and donors have taken a wait-and-see position in view of the situation in Zimbabwe and Mbeki's efforts at reconciling the demands of the poor with those of development.

The NEPAD office identified six conventional electricity projects, two of which are in SADC: a 1300-MW hydropower scheme downstream from the Cahora Bassa dam in Mozambique and an interconnector between Malawi and Mozambique. Ironically, modern renewable energy projects are not

part of the NEPAD wish list, although Africa enjoys 96% of the world's best sunshine.

An African power pool has also been proposed by South Africa's state monopoly utility. The World Bank, the African Development Bank, the West African Development Bank, and others have shown interest in a proposed West African power pool, which would involve several major electrical power stations and interconnectors at a total cost of $13 billion. However, international investors remain lukewarm because of the region's tradition of military coups.

The often quoted nominal 39,000 MW Inga hydropower, which actually could produce a maximum of 26,000 MW, has been criticized with regard to cost, time, and technical considerations, e.g., untested long-distance high-tension transmission technology. In addition, there are grave concerns about the risks in the conflict-ridden DRC.

The previously discussed schemes tend to have common traits:

1. With a view to attracting international finance with associated high transaction costs, the proposed schemes are very large by African standards. This means that African contractors are out of the game, except for performing menial tasks. At best, South African contractors would participate in worthwhile work, thereby enlarging the existing continental discrepancy.
2. All schemes are based on the dated concept of supply side-driven interventions typically promoted by large international finance, engineering, and Enron-type utility interests combined with local political positioning. The modern concept of need-driven integrated resource planning with its concomitant developmental benefits is conspicuously absent.
3. The schemes are of very large scale, tying up huge amounts of money and other resources that are far beyond Africa's ability to absorb the electricity in productive enterprises. A system of smaller, localized, modular, and incremental renewable energy programs would be much more appropriate due to Africa's immense distances and abundant renewable resources.
4. The schemes blithely ignore Africa's state of political instability, which renders centralized electricity generation systems with long-distance transmission lines extremely vulnerable, as demonstrated by the Cahora Bassa hydropower scheme.
5. It is a tacit assumption of all schemes that large-scale electrification leads to development. Numerous projects throughout the world have shown the opposite to be true: Electrification follows development. Gunter Schramm of the World Bank states that "electricity by itself does not provide new income sources. As has been shown again and again, electricity follows, rather than leads economic development."
6. Although megaelectricity schemes are important to some rulers they often lead to the removal of national protectionism thereby opening local markets to overwhelming global competition. This global competition has often grown by a combination of national subsidies like the U.S. and EU agribusiness, and by national protection like the current U.S. steel industry. The developing world perceives the World Bank and International Monetary Fund as pontificating: "Do as we say, not as we did and do."

2.3 Social

As noted by Ashton, the total population within SADC is approximately 201 million. The DRC has the largest population (52 million). Of the SADC total population, 34% is urbanized, 71% literate, 43.5% malnourished, and 9% of adults are HIV/AIDS infected. A total of 15.7% have malaria, leading to 300,000 deaths each year. Approximately 500,000 have tuberculosis, causing approximately 100,000 deaths per year. Of the two-thirds majority living in rural areas, 51.1% have no access to improved water and 52.1% no sanitation, whereas in urban areas these percentages are 10.8% and 21.9%, respectively.

There are approximately 400 languages, not dialects. South Africa has 11 official languages. The number of religious denominations is estimated to be 10,000, with 6000 in South Africa.

The cultural patterns range from prehistoric hunter–gatherers, represented by the San, to iron-age herdsmen, burn-and-slash migrant peasants, sedentary subsistence and commercial farmers, industrialists, and contemporary postindustrial cosmopolites.

Not surprisingly, the Human Development Index (HDI) varies widely from approximately 0.3 to approximately 0.7. Likewise, the HDI ranking is between 120 and 170.

2.4 Economic

SADC's total per capita income was $570 billion in 2000, yielding an annual gross domestic product (GDP) per capita of $2833. This ranges from approximately $7600 in Botswana to an unknown

figure in Zimbabwe, where the inflation rate is 400%. Two-thirds of the population lives below the poverty line of $2 per day, ranging from 40% in the Kingdom of Swaziland to more than 80% in the Republic of Zimbabwe. The GINI coefficient (the gap between highest and lowest 10% income) is 0.58, with a range of 0.38–0.70. The sub-Saharan power sector received $363 million during 1990–1998, representing a mere 0.8% of the total $46.39 billion foreign direct investment flow to the entire developing world.

Most economic indicators have been declining. A limited number of scientific publications, patents, and inventions of SADC mostly stem from South Africa. The mineral resources of SADC are in stark contrast with the economic output. Gold, diamonds, copper, zinc, iron, gems, and rare metals are mined on a large scale.

Gas has been found along the western, southern, and eastern coasts as well as in inland Botswana. From Angola northward, oil is being extracted. Open cast coal mines are found in large tracts delivering the feedstock for more than half of Africa's electricity and to Sasol. In addition, cost-effective renewable energy resources by far exceed current and projected needs.

Despite the abundance of raw materials and sustainable energy resources, SADC has not learned to beneficiate the resources, remaining largely dependent on expensive imported value-added products and know-how.

2.5 RE Technological

There are 33 telephone lines, 39 cell phones, 39 TVs, 253 radios, and only 18 Internet users per 1000 people in SADC. The number of Internet users range from 0.1 (DRC) to 71 (South Africa) per 1000. The paved road length per person ranges from 3.09 km (Namibia) to 0.02 km (DRC), with an average of 0. 9 km.Whereas Botswana has 0.54 km railway length per 1000 inhabitants, Lesotho has zero. The SADC average is 0.34 km. It must be borne in mind that after waterways, railways provide the most energy-efficient transport mode. Road transport is relatively inefficient at the higher altitudes of southern Africa, and petroleum products are often imported.

It appears that SADC countries, with the exception of South Africa, have invested relative little in conventional energy-intensive infrastructure such as centralized coal-fired or nuclear power stations with transmission networks. Furthermore, two-thirds of the population lives in widely dispersed rural areas and has low energy consumption needs and very low income levels, which do not justify grid extension. Extending the national grid into these areas would place an unrealistic burden on both the national economy and the recipients who are supposed to be beneficiaries.

Given the existing low investment in old fossil-fueled infrastructure, the very high cost and risk of extending this into thinly populated, low-consumption rural areas, and the abundance of renewable sources such as sun, wind, biofuel, and microhydro power, it seems obvious to change to clean modern and environmentally friendly technologies. However, a number of donor-driven projects introducing 50 W_p photovoltaic solar home systems (SHSs) in remote rural areas have led to disappointing results. The reasons are not well publicized:

1. SADC governments tend to have a centralist approach and try to channel all initiatives through government departments. Even in the developed world, this is not necessarily the most efficient and transparent process.
2. Localized government interventions with subsidized SHSs destroy the private enterprise market and cause suspicion of corruption.
3. Inferior products and underdeveloped technologies were introduced because there was no willingness or capacity to control quality.
4. Installation and especially maintenance proved to be extremely difficult in remote rural areas, where telecommunication and transport infrastructure is problematic, if not totally absent.
5. Existing utilities viewed SHSs as a threat and prohibited SHS developments near their power lines or suddenly brought the grid to areas where SHSs had been established. They also created the expectation, supported by politicians, that universal grid-connected power is a reality in the very near future. This established a reluctance to invest in SHSs.
6. In hindsight, it appears that the introduction of a novel technology into an impoverished market under the most trying physical conditions was not a good idea.
7. As a result of insufficient or misleading information, SHS users had unrealistic performance expectations, which led to the stigmatization of SHSs as the poor man's power. The rich role models were not seen to be using SHSs. It seemed that an experiment was being conducted on the poor, who could least afford it.
8. Experience in Europe and Japan demonstrated that the major growth in RE technologies such as

SHSs is in grid-connected applications within the framework of a RE grid-feeder law. This law encourages reverse metering of RE-generated electricity fed into the grid at higher tariffs than the fossil fuel grid tariffs. The difference is shared by all grid users and is negligible. Batteries—normally the Achilles' heel of SHSs—are not required because the grid functions as the storage medium. This reduces capital and maintenance costs. Additionally, maintenance is cheaper due to easier access and communication. The well-to-do more readily introduce new technologies and demand service. All this contributes to a growing acceptance and desirability of photovoltaic (PV) systems as a status symbol of success and progress. So the mass market becomes established, leading to products and services that are acceptable and affordable to the less fortunate. After all, electronic watches, radios, and cell phones were not initially introduced into the low-cost end of the market. Learning from their own experience and from abroad, SADC countries can alleviate poverty and initiate sustainable development by initially introducing RE technologies using the successful and proven grid-feeder tariff structure. This will establish indigenous business, create jobs, and transform the market rapidly and sustainably. In this way, governments do not delay progress by interfering with implementation but, rather, create a conducive framework.

Most RETs are imported because of a lack of awareness on the part of decision makers and the public. R&D investment in RETs, energy efficiency, and government incentives have been neglected. The potential of clean development mechanisms has yet to be realized.

3. ANGOLA

3.1 Natural/Physical

Angola is rich in oil, gas, and mineral resources. It also has considerable solar potential (5.4 kWh/m^2/day in midwinter) in the southern region, except the coastal areas. The potential of small hydro is noteworthy. Wind and ocean energy resources remain to be assessed.

3.2 Institutional/Political

Governance institutions and infrastructure have suffered severely during the prolonged war, which, strangely, did not disrupt petroleum production. This industry accounts for 54% of the GDP and 83.5% of the government tax revenue. Rural areas are not linked to the electricity grid, which has been sabotaged extensively. There is strong government control over tariffs.

3.3 Social

The life expectancy in Angola is the lowest of all SADC countries (due to war and HIV/AIDS). Literacy is also the lowest.

3.4 Economic

Foreign direct investment (FDI) has been twice as much as in Tanzania and far more than that for all other SADC countries. It has gone into the oil business; the per capita GDP is the fourth lowest. Both the African competitiveness ranking and HDI are the lowest. No concerted effort toward RE or energy efficiency has been undertaken.

3.5 Technological

There is no awareness of modern RETs, nor is there any local production. The high illiteracy rate is a barrier to employment. However, the need for PV, SWH, crop drying, and small hydropower is staggering.

4. BOTSWANA

4.1 Natural/Physical

The landlocked country has diamonds, copper, nickel, and coal of high rock and sulfur content, and the winter sunshine in excess of 6.5 kWh/m^2/day places it in the core area of the world record sunshine. This enables all direct thermal applications, such as solar chimneys, solar ponds, solar concentrating, SWH, and PV.

4.2 Institutional/Political

A yearly National Development Plan has resulted in clearly defined targets and budgets. The Ministry of Mineral, Energy & Water Affairs (MMEWA) formulates, directs, and coordinates policy through the Energy Affairs Division, whereas the Botswana Power Cooperation, a parastatal under MMEWA, is a vertically integrated electricity utility operating the coal-fired power station at Murule that delivers 58%

of the national grid electricity. The remainder is imported.

Botswana has enjoyed long-term political stability, applies the death penalty, has a low crime rate, and has established investor-friendly policies. The Botswana Technology Center, the Rural Industries Innovation Center, and nongovernmental organizations are active in implementing RETs.

4.3 Social

Botswana has the highest regional urbanization rate of 46% and third highest life expectancy of 67 years, although HIV/AIDS is prominent. It is ranked third in competitiveness, with a comparatively low literacy rate of 67%.

4.4 Economic

The per capita GDP is the third highest and has been consistently so for a number of years. Its HDI is 57.2%, ranking lower than that of the Seychelles, Mauritius, South Africa, and Swaziland. Grid electricity is relatively expensive, which encourages the use of capital-intensive RETs.

4.5 Technological

Botswana is the region's leader in the application of SWHs and has its own manufacturing industry. Problems of scaling and high salinity experienced with direct thermosiphon systems led to the use of indirect systems. These are installed mainly in government and institutional buildings. However, the market is booming, with 8000–10,000 m^2 installations per year ($2.5 million/year) and an installed capacity of 50,000 m^2. This amounts to 0.053 m^2 per capita, which is low by world standards.

PV installations are in use in the telecommunications sector. Government initiatives drive the PV market since grid extension is the costlier option for smaller structures such as housing for teachers and the defense force, prisons, public buildings, and government buildings in rural towns. Rural energization by SHSs is gaining momentum. The current market is estimated to be 13.4 kWh/year ($70,000/year), with an approximate growth rate of 12% per year.

There is some local manufacture of balance of system components. The Botswana Technology Center is active in energy efficient/solar passive buildings. This institution has also performed a wind mapping project.

5. DEMOCRATIC REPUBLIC OF CONGO

5.1 Natural/Physical

This tropical rain forest straddles the equator and is the most northerly SADC country. It is well endowed with mineral resources, oil, and gas, and the Congo River has considerable potential for hydropower at Inga (26,000 MW).

5.2 Institutional/Political

Unfortunately, since liberation the DRC has experienced conflicting foreign and local interests with regard to its oil and mineral resources and seemingly unending wars. This has destabilized the area, with ripple effects on the whole of Africa. Governance is in a survival mode. Statistics are not reliable.

5.3 Social

The DRC has the largest population in the SADC, with a life expectancy of 51 years and HDI of 43.1%.

5.4 Economic

GDP was $230/capita in 1998, which is the second lowest in the region; there appear to be no recent statistics. The FDI in 1995 was estimated to be $2 million. There is neither a global nor an Africa competitiveness rating.

5.5 Technological

The DRC does not publish any official documentation on RE. The often mentioned hydropower potential of the Congo River seems fraught with political uncertainty. In addition, the major consumer in the near term would be South Africa, which would require more than 3000 km of new power lines, in part over land-mined areas.

6. LESOTHO

6.1 Natural/Physical

The mountain kingdom of Lesotho is an enclave within South Africa and Mozambique. Owing to its altitude (3096 m), it is much colder than its latitude (30°S) would indicate. Snow is not exceptional. The existing Oxbow hydro scheme exports to South

Africa (with a planned additional capacity of 200 MW_p). The inhabitants' use of firewood has practically denuded the land of trees, although reforestation conferences are popular. There is ample microhydro potential. Daily winter sunshine is 5.5 kWh/m^2/day.

6.2 Institutional/Political

The Lesotho Energy Master Plan of 1988 was revised in 1999, with the Lesotho Electricity Master Plan Strategy of 1996 as a subcomponent, updated in 1998. Owing to the sparse population and the mountainous nature, only approximately 3% of the population has access to grid electricity, which is planned to increase to 5% by 2003. The Lesotho Electricity Corporation is being privatized.

6.3 Social

Of the total population, 17% is urbanized, but there is a relatively high literacy rate of 78%. The life expectancy is 59.4 years, whereas the HDI is 53.5%.

6.4 Economic

The GDP per capita is $920, and the Africa competitiveness ranking is 13.

6.5 RE Technological

As a result of the low grid electrification, dispersed population, high solar radiation, and deforestation, Lesotho is a good country for solar applications. This is limited by the low disposable income of the population and the lack of trained installers.

The high altitude causes frost conditions, necessitating special precautions with SWHs. Four small hydro systems exist (3268 MW), and there is potential for more. Approximately 60 kW_p of PV has been installed, with limited growth prospects.

7. MALAWI

7.1 Natural/Physical

The country on the shores of Lake Malawi (706 m altitude) enjoys more than 5 kWh/m^2/day of sunshine during the winter. The vegetation varies between savannah and tropical rain forest.

7.2 Institutional/Political

The Malawi legal system is based on English and local traditions. The energy policy stems from the Vision 2020 development plan, and the Electricity Council fulfills a regulatory function. A National Sustainable Renewable Energy Program was in place before the 2002 World Summit on Sustainable Development.

7.3 Social

Malaria, tuberculosis, HIV/AIDS, and continued malnutrition are the most pressing health problems. The literacy rate is 40% and secondary school enrollment 5%. The HDI is 40%, with a life expectancy of 52 years.

7.4 Economic

In African competitiveness, Malawi ranks 19th, with a GNP per capita of $200. Foreign investment is approximately $1.8 billion.

7.5 RE Technological

A total of 97.6% of Malawi's 214-MW grid electricity is hydro generated, and the government has borrowed $8 million from the Development Bank of Southern Africa for extended hydroelectric power. Only 3% of rural households have access to grid electricity. Wood fuel continues to dominate the fuel economy, where households consume 70% of noncommercial wood fuel. The United Nations Educational, Scientific, and Cultural Organization (UNESCO) has assisted with a solar energy promotion program.

The installed capacity of PV is approximately 50 kW_p, increasing at approximately 4 kW_p annually. The potential is considerable. The SWH market is not very active. Approximately 3000 m^2 has been installed, amounting to a negligible market penetration.

8. MAURITIUS

8.1 Natural/Physical

This 2040 km^2 island is situated in the southerly warm Indian Ocean Current at approximately 20°S latitude, receiving 4.75 kWh/m^2/day of sunshine in winter. The climate is tropical during summer (22–29° C) and subtropical in winter (18–23° C). This is

where the ebony forests and the Dodo became extinct. Rainfall varies from 1150 mm in the west to 2300 mm on the 580-m altitude plateau. Cyclones are not unusual.

8.2 Institutional/Political

The legal system is based on French and English law. Creole is widely spoken, with English as official language. In the absence of natural fossil resources, energy legislation is guided by the development of local RE resources and the involvement of the private sector, which utilizes hydropower and bagasse (sugarcane residues). However, the bulk is imported fossils. The energy demand is growing at 5% per year.

8.3 Social

The population of 1.1 million has a relatively high literacy rate of 81%, a life expectancy of 70 years, and the highest SADC urbanization of 43%. Consequently, the HDI is 77.2%, which is by far the highest in southern Africa.

8.4 Economic

Mauritius ranks second out of 24 in African competitiveness, and it is one of the few with a global competitiveness rating on record (32nd out of 75). The GNP per capita was $ 3700 in 1998. Mauritius has high credit worthiness and was ranked first in Africa in 1996. Manufacturing, tourism, and financial/professional services lead the economy.

8.5 RE Technological

Diesel engines generate 61.7% (176 MW) of the electricity. A seasonal contribution of 54.2 MW comes from hydro plants and 90.5 MW from independent power producers, mainly bagasse plants. The entire population has electrical grid access. Mauritius is the SADC pioneer of grid-connected RE, including PV. Wind speeds of 8 m/s make wind turbines an attractive option. A total of 20,000 SWHs have been installed, representing a market penetration of 8% in the household market. The growth is stable at 2000 m^2 ($1 million) per year.

More growth in grid-connected and stand-alone (on-island) PV is envisaged. Mauritius demonstrates that electrification follows development and that cheap energy is not a competitive advantage.

9. MOZAMBIQUE

9.1 Natural/Physical

Mozambique is a mostly low-lying country on the warm Agulhas Current of the West Indian Ocean, extending from 11 to 27°S latitude in a tropical to subtropical climate. Winter insolation is 5 kWh/m^2/day (approximately twice the sunshine of Bilbao). It features an area of 799,380 km^2 and a coastline of 2515 km with two major African rivers—the Zambezi and Limpopo—traversing. The huge Cahora Bassa hydroelectric dam, which exports electricity, is on the Zambezi River. The Pande field northeast of Maputo will soon export natural gas to the petrochemical plants of Sasol in South Africa. There are also extensive coalfields at Metangula, Itule, Tete Msanghansuvu, and Chiomo.

9.2 Institutional/Political

After decolonization in 1975, a prolonged civil war began that ended in the 1999 general elections, leading to economic development from a low base. Mozambique ratified the SADC trade protocol and has the lowest import tariffs, along with Malawi. An energy-intensive aluminum smelter is under construction. The RE resources have not been assessed.

9.3 Social

Of the approximately 16.8 million people, 23% are urbanized. The life expectancy is 46 years, and literacy is 28%—the lowest in SADC. Portuguese is the official language. The HDI recently increased from 28.1 to 32.2%, whereas the African competitiveness rating is 18 of 24.

9.4 Economic

The joint Maputo corridor project linking South Africa's infrastructure to upgraded harbor facilities will boost the economy. Despite climate disasters, the Mozambique economy has grown remarkably. Foreign reserves increased from $195.25 million in 1995 to $652 million in 1999. FDI was $4.07 billion in 1999.

Mozambique will own the Cahora Bassa scheme by 2014, producing 4000 MW upon completion of phase II.

9.5 RE Technological

Despite favorable solar conditions and only 7% grid connection, PV penetration is only approximately 175 kW_p, including 150 clinics. A study on PV was completed by the World Bank, but the document was not accessible. SWH is mostly limited to holiday resorts. Wind and small hydro IPP potential is estimated to be considerable, but it is unexplored.

Poverty and low energy demand resulting from civil war are barriers to short-term RE development. The joining of the Trans-Boundary Game Reserve with the existing South African Kruger National Park should offer RE opportunities.

10. NAMIBIA

10.1 Natural/Physical

Namibia, which has an area of 842,269 km^2, is bordered by the Atlantic Ocean's cold Benguella Current and has a mostly arid climate with semiarid and subtropical regions. Winter sunshine reaches 6.8 kWh/m^2/day, the world's highest. The coastal strip is often misty during the night. Extreme daily temperature swings are typical. Namibia is very rich in diamonds (Sperrgebiet), other precious and semi-precious stones, ores, and uranium (Rössing). The perennial Orange and Cunene Rivers are the north and south boundaries. The Kudu gas field is situated off the coast between Oranjemund and Lüderitz.

10.2 Institutional/Political

The former German colony was taken by South African troops during World War II and became independent in 1990. The 1998 "White Paper on Energy Policy" refers to RE as an integral and equal component, with special reference to rural water supply and electrification. The restructured utility, Nampower, retains its generation and transmission asset, whereas IPPs provide new generation capacity. Similar to the proposed South African scheme, regional electricity distributors will be responsible for distribution. Namibia imports energy.

10.3 Social

The population of approximately 1.7 million amounts to only 1.7 persons/km^2, the lowest density of SADC. Approximately 27% of the population is urbanized, the literacy rate is 76%, life expectancy is 61 years, and there is a low HDI.

10.4 Economic

Namibia has a GDP/capita of $1370 and is ranked fourth in the African competitiveness rating—the third highest in SADC. Its foreign reserves increased from $221 million in 1995 to $305 million in 1999. The main GDP shares are government services (22.4%) followed by mining (16.4%) and manufacturing (11.8%), indicating an overweight government.

10.5 RE Technological

Namibia has ideal climatic conditions for RE. Domestic SWH installations are in use in government buildings. However, the 24,000 m^2 installed capacity yields a very small market penetration of 0.001 m^2/person and there remains great potential.

PV systems are applied in telecommunication, water pumping, and SHSs. Grid-feeder applications are not known. The total installed capacity is approximately 1 MW_p, with 446 kW_p in the household sector, which is expected to grow at approximately 15 kW_p/year ($100,000/year).

Wind resources of 5–8 m/s along the coast led to advanced feasibility studies for a 5- to 20-MW grid-connected wind park at Lüderitz. This was turned down by Nampower. Traditional windmills for pumping water are gradually being replaced by PV.

11. SEYCHELLES

11.1 Natural/Physical

This archipelago of 115 islands totaling 455.3 km^2 is located 4° south of the equator in the convergence area of the warm monsoon drift and the warm southern trade wind current. The southeast trade winds blow from May to September. During the rest of the year, the northwest monsoon brings tropical rainfall, higher humidity, and temperatures up to 32°C. The area lies outside the cyclone belt.

The world heritage site Vallée de Mai is located on the island of Praslin and is the home of the world-renowned coco-de-mer and the endangered black parrot.

The annual rainfall of 2238 mm is high, but 98% is lost because of the steep topography and evapotranspiration.

11.2 Institutional/Political

Seychelles law is a hybrid of civil and English common law. An energy policy developed by the Ministry of Industry and International Business: Energy Affairs Division guides development, whereas the Public Utilities Corporation: Electricity Division is responsible for electricity generation, transmission, and distribution according to the traditional vertically integrated model.

11.3 Social

Most Seychellois speak Créole, French, and English, reflecting a colonial past, including Arabs and Portuguese taking up victuals and even a period of French and English pirates from 1685 to 1730. At 87.9% (1994), the Seychellois have the highest literacy within SADC and share the highest life expectancy of 70 years with Mauritius. The HDI is 81%, and there is no competitiveness rating.

11.4 Economic

Transport, distribution, and communications (28.3%) dominate the GDP, followed by manufacturing and handicraft (14.5%), government services (13.5%), and the growing finance and business services (11.8%). Fisheries and tourism reflect the traditional income base, which is changing from centralist control to greater private sector participation. The GDP per capita is $ 7384 (1999)—the highest in the SADC region and 40 times higher than that of Malawi.

11.5 RE Technological

A total of 95% of the population has access to expensive grid electricity generated by heavy fuel oil instead of diesel. A 50-MW ($4.8 million) power plant was built at Roche Caiman, approximately 2 km from Victoria.

Seychelles Petroleum provides oil and liquid petroleum gas (LPG). There is a government campaign to phase out kerosene for household cooking in favor of LPG. The search for hydrocarbon in the Exclusive Economic Zone continues under the Seychelles National Oil Company. High electricity costs led to the installation of more than 2400 m^2 SWHs yielding a market penetration of 0.03 m^2/capita and growing by 400 m^2 ($120,000) annually.

Steady wind regimes and high fossil fuel imports should lead to the use of offshore wind turbines. Recent international experience demonstrated that grid-connected turbines feed 50% of the capacity into the grid. This translates into a wind energy potential of 25 MW.

PV SHSs are used on the islands. Biogas and biofuel are not being exploited because of a lack of awareness.

12. SOUTH AFRICA

12.1 Natural/Physical

This 1,221,000-km^2 country occupies the southern tip of the African continent between 22 and 34°S latitude. Its 2968-km coastline borders the Indian and Atlantic Oceans. Prince Edward and Marion Islands 1920 km south of Cape Town are also part of the territory. A mountain range along the southeastern coast limits precipitation in the interior, making the country semiarid with 464 mm of annual rainfall compared to the global average of 857 mm.Winter sunshine varies from 4.5 kWh/m^2/day along the south and eastern coast to 6.8 kWh/m^2/day in the northwestern inland areas. Good wind potential exists along the coasts and mountain areas.

12.2 Institutional/Political

The "Energy White Paper" was published by the Department of Minerals and Energy in 1999, and the "Draft White Paper on the Promotion of Renewable Energies Part 1" (begun in 1998 and published in Dec. 2003) while "Energy Efficiency Part 2" (begun in 1998) is expected to be published in the near future. The 1999 "White Paper" mandates breaking up of the vertically integrated electricity monopoly Eskom, which achieved the electrification of more than 2 million households since 1992. This restructuring of Eskom into the envisaged regional electricity distributors is imminent. An independent national energy regulator oversees energy licensing and tariffs, including electricity. A large rural off-grid energization drive using private sector monopolies was launched in 1999, and implementation is imminent. South Africa acceded to the Kyoto Protocol as a developing country.

12.3 Social

The population of 43 million is 30% urbanized, 82.2% (1991) literate, had a life expectancy of 66 years in 1991 that has been reduced to 47.7 years,

and has a HDI of 6.5%. Afrikaans, English, and nine official native languages are recognized as official languages. In addition, Portuguese and other European, African, and Asian languages are spoken.

12.4 Economic

Strict monetary policy is being applied in order to reduce the inflation rate. The exchange rate of the local currency (Rand) against the dollar decreased by 39.8% from 1995 to 2002, whereas the GDP per head increased by 6.4% at constant 1995 prices. Weakening of the U.S. dollar has resulted in an improved rate of 7.20 Rand per dollar. The international credit rating is 40, the global competitiveness rating is 34 out of 75, and the Africa competitiveness rating is 7 out of 24.

South Africa's energy intensity is 15%, which is nearly double the global 8%. Eskom is the world's fifth largest electricity utility (39,870 MW installed capacity), supplying 95% of the country's electricity, which is 95% coal generated.

South Africa is the world's third largest per capita CO_2 emitter, after the United States and Canada, contributing 1.7% to global emissions but only 0.4% to the global GDP.

12.5 RE Technological

RE energy has been neglected with regard to R&D and implementation. A national wind turbine demonstration site is being developed at Darling in the Cape and another test site has been started at Klipheuwel by Eskom.

A 200-MW agricultural upwind chimney delivering 24-h load-following electricity as well as agricultural produce is being considered in the Northern Cape Province. A feasibility study for a 100-MW solar thermal plant is under way by Eskom, which also erected an experimental dish sterling machine of 25 kW. That was inaugurated during the World Summit on Sustainable Development at the Development Bank of Southern Africa. The CSIR in Pretoria is investigating wave energy generators.

Currently, only the on-shore wind potential of the approximately 3000-km coastline is being assessed. If the wind energy contribution is capped at 50% of the present capacity, it amounts to approximately 20 GW, increasing to 25 GW in 2012.

The World Bank 10-year Global Environment and Local Development project is summarized in Table I.

The project includes the energy-efficient (solar-passive) design and construction of 300,000 low-income houses. Currently, there are 184,000 m^2 SWHs, with a potential for 43 million m^2 by 2020, including domestic and commercial glazed and unglazed SWHs. There are no subsidies.

TABLE I

World Bank Renewable Energy Initiative in South Africa, 2003

	Installed/saved (MW)	Annual generation (GWh)	Estimated capital cost ($M)
Commercial solar water heating	NA	690	510
Biomass cogeneration	220	1320	172
Paper and pulp waste	195	880	174
Municipal solid waste/landfill gas	125	825	145
Wind/other	60	247	56
Total	600	3962	1056

The announcement of the rural government-subsidized SHS program in 1999 comprising 250,000 units of 50 W to be built during a 5-year period created great expectations, but in early 2003 the Department of Minerals and Energy still had implementation problems. The total national unsubsidized PV capacity in 2003 was more than 8 $MWh/year_p$.

The bioenergy potential is given in Table II. The hydropower potential is 8,360 MW or 73,230 GWh/year, whereas the installed capacity was 68 MW in 2000. The potential wave energy is 56,800 MW. There is no installed capacity. The 2020 potential savings in energy-efficient buildings is 36,000 GWh/year.

Job creation is a major motivation for renewable energy application. Biodiesel can create more than 250,000 new jobs, energy-efficient buildings 250,000, PV 125,000, one solar chimney 43,000, solar water heating more than 15,000, and solar cookers 10,000. This totals more than 693,000 permanent work opportunities in a country with an estimated unemployment rate higher than 40%.

13. SWAZILAND

13.1 Natural/Physical

The Kingdom of Swaziland covers an area of 17,364 km^2 and is bounded by South Africa and Mozambique. It lies at the 26°S latitude on the

TABLE II
Bioenergy Potential[a]

Bioenergy	2003 potential (GWh/a)
Bagasse	1400
Sawmills	7639
Pulp mills	4528
Agricultural wastes, manure, litter, grass	5615
Biodiesel	3,500,000
Bioethanol	1200
Total	3,520,382

[a] From Sustainable Energy Society of Southern Africa (2002).

eastern side of the escarpment ranging from 98 to 1800 m in altitude. This causes orographic summer rains. The average annual rainfall is between 1016 and 2286 mm, which is high by southern Africa standards. Winter sunshine is more than 5.0 kWh/m^2/day, with temperatures between 5 and 19°C, whereas summer temperatures vary between 15 and 25°C.

13.2 Institutional/Political

Swaziland's legal system is based on traditional Swazi national courts and constitutional courts derived from Roman–Dutch law. A national energy policy formulation project was completed by the energy section of the Ministry of Natural Resources and Energy assisted by Danish Cooperation for the Environment and Development.

The Swaziland Electricity Board (SEB) is a government-owned utility and provides 70% of the final commercial electricity, of which 30% is generated by SEB's hydro and diesel plants. The remainder is imported from neighboring South Africa's Eskom. Sugar and pulp cogeneration plants provide the 30% of the remaining national electricity supply not delivered by SEB.

A rural electrification policy envisages "that the access to energy is made available for all by 2010" and that "access to electricity is made available for all by 2020." This includes off-grid electrification. The primary focus is on schools, health care facilities, and other essential public facilities.

13.3 Social

English is the official language, with siSwazi spoken by the majority of the 1.02 million (1999) people. The literacy rate is 78%, urbanization 34%, HDI 57.7%, and life expectancy 57 years.

13.4 Economic

The GDP per capita is $1268 (1999), with the major contributors being manufacturing (36.9%); government services (15.3%); wholesale, retail, hotels, and restaurants (10%); and agriculture (9.8%). More than 80% of commodities, including petroleum products, come from South Africa. The African competitiveness ranking is 10 out of 24.

13.5 RE Technological

Renewable energy from bagasse and pulp cogeneration comprises a significant 30% of delivered energy. SWH is underdeveloped. PV systems are applied in an estimated total capacity of 50 kW_p, with approximately 400 domestic lighting systems (16 kW_p) and a growth of approximately 12 kW_p per year. With a 10% market penetration of stand-alone systems, the potential market is 600 kW_p. Two small hydro systems are in operation.

14. TANZANIA

14.1 Natural/Physical

This country is a merger of the former Tanganyika and Zanzibar, which comprises the Ungiya and Pemba Islands in the Indian Ocean. In the west, it extends to Lakes Nyasa and Tanganyika and in the north to Lake Victoria. The world's largest crater, the Ngorongoro, rises to 3647 m.

The land lies between 1 and 11°S of the Equator and covers an area of 945,200 km^2. The floor of Lake Tanganyika is part of the Great Rift Valley and is Africa's lowest point at 358 m below sea level.

There are four main climatic zones: the hot and humid coastal plains; the hot and arid central plateau; the high, moist lake regions; and the temperate highlands. The northeast monsoon brings the hottest temperatures from December to March. Shifting south in March to May, it carries heavy intermittent rains. The southwest monsoon brings cooler, dry weather from June to September. The short wet season is interspersed in November and December. Annual rainfall is 1250 mm on the southeast slopes of the volcanoes and less than 600 mm in the central plateau.

14.2 Institutional/Political

Tanzania gained independence from British rule in 1961. The United Nations Development Program helped to develop the "National Framework for Renewable Energy Development" as part of the National Program for Renewable Energy. Tanzania is one of the few SADC countries with a national electricity regulator and an IPP structure.

14.3 Social

The estimated population is 32 million (1999), of which 30% is urbanized and 84% literate. The life expectancy is 50 years, with a HDI of 44%. KiSwahili is the official language. English is the business language mostly spoken by the 3% of urban Asians. Religions are Muslim, Christian, and traditional in approximately equal percentages. HIV/AIDS is a concern.

14.4 Economic

Tanzania has an old tradition in trading predating Arab slave, gold, ivory, and copper trading, which was eventually taken over by the British. Currently, agriculture accounts for 57% of the GDP, grown on arable land limited to 4% of the total area. The GDP per capita is $242 (1999), and the Africa competitiveness rank is 7 out of 24.

14.5 RE Technological

There are gas fields (33 billion m^3) at Songo-Songo and 1200 million tons of coal at Ufipa, Galula, Songwe, Ruhuhu, Songea, and Mkusi. Informal fuelwood provides 90% of all energy needs, petroleum provides 9%, and hydroelectricity and coal provide the balance. The SWH market is underdeveloped.

Approximately 500 kW_p of PV has been installed in clinics and schools in rural and urban areas. Approximately 60 small hydro plants (30 MW_p) have been installed, with an additional 50 identified. Approximately 1000 biogas plants have been installed, representing the most ambitious program in SADC. The follow-up is uncertain.

15. ZAMBIA

15.1 Natural/Physical

Zambia is landlocked in a tropical belt on a plateau at 1300 m covering 752,612 km^2. Summer temperatures range from 27 to 32°C, whereas the winter range is 16–27°C. Solar radiation in winter is more than 5.0 kWh/m^2/day, rendering it suitable for solar applications. The mighty Zambezi and Lake Kariba form the southern boundary, where it can be very hot during October. Annual rainfall during the warm, humid season from November to April is 508–1270 mm.

15.2 Institutional/Political

Zambia's borders are the result of Cecil Rhodes imperialism, which fell apart in 1964. In 1972, it became a one-party state until general elections were held in late 1991. The 1994 energy policy enjoys political support. There is a national electricity regulator and a reformed electricity system. A grid and non-grid electrification program is in place. Zambia has by far the best energy-efficiency organization in the SADC.

15.3 Social

Zambia comprises approximately 10 million people (1999) of the most diverse cultures who speak more than 70 dialects and have diverse lifestyles, including fishing, cultivating, and ranching. Christians comprise 80% of the population, and the rest believe in Traditional, Islam, Hinduism, and Buddhism. The literacy rate is 79%, and 38% of the population is urbanized, representing the highest percentage in the continental SADC. The life expectancy is a 46 years, and the HDI is 43.3%.

15.4 Economic

Zambia is the world's fourth largest copper producer and owns 6% of the known global reserves. Copper accounted for 50% of the country's export earnings in 1998. Zambia also produces more than 20% of the world's emeralds. Although the country received debt relief up to 67%, the debt burden remained unsustainable. The GDP per capita was $302 in 1999, and the African competitiveness ranking is 12 out of 24.

15.5 RE Technological

Zambia produces 99% of its electricity by cheap hydropower used mainly in the mines, whereas only 20% of the population has access to grid electricity. Proven coal reserves are 30 million tons. Petroleum is wholly imported, draining approximately 10% of foreign exchange.

SWH has a minor role. Small-scale, stand-alone PV systems are in use with an estimated capacity of 1 MW. More than 20 small hydro systems have been installed and their number is increasing. IPPs offer good opportunities.

16. ZIMBABWE

16.1 Natural/Physical

Zimbabwe (390,575 km^2) shares Lake Kariba with Zambia and is situated between the Limpopo and Zambezi Rivers, wholly within the tropics between 15 and 22°S at a high altitude of 800–1500 m above sea level. The average rainfall is between 196 mm in summer and 10 mm in winter. Most of Zimbabwe receives more than 5 kWh/m^2/day in winter, representing a very good climate for solar applications.

16.2 Institutional/Political

Comrade President Mugabe is a prominent proponent of the World Solar Summit initiated by UNESCO. A major Global Environmental Fund PV program was launched in Zimbabwe. A rural electrification initiative is cross-subsidized by a levy on all electricity sales. Electricity is imported on a large scale from neighboring countries.

16.3 Social

Zimbabwe estimated its literacy rate to be 80% and its urbanization to be 31%. Life expectancy is 50 years, whereas the HDI is 55.1%. There is widespread starvation.

16.4 Economic

The GDP per capita is $505 (1999), whereas the Africa competitiveness rating is 23 out of 24, and it was ranked 75 out of 75 according to the Global Competitiveness Report (2001/2002). The 2003 inflation rate was 400%.

16.5 RE Technological

Most of the 0.75-MW_p PV installations were donor funded, an activity that destroyed private initiative and was reduced for political reasons. Domestic SWHs used to be installed at a rate of 1000 m^2 ($220,000) per year. No current statistics are available. Zimbabwe's political situation impacts the whole SADC.

Glossary

biomass integrated gasification combined cycle A composite system that converts biomass feedstock into gas fuel for an electric generating unit that consists of one or more gas turbines with a portion of the required energy input provided by exhaust heat of the turbine to increase efficiency.

closed-loop biomass A process in which biomass feedstocks are grown specifically for the purpose of energy production. During the growing process, the feedstock absorbs CO_2, offsetting the forthcoming CO_2 emissions to be realized during energy use.

cofiring generation The use of a supplemental fuel in a boiler in addition to the primary fuel the boiler was originally designed to use.

criteria pollutant A pollutant determined to be hazardous to human health and regulated under the Environmental Protection Agency's (EPA) National Ambient Air Quality Standards. The 1970 amendments to the Clean Air Act require the EPA to describe the health and welfare impacts of a pollutant as the "criteria" for inclusion in the regulatory regime.

district heat Steam or hot water from an outside source used as an energy source in a building. The steam or hot water is produced in a central plant and piped into the building. The district heat may be purchased from a utility or provided by a physical plant in a separate building that is part of the same facility (e.g., a hospital complex or university).

greenhouse gases Those gases, such as water vapor, carbon dioxide, nitrous oxide, methane, hydrofluorocarbons, perfluorocarbons, and sulfur hexafluoride, that are transparent to solar (short-wave) radiation but opaque to long-wave radiation, thus preventing long-wave radiant energy from leaving the earth's atmosphere. The net effect is a trapping of absorbed radiation and a tendency to warm the planet's surface.

hot dry rock Heat energy residing in impermeable, crystalline rock. Hydraulic fracturing may be used to create permeability to enable circulation of water and removal of the heat.

landfill gas Natural gas (primarily methane gas) produced as a result of decaying waste at municipal landfills.

one sun Natural solar insulation falling on an object without concentration or diffusion of the solar rays.

renewable energy Resources that are naturally replenishing but flow limited. They are virtually inexhaustible in duration but limited in the amount of energy that is available per unit of time. Renewable energy resources include biomass, hydroelectric, geothermal, wind, and solar. Alternate transportation fuels include liquefied petroleum gas, ethanol, methanol, natural gas, electricity, and biodiesel.

run-of-river hydroelectric plant An electric generating plant using the power of moving water as it occurs and having little or no reservoir capacity for storage.

Interest in the use of renewable energy in the United States has increased during the past few decades beginning with the oil embargo of the early 1970s. Renewable energy is used in the residential, commercial, industrial, and transportation sectors. It is used to produce electricity at central grid-connected generators and at dispersed locations; cogeneration primarily in the industrial sector; heat in the industrial, residential, and commercial sectors; and ethanol for vehicle propulsion. During this time period, the U.S. energy policy has evolved around

two central themes: (i) energy/economic security and (ii) resource and environmental sustainability.

1. INTRODUCTION

Energy/economic security refers to the reliability of energy supplies and the stability of energy prices, which significantly influence individual and business expenditures and investment decisions. In the past, disruptive energy supplies and volatile energy prices have detrimentally affected economic growth and made decisions to invest in additional energy supplies and new energy technologies more difficult and risky. Renewable energy has the potential to mitigate these effects. Its prices are not volatile, and once the capital is invested, the fuel prices are stable and in most cases negligible. Any reduction in the demand for conventional fuels reduces the price of that conventional fuel for all units consumed. Even if a new technology does not actually penetrate the market, its availability, on the shelf, limits price levels for conventional fuels. Renewable energy also enhances energy diversification, reduces capital outflows, and utilizes domestic labor and resources.

Renewable energy also plays an important role in reducing emissions from fossil fuels when used in their place. These emissions include greenhouse gases and criteria pollutants such as sulfur oxide (SO_x) and nitrous oxide (NO_x). Renewable fuels, with the exception of biomass, have little or no emissions. The use of closed-loop biomass reduces carbon emissions, a very important component of greenhouse gases. Cofiring of biomass and coal to produce electricity may also reduce the emission of SO_x and NO_x.

The use of renewable energy also has some disadvantages, principally related to cost. Renewable technologies are usually more expensive than conventional technologies and frequently require larger up-front capital investments. Also, there are land-use and other environmental issues related to their use.

The following are the most important renewable fuels in use today:

Hydroelectric power (hydropower): The use of flowing water to produce electrical energy.

Biomass/biofuels: Organic matter that includes forest thinnings, forest and mill residues, agricultural by-products and crops, derived oils and wastes, wood and wood wastes, animal wastes, livestock operation residues, aquatic plants, fast-growing trees and plants, and municipal and industrial wastes. Biofuels refers to liquid fuels derived from biomass feedstocks.

Geothermal energy: Hot water or steam extracted from geothermal reservoirs in the earth's crust that can be used for geothermal heat pumps, space and district heating, water heating, or electricity generation.

Wind energy: Kinetic energy present in wind motion that can be converted to mechanical energy for driving pumps, mills, and electric power generators.

Solar energy: The radiant energy of the sun, which can be converted into other forms of energy, such as heat or electricity.

This article presents basic information on renewable energy including a cursory discussion of its principal elements. The focus is on providing data for 2001 while explaining the role of renewable technologies in the U.S. energy marketplace.

2. OVERVIEW OF RENEWABLE ENERGY

The use of renewable energy in the United States peaked during the mid-1990s at approximately 7.5 quadrillion Btus (quads), increasing from slightly more than 4 quads in 1970 (Fig. 1). Almost half of this increase occurred in the electric power sector and another one-fourth occurred in the industrial sector. The remaining growth occurred in the residential, commercial, and transportation sectors and net imports of renewable energy. Hydropower, biomass, and geothermal energy account for most of the growth.

Since the mid-1990s, however, renewable energy consumption has declined approximately 25% due to the reduced water availability for hydropower. In 2001, renewable energy consumption amounted to 5.668 quadrillion Btus (Fig. 2), which represents 6% of total U.S. energy consumption. Even with the decline in the availability of hydropower, biomass and hydropower still accounted for 92% of total renewable energy consumption.

In 2001, more than 60% of total renewable energy consumed (3.5 quads) was used to produce electricity (Table I). In addition, the industrial sector used 1.4 quads for nonelectric purposes (process heat and steam). The renewable energy use in the industrial sector was primarily a wood or wood waste feedstock. The transportation sector consumed only 0.1 quads of renewable energy

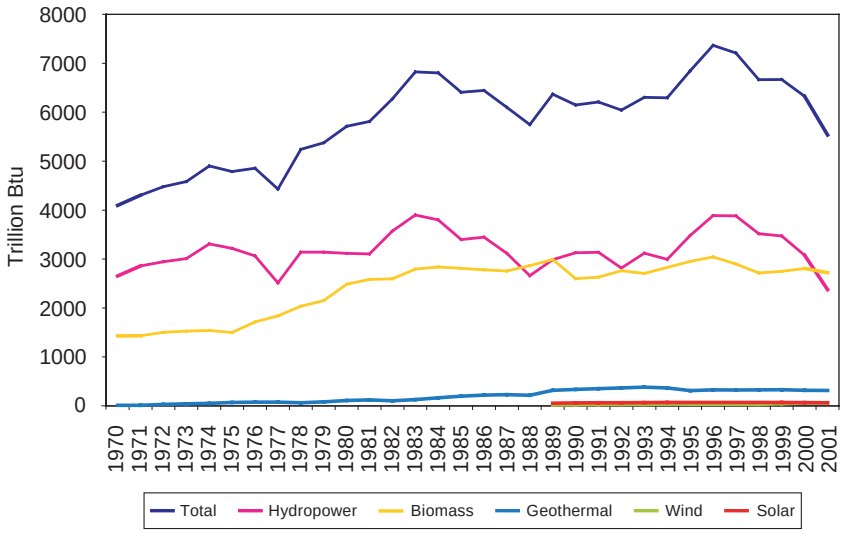

FIGURE 1 Growth in renewable energy consumption by source. From Energy Information Administration (2002). Annual energy review, 2001. Energy Information Administration, Washington, DC.

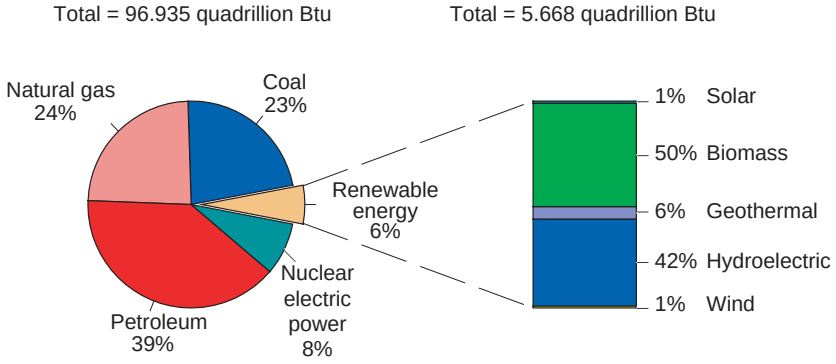

FIGURE 2 The role of renewable energy consumption in the nation's energy supply, 2001. From Energy Information Administration (2002, Fig. H1).

(ethanol). Although the use of ethanol in gasoline has doubled during the past decade, it represents only approximately 0.5% of total transportation fuel consumption.

The increased use of renewable technologies, other than hydropower, during the latter quarter of the 20th century is largely the result of government incentives and regulations (Table II). The federal government provided financial incentives and funds for research and development (R&D) during this period. By 1982, most renewable energy projects were eligible for a 10% investment tax credit, a 15% business renewable energy investment tax credit, a 40% residential tax credit, and a 5-year accelerated depreciation schedule. However, the most significant impetus to the evolution of the renewable industry was the passage of the Public Utility Regulatory Policies Act of 1978 [Public Law (P.L.) 96-917].

3. BIOMASS ENERGY

The Energy Information Administration's (EIA) current data accounts divide biomass/biofuels into four categories: wood and wood waste, municipal solid waste, other biomass waste, and corn ethanol.

Wood and wood waste come primarily from U.S. forestlands or timberlands. Other sources include private land clearing and silvaculture, and urban tree and landscape residues. Wood is almost entirely derived from U.S. timberlands, which contain round-wood, timber stock consisting of 92% sound trees

TABLE I

U.S. Renewable Energy Balances, 2001[a]

Sector and source	Energy consumption (quadrillion Btus)			Electricity net generation (thousand kWh)	Electricity net summer capacity (MW)
	Electric	Nonelectric	Total		
Total	3.541	2.127	5.668	312,767,216	96,741

Conventional hydroelectric (exports)	0.084		0.084	8,209,880	

[a] *Source*. Energy Information Administration. (2002).

(called growing stock) and 8% rotten, cull, or "salvable" dead trees.

Pure wood for fuel (known as fuelwood) actually accounts for a very small percentage of biomass energy consumption. The majority is wood waste. Waste wood includes principally manufacturing and wood processing wastes from wood mills. Primary wood mills include sawmills, veneer mills, and pulp mills. Secondary mills include manufacturers of dimension lumber, trusses and building components, flooring, windows and doors, cabinets, pallets, poles and fencing, barrels, boats, highway transport trailers, manufactured homes, and musical instruments. Mill waste residues are used primarily as fuel,

TABLE II

Key Milestones for Renewable Fuels

Year	Milestone	Description
1973	OPEC oil embargo	OPEC disrupted oil supplies and raised crude oil prices by 70%.
1974	Oil embargo ends	Project independence was Initiated to review strategic energy options.
1978	Public Utility Regulatory Policies Act of 1978 (PURPA)	PURPA mandated the purchase of electricity at the utilities "avoided cost" from qualifying facilities (QFs) meeting certain technical standards regarding energy source and efficiency. QFs were also exempted from both state and federal regulation under the Federal Power Act and the Public Utility Holding Company Act.
1978	Energy tax credit	A 15% energy tax credit was added to an existing 10% investment tax credit, providing incentive for capital investment in photovoltaic applications and solar thermal generation facilities for independent power producers.
1978	Energy tax act	The Energy Tax Act of 1978 (Public Law 95-618) gave a ¢ per gallon exemption from federal excise taxes to motor fuels blended with ethanol (minimum 10% ethanol) and granted a 10% energy investment tax credit for biomass–ethanol conversion equipment (in addition to the 10% investment tax credit available).
1980	Crude Oil Windfall Profits Act	The act (Public Law 96-223) extended the per gallon federal excise tax exemption for ethanol blends to December 31, 1992, and extended the energy investment tax credit to December 31, 1985. An income tax credit was also provided to alcohol fuel blenders—40 ¢ per gallon for 190-proof alcohol and 30 ¢ per gallon for 150–190 proof. The total federal tax credit for a turbine was increased to 25%. The act also raised the residential tax credit to 40% of the first $10,000 investment in photovoltaic applications.
1980	Energy Security Act	The act (Public Law 96-294) offered insured loans for small ethanol producers (less than 1 million gallons per year), loan guarantees that covered up to 90% of construction costs on ethanol plants, price guarantees for biomass energy projects, and purchase agreements for biomass energy used by federal agencies. It also established the Department of Energy (DEO) Office of Alcohol Fuels and authorized $600 million for both the U.S. Department of Agriculture (USDA) and the DOE for biomass research. Subsequent recisions altered this allocation to $20 million for the USDA and $800 million for the DOE to use for alcohol fuel loans. The Consolidated Farm and Rural Development Act of 1980, which rescinded the $505 million allocated to the USDA, appropriated $250 million for alcohol loan guarantees that were used to support 12 firms.
1981	California State energy tax credit	The state of California enacted a 25% tax credit for the capital costs of renewable energy systems.
1983	California Standard Offer Contracts	California's Standard Offer Contract system for QFs provided renewable electric energy systems a relatively firm and stable market for their output.
1984	Tax Reform Act	The act (Public Law 97-424) raised the gasohol exemption from 5 to 6 ¢ per gallon, with the overall tax unchanged at 9 ¢ per gallon of retail fuel. The blender's income tax credit was increased to 60 ¢ per gallon for the 190-proof alcohol and 45 ¢ for the 150–190 proof.
1990	Omnibus Budget Reconciliation Act	The act (Public Law 101-508) decreased the gasohol tax exemption from 6 to 5.4 ¢ per gallon. Tax credits for neat

continues

Table II continued

Year	Milestone	Description
		ethanol sales remained unchanged at 6¢ per gallon. The expiration date was extended to 2002.
1990	Clean Air Act Amendments	The amendments (Public Law 101-549) mandated the winter use of oxygenated fuels in 39 major carbon monoxide nonattainment areas (areas where Environmental Protection Agency emissions standards for carbon dioxide had not been met) and required year-round use of oxygenates in 9 severe ozone nonattainment areas in 1995. The 1990 amendments also establish the Acid Rain Program, which is designed to reduce the adverse effects of acid deposition. This improvement will be achieved primarily through reductions of SO_2 and NO_x emissions by electricity producers.
1992	Energy Policy Act	The act (EPACT) (Public Law 102–486) established a permanent 10% tax credit for investments in solar and geothermal equipment. Established a 10-year, 1.5¢ per kilowatthour (kWh) production tax credit for privately owned as well as investor-owned wind projects and biomass plants using dedicated crops (closed loop) brought on line between 1994 and 1993, respectively, and June 30, 1999. The act instituted the Renewable Energy Production Incentive, which provides a 1.5¢/kWh incentive, subject to annual congressional appropriations (section 1212), for generation from biomass (except municipal solid waste), geothermal (except dry steam), wind, and solar from tax exempt publicly owned utilities and rural cooperatives. Indefinitely extended the 10% business energy tax credit for solar and geothermal projects. It provides a tax credit (variable by gross vehicle weight) for dedicated alcohol-fueled vehicles, a limited tax credit for alcohol dual-fueled vehicles, and, a tax deduction for alcohol fuel dispensing equipment.
1995	Federal Energy Regulatory Commission (FERC) prohibition on QF contracts above avoided cost	In a ruling against the California Public Utility Commission, FERC refused to allow a bidding procedure that would have the effect of allowing rates above avoided cost from renewable QFs.
Mid-1990s	ISO4 contract Rollover in California at lower rates	Ten-year QF contracts written during the mid-1980s at rates of 6¢/kWh and higher began rolling over at mid-1990s avoided costs of approximately 3¢/kWh. This "11th-year cliff" creates financial hardship for most QFs on ISO4 contracts.

with the next most important application being use as pulp and fiber for making paper products. The paper production process, in turn, yields a by-product known as black liquor, which is the single largest source of biomass energy. Pulp and paper mills use large quantities of wood bark, edgings, and residues from their own log-stripping operations and also buy them from facilities such as sawmills.

Waste wood also includes construction and demolition debris, wood from pallets and containers, and wood pellets. Waste wood is also salvaged for fuel by private owners from woodlots, farm fence rows, cropland clearing, orchards, and operations of private urban silvaculture. Urban tree and landscape residues consist of tree limbs, tops, brush, leaves, stumps, and grass clippings. They are generated by commercial tree care firms, municipal tree trimming operations, electric utility power line maintenance departments, orchards, and landscapers.

Municipal solid waste (MSW) includes durable and nondurable goods; containers and packaging; food wastes; yard wastes; and miscellaneous waste from residential, commercial, institutional, and some industrial sources. Examples of MSW include yard trimmings (lawn clippings and branches), newspapers and magazines, office paper, boxes and packaging, glass, metal, plastics, rubber, clothing, and food scraps and cafeteria wastes. MSW also includes such large and durable items as furniture, wood pallets, and appliances. MSW management begins with methods of reducing the quantities of trash generated in the first place (source

reduction). However, once the trash has been produced, MSW management involves four components: composting, recycling, waste-to-energy via combustion, and landfilling.

The last two categories of biomass/biofuels are relatively small. Other biomass waste is a catch-all category that includes agricultural by-products and crops; sludge waste; tires; and other biomass solids, liquids, and gases. Biofuels consists of liquid biomass (primarily ethanol from corn) used in the transportation sector.

3.1 Current Data

In 2001, biomass/biofuels contributed more than 2.8 quads to U.S. energy accounts (Table III). More than 2 quads of this energy was used to produce steam or process heat for the industrial sector. The remaining 0.8 quads was used to produce approximately 60 billion kilowatt-hours (kWh) of electricity generation. More than half of the electricity generation came from the electric power sector, with most of the remainder resulting from cogeneration in the industrial sector. There was a small amount of cofiring with coal in the electric power sector.

The largest fuel category was wood/wood waste, comprising more than 75% of the total account balance. Nine products represent the wood/wood waste category: black liquor, red liquor, sludge wood, spent sulfite liquor, peat, paper pellets, railroad ties, utility poles, and wood/wood waste. The second largest contributor was the use of MSW at waste-to-energy combusting facilities and landfills. Other biomass, which consists of agricultural by-products/crops, straw, sludge waste, tires, medical wastes, solid by-products, fish oil, liquid acetonitrite waste, tall oil, waste alcohol, digester gas, and methane, amounted to 117 trillion Btus. The transportation sector, consisting of ethanol from corn, contributed only 133 trillion Btus to the data accounts.

3.2 Technology and Applications

Biomass combustion in the electric power, industrial, and residential sectors is the principal energy use of biomass today. To a much lesser extent, biomass can be transformed into a gas such as landfill gas, and biofuels can be created for use in the transportation sector. Biomass-fired combustion systems are commercially available to produce steam, electricity, and heat in various applications in the industrial, electric power, and residential sectors. Direct combustion systems in the industrial and electric power sectors are usually classified according to the way the biomass is burned: pile, grate, suspension, or fluidized bed.

A Dutch oven is an example of a pile-burning system. Two chambers are used for combustion: The first chamber dries and partially burns the fuel, and the second chamber completes the burning process. Some versions of the Dutch oven design include grates that facilitate drying and transport of the fuel and cofiring capability. The spreader-stoker is an example of a grate-burning system. After the fuel is spread on a grate, it is blown into a combustion chamber and burnt in suspension. Any unburnt fuel falls onto a grate, where combustion is completed. In suspension burners the fuel is burnt in an air stream. Examples of suspension burners are cyclonic burners and solid fuel injection burners. A heated bed of sand kept in constant motion is the surface for fuel combustion in a fluidized-bed combustion system.

An advanced biomass combustion technology is the biomass integrated gasification combined-cycle generating plant. It is assumed that hot gas filtration will be used for gas cleanup purposes in this technology. The advantages of the newer hot gas cleanup technology are that it generates less wastewater and it allows the process to be operated at higher efficiencies than those of the cold gas cleanup alternative. The disadvantages are limited operational experience, higher costs, and greater complexity.

MSW is combusted into energy throughout the country, producing steam, electricity, or both. Two basic approaches are used: mass burning and refuse-derived fuel (RDF). The two most common types of mass-burn facilities are waterwall incinerators and the smaller modular combustion units. At mass-burn facilities, residential and commercial waste is deposited into a pit and moved to the furnaces with overhead cranes with little sizing or separation. The wastes are usually burned on a grate and the heat is used to create steam, which can be sold directly to industrial or commercial customers or used to power a turbine to generate electricity. Waterwall furnace designs burn waste, heating the water that circulates through the walls of the combustion chamber in steel tubes, resulting in the production of steam. Modular mass-burn facilities are small-scale combustion units that can be fabricated at the factory and shipped fully assembled or shipped in modules and assembled at the construction site.

The first stage of a RDF system is the preparation of the fuel. Raw MSW is processed to form a more homogeneous product by removing noncombustible materials, such as metal, glass, grit, and sand. Sometimes, the remaining RDF is pelletized. It may be sold to outside parties or burned on-site in a furnace. In some cases, RDF is cofired with coal.

The residential/commercial sector uses five types of wood-burning equipment: free-standing stoves, fireplaces, fireplace inserts, central heating equipment for houses, and large boilers for apartment buildings and commercial buildings. Each type is produced in different sizes, has different performance parameters, and is made from a variety of construction materials (steel, iron, and alloys). Fireplaces are the most common type but are rarely used for heating an entire house because of their low efficiency and rapid consumption of wood. Many fireplaces result in a net heat loss because they require a large amount of air from the house that is replaced with cold outside air. Improvements to fireplaces can be made by adding enclosures, heat blowers, an outside air source, or fireplace inserts. Free-standing stoves are the main type of wood-burning equipment used for home heating. The two basic woodstove designs are the radiating and the circulating stoves.

Biomass (i.e., MSW in landfills) is also a source of landfill gas (LFG) that can be recovered and the energy can be used for direct heating, electricity generation, chemical feedstock, purification to pipeline-quality gas, and heat recovery. Each of these methods has a variety of LFG applications:

1. Direct heating applications
   - Industrial boilers
   - Space heating and cooling
   - Industrial heating/cofiring

2. Electricity generation applications
   - Processing and use in reciprocating internal combustion engines
   - Processing and use in gas and steam turbines
   - Processing and use of fuel cells

3. Feedstock in chemical manufacturing processes
   - Conversion to methanol (and optional subsequent industrial or vehicular fuel use)
   - Conversion to diesel fuel (and subsequent use as vehicular fuel)

4. Purification to pipeline-quality gas
   - Utilization as vehicular fuel
   - Incorporation into local natural gas network

5. Heat recovery from landfill flares

The primary approach for converting biomass to alcohol fuels is the fermentation of corn into ethanol. The largest potential source of ethanol in the United States is the biochemical conversion of cellulosic biomass into ethanol.

3.3 Niche Markets and Outlook

The conversion of biomass into energy is in large part a waste disposal option. The waste is already available, close by, and must be disposed of. In these cases, the amount of waste available is a constraint to growth in the biomass energy industry. In addition, there are several existing and potential niche markets for biomass energy as a means of alleviating environmental and security concerns associated with the use of fossil energy.

There are approximately 30 facilities that cofire biomass and coal in existing coal-fired boilers. Coal-fired boilers can combust a premixed combination of biomass and coal fed through an existing coal-feed system or retrofitted with a separate feed system for biomass. Generally, the proportion of biomass consumed ranges from 1 to 10%. The substitution of biomass for coal at electric power plants reduces emissions of SO_2 and NO_x.

A second niche market that is growing very rapidly is the conversion of LFG into energy. Several factors have contributed to this growth: U.S. Supreme Court rulings that eliminated flow control contracts that previously directed the waste to in-state waste-to-energy combustion facilities, federal tax credits, and environmental benefits. The environmental advantages of energy recovery include decreased emissions of methane, nonmethane organic compounds, and toxics (e.g., benzene, carbon tetrachloride, and chloroform). Although carbon dioxide (CO_2) emissions increase with the energy recovery option, the net atmospheric balance is a positive one because CO_2 emissions are significantly less radiative (i.e., the alleged greenhouse effect is less) than methane emissions.

Another possible niche market application for biomass is in the transportation sector. As mentioned previously, ethanol is the only renewable fuel used in substantial quantities in the transportation sector. Ethanol is made from corn. During the past two decades, it has received an excise tax exemption, generally 5 or 6¢ per gallon on a 10% ethanol/90% gasoline blend. Even with a subsidy, methyl tertiary-butyl ether was viewed until recently as the more economic and practical choice as an oxygenate additive to gasoline or as a component of RFG.

Ethanol can also be the primary component in a transportation fuel, such as E85 (85% ethanol/15% gasoline). Despite the fact that there are approximately 3 million vehicles on the road that can use any combination of E85 and regular gasoline, only 0.7% of all ethanol is E85. This reflects the difficulty in developing an E85 refueling infrastructure, and the fact that E85 on a heating value basis has generally been at least as costly as gasoline. Should a less costly source/method of ethanol become available (e.g., lignocellosic biomass conversion and biomass gasification), fleets capable of centralized refueling would provide a major entry point for E85 into the transportation sector.

For biomass to provide large amounts of energy, dedicated crops must be developed and used for electricity generation and as an alternative to gasoline in the transportation sector. To the extent that biomass is closed-loop, its use as a substitute for fossil fuel results in a reduction in CO_2 emissions, the most significant and most difficult to harness of the greenhouse gases. The use of biomass as a substitute for gasoline could potentially mitigate energy/economic concerns associated with the import of oil from the Organization of Petroleum Exporting Countries.

4. HYDROELECTRIC ENERGY (HYDROPOWER)

Water resources that are used for power production are found in 48 of the 50 states. Generating electricity using water has several advantages. The major advantage is that water is a source of relatively inexpensive power. In addition, because there is no fuel combustion, there is little air pollution in comparison with fossil fuel plants and limited thermal pollution compared with nuclear plants. Like other energy sources, the use of water for

generation has limitations, including environmental impacts caused by damming rivers and streams, which affects the habitats of the local plant, fish, and animal life.

4.1 Current Data

As of 2001, conventional hydroelectric net summer capacity totaled 79,379 MW, which generated 232,949,965 thousand net kWh of electricity. Of that total, 92% was generated by electric utilities and independent power producers in the electric power sector, followed by generation in the industrial and commercial sectors, respectively.

4.2 Technology and Applications

There are two types of conventional hydroelectric plants: storage and run-of-river. Storage plants consist of a dam, which impedes water and regulates its flow. These plants store up to a season's supply of water. Run-of-river plants have very small impoundment, storing a day's supply of water. Source water may be from free-flowing rivers, streams, or canals. In both types of plants, the water is guided to a turbine by a penstock (tube), which in turn drives a generator to produce electricity. The amount of generation is dependent on precipitation. This is especially true for run-of-river plants, which have very small impoundment. Hydroelectric facilities can be used when demand is high because hydro units can respond to rapid load changes, which is not possible with steam-powered thermal facilities.

Challenges faced by the industry include mandatory relicensing for investor-owned facilities, improving operating efficiency, and mitigating adverse environmental effects. The U.S. Department of Energy, through its Advanced Hydropower Turbine System program, is working to improve operating efficiency and will assist in addressing some of the environmental issues. The program is expected to be completed by 2010.

4.3 Niche Markets and Outlook

The relicensing process is placing new conditions on hydroelectric operations and, therefore, productivity. Generally, relicensed plants (i.e., the current stock) will have slightly decreased generation. Although most good sites have already been developed, it was estimated in 1998 that there were 5677 sites with a total undeveloped capacity of approximately 30,000 MW available for power production, after accounting for environmental, legal, and institutional constraints. This total includes approximately 8500 MW where no facility exists, approximately 17,000 MW where a dam exists but no hydroelectricity is generated, and approximately 4300 MW of incremental hydropower potential at existing sites from capacity additions or improved efficiencies. Finally, there is some, as yet not quantified, amount of capacity that could be added by refurbishing existing plants.

5. GEOTHERMAL ENERGY

Geothermal energy is heat in the earth's crust brought to the surface from underground reservoirs of steam or hot water. As used at electric generating facilities, hot water or steam (hydrothermal resources) extracted from the earth's crust supplies steam to turbines that drive generators to produce electricity at electric power plants. Eventually, it is hoped that continued development of extraction methods will allow geothermal power production from so-called "hot dry rock" formations, which would open significantly more resources than currently utilized. Most of the known high-temperature hydrothermal resource areas in the United States are in the western part of the country. Electricity from geothermal resources is currently produced in California, Nevada, Utah, Hawaii, and New Mexico.

5.1 Current Data

In 2001, there were 43 operational geothermal power plants in the United States. Those with a capacity of 1 MW or more totaled 2793 MW, which generated 13,813 thousand MWh of electricity, the third most of all renewables after hydroelectricity and biomass. Direct use applications included space and district heating; industrial, such as food dehydration (the drying of vegetable and food products); greenhouse; aquaculture; spas and pools; and snow melting. These contributed 9 trillion Btus to U.S. energy consumption in 2001, whereas geothermal heat pumps contributed 13.5 trillion Btus. The energy consumption of each roughly doubled since 1990. Shipments of geothermal heat pumps by manufacturers have averaged 36,869 per year during the period 1996–2000.

With regard to environmental considerations, geothermal energy does not require fuel burning to produce heat or electricity. Although geothermal steam and flash plants emit mostly water vapor, some

harmful compounds, such as sulfur oxides, nitrogen oxides, hydrogen sulfide, and particulates, are also released. These plants use available emission control systems to meet the most stringent clean air standards. Binary cycle power plants run on a closed-loop system, so no gases are emitted. Whereas binary cycle plants are typically air cooled, the other plant types require a source of cooling water.

Other land uses can coexist with geothermal plants with little interference or fear of accidents. At some sites, however, there are important cultural objections to geothermal development from native populations.

Finally, a typical geothermal plant requires several wells. Although drilling these wells has an impact on the land, using advanced directional or slant drilling minimizes the impact. Several wells can be drilled from one pad, so less land is needed for access roads and fluid piping.

5.2 Technology and Applications

5.2.1 Power Plants

Geothermal power plants are reliable and productive, with a secure fuel supply. They provide baseload power and operate at capacity factors of 85–90% or more. Plants can be built in a modular fashion. This modularity provides flexibility; additional units can be added as needed.

There are three types of geothermal electricity-generating technologies in operation: dry steam, flash steam, and binary cycle. Dry steam plants use steam directly to turn a turbine, which drives a generator that produces electricity. In the United States, these plants are found exclusively at geysers, a high-quality steam-dominated resource.

Hydrothermal fluids above approximately 338°F (170°C) can be used in flash steam plants to make electricity. For these power plants, hot geothermal fluids come out of the ground under pressure and above boiling, and are sprayed into a tank held at a much lower pressure than the fluid, causing some of the fluid to rapidly vaporize or "flash" to steam. The steam then drives a turbine and generator. A second-stage, even lower pressure phase is employed in dual-flash plants to extract additional energy from fluids unflashed in the first phase.

Most geothermal areas contain moderate-temperature water (<338°F). Energy is extracted from these fluids in binary cycle power plants. Hot geothermal fluid and a secondary (hence, binary) fluid with a much lower boiling point than that of water pass through a heat exchanger. Heat from the geothermal fluid causes the secondary fluid to vaporize and drive the turbines.

5.2.2 Direct Use Applications

Direct use systems use lower temperature water [68–302°F (20–150°C)] to provide direct heat for residential, industrial, and commercial uses. These uses of heat from the earth eliminate the need to burn fuel, preventing thousands of tons of greenhouse gases from being emitted.

Direct use systems are typically composed of three components: a production facility, usually a well, to bring the hot water to the surface; a mechanical system—piping, heat exchanger, and controls—to deliver the heat to the space or process; and a disposal system—injection well or storage pond—to receive the cooled geothermal fluid.

The geothermal heat pump is an electric heat pump that uses the earth as a heat source for heating or as a heat sink for cooling. A water and antifreeze mixture circulates through pipes buried in the ground or in subsurface waters (a vertical or horizontal closed loop) and transfers thermal energy to a heat exchanger in the heat pump. The heat exchanger works through a water-to-refrigerant loop. Another variation is the open-loop system that uses groundwater pumped to the heat exchanger in the heat pump. Geothermal heat pumps offer a distinct advantage over the use of air as a source or sink because the ground is at a more favorable temperature. Compared to air, the ground is warmer in winter and cooler in summer. Therefore, geothermal heat pumps demonstrate better performance over air-source heat pumps.

5.3 Niche Markets and Outlook

Challenges faced by the geothermal power industry include the significant risk and uncertainty in locating and tapping commercially useful resources, even in land areas known to have geothermal resources; the high cost of drilling wells; the lack of advanced technology to find and characterize geothermal resources without expensive drilling; and the need to develop technology to allow commercial production from beyond the limited natural hydrothermal resource base.

Current geothermal energy research is addressing these challenges by focusing on resource exploration, drilling technologies, reservoir engineering, and power plant operating efficiencies. The objective of this research is to find and utilize available resources and lower the cost of producing electric power.

6. WIND ENERGY

Winds are created by uneven heating of the atmosphere by the sun, irregularities in the earth's surface, and the rotation of the earth. As a result, winds are strongly influenced and modified by local terrain, bodies of water, weather patterns, vegetative cover, and other such factors. Wind turbines work because they slow down the speed of the wind. The wind flows over the airfoil-shaped blades creating lift, similar to the effect on airplane wings, causing them to turn. The blades are connected to a driveshaft that turns an electric generator to produce electricity.

Although wind energy currently provides less than 2% of U.S. renewable electricity generation, the United States is rich in wind resources. However, the small fraction of this resource that can be economically exploited and the quantity of electricity that can be accommodated on the transmission grid remain highly uncertain in the evaluation of the total resource potential. Some states with good wind resources have difficult terrain, large areas excluded from development for environmental or other land use reasons, or, as in the case of North and South Dakota, are far from demand centers.

Wind power development in the United States began in the early 1980s and was almost exclusively in California due to the favorable regulatory environment and incentives for renewable energy development. It was not until 1999 that significant wind capacity appeared in other states, such as Iowa, Minnesota, and Texas. Development in these states was due in part to state mandates and renewable portfolio standards. In 2001, 20 states reported wind capacity, for a U.S. total of more than 4000 MW. The current expansion is possible because the levelized cost of wind power is becoming competitive with that of power from fossil fuels particularly when the federal production tax credit is factored in, coupled with a wide range of state incentives that benefit wind development. Excluding California, whose wind plants were developed mainly in the 1980s and 1990s, approximately 60% of U.S. wind capacity added during the 3-year period 1999–2001 was in states that currently have renewable portfolio standards.

6.1 Technology and Applications

The most common turbine used in the United States is the three-bladed horizontal axis upwind turbine, but two-bladed horizontal axis downwind turbines and vertical axis turbines also exist. Lattice- or tubular-type towers support the rotor blades and nacelle (an enclosure that houses key components of the turbine, including the gearbox and generator). In 2000, turbines with 600- to 900-kW capacity were popular at new wind farms. However, larger wind farms have been developed since using models with 1300- to 1800-kW capacity. The larger turbines can usually take advantage of some economies of scale and faster wind speeds at the higher heights of their towers. Rotors for the 1500-kW turbines are typically 70–80 m in diameter and are mounted on towers 60–80 + m tall. In the future, multi-megawatt turbines may be possible. For example, GE Wind Energy started testing a prototype 3600-kW turbine in 2002. This model has been selected for the proposed Cape Cod, Massachusetts, project, which may be one of the first offshore projects in the United States.

A handful of manufacturers supply most of the U.S. market for utility-scale turbines. Of these, only one, GE Wind, is domestic; the remainder are European owned. GE Wind came into being in mid-2002 after the acquisition of some of Enron Wind's assets. It is a vertically integrated company providing a wide array of services from planning to operations and maintenance. It has turbine-manufacturing facilities in Tehachapi, California, as well as in Spain and Germany.

Vestas is a leading manufacturer of wind turbines worldwide and supplies U.S. markets with nacelles and blades manufactured in its home country, Denmark. Towers for U.S. projects are procured from suppliers in the United States. There are plans for a future Vestas manufacturing facility in Portland, Oregon. NEG Micon is another Danish turbine manufacturer supplying the U.S. market. It had a manufacturing facility in Champaign, Illinois, but this is currently operating only as a service and repair facility. Its nacelles come from Denmark, whereas blades and towers come from U.S. suppliers. Bonus Energy also supplies U.S. markets with turbines, nacelles, and blades manufactured in Denmark; some towers used in Bonus projects are manufactured in the United States. Nordex is a German manufacturer of wind turbines with interests in the United States. Other domestic companies supply small wind turbines, such as Atlantic Orient Corporation (in the 50-kW range) and Bergey Wind (<10 kW).

6.2 Current Data

By the end of 2001, there were utility-scale wind farms in 20 states. Six states accounted for more than 88% of U.S. capacity (Table IV). In 2001, these wind farms

TABLE IV

U.S. Wind Nameplate Capacity (MW), 2001[a]

Total	4079
California	1608
Texas	1060
Minnesota	300
Iowa	277
Oregon	173
Washington	166

[a] *Source*. U.S. Department of Energy, Energy Information Administration, unpublished data.

produced approximately 6 billion kWh of electricity or approximately 2% of total renewable generation. Wind farms were operating in 10 more states by the end of 2002, with more planned for 2003.

6.3 Niche Markets and Outlook

The nature of wind as an energy source dictates that wind farms have to be located where the wind is occurring. This may be distant from load centers. Furthermore, the location for optimal gathering of wind may be in a terrain in which it is very difficult to erect a turbine tower. This has led to the development of semi-self-erecting towers. Also, bird kills is an issue, especially when towers were constructed with trestles that inadvertently served as nesting places. Newer, sleek, tubular towers do not provide such spaces.

In some areas of the country, the transmission grid is seriously congested and it is difficult and costly to construct new lines. Wind is intermittent and commonly operates with capacity factors under 35%, so backup power must be available when the wind is not blowing. Sometimes, this is accomplished relatively easily by coupling wind power with hydropower, as it is frequently done in California. However, sometimes the situation is more complicated. Also, most grid tariffs and operating procedures were not designed to consider intermittent generation and may not adequately accommodate its unique characteristics. Although new procedures for rate determination are the subject of debate (e.g., the Federal Energy Regulatory Commission's Standard Market Design), the ability to develop technology that could more reliably forecast future wind conditions is an issue. Also, economic large-scale storage is not commercially available.

Federal support for wind power has had gaps. Twice in recent years, the Federal Production Tax Credit (PTC) has expired. On both occasions, there was a period of uncertainty, and project plans were halted or delayed for a number of months until the credit was renewed. The PTC will expire again at the end of 2003.

The EIA's forecast to 2025 projects that wind power will increase in the United States. However, the rate of growth slows in the latter years of the forecast as current incentives and mandates expire and wind economics remain somewhat marginal. The EIA projects that total U.S. wind capacity will expand to 12,000 MW by 2025.

7. SOLAR ENERGY

Using the sun's energy to produce heat or electricity is not a new idea. Technologies that capture the radiation of the sun and use it to produce energy have been available in one form or another for centuries. They continue to be defined and developed today. As of 2003, solar thermal devices were used in a variety of ways, from heating swimming pools to creating steam for electricity generation, whereas photovoltaic (PV) devices use semiconducting materials to convert sunlight directly into electricity. Passive solar systems make use of spontaneous movement of heat by conduction, convection, radiation, or evaporation. (Passive solar systems are not further discussed in this article due to a lack of data.)

Solar energy technologies have important advantages for electric utility and other users. First, the solar resource has no "fuel" cost and is abundantly available. In many areas of the country, the sun shines intensely on a daily basis, providing a nearly unlimited power resource for devices that convert the sun's insolation into useful energy. Second, solar daily output often matches air-conditioning loads and thus provides high value. Third, most solar equipment is modular, allowing supply to be adjusted to demand. Fourth, most PV technologies can easily be operated in remote off-grid areas without transmission and distribution costs. Finally, solar technologies are environmentally clean, with no operating wastes, air pollution, or noise.

Solar energy technologies have some limitations for widespread use. Although costs have declined substantially during the past three decades, they are still very expensive relative to conventional technologies. Also, sunlight is intermittent, resulting in storage and load-matching problems.

7.1 Current Data

Total shipments of solar thermal collectors were 11.2 million square feet in 2001. This represented an

increase of 34% from the 2000 total of 8.4 million square feet. There were 26 companies shipping solar collectors in 2001, the same as in 2000. Import shipments totaled 3.5 million square feet, whereas export shipments totaled 0.8 million square feet. PV cell and module shipments reached 97.7 peak MW in 2001. For the first time in more than 8 years, exports declined, decreasing to 61.4 peak MW. Exports accounted for 63% of total shipments in 2001 compared to 78% in 2000.

7.2 Technology and Applications

Solar energy technologies are classified into two major categories by the type of energy used: solar thermal devices, which use the sun's heat energy, and PV devices, which use the energy inherent in the solar photons and convert it directly into electricity. A solar thermal collector usually consists of a frame, glazing, and an absorber, together with the appropriate insulation. The heat collected by the collector may be used immediately or stored for later use. A PV cell is an electric device consisting of layers of semiconductor materials fabricated to form a junction (adjacent layers of materials with different electric characteristics) and electrical contacts, being capable of converting incident light directly into electricity (direct current). A PV module is two or more cells attached and designed to be used for PV power systems.

7.2.1 Types of Solar Technologies

Data are collected by the EIA on solar–thermal collectors and PV cells and modules. These data provide information on solar energy applications.

7.2.1.1 Solar thermal collector types Solar thermal collectors are classified as low-, medium-, and high-temperature collectors. Low-temperature collectors provide heat up to 110°F through either metallic or nonmetallic absorbers and are used for applications such as swimming pool heating, which has dominated the industry since the rescission of the energy investment tax credits in 1985. Medium-temperature collectors provide heat higher than 110°F (usually 140–180°F) through either glazed flat-plate collectors that use air or liquid as the heat-transfer medium or concentrator collectors that concentrate the heat of incident insulation to greater than one sun. Before the expiration of the energy tax credits at the end of 1985, medium-temperature collector manufacturers dominated the market during the 1970s and early 1980s. Medium-temperature collectors are used for water, space, and process heating. Evacuated-tube collectors are included in this category. High-temperature collectors are parabolic dish and trough collectors used primarily by utilities and nonutility power producers in the generation of electricity for the grid. High-temperature solar thermal collectors, which operate at temperatures higher than 180°F, are used primarily for R&D projects.

7.2.1.2 Photovoltaic cell and module types PV cells and modules are classified into three categories by product type: crystalline silicon cells and modules (including single-crystal, cast silicon, and ribbon silicon), thin-film cells and modules (made from a number of layers of photosensitive materials such as amorphous silicon), and concentrator cells and modules (in which a lens is used to gather and converge sunlight onto the cells or module surface). Crystalline silicon cells and modules dominate the PV industry.

7.2.2 Uses of Solar Technologies

7.2.2.1 Solar thermal collectors Since 1986, the largest end use for solar thermal collectors has been for heating swimming pools. In 2001, solar swimming pool heaters represented 97% of solar thermal collector shipments (Table V). This application usually involved the use of low-temperature collectors. A common low-temperature pool-heating solar collector is a black plastic or rubber-like sheet with tubing through which water is circulated. The heat of the sun is transferred directly from the black absorbing material to the water circulating through the tubing to supply heat to the pool.

The second largest end use was for domestic hot water systems, which represented 2% of solar collector shipments (Table V). Typical solar water-heating systems feature flat-plate collectors or collectors installed in an internal collector storage or thermosiphon system. Unlike pool-heating systems, domestic solar water-heating systems almost always have a conventional backup (i.e., gas or electric). Medium-temperature collectors also were shipped for space heating and for installation into systems that provide both space and water heating and process heating. High-temperature parabolic dish and trough collectors were shipped for electricity generation and hot water in the past when electricity and natural gas prices were expected to increase very rapidly.

TABLE V

Shipments of Solar Collectors by Market Sector, End Use, and Type, 2000 and 2001 (in Thousands of Square Feet)[a]

7.2.2.2 Uses of photovoltaic cells and modules The largest end-use application of PV cells and modules is for electricity generation (combined grid-interactive and remote). Grid-interactive and remote (i.e., stand-alone) power generation includes applications for grid distribution and general remote uses, such as residential power and power for mobile homes. In 2001, electric generation accounted for 50% of total PV shipments (Table VI).

7.3 Niche Markets and Outlook

Solar technologies require either significant cost reductions or a combination of cost reductions and an increase in natural gas prices to become cost competitive in most grid applications. Some obstacles slowing commercialization are technology specific, whereas others are more general. The primary obstacle is that solar technologies cannot currently compete with conventional fossil-fueled technologies in grid-connected applications. On the other hand, some niche applications, such as photovoltaics for transmission and distribution support at the end of a fully loaded distribution line, have value above that of a new generating plant. Such applications may permit the technology to establish itself and benefit from economies of scale and learning effects.

Glossary

biofuels Liquid fuels used in transportation that are derived from renewable biomass resources. Not limited to transportation, these fuels can also be used for heating and electricity generation. The main fuels promoted are ethanol, gasohol, biodiesel, bio-oil, and methanol.

capital costs The initial investment costs associated with a renewable energy installation, as distinct from operating and maintenance (all technologies) or fuel costs (in the case of biomass).

distributed generation Generation of electricity at or near the point of end use, often in small quantities, rather than remotely in a large centralized power plants.

independent power producer An organization that produces electric power (i.e., from a wind farm) and sells that power under contract (called a power purchase agreement) to the electric utility or to a third party. If to a third party, the electricity must be transferred over the utility transmission system, usually for a fee.

microcredit Small amounts of credit made available to households or small businesses for investments in high-capital-cost renewable energy supplies or services, usually within a rural development context.

power sector restructuring A political/policy process causing changes in the institutions, ownership, rates and tariffs, power market rules, competition, or financing in the electric power industry (primarily among power generators and electric utilities).

The 1990s saw an explosion of energy policy changes around the globe. Driven by economic, environmental, security, and social concerns, energy regulation has been in great flux. Many of the changes are having a profound influence on renewable energy, both from policies explicitly designed to promote renewable energy and from other policies that indirectly influence incentives and barriers for renewable energy. This article considers six different types of policies that affect renewable energy development, both directly or indirectly: renewable energy promotion policies, transport biofuels policies, emissions reduction policies, electric power restructuring policies, distributed generation policies, and rural electrification policies. Each policy reduces one or more key barriers that impede the development of renewable energy. These barriers are discussed first. In general, most renewable energy policies address cost-related barriers in some manner. Many policies address the requirements for utilities to purchase renewable energy from power producers. Most policies also address the perceived risks of renewable energy in one form or another (i.e., technical, financial, legal). Still others primarily address regulatory and institutional barriers. Some related policies may heighten barriers to renewable energy rather than reduce them.

1. BARRIERS TO RENEWABLE ENERGY

The need for enacting policies to support renewable energy is often attributed to a variety of barriers, or conditions that prevent investments from occurring. Often the result of barriers is to put renewable energy at an economic, regulatory, or institutional disadvantage relative to other forms of energy supply. Barriers include subsidies for conventional forms of energy, high initial capital costs coupled with lack of fuel-price risk assessment, imperfect capital markets, lack of skills or information, poor market acceptance, technology prejudice, financing risks and uncertainties, high transactions costs, and a variety of regulatory and institutional factors. Many of these barriers could be considered market distortions that unfairly discriminate against renewable energy, while others have the effect of increasing the costs of renewable energy relative to the alternatives. Barriers are often quite situation specific in any given region or country; nevertheless, three broad categories of barriers are discussed in this section. Table I summarizes the key renewable energy policies and barriers presented.

1.1 Costs and Pricing

Many argue that renewable energy costs more than other energy sources, resulting in cost-driven decisions and policies that avoid renewable energy. In practice, a variety of factors can distort the comparison. For example, public subsidies may lower the costs of competing fuels. Although it is true that initial capital costs for renewable energy technologies are often higher on a cost-per-unit basis (i.e., $/kW), it is widely accepted that a true comparison must be made on the basis of total life-cycle costs. Life-cycle costs account for initial capital costs, future fuel costs, future operation and maintenance costs, decommissioning costs, and equipment lifetime. Here lies part of the problem in making comparisons: What are fuel costs going to be in the future? How should future costs be discounted to allow comparison with present costs based on expected interest rates? The uncertainties inherent in these questions affect cost comparisons. Existing analytical tools for calculating and comparing costs can discriminate against renewable energy if they do not account for future uncertainties or make unrealistic assumptions.

Many policies attempt to compensate for cost-related barriers by providing additional subsidies for renewable energy in the form of tax credits or incentives, by establishing special pricing and power-purchasing rules, and by lowering transaction costs. Despite many calls for reducing subsidies for fossil fuels and nuclear power, in practice this proves politically difficult. Thus, practical policies have tended to focus on increasing subsidies for renewable energy rather than reducing subsidies for fossil fuels and nuclear power.

1.1.1 Subsidies for Competing Fuels

Large public subsidies, both implicit and explicit, are channeled in varying amounts to all forms of energy, which can distort investment cost decisions. Organizations such as the World Bank and International Energy Agency put global annual subsidies for fossil fuels in the range of $100 billion to $200 billion, although such figures are very difficult to estimate (for comparison, the world spends some $1 trillion annually on purchases of fossil fuels). Public subsidies can take many forms: direct budgetary transfers, tax incentives, R&D spending, liability insurance, leases, land rights-of-way, waste disposal, and guarantees to mitigate project financing or fuel price risks. Large subsidies for fossil fuels can significantly lower final energy prices, putting renewable energy at a competitive disadvantage if it does not enjoy equally large subsidies.

1.1.2 High Initial Capital Costs

Even though lower fuel and operating costs may make renewable energy cost competitive on a life-cycle basis, higher initial capital costs can mean that renewable energy provides less installed capacity per initial dollar invested than conventional energy sources. Thus, renewable energy investments generally require higher amounts of financing for the same capacity. Depending on the circumstances, capital markets may demand a premium in lending rates for financing renewable energy projects because more capital is being risked up front than in conventional energy projects. Renewable energy technologies may also face high taxes and import duties. These duties may exacerbate the high first-cost considerations relative to other technologies and fuels.

1.1.3 Difficulty of Fuel Price Risk Assessment

Risks associated with fluctuations in future fossil fuel prices may not be quantitatively considered in decisions about new power generation capacity because these risks are inherently difficult to assess. Historically, future fuel price risk has not been considered an important factor because future fossil

fuel prices have been assumed to be relatively stable or moderately increasing. Thus, risks of severe fluctuations are often ignored. However, with greater geopolitical uncertainties and energy market deregulation has come new awareness about future fuel price risks. Renewable energy technologies avoid fuel costs (with the exception of biomass) and so avoid fuel price risk. However, this benefit, or risk-reduction premium, is often missing from economic comparisons and analytical tools because it is difficult to quantify. Further, for some regulated utilities, fuel costs are factored into regulated power rates so that consumers rather than utilities bear the burden of fuel price risks, and utility investment decisions are made without considering fuel price risk.

1.1.4 Unfavorable Power Pricing Rules

Renewable energy sources feeding into an electric power grid may not receive full credit for the value of their power. Two factors are at work. First, renewable energy generated on distribution networks near final consumers rather than at centralized generation facilities may not require transmission and distribution (i.e., would displace power coming from a transmission line into a node of a distribution network). But utilities may only pay wholesale rates for the power, as if the generation was located far from final consumers and required transmission and distribution. Thus, the locational value of the power is not captured by the producer. Second, renewable energy is often an intermittent source whose output level depends on the resource (i.e., wind and sun) and cannot be entirely controlled. Utilities cannot count on the power at any given time and may lower prices for it. Lower prices take two common forms: (1) a zero price for the capacity value of the generation (utility only pays for the energy value) and (2) an average price paid at peak times (when power is more valuable), which is lower than the value of the power to the utility—even though the renewable energy output may directly correspond with peak demand times and thus should be valued at peak prices.

1.1.5 Transaction Costs

Renewable energy projects are typically smaller than conventional energy projects. Projects may require additional information not readily available, or they may require additional time or attention to financing or permitting because of unfamiliarity with the technologies or uncertainties over performance. For these reasons, the transaction costs of renewable energy projects—including resource assessment, siting, permitting, planning, developing project proposals, assembling financing packages, and negotiating power-purchase contracts with utilities—may be much larger on a per kilowatt (kW) capacity basis than for conventional power plants. Higher transaction costs are not necessarily an economic distortion in the same way as some other barriers, but simply make renewables more expensive. However, in practice some transaction costs may be unnecessarily high, for example, overly burdensome utility interconnection requirements and high utility fees for engineering reviews and inspection.

1.1.6 Environmental Externalities

The environmental impacts of fossil fuels often result in real costs to society, in terms of human health (i.e., loss of work days, health care costs), infrastructure decay (i.e., from acid rain), declines in forests and fisheries, and perhaps ultimately, the costs associated with climate change. Dollar costs of environmental externalities are difficult to evaluate and depend on assumptions that can be subject to wide interpretation and discretion. Although environmental impacts and associated dollar costs are often included in economic comparisons between renewable and conventional energy, investors rarely include such environmental costs in the bottom line used to make decisions.

1.2 Legal and Regulatory

1.2.1 Lack of Legal Framework for Independent Power Producers

In many countries, power utilities still control a monopoly on electricity production and distribution. In these circumstances, in the absence of a legal framework, independent power producers may not be able to invest in renewable energy facilities and sell power to the utility or to third parties under so-called power purchase agreements. Or utilities may negotiate power purchase agreements on an individual ad hoc basis, making it difficult for project developers to plan and finance projects on the basis of known and consistent rules.

1.2.2 Restrictions on Siting and Construction

Wind turbines, rooftop solar hot-water heaters, photovoltaic installations, and biomass combustion facilities may all face building restrictions based on height, aesthetics, noise, or safety, particularly in urban areas. Wind turbines have faced specific

TABLE I

Summary of Renewable Energy Policies and Barriers

Policies	Description	Key barriers addressed
Renewable Energy Promotion Policies		
Price-setting and quantity-forcing policies	Mandates prices to be paid for renewable energy or requires a fixed amount or share of generation to be renewable	High costs, unfavorable power pricing rules, perceived risks
Cost-reduction policies	Reduces investment costs through subsidies, rebates, tax relief, loans and grants	High costs, perceived risks
Public investments and market facilitation activities	Provides public funds for direct investments or for guarantees, information, training, etc. to facilitate investments	Transaction costs, perceived risks, lack of access to credit, information, and skills
Power grid access policies	Gives renewable energy equal or favorable treatment for access to power grids and transmission systems	Independent power producer frameworks, transmission access, interconnection requirements
Transport Biofuels Policies		
Biofuels mandates	Mandates specific shares of transport fuel consumption from biofuels	Lack of fuel production or delivery infrastructure
Biofuel tax policies	Provides tax relief for biofuels	High costs
Emissions Reduction Policies		
Renewable energy set-asides	Allocates, or sets aside, a percentage of mandated environmental emissions reductions to be met by renewable energy	Environmental externalities
Emissions cap and trade policies	Allows renewables to receive monetary credit for local pollutant emissions reductions	Environmental externalities
Greenhouse gas mitigation policies	Allows renewables to receive monetary credit for greenhouse-gas emissions reductions	Environmental externalities
Power-Sector Restructuring Policies		
Competitive wholesale power markets	Allows competition in supplying wholesale generation to the utility network and eliminates wholesale pricing restrictions.	May heighten barriers of high costs, lack of fuel price risk assessment, unfavorable power pricing rules
Self-generation by end users	Allows end users to generate their own electricity and either sell surplus power back to the grid or partly offset purchased power	May reduce barrier of interconnection requirements, but heighten barriers of high costs, lack of fuel price risk assessment
Privatization or commercialization of utilities	Changes government-owned and operated utilities into private or commercial entities	May reduce barrier of subsidies, but heighten barriers of high capital costs and perceived risks
Unbundling of generation, transmission and distribution	Eliminates monopolies so that separate entities provide generation, transmission, and distribution	May provide greater incentives to self-generate, including with renewable energy
Competitive retail power markets	Provides competition at the retail level for power sales, including "green power" sales	May reduce barriers of high costs, lack of information, transaction costs
Distributed Generation Policies		
Net metering	Values renewable energy production at the point of end use and allows utility networks to provide "energy storage" for small users	Unfavorable power pricing rules
Real-time pricing	Values renewable energy production at the actual cost of avoided fossil fuel generation at any given time of the day	Unfavorable power pricing rules
Capacity credit	Provides credit for the value of standing renewable energy capacity, not just energy production	Unfavorable power pricing rules

continues

Table I continued

Policies	Description	Key barriers addressed
Interconnection regulations	Creates consistent and transparent rules, norms, and standards for interconnection	Interconnection requirements, transaction costs
Rural Electrification Policies		
Rural electrification policy and energy service concessions	Makes renewable energy part of rural electrification policy and planning and creates regulated businesses to serve rural customers	Subsidies for competing fuels, lack of skills and information, high costs, lack of access to credit
Rural business development and microcredit	Supports private entrepreneurs to provide renewable energy products and services to end users and offer consumer credit for purchases	Lack of skills, lack of access to credit
Comparative line extension analyses	Analyzes the relative costs of renewable energy with conventional fuels and power delivery	Subsidies for competing fuels, lack of information

environmental concerns related to siting along migratory bird paths and coastal areas. Urban planning departments or building inspectors may be unfamiliar with renewable energy technologies and may not have established procedures for dealing with siting and permitting. Competition for land use with agricultural, recreational, scenic, or development interests can also occur.

1.2.3 Transmission Access

Utilities may not allow favorable transmission access to renewable energy producers or may charge high prices for transmission access. Transmission access is necessary because some renewable energy resources like windy sites and biomass fuels may be located far from population centers. Transmission or distribution access is also necessary for direct third-party sales between the renewable energy producer and a final consumer. New transmission access to remote renewable energy sites may be blocked by transmission-access rulings or right-of-way disputes.

1.2.4 Utility Interconnection Requirements

Individual home or commercial systems connected to utility grids can face burdensome, inconsistent, or unclear utility interconnection requirements. Lack of uniform requirements can add to transaction costs. Safety and power-quality risk from nonutility generation is a legitimate concern of utilities, but a utility may tend to set interconnection requirements that go beyond what is necessary or practical for small producers in the absence of any incentive to set more reasonable but still technically sound requirements. In turn, the transaction costs of hiring legal and technical experts to understand and comply with interconnection requirements may be significant. Policies that create sound and uniform interconnection standards can reduce interconnection hurdles and costs.

1.2.5 Liability Insurance Requirements

Small power generators (particularly home photovoltaic systems feeding into the utility grid under so-called net metering provisions) may face excessive requirements for liability insurance. The phenomenon of islanding, which occurs when a self-generator continues to feed power into the grid when power flow from the central utility source has been interrupted, can result in serious injury or death to utility repair crews. Although proper equipment standards can prevent islanding, liability is still an issue. Several U.S. states have prohibited utilities from requiring additional insurance beyond normal homeowner liability coverage as part of net metering statutes.

1.3 Market Performance

1.3.1 Lack of Access to Credit

Consumers or project developers may lack access to credit to purchase or invest in renewable energy because of lack of collateral, poor creditworthiness, or distorted capital markets. In rural areas, microcredit lending for household-scale renewable energy systems may not exist. Available loan terms may be too short relative to the equipment or investment lifetime. In some countries, power project developers have difficulty obtaining bank financing because of uncertainty as to whether utilities will continue to honor long-term power purchase agreements to buy the power.

1.3.2 Perceived Technology Performance Uncertainty and Risk

Proven, cost-effective technologies may still be perceived as risky if there is little experience with them in a new application or region. The lack of visible installations and familiarity with renewable

energy technologies can lead to perceptions of greater technical risk than for conventional energy sources. These perceptions may increase required rates of return, result in less capital availability, or place more stringent requirements on technology selection and resource assessment. "Lack of utility acceptance" is a phrase used to describe the historical biases and prejudices on the part of traditional electric power utilities. Utilities may be hesitant to develop, acquire, and maintain unfamiliar technologies, or give them proper attention in planning frameworks. Finally, prejudice may exist because of poor past performance that is out of step with current performance norms.

1.3.3 Lack of Technical or Commercial Skills and Information

Markets function best when everyone has low-cost access to good information and the requisite skills. But in specific markets, skilled personnel who can install, operate, and maintain renewable energy technologies may not exist in large numbers. Project developers may lack sufficient technical, financial, and business development skills. Consumers, managers, engineers, architects, lenders, or planners may lack information about renewable energy technology characteristics, economic and financial costs and benefits, geographical resources, operating experience, maintenance requirements, sources of finance, and installation services. The lack of skills and information may increase perceived uncertainties and block decisions.

2. RENEWABLE ENERGY PROMOTION POLICIES

Policies whose specific goal is to promote renewable energy fall into three main categories: (1) price-setting and quantity-forcing policies, which mandate prices or quantities; (2) investment cost reduction policies, which provide incentives in the form of lower investment costs; and (3) public investments and market facilitation activities, which offer a wide range of public policies that reduce market barriers and facilitate or accelerate renewable energy markets. Historically, governments have enacted these policies in a rather ad hoc manner. More recently, national renewable energy targets (also referred to as goals) have emerged as a political context for promoting specific combinations of policies from all three categories. Such targets focus on the aggregate energy production of an entire country or group of countries. Targets may specify total primary energy from renewables or minimum renewable energy shares of electricity generation.

Several countries have adopted or are proposing national renewable energy targets. The European Union collectively has adopted a target of 22% of total electricity generation from renewables by 2010, with individual member states having individual targets above or below that amount. Japan has adopted a target of 3% of total primary energy by 2010. Recent legislative proposals in the United States would require 10% of electricity generation from renewables by 2020. China and India are the first developing countries to propose renewable energy targets. India has proposed that by 2012, 10% of annual additions to power generation would be from renewable energy; China has a similar goal of 5% by 2010. Other countries with existing or proposed targets are Australia, Brazil, Malaysia, and Thailand. In addition, countries from around the world placed increased attention on renewable energy targets at the United Nations World Summit for Sustainable Development in 2002.

2.1 Price-Setting and Quantity-Forcing Policies

Price-setting policies reduce cost- and pricing-related barriers by establishing favorable pricing regimes for renewable energy relative to other sources of power generation. The quantity of investment obtained under such regimes is unspecified, but prices are known in advance. Quantity-forcing policies do the opposite; they mandate a certain percentage or absolute quantity of generation to be supplied from renewable energy, at unspecified prices. Often price-setting or quantity-forcing policies occur in parallel with other policies, such as investment cost–reduction policies.

The two main price-setting policies seen to date are the PURPA legislation in the United States and electricity feed-in laws in Europe. The two main quantity-forcing policies seen to date are competitively bid renewable-resource obligations and renewable portfolio standards.

2.1.1 U.S. Public Utility Regulatory Policies Act (PURPA)

PURPA was enacted in 1978 in part to encourage electric power production by small power producers using renewable resources to reduce U.S. dependence

on foreign oil. The policy required utilities to purchase power from small renewable generators and cogenerators, known as qualifying facilities, through long-term (10-year) contracts at prices approximating the avoided costs of the utilities. These avoided costs represented the marginal costs to the utilities of building new generation facilities, which could be avoided by purchasing power from the qualifying facilities instead. Avoided cost calculations typically assumed an aggressive schedule of escalating future energy prices, making contract prices to qualifying facilities quite attractive.

For example, standard offer contracts under PURPA in California in the 1980s set the avoided cost of generation in the range 6 to 10 cents/kWh—very favorable rates, which initially spurred many investments by renewable energy producers. However, by the 1990s energy prices had not risen as originally expected and a large number of natural-gas-fired independent generation came online in California. Power surpluses emerged, wholesale power prices declined, and declining standard offer rates led to reduced competitiveness of renewable energy and a significant slowdown in construction of new capacity.

2.1.2 Electricity Feed-in Laws

The electricity feed-in laws in Germany, and similar policies in other European countries in the 1990s, set a fixed price for utility purchases of renewable energy. For example, in Germany starting in 1991, renewable energy producers could sell their power to utilities at 90% of the retail market price. The utilities were obligated to purchase the power. The German feed-in law led to a rapid increase in installed capacity and development of commercial renewable energy markets. Wind power purchase prices were highly favorable, amounting to about DM 0.17/kWh (US 10 cents/kWh), and applied over the entire life of the plant. Total wind power installed went from near zero in the early 1990s to over 8500 MW by 2001, making Germany the global leader in renewable energy investment.

Partly because retail electricity prices declined with increasing competition due to electricity deregulation, which made producers and financiers wary of new investments, a new German Renewable Energy Law of 2000 changed electricity feed-in pricing. Pricing became based on fixed norms unique to each technology, which in turn were based on estimates of power production costs and expectations of declines in those costs over time. For example, wind power prices remained at the previous level of DM 0.17/kWh for plants commissioned in 2001, but only for the first 5 years of operation, after which prices paid declined. Solar PV prices were set initially at DM 0.99/kWh. All prices had built-in declines over time (i.e., 1.5% annual decreases in starting tariffs paid for wind power plants commissioned in subsequent years). This provision addressed one of the historical criticisms of feed-in approaches, which was that they did not encourage technology cost reductions or innovation. The new law's provisions for regular adjustments to prices addressed technological and market developments. The law also distributed the costs of the policy (i.e., the additional costs of wind power over conventional power) among all utility customers in the country. This issue of burden sharing had become a significant political factor in Germany by 2000 because the old law placed a disproportionate burden on utility customers in specific regions where wind power development was heaviest.

Other countries in Europe with renewable electricity feed-in laws include Denmark, France, Greece, Italy, Portugal, Spain, and Sweden. A combination of feed-in tariffs, production subsidies of DK 0.10/kWh, and a strong domestic market helped the Danish wind industry maintain a 50% market share of global wind turbine production for a number of years.

2.1.3 Competitively-Bid Renewable-Resource Obligations

The United Kingdom tried competitive bidding for renewable-energy-resource obligations during the 1990s under its Non-Fossil-Fuel Obligation (NFFO) policy. Under the NFFO, power producers bid on providing a fixed quantity of renewable power, with the lowest-price bidder winning the contact. With each successive bidding round (there were four total), bidders reduced prices relative to the last round. For example, wind power contract prices declined from 10 p/kWh in 1990 under NFFO-1 to 4.5 p/kWh in 1997 under NFFO-4. One of the lessons some have drawn from the UK experience is that competitively determined subsidies can lead to rapidly declining prices for renewable energy. However, there has also been criticism that the NFFO process encouraged competing projects to bid below cost in order to capture contracts, with the result that successful bidders were unable to meet the terms of the bid or ended up insolvent. This criticism proved valid in practice; contracts awarded to low bidders did not always translate into projects on the ground. The UK abandoned the NFFO approach after the fourth

round of bidding in 1997. Other countries with similar competitively bid renewable resource mechanisms have included Ireland (under the Alternative Energy Requirement program), France (under the EOLE program), and Australia (under the Renewable Energy Commercialisation Program program).

2.1.4 Renewable Energy Portfolio Standards (RPS)

An RPS requires that a minimum percentage of generation sold or capacity installed be provided by renewable energy. Obligated utilities are required to ensure that the target is met, either through their own generation, power purchases from other producers, or direct sales from third parties to the utility's customers. Typically, RPS obligations are placed on the final retailers of power, who must purchase either a portion of renewable power or the equivalent amount of green certificates (see the next section). Two types of standards have emerged: capacity-based standards set a fixed amount of capacity by a given date, while generation-based standards mandate a given percentage of electricity generation that must come from renewable energy.

In the United States, many RPS policies have occurred as part of utility restructuring legislation. These are typically generation-based standards with phased implementation to allow utilities to reach incrementally increasing targets over a number of years. At least 12 U.S. states have enacted an RPS, ranging from 1 to 30% of electricity generation. However, the amount of new and additional generation expected from these standards varies widely depending on existing renewable energy capacity. For example, Maine historically generates over 40% of its power from renewable resources, so its 30% standard is unlikely to result in any new renewable generation. In contrast, California's requirement to increase renewable sales from 10.5% in 2001 to 20% by 2017 will likely result in a significant amount of new in-state renewable energy generation. Texas implemented an RPS in 2000 requiring 2000 MW of new renewable capacity by 2008. Partly due to federal production tax credits, Texas has been substantially ahead of schedule, with half of the targeted capacity in place by 2002.

In Europe, the Netherlands has been a leader among RPS initiatives. Dutch utilities have adopted an RPS voluntarily, based on targets of 5% of electricity generation by 2010, increasing to 17% by 2020. Other countries with regulatory requirements for utilities or electricity retailers to purchase a percentage of renewable power include Australia, Brazil, Belgium, Denmark, France, Japan, Spain, Sweden, and the United Kingdom. The UK's Renewables Obligation on suppliers will rise in annual steps from 3% in 2003 to 10% in 2010. In Denmark, legislation obliges end users to purchase 20% of their electricity from renewable sources by 2003.

In Brazil, a policy enacted during the electricity crisis of 2001 requires national utilities to purchase more than 3000 MW of renewable energy capacity by 2016. Purchase prices are set by the government at 80% of the national average electricity retail price. Thus, in contrast to most national policies elsewhere, Brazil's policy is effectively both price setting and quantity forcing.

2.1.5 Renewable Energy (Green) Certificates

Renewable energy (green) certificates are emerging as a way for utilities and customers to trade renewable energy production or consumption credits in order to meet obligations under RPS and similar policies. Standardized certificates provide evidence of renewable energy production and are coupled with institutions and rules for trading that separate renewable attributes from the associated physical energy. This enables a paper market for renewable energy to be created independent of actual electricity sales and flows. Green certificate markets are emerging in several countries, allowing producers or purchasers of renewable energy who earn green certificates to sell those certificates to those who need to meet obligations but have not generated or purchased the renewable power themselves. Those without obligations but who wish to voluntarily support green power for philosophical or public relations reasons may also purchase certificates.

Public and private institutions are emerging that keep track of renewable energy generation, assign certificates to generators, and register trades and sales of certificates. Green certificate trading is gaining ground in the UK, Belgium, Denmark, Australia, and the United States. Europe embarked on a test phase of an EU-wide renewable energy certificate trading system during 2001 and 2002. This Renewable Energy Certificate System (RECS) was established as a formal association in December 2002 with over 100 members in 14 different countries. Certificates for over 22,500 GWh were issued through 2003.

2.2 Cost-Reduction Policies

A number of policies are designed to provide incentives for voluntary investments in renewable energy by reducing the costs of such investments.

These policies can be characterized as falling in five broad categories: policies that (1) reduce capital costs up front (via subsidies and rebates), (2) reduce capital costs after purchase (via tax relief), (3) offset costs through a stream of payments based on power production (via production tax credits), (4) provide concessionary loans and other financial assistance, and (5) reduce capital and installation costs through economies of bulk procurement.

2.2.1 Subsidies and Rebates

Reduction in the initial capital outlay by consumers for renewable energy systems is accomplished through direct subsidies, or rebates. These subsidies are used to buy down the initial capital cost of the system so that the consumer sees a lower price. In the United States, at least nineteen states offer rebate programs at the state, local, or utility level to promote the installation of renewable energy equipment. The majority of the programs are available from state agencies and municipally owned utilities and support solar water heating or photovoltaic systems, though some include geothermal heat pumps, small wind generators, passive solar, biomass, and fuel cells. Homes and businesses are usually eligible, although some programs target industry and public institutions as well. In some cases, rebate programs are combined with low- or no-interest loans.

Sustained efforts to increase the use of renewables have been made via coordinated, multiyear, multipolicy initiatives. For example, Japan, Germany, and the United States subsidize capital costs of solar PV as part of their market transformation program.

- Japan's Sunshine Program provides capital subsidies and net metering for rooftop PV systems. From 1994 to 2000, the government invested 86 billion yen ($725 million USD), resulting in 58,000 system installations and over 220 MW of PV capacity. Subsidies began at 900,000 yen/peak-kW (US$5/peak-watt) in 1994, and were gradually reduced to 120,000 yen/peak-kW (US$1/peak-watt) in 2001 as PV prices fell.
- Germany began a 1000 solar roofs program in 1991 that offered subsidies for individual household purchases of solar PV of up to 60% of capital system costs. The program was expanded in 1999 to 100,000 roofs over 5 years, providing 10-year low-interest loans to households and businesses. As a result of favorable feed-in tariffs and low-interest loans, the program was expected to provide 300 peak-MW of PV capacity.
- The United States launched a million solar roofs initiative in 1997 to install solar PV systems and solar thermal systems on 1 million buildings by 2010. The program includes long-term, low-interest customer financing, government procurement for federal buildings, commercialization programs, and production incentives. Individual states also have capital subsidy programs for PV, with the California Energy Commission offering rebates of up to $4.50/peak-watt or 50% off the system purchase price, New York and New Jersey offering up to $5/peak-watt subsidies, and New York rebating as much as 70% of the cost of eligible equipment as of 2002.

Subsidy programs also exist for wind power, such as Denmark's DK 0.10/kWh (US 1.5 cents/kWh) production subsidy paid to utilities. Among developing countries, Thailand provided subsidies for small renewable energy power producers starting in 2000, soliciting bids for 300 MW of small renewable power and providing production subsidies above standard power purchase rates for at least the first 5 years of operation of each facility.

2.2.2 Tax Relief

Tax relief policies to promote renewable energy have been employed in the United States, Europe, Japan, and India. Tax relief has been especially popular in the United States, where a host of federal and state tax policies address energy production, property investments, accelerated depreciation, and renewable fuels. State policies vary widely in scope and implementation. At least 17 states have personal tax incentives, 21 states have corporate tax incentives, 16 states have sales tax incentives, and 24 states have property tax incentives.

2.2.2.1 Investment Tax Credits Investment tax credits for renewable energy have been offered for businesses and residences. In the United States, businesses receive a 10% tax credit for purchases of solar and geothermal renewable energy property, subject to certain limitations. Some U.S. states have investment tax credits of up to 35%.

2.2.2.2 Accelerated Depreciation Accelerated depreciation allows renewable energy investors to receive the tax benefits sooner than under standard depreciation rules. The effect of accelerated depreciation is similar to that of investment tax credits. In the United States, businesses can recover investments in solar, wind, and geothermal property by depreciating them over a period of 5 years, rather than the

15- to 20-year depreciation lives of conventional power investments.

India's accelerated depreciation policy allowed 100% depreciation in the first year of operation, helping spur the largest wind power industry among developing countries. However, this policy led to large investments without sufficient regard to long-term operating performance and maintenance, resulting in capacity factors lower than for wind power installations elsewhere. This led many to conclude that production-based incentives are preferable to investment tax credits and accelerated depreciation, although Germany's investment tax credits accompanied by wind turbine technical standards and certification requirements avoided the problems found in India.

2.2.2.3 Production Tax Credits A production tax credit provides the investor or owner of qualifying property with an annual tax credit based on the amount of electricity generated by that facility. By rewarding production, these tax credits encourage improved operating performance. A production tax credit in Denmark provides DK 0.10/kWh (US 1.5 cents/kWh) for wind power, but few other countries have adopted similar credits. In the United States the Renewable Electricity Production Credit (PTC) provides a per kWh tax credit for electricity generated by qualified wind, closed-loop biomass, or poultry waste resources. Federal tax credits of 1.5 cents/kWh (adjusted annually for inflation) are provided for the first ten years of operation for all qualifying plants that entered service from 1992 through mid-1999, later extended to 2001 and then to 2003.

At least five U.S. states have state or local production incentives for distributed electrical generation, renewable fuels, or both. These policies are similar to the federal PTC, with specific limits on technologies, dates-in-service, and maximum payout per provider and per year. Funds to support the incentives are obtained from a mixture of sources, including general funds, public benefit or environmental funds, and green electricity sales (so-called green tags).

2.2.2.4 Property Tax Incentives At least 24 U.S. states have property tax incentives for renewable energy. These incentives are implemented on many scales—state, county, city, town, and municipality. These are generally implemented in one of three ways: (1) renewable energy property is partially or fully excluded from property tax assessment, (2) renewable energy property value is capped at the value of an equivalent conventional energy system providing the same service, and (3) tax credits are awarded to offset property taxes.

2.2.2.5 Personal Income Tax Incentives Credits against personal state income taxes are available in many U.S. states for purchase of or conversion to eligible renewable energy systems and renewable fuels. In some cases, taxpayers can deduct the interest paid on loans for renewable energy equipment.

2.2.2.6 Sales Tax Incentives At least 16 U.S. states have policies that provide retail sales tax exemptions for eligible renewable energy systems and renewable fuels. Most exempt 100% of the sales tax for capital expenses and provide specific cents-per-gallon exemptions for renewable fuels. Some policies specify maximum or minimum sizes for eligible systems.

2.2.2.7 Pollution Tax Exemptions The Netherlands is an example where so-called green power is exempt from a new and rising fossil-fuel tax on electricity generation that is paid by end users. Starting in 2001, that fossil-fuel tax rose to the equivalent of US 5 cents/kWh, providing a large tax incentive for Dutch consumers.

2.2.2.8 Other Tax Policies A variety of other tax policies exist, such as income tax exemptions on income from renewable power production, excise duty and sales tax exemptions on equipment purchased, and reduced or zero import tax duties on assembled renewable energy equipment or on components. India, for example, has allowed 5-year tax exemptions on income from sales of wind power.

2.2.3 Grants

Many countries have offered grants for renewable energy purchases. For example, beginning in 1979, Denmark provided rebates of up to 30% of capital costs for wind and other renewable energy technologies. These rebates declined over time. In the United States, county and state governments and utilities provide grants for renewable energy ranging in size from hundreds to millions of dollars.

2.2.4 Loans

Loan programs offer financing for the purchase of renewable energy equipment. Loans can be market rate, low interest (below-market rate), or forgivable.

In many U.S. states, loans are available to virtually all sectors—residential, commercial, industrial, transportation, public, and nonprofit. Repayment schedules vary, with terms of up to 10 years common. Interest rates for renewable energy investments can often be 1% or more higher than those for conventional power projects because of the higher perceived risks involved, so government-subsidized loans that offer below-market interest rates are also common.

Renewable energy loans can take many forms. Residential loans may range from $500 to $10,000 or more, while commercial and industrial loans may extend to the millions. Funding comes from a variety of sources, including municipal bonds, system benefit funds, revolving funds, and utility penalty or overcharge funds. Financing may be for a fraction to 100% of a project. Some loan programs have minimum or maximum limits, while others are open ended. Loan terms range from 3 years to the life of a project. Some loans are contractor driven and may include service contracts in the loan amount. Sometimes grants and loans are combined; for example, Iowa provides a 20% forgivable loan combined with an 80% loan at prime rate for renewable fuels projects.

In some developing countries, notably India, China, and Sri Lanka, multilateral loans by lenders such as the World Bank have provided financing for renewable energy, usually in conjunction with commercial lending. One of the most prominent examples is the India Renewable Energy Development Agency (IREDA), which was formed in 1987 to provide assistance in obtaining international multilateral agency loans and in helping private power investors obtain commercial loans. By 2001, IREDA had disbursed the equivalent of more than US$400 million in loans for renewable energy projects in India, resulting in more than 1600 MW of renewable power generation.

2.3 Public Investments and Market Facilitation Activities

2.3.1 Public Benefit Funds

In the United States, public funds for renewable energy development are raised through a System Benefits Charge (SBC), which is a per-kWh levy on electric power consumption. Some analysts suggest that state clean energy funds seem to be one of the more effective policies in promoting renewable energy development to result from electricity restructuring. It is estimated that 14 U.S. states will collect $3.5 billion through 2011 in system benefits charges. Similar levies exist in some European countries for fossil-fuel-based generation. In general, the funds serve a variety of purposes, such as paying for the difference between the cost of renewables and traditional generating facilities, reducing the cost of loans for renewable facilities, providing energy efficiency services, funding public education on energy-related issues, providing low-income energy assistance, and supporting research and development.

2.3.2 Infrastructure Policies

Market facilitation supports market institutions, participants, and rules to encourage renewable energy technology deployment. A variety of policies are used to build and maintain this market infrastructure, including policies for design standards, accelerated siting and permitting, equipment standards, and contractor education and licensing. Additionally, policies to induce renewable technology manufactures to site locally and direct sales of renewable systems to customers at concessionary rates facilitate market development.

2.3.2.1 Construction and Design Policies Construction and design standards include building-code standards for PV installations, design standards evaluated on life-cycle cost basis, and performance requirements. Policy examples include Tucson, Arizona, which requires that commercial facilities achieve a 50% reduction in energy usage over 1995 Model Energy Code, and Florida, which requires that all new educational facilities include passive solar design.

2.3.2.2 Site Prospecting, Review and Permitting Federal and state programs reduce barriers to renewable energy development through resource, transmission, zoning, and permitting assessments. This particularly helped early promotion of wind energy projects in California. On a national scale the Utility Wind Resource Assessment Program funds a number of supporting activities, including up to 50% of the cost of wind resource assessments. India also has a large wind assessment program, with more than 600 stations in 25 states providing information to project developers on the best sites for development.

2.3.2.3 Equipment Standards and Contractor Certification A variety of equipment-related standards

and certification measures have been applied to ensure uniform quality of equipment and installation, increasing the likelihood of positive returns from renewable energy installations. Contractor licensing requirements ensure that contractors have the necessary experience and knowledge to properly install systems. Equipment certifications ensure that equipment meets certain minimum standards of performance or safety.

2.3.2.4 Industrial Recruitment Industrial recruitment policies use financial incentives such as tax credits, grants, and government procurement commitments to attract renewable energy equipment manufacturers to locate in a particular area. These incentives are designed to create local jobs, strengthening the local economy and tax base, and improving the economics of local renewable development initiatives.

2.3.2.5 Direct Equipment Sales These programs allow the consumer to buy or lease renewable energy systems directly from electric provider at below-retail rates. Some programs provide a capital buydown. Examples include Arizona, which provides a buydown of $2/peak-watt for PV, and California's Sacramento Municipal Utility District, which offers a 50% buydown plus 10-year financed loans and net metering.

2.3.3 Government Procurement

Government procurement policies aim to promote sustained and orderly commercial development of renewable energy. Governmental purchase agreements can reduce uncertainty and spur market development through long-term contracts, preapproved purchasing agreements, and volume purchases. Government purchases of renewable energy technologies in early market stages can help overcome institutional barriers to commercialization, encourage the development of appropriate infrastructure, and provide a market path for technologies that require integrated technical, infrastructure, and regulatory changes.

2.3.4 Customer Education and Mandated Generation Disclosure Information

U.S. restructuring and deregulation policies mandate that information be provided to customers about choice of electricity providers and characteristics of electricity being provided (such as emissions and fuel types). In many states, general education to raise customer awareness about renewable energy and the environmental impacts of energy generation is required, typically via websites and printed materials.

2.3.5 Solar and Wind Access Laws

Renewable access laws address access, easements, and covenants. Access laws provide a property owner the right to continued access to a renewable resource. Easements provide a privilege to have continued access to wind or sunlight, even though development or features of another person's property could reduce that access. Easements are often voluntary contracts and may be transferred with the property title. Covenant laws prohibit neighborhood covenants from explicitly restricting the installation or use of renewable equipment. Policy mechanisms include access ordinances, development guidelines addressing street orientation, zoning ordinances with building height restrictions, and renewable permits.

3. TRANSPORT BIOFUELS POLICIES

Biofuels mandates and tax policies in Brazil, the United States, and Europe have supported accelerating development of biofuels. Biofuels mandates require that a certain percentage of all liquid transport fuels be derived from renewable resources. Tax policies may provide tax credits or exemptions for production or purchase of biofuels.

Brazil has been quite successful with biofuels mandates under its ProAlcool program, which has promoted the use ethanol for transportation fuel since the 1980s. In addition to a variety of economic incentives and subsidies, Brazil has mandated that ethanol be blended with all gasoline sold in the country. Brazil has also required that all gas stations sell pure ethanol. This last requirement made it commercially viable for the automotive industry to produce ethanol-only (neat ethanol) cars. However, the share of ethanol-only cars purchased annually, after rising to 95% by 1985, subsequently declined for a number of reasons. Most cars now use the "gasohol" ethanol/gasoline blend, and more than 60% of Brazil's sugar cane production goes to produce 18 billion gallons of ethanol each year, representing 90% of global ethanol production. In 2000, over 40% of automobile fuel consumption in Brazil was ethanol.

The United States, the world's second largest ethanol producer after Brazil, has a number of biofuels tax policies and mandates. The Energy Security Act of 1979 created a federal ethanol tax credit of up to 60 cents per gallon for businesses that sell or use alcohol as a fuel. Gasoline refiners and distributors may also receive an excise tax exemption

of up to 5 cents/gallon for blending their fuels with ethanol. State-level ethanol policies also exist, whose origins in the 1980s can be traced back to initiatives by Iowa to use its corn crop for energy. Several policies in Iowa were established to encourage ethanol consumption, including a mandate for government vehicles to use ethanol-blended fuel, and a 1-cent-per-gallon fuel sales tax exemption for ethanol-blended fuels. In 1998, both the federal government and the state of Iowa extended their ethanol tax exemptions until the year 2007. In part due to ethanol incentives, more than 60 ethanol production facilities have become operational in the United States since 1976, with a production capacity of more than 2.4 billion gallons per year. A recent U.S. legislative proposal, called a renewable fuels standard, would triple biofuel use within 10 years.

In Europe, Germany is the largest user of biodiesel and provides tax incentives for 100% pure biodiesel. These incentives have had a large effect; German consumption of biodiesel went from 200 million gallons in 1991 to 750 million gallons in 2002. Other EU members provide tax incentives for 2 to 5% biodiesel blends. Germany, Austria, and Sweden use 100% pure biodiesel in specially adapted vehicles, and biodiesel is mandated in environmentally sensitive areas in Germany and Austria. Other countries producing biodiesel are Belgium, France, and Italy, the later two also providing tax incentives. The European Commission has recently proposed a biofuel directive with targets or mandates for biofuels up to 6% of all transportation fuel sold.

Among other developing countries, Thailand is considering tax policies for biofuels, including excise tax exemptions for ethanol and income tax waivers for investments in biofuels facilities. Malaysia and Indonesia also utilize biodiesel.

4. EMISSIONS REDUCTION POLICIES

Policies to reduce power plant emissions, including NO_x, SO_x, and CO_2, have the potential to affect renewable energy development. Many emissions-reduction policies create allowances for certain emissions (representing the right to emit a certain amount of that pollutant). Credits available to renewable energy generation can offset these allowed emissions. Such credits have market value and are often traded to allow electricity generators to comply with emission regulations at least cost. Three innovative examples of U.S. air quality standards, acid rain prevention programs, and state-level greenhouse-gas reduction initiatives illustrate the potential of emissions reductions policies to affect renewable energy.

4.1 Renewable Energy Set-Asides

To meet National Ambient Air Quality Standards, the U.S. Environmental Protection Agency requires 22 U.S. states and the District of Columbia to reduce NO_x emissions significantly by 2007. States can meet emission reduction targets through actual emission reductions or purchase of emission reduction credits from other states participating in a region-wide NO_x trading program. States can allocate, or set-aside, a percentage of the total state NO_x allowances to energy efficiency and renewable energy. Eligible renewable energy producers receive these set-aside allowances and can sell them to fossil-fuel-based electricity generators to enable those generators to stay within their NO_x allocation. The additional revenue from sales of these set-aside allowances can potentially provide stimulus for renewable energy development, although to date few states have implemented renewable energy set-asides.

4.2 Emissions Cap-and-Trade Policies

Under the 1990 Clean Air Act the United States instituted a cap-and-trade mechanism to reduce SO_2 emissions and facilitate least-cost compliance. Under the Acid Rain subprogram, 300,000 SO_2 emissions allowances (rights to emit SO_2) were set aside for utilities that employed renewable energy or energy-efficiency measures. Allowances were to be earned from 1992 through 1999, allocated at a rate of one allowance (one ton of SO_2 avoided) per 500 MWh of generation produced by renewable energy or avoided through increased energy efficiency. This program was not particularly effective, as only one-tenth of the 300,000 allowances were allocated to energy efficiency or renewable energy. Analysis suggests that allowance prices set by the market were not high enough to justify renewable energy investments. In addition, the program restricted participation to utilities, excluding other power generators, which also contributed to under-subscription.

4.3 Greenhouse Gas Mitigation Policies

The New Jersey Sustainability Greenhouse Gas (GHG) Action Plan was designed to promote the capture of landfill methane gas for power generation, thus avoiding methane emissions (methane has a

high global warming potential). A loan fund provides New Jersey companies with low-interest loans to support initiatives including development of biomass/landfill methane energy resources, and emission offsets from landfill methane and other renewable power generation could potentially be included in GHG trading systems.

5. POWER-SECTOR RESTRUCTURING POLICIES

Power sector restructuring is having a profound effect on electric power technologies, costs, prices, institutions, and regulatory frameworks. Restructuring trends are changing the traditional mission and mandates of electric utilities in complex ways, and affecting environmental, social, and political conditions. There are five key trends underway that continue to influence renewable energy development, both positively and negatively, as discussed next.

5.1 Competitive Wholesale Power Markets and Removal of Price Regulation on Generation

Power generation is usually one of the first aspects of utility systems to be deregulated. The trend is away from utilities monopolies toward open competition, where power contracts are signed between buyers and sellers in wholesale power markets. Distribution utilities and industrial customers gain more choices in obtaining wholesale power. Such markets may often begin with independent-power-producer (IPP) frameworks. As wholesale electricity becomes more of a competitive market commodity, price becomes relatively more important than other factors in determining a buyer's choice of electricity supplier.

The potential effects of competitive wholesale markets and IPPs on renewable energy are significant. Wholesale power markets allow IPPs to bypass the biases against renewables that traditional utility monopolies have had. Indeed, one of the very first major markets for renewable energy in the 1980s was in California, spurred by the PURPA legislation discussed earlier. In some countries, IPP frameworks have been explicitly enacted to support renewable energy. Examples are Sri Lanka and Thailand, where utility monopolies were broken and renewable energy IPPs can sell power to the grid. However, other effects of wholesale competition may stifle renewable energy development. As low-cost combined-cycle gas turbines begin to dominate new generation, renewable energy has difficulty competing on the basis of price alone. In addition, the emergence of short-term power contracts and spot markets favor generation technologies with higher variable costs and lower capital costs, like fossil fuels, rather than capital-intensive but low-operating-cost technologies like renewables.

5.2 Self-Generation by End Users and Distributed Generation Technologies

Independent power producers may be the end users themselves rather than just dedicated generation companies. With the advent of IPP frameworks, utility buyback schemes (including net metering), and cogeneration technology options, more and more end users, from large industrial customers to small residential users, are generating their own electricity. Their self-generation offsets purchased power and they may even sell surplus power back to the grid. Traditionally, regulated monopoly utilities have enjoyed economic advantages from large power plants and increasing economies of scale. These advantages are eroding due to new distributed generation technologies that are cost competitive and even more efficient at increasingly smaller scales. In fact, newer technologies reduce investment risks and costs at smaller scales by providing modular and rapid capacity increments.

Renewable energy is well suited to self-generation but faces competition from other distributed generation technologies, especially those based on natural gas. Gas has become the fuel of choice for small self-producers because of short construction lead times, low fuel and maintenance costs, and modular small-scale technology. However, with restructuring, a host of distributed generation policies, including net metering, become possible (see the section on distributed generation policies). These policies often spur renewable energy investments. On the other hand, self-generators may be penalized by utility-wide surcharges that accompany restructuring, such as those for stranded generation assets (called nonbypassable competitive transition charges in the United States). Self-generators who use renewable energy must still pay these charges, based on the amount of electricity they *would* have purchased from the grid, even if actual grid consumption is small.

5.3 Privatization or Commercialization of Utilities

In many countries, utilities, historically government owned and operated, are becoming private for-profit entities that must act like commercial corporations. Even if utilities remain state owned, they are becoming commercialized—losing state subsidies and becoming subject to the same tax laws and accounting rules as private firms. In both cases, staffing may be reduced and management must make independent decisions on the basis of profitability.

The effects of privatization and commercialization on renewable energy are difficult to judge. The environmental effects of privatization can be positive or negative, depending on such factors as the strength of the regulatory body and the political and environmental policy situation in a country. Private utilities are more likely to focus more on costs and less on public benefits, unless specific public mandates exist. On the positive side, privatization may promote capital-intensive renewable energy by providing a new source of finance—capital from private debt and equity markets. However, the transition from public to private may shorten time horizons, increase borrowing costs, and increase requirements for high rates of return. All of these factors would limit investments in capital-intensive renewable energy projects in favor of lower-capital-cost, higher-operating-cost fossil-fuel technologies.

5.4 Unbundling of Generation, Transmission, and Distribution

Utilities have traditionally been vertically integrated, including generation, transmission, and distribution functions. Under some restructuring programs, each of these functions is being unbundled into different commercial entities, some retaining a regulated monopoly status (particularly distribution utilities) and others starting to face competition (particularly generators).

Unbundling can provide greater consumer incentives to self-generate using renewable energy. If retail tariffs are unbundled as well, so that generation, transmission, and distribution costs are separated, customers have more incentive to self-generate, thereby avoiding transmission and distribution charges. In addition, open-access transmission policies that go along with unbundling have been explicitly targeted to promote renewable energy in some countries. In India, open-access policies helped catalyze the wind industry there by allowing firms to produce wind power in remote regions with good wind resources and then "wheel" the power over the transmission system to their own facilities or to third parties. Brazil enacted a 50% reduction of transmission wheeling fees for renewable energy producers, which has been credited with promoting a booming small hydro industry there. However, unbundling can also penalize inherently intermittent renewable energy if producers have to pay transmission charges on a per-capacity basis. That is, even when the transmission capacity is not being used (say the wind is not blowing), transmission charges must be paid, resulting in high average transmission costs per kWh.

5.5 Competitive Retail Power Markets and Green Power Sales

Competition at the retail level, the newest phenomena in power sector restructuring, means that individual consumers are free to select their power supplier from among all those operating in a given market. Competitive retail power markets have allowed the emergence of so-called green power suppliers who offer to sell renewable energy, usually at a premium. As green power sales grow, these suppliers are forced to investment in new renewable energy capacity to meet demand or buy power from other renewable energy producers. Green power markets have begun to flourish where retail competition is allowed, but often only in conjunction with other renewable energy promotion policies.

The Netherlands is perhaps the best-known example. Following restructuring in 2001, 1 million green power customers signed up within the first year. However, incentives played a role; a large tax on fossil-fuel generated electricity, from which green power sales were exempt, made green power economically competitive with conventional power. In the United States, green power markets are emerging in several states in response to state incentives and aggressive marketing campaigns by green power suppliers. At least 30 U.S. states have green pricing programs. Four states have mandatory green power policies that require utilities to offer customers opportunities to support renewable energy. California became one of the largest markets, with more than 200,000 customers, but this was aided by a 1 cent/kWh subsidy to green power, paid for by a system benefits charge (see the section on renewable energy promotion policies).

6. DISTRIBUTED GENERATION POLICIES

Distributed generation avoids some of the costs of transmission and distribution infrastructure and power losses, which together can total up to half of delivered power costs. Policies to promote distributed generation—including net metering, real-time pricing, and interconnection regulations—do not apply only to renewable energy but nevertheless can strongly influence renewable energy investments.

6.1 Net Metering

Net metering allows a two-way flow of electricity between the electricity distribution grid and customers with their own generation. When a customer consumes more power than it generates, power flows from the grid and the meter runs forward. When a customer installation generates more power than it consumes, power flows into the grid and the meter runs backward. The customer pays only for the net amount of electricity used in each billing period and is sometimes allowed to carryover net electricity generated from month to month. Net metering allows customers to receive retail prices for the excess electricity they generate at any given time. This encourages customers to invest in renewable energy because the retail price received for power is usually much greater than it would be if net metering were not allowed and customers had to sell excess power to the utility at wholesale rates or avoided costs. Electricity providers may also benefit from net metering programs, particularly with customer-sited PV, which produces electricity during peak periods. Such peak power can offset the need for new central generation and improve system load factors.

At least 38 U.S. states now have net metering laws. Size limits on net metered systems typically range from 10 kW to 100 kW, with the exception of a few states that do not limit system size or overall enrollment. Net metering is common in parts of Germany, Switzerland, and the Netherlands and allowed by at least one utility in the UK. Thailand is one of the few developing countries to have enacted net metering laws, following a pilot project for net-metered rooftop PV in the 1990s.

6.2 Real-Time Pricing

Real-time pricing, also known as dynamic pricing, is a utility rate structure in which the per-kWh charge varies each hour based on the utility's real-time production costs. Because peaking plants are more expensive to run than baseload plants, retail electricity rates are higher during peak times than during shoulder and off-peak times under real-time pricing. When used in conjunction with net metering, customers receive higher peak rates when selling power into the grid at peak times. At off-peak times the customer is likely purchasing power from the grid, but at the lower off-peak rate. Photovoltaic power is often a good candidate for real-time pricing, especially if maximum solar radiation occurs at peak-demand times of day when power purchase prices are higher. Real-time metering equipment is necessary, which adds complexity and expense to metering hardware and administration.

Real-time pricing has been used with some large power consumers for decades. For example, power companies in Nova Scotia and New York state offer real time pricing rates for large commercial and industrial customers that vary hourly according to the varying cost of generation. In a recent pilot project, California installed 23,000 real-time meters for large customers at a cost of $35 million. In response, summer peak demand by those customers dropped by 500 MW under time-of-use pricing, which would allow the utility to avoid $250 million to $300 million in capacity additions. Although real-time pricing has not become widespread, with favorable rate structures it has the potential to provide significant incentives for grid-connected renewable development.

6.3 Interconnection Regulations

Nondiscriminatory interconnection laws and regulations are needed to address a number of crucial barriers to interconnection of renewable energy with the grid. Interconnection regulations often apply to both distributed generation and remote generation with renewable energy that requires transmission access, such as wind power.

6.3.1 Legal Access

The ability to legally connect a renewable energy system to a grid depends on federal, state, and local government rules and regulations. These policies both allow connection and determine how physical connection is achieved. In the United States, the legal right to connect to the grid is provided for in federal laws such as the Public Utilities Regulatory Policies Act (PURPA) of 1978 and by state net metering statutes.

6.3.2 Dynamic Generation and Transmission Scheduling

Historically, transmission policies have often imposed severe penalties on unscheduled deviations from projected (advance-scheduled) power generation. These penalty structures render intermittent generation, such as wind or PV, uneconomic. Real-time accounting of power transfer deviations that provides charges or credits to producers based on the value of energy at the time of the deviation, as well as elimination of discriminatory deviation penalties, allows intermittent renewable energy to compete more equitably with traditional generation. Policies that allow near-time or real-time scheduling of the output levels of intermittent resources can further reduce deviation costs. For example, wind farms are able to predict their output much more accurately up to an hour in advance of generation and thus can be better scheduled hour by hour rather than a day ahead.

6.3.3 Elimination of Rate Pancaking

Because distributed renewables, such as wind, are often remotely located, they can incur high transmission fees as power crosses multiple jurisdictions to get to the customer. Such cumulative addition of transmission fees is known as rate pancaking. Elimination of access rate pancaking, either by consolidation of long-distance tariffs under a regional transmission organization or by creating access waiver agreements between multiple owner/operators can reduce discrimination against wind and other remote distributed renewables.

6.3.4 Capacity Allocation

When demand for a transmission path exceeds its reliable capacity, transmission congestion occurs. In such circumstances, system operators must allocate available capacity among competing users. Traditional utility policies often favor early market entrants, grandfathering them into capacity allocation rules. Wind power is particularly susceptible to transmission constraints, as it is generally located far from load. Elimination of grandfathering would allow transmission users to bid for congested capacity on an equal footing. Allowing wind to bid for congested capacity closer to the operating hour and reducing congestion through transmission line upgrades would also reduce barriers to wind energy development.

6.3.5 Standard Interconnection Agreements

Utilities may require the same interconnection procedures for small systems as are required for large independent power-production facilities. The process of negotiating a power purchase/sale contract with the utility can be very expensive, and utilities can charge miscellaneous fees that greatly reduce the financial feasibility of small grid-connected renewable installations. Standardized interconnection agreements can expedite this process. Some believe that Texas provides a good model for renewable interconnection. Under a standard agreement, renewable developers pay only for the direct costs of connecting the plant to the local system, but not for upgrades to the grid necessary to carry additional capacity. This allows generators to compete more equally.

7. RURAL ELECTRIFICATION POLICIES

Historically, renewable energy in developing countries has come from direct donor assistance and grants for equipment purchases and demonstrations. In recent years a number of new approaches have emerged for promoting renewable energy in off-grid rural areas, including energy service concessions, private entrepreneurship, microcredit, and comparative line extension analysis.

7.1 Rural Electrification Policy and Energy Service Concessions

Many developing countries have explicit policies to extend electric networks to large shares of rural populations that remain unconnected to power grids (globally, an estimated 1.7 billion people). However, in many areas, full grid extension is too costly and unrealistic. Policies and rural electrification planning frameworks have recently started to emerge that designate certain geographic areas as targets for off-grid renewable energy development. These policies may also provide explicit government financial support for renewable energy in these areas. Such financial support is starting to be recognized as a competitive alternative to government subsidies for conventional grid extensions. Countries taking the lead with such policies include Argentina, China, India, Morocco, the Philippines, South Africa, and Sri Lanka.

One form this government support can take is so-called energy service concessions. With a concession, the government selects one company to exclusively serve a specific geographic region, with an obligation to serve all customers who request service. The

government also provides subsidies and regulates the fees and operations of the concession. Rural energy-service concessions may employ a mixture of energy sources to serve customers, including diesel generators, minihydro, photovoltaic, wind, and biomass. Argentina, Morocco, and South Africa have initiated policies to develop rural concessions, with ambitious targets of 200,000 rural households in South Africa and 60,000 in Argentina. But the actual experience with this approach has been limited so far to just a few thousand installations.

7.2 Rural Business Development and Microcredit

Private entrepreneurship is increasingly recognized as an important strategy to fulfill rural energy goals. Thus, rural electrification policies have begun to promote entrepreneurship. Promising approaches are emerging that support rural entrepreneurs with training, marketing, feasibility studies, business planning, management, financing, and connections to banks and community organizations. These approaches include bundling renewable energy with existing products. Bundling can reduce costs if vendors of existing products and services add renewable energy to their activities—and use their existing networks of sales outlets, dealers, and service personnel. Dealers of farm machinery, fertilizers, pumps, generators, batteries, kerosene, LPG, water, electronics, telecommunications, and other rural services can bundle renewable energy with these services.

In conjunction with entrepreneurship, consumer microcredit has emerged as an important tool for facilitating individual household purchases of renewable energy systems like solar home systems. Credit may be provided either by the system vendors themselves, by rural development banks, or by dedicated microcredit organizations. Notable examples of consumer microcredit for solar home systems have emerged in five developing countries. In Bangladesh, Grameen Shakti, a nonprofit vendor, has offered consumer credit for terms up to 3 years. The Vietnam Women's Union offered similar credit terms for systems sold by private vendors. In Sri Lanka, Sarvodaya, a national microfinance organization, has offered credit on terms up to 5 years. In Zimbabwe, vendors sold several thousand systems on credit provided by the Agricultural Finance Corporation. And in India, new forms of rural microcredit have started to emerge. By 2002, the cumulative number of solar home system purchases made with credit in these countries had exceeded 50,000, but this was still a small fraction of the total number of solar home systems worldwide, estimated at 1.2 million.

7.3 Comparative Line Extension Analyses

Economic comparisons of line extension versus distributed renewable energy investment are also emerging in developed countries. At least four U.S. states have power line extension policies requiring that, in cases where utility customers must pay a portion of construction costs for utility power line extension to a remote location, the utility must provide information about onsite renewable energy technology options. Some of these policies require the utility to perform a cost-benefit analysis comparing line extension with off-grid renewable energy. Renewable energy options may be less expensive for rural customers, but without line extension policies, many customers would not be aware of this.

8. SUMMARY

Public support for renewable energy expanded rapidly in the late 1990s and early 2000s. A wide variety of policies are designed explicitly to promote renewable energy, while other policies focus on power sector restructuring or environmental issues more broadly and have more indirectly affected renewable energy. Experience with renewable energy policies around the world is still emerging, and more understanding is needed of the impacts of various policies. Thus, many policies could still be considered experimental in nature. Of all the policies surveyed in this article, the ones that appear to have contributed the most to renewable energy development during the 1990s and early 2000s are (1) direct equipment subsidies and rebates, net metering laws, and technical interconnection standards in the case of solar PV; (2) investment tax credits, production tax credits, and European electricity feed-in laws in the case of wind; (3) grid-access and wheeling policies supporting independent power producers and third-party sales in the case of biomass and small hydro power. Many of the trends toward restructuring of power-sector institutions and regulation that were underway throughout the 1990s have had both positive and negative influences on renewable energy. Policymakers and policy advocates have many options from which to choose and a slowly emerging body of experience and results to guide those choices.

Glossary

bioenergy The energy derived from any cellulosic plant or agricultural or animal material that is used a fuel.
hydropower The energy derived, at a variety of scales, from water pressure; used to drive turbines.
learning curve A mathematical description of the relationship between the average price of a manufactured commodity and the market price. For a wide variety of materials, the decrease in market price is roughly 20% for each doubling of the total quantity of the item manufactured.
photovoltaics Semiconductor technology involving photon bombardment, which permits the flow of electrons.
renewable energy The energy derived from solar, wind, biomass, geothermal, or hydro sources. There is some debate about hydropower, of which the different sources are considered either to all fall into the renewable category, or are considered renewable only when involving either a small system or a "run of the river" technology.
wind energy The energy contained in the movement of air masses, generally captured by the use of mechanical blades driven by wind energy.

The potential of renewable energy sources is enormous, because, in principle, they can meet many times the world's energy demand. Renewable energy sources such as biomass, wind, solar, hydropower, and geothermal can provide sustainable energy services, based on the use of routinely available, indigenous resources. As the costs of renewable sources decline and the price of oil and gas continue to fluctuate, a transition to renewables-based energy systems is looks increasingly likely. In the past 30 years, solar and wind power systems have experienced rapid sales growth, declining capital costs, declining costs of electricity generated, and continued improvement in performance characteristics. In fact, fossil fuel and renewable energy prices, and the social and environmental costs of each, are heading in opposite directions, and the economic and policy mechanisms needed to support the widespread dissemination and sustainable markets for renewable energy systems are rapidly evolving. It is becoming clear that future growth in the energy sector will be primarily in the new regime of renewable energy, and to some extent natural gas-based systems, not in conventional oil and coal sources. Because of these developments, market opportunity now exists to both innovate and to take advantage of emerging markets to promote renewable energy technologies, with the additional assistance of governmental and popular sentiment. The development and use of renewable energy sources can enhance diversity in energy supply markets, contribute to securing long-term sustainable energy supplies, help reduce local and global atmospheric emissions, and provide commercially attractive options to meet specific energy service needs, particularly in developing countries and rural areas, creating new employment opportunities.

1. INTRODUCTION

Conventional energy sources based on oil, coal, and natural gas have proved to be highly effective drivers

of economic progress, but at the same time damaging to the environment and to human health. Furthermore, fossil fuel-driven economies tend to be cyclical in nature, due to the effects of oligopoly in production and distribution. The traditional fossil fuel-based energy sources are facing increasing pressure on a host of environmental fronts, with perhaps the most serious challenge confronting the future use of coal being the Kyoto Protocol greenhouse gas (GHG) reduction targets. It is now clear that any effort to maintain atmospheric levels of CO_2 below even 550 ppm cannot be based fundamentally on an oil- and coal-powered global economy, barring radical carbon sequestration efforts.

The potential of renewable energy sources is enormous; they have the potential to meet many times the world's energy demand. Renewable energy sources such as biomass, wind, solar, hydropower, and geothermal can provide sustainable energy services, based on the use of routinely available, indigenous resources. A transition to renewables-intensive energy future is looking increasingly likely. The costs of solar and wind power systems have dropped substantially in the past 30 years, and continue to decline, whereas the price of oil and gas continue to fluctuate. Renewable energy prices and the social and environmental costs of using fossil fuels are heading in opposite directions. Furthermore, the economic and policy mechanisms needed to support the widespread dissemination and sustainable markets for renewable energy systems have also rapidly evolved. It is becoming clear that future growth in the energy sector is primarily in the new regime of renewable (and to some extent natural gas-based) systems, and not in conventional oil and coal sources. Financial markets are awakening to the future growth potential of renewable and other new energy technologies, and this is a likely harbinger of the economic reality of truly competitive renewable energy systems.

Renewable energy systems are usually founded on a small-scale, decentralized paradigm that is inherently conducive to, rather than at odds with, many electricity distribution, cogeneration (combined heat and power), environmental, and capital cost issues. As an alternative to custom, onsite construction of centralized power plants, renewable systems based on photovoltaic (PV) arrays, windmills, biomass, or small hydropower setups can be viewed as mass-produced "energy appliances" capable of being manufactured at low cost and tailored to meet specific energy loads and service conditions. These systems can have dramatically reduced as well as widely dispersed environmental impacts, rather than larger, more centralized impacts that in some cases are serious contributors to ambient air pollution, acid rain, and global climate change.

Renewable energy sources currently supply somewhere between 15 and 20% of the world's total energy demand. The supply is dominated by traditional biomass, mostly fuel wood used for cooking and heating, especially in developing countries in Africa, Asia, and Latin America. A major contribution is also obtained from the use of large hydropower systems with nearly 20% of the global electricity supply being provided by this source. New renewable energy sources (solar energy, wind energy, modern bioenergy, geothermal energy, and small hydropower) are currently contributing about 2%. A number of scenario studies have investigated the potential contribution of renewables to global energy supplies, indicating that in the second half of the 21st century their contribution might range from the present figure of nearly 20% to more than 50%, with the right policies in place.

2. BIOMASS ENERGY

2.1 Introduction

Biomass is the term used for all organic material originating from plants (including algae), trees, and crops and is essentially the collection and storage of the sun's energy through photosynthesis. Biomass energy, or bioenergy, is the conversion of biomass into useful forms of energy such as heat, electricity, and liquid fuels.

Biomass for bioenergy comes either directly from the land, as dedicated energy crops, or from residues generated in the processing of crops for food or other products, such as pulp and paper from the wood industry. Another important contribution is from postconsumer residue streams, including construction and demolition wood, pallets used in transportation, and the clean fraction of municipal solid waste (MSW). The process that converts biomass to bioenergy can be considered as management of the flow of solar-generated materials, food, and fiber in our society. These interrelationships are shown in Fig. 1, which presents the various resource types and applications, showing the flow of their harvest and residues to bioenergy applications. Not all biomass is directly used to produce energy, but rather can be converted into intermediate energy carriers called biofuels. This includes charcoal (higher energy

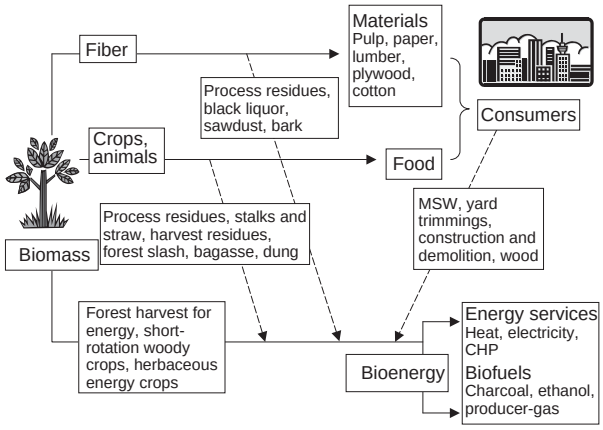

FIGURE 1 Biomass and bioenergy flowchart. MSW, Municipal solid waste; CHP, combined heat and power. From Overend (2000).

density solid fuel), ethanol (liquid fuel), or producer gas (from gasification of biomass).

Biomass was the first energy source harnessed by humans, and for nearly all of human history, wood has been our dominant energy source. Only during the past century, with the development of efficient techniques to extract and burn fossil fuels, have coal, oil, and natural gas replaced wood as the industrialized world's primary fuel. Today, some 40 to 55 exajoules (EJ $= 10^{18}$ joules) per year of biomass is used for energy, out of about 450 EJ per year of total energy use, or an estimated 10–14%, making it the fourth largest source of energy behind oil (33%), coal (21%), and natural gas (19%). The precise amount is uncertain because the majority is used noncommercially in developing countries, where biomass accounts for an estimated one-third of primary energy use. In the poorest countries, up to 90% of all energy is supplied by biomass. Over 2 billion people cook by direct combustion of biomass, and such traditional uses typically involve the inefficient use of biomass fuels, largely from low-cost sources such as natural forests, which can further contribute to human health impacts, deforestation, and environmental degradation.

The picture of biomass utilization in developing countries is sharply contrasted by that in industrialized countries. On average, biomass accounts for only 3–4% of total energy use in the latter, although where policies supportive of biomass use are in place, e.g., in Austria, Sweden, and Finland, the biomass contribution reaches 12, 18, and 23%, respectively. Most biomass in industrialized countries is converted into electricity and process heat in cogeneration systems (combined heat and power production) at industrial sites or at municipal district heating facilities. This enables a greater variety of energy services to be derived from the biomass sources, which are much cleaner than fossil fuels, and more efficient use of the available biomass resources than is typical in developing countries.

Biomass energy has the potential to be "modernized" worldwide—that is, produced and converted efficiently and cost-competitively into more convenient forms such as gases, liquids, or electricity. A variety of technologies can convert solid biomass into clean, convenient energy carriers over a range of scales, from household/village to large industrial. Some of these technologies are commercially available today whereas others are still in the development and demonstration stages. If widely implemented, such technologies could enable biomass energy to play a much more significant role in the future than it does today, especially in developing countries.

2.2 Future Role of Biomass

Modernized biomass energy is projected to play a major role in the future global energy supply. This is being driven not so much by the depletion of fossil fuels, which has ceased to be a defining issue with the discovery of new oil and gas reserves and the large existing coal resources, but rather by the recognized threat of global climate change, caused largely by the burning of fossil fuels. The carbon neutrality of biomass energy (when produced sustainably) and its relatively even geographical distribution, coupled with the expected growth in energy demand in developing countries, where affordable alternatives are not often available, make it a promising energy source in many regions of the world for the 21st century.

Most households in developing countries that use biomass fuels today do so either because it is available at low (or zero) financial cost or because they lack access to or cannot afford higher quality fuels. As incomes rise, preferences tend to shift away from biomass. For example, in the case of cooking, consumer preferences shift with increasing income from dung to crop residues, fuel wood, coal, charcoal, kerosene, liquefied petroleum gas, natural gas, and electricity (the well-known household energy ladder). This shift away from biomass energy as incomes rise is associated with the quality of the energy carrier used, rather than with the primary energy source. If biomass energy is instead modernized, then wider use is conceivable, along with

TABLE I

Role of Biomass in Future Global Energy Use[a]

Source	Time frame (year)	Total projected global energy demand (EJ/year)	Contribution of biomass to energy demand [EJ/year (percentage of total)]	Remarks
Shell Petroleum (1996)	2060	940	207 (22%)	Sustained growth[b]

benefits such as reduced indoor air pollution. For example, in household cooking, compared to solid fuels, gaseous or liquid cooking fuels can be used far more efficiently and conveniently, reaching many more families and emitting far fewer toxic pollutants.

Estimates of the technical potential of biomass energy are much larger than the present world energy consumption. If agriculture is modernized up to reasonable standards in various regions of the world, several billions of hectares may be available for biomass energy production well into this century. This land would comprise degraded and unproductive lands or excess cropland, preserving the world's nature areas and quality cropland. Table I gives a summary of the potential contribution of biomass to the world's energy supply according to a number of studies and influential organizations. Although the percentile contribution of biomass varies considerably, depending on the expected future energy demand, the absolute potential contribution of biomass in the long term is high, from about 100 to 300 EJ per year.

An Intergovernmental Panel on Climate Change (IPCC) study has explored five energy supply scenarios for satisfying the world's growing demand for energy services in the 21st century while limiting cumulative CO_2 emissions between 1990 and 2100 to fewer than 500 gigatonnes (Gt) of carbon. In all scenarios, a substantial contribution from carbon-neutral biomass energy as a fossil fuel substitute is included to help meet the CO_2 emissions targets. When biomass is grown at the same average rate as it is harvested for energy, it is approximately carbon neutral: carbon dioxide extracted from the atmosphere during growth is released back to the atmosphere during conversion to energy. Figure 2 shows the results for the IPCC's most biomass-intensive scenario, whereby biomass energy contributes

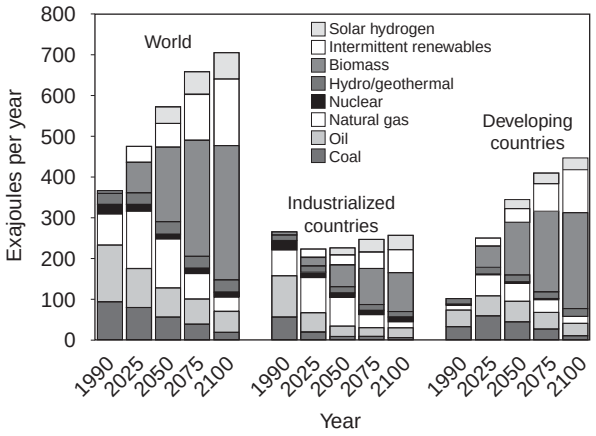

FIGURE 2 Primary commercial energy use by source for the biomass-intensive variant of the Intergovernmental Panel on Climate Change 1996 model, shown for the world, for industrialized countries, and for developing countries. From Sivan and Larson (2000).

180 EJ/year to global energy supply by 2050, satisfying about one-third of the total global energy demand and about half of total energy demand in developing countries. Roughly two-thirds of the global biomass supply in 2050 is assumed to be produced on high-yield energy plantations covering nearly 400 million hectares, or an area equivalent to one-quarter of present planted agricultural area. The other one-third comes from residues produced by agricultural and industrial activities. On the other hand, the large role biomass is expected to play in future energy supplies can be explained by several considerations. First, biomass fuels can substitute more or less directly for fossil fuels in the existing energy supply infrastructure. Intermittent renewables such as wind and solar energy are more challenging to the ways we distribute and consume energy. Second, the potential resource is large. Third, in developing countries, demand for energy is rising rapidly due to population increases, urbanization, and rising living standards. Although some fuel switching occurs in the process, the total demand for biomass will also tend to increase, as is currently seen for charcoal. Consequently, there is a growing consensus that energy policies will need to be concerned about the supply and use of biofuels while supporting ways to use these fuels more efficiently and sustainably.

2.3 Biomass Energy Conversion Technologies and Applications

Generating modern energy carriers (electricity, gas, and liquid fuels) from biomass, for use at the household ($\sim$10 kW), community ($\sim$100 kW), or industrial ($\sim$MW) scale, can be accomplished by a variety of technologies. The different technologies tend to be classed in terms of either the conversion process they use or the end product produced.

2.3.1 Combustion

The predominant technology in the world today for electricity generation from biomass, at scales above 1 MW, is the steam–Rankine cycle. This consists of direct combustion of biomass in a boiler to raise steam, which is then expanded through a turbine. The steam–Rankine technology is a mature technology introduced into commercial use about 100 years ago. The typical capacity of existing biomass power plants ranges from 1 to 50 MWe (megawatts, electricity), with an average around 20 MWe. Energy conversion efficiencies are relatively low (15–25%), due to their small size, although technologies and processes to increase these efficiencies are being developed. Steam cycle plants are often located at industrial sites, where the waste heat from the steam turbine is recovered and used for meeting industrial process heat needs. Such combined heat and power (CHP), or cogeneration, systems provide greater levels of energy services per unit of biomass consumed than do systems that generate only power, and can reach overall efficiencies of greater than 80%.

Biomass power generating capacity grew rapidly in the United States in the 1980s largely as the result of incentives provided by the Public Utilities Regulatory Policies Act of 1978 (PURPA), which required utilities to purchase electricity from cogenerators and other qualifying independent power producers at a price equal to the utilities' avoided costs. Currently in the United States, the installed biomass-electric generating capacity is about 7 GW (not including generating capacity of $\sim$2.5 GW from MSW and $\sim$0.5 GW from landfill gas). The majority of this capacity is located at pulp and paper mills, where biomass fuels are available as by-products of processing. There are also a substantial number of biomass power plants in California that use agricultural processing wastes as fuel. A significant number of biomass power plants are also found in Scandinavia, especially Sweden, where carbon taxes have encouraged recent expanded use of such systems for combined district heating and power production. By comparison to the steam–Rankine power-generating capacity installed in Organization for Economic Cooperation and Development (OECD) countries, there is relatively little capacity installed in developing countries. The most significant installation of steam–Rankine capacity in developing countries is at factories making sugar and/or ethanol from sugarcane, using bagasse, the fiber residue that remains after juice extraction from sugarcane.

The costs of steam–Rankine systems vary widely, depending on the type of turbine, the type of boiler, the pressure and temperature of the steam, and other factors. An important characteristic of steam turbines and boilers is that their capital costs (per unit of capacity) are scale sensitive. This, together with the fact that biomass steam–Rankine systems are constrained to relatively small scales (due to biomass fuel transport cost limitations), typically leads to biomass steam–Rankine systems that are designed to reduce capital costs at the expense of efficiency. For example, biomass-fired systems are typically designed with much more modest steam pressure and temperature than is technologically feasible, enabling

lower grade steels to be used in boiler tubes. This lowers both the costs and the efficiency. Because there are untapped supplies of low-cost biomass feedstocks available in many regions of the world, the economics of steam–Rankine systems are probably reasonable. For example, sugarcane-processing industries and sawmills present major opportunities for steam–Rankine-based combined heat and power generation from biomass.

An alternative to the direct-fired biomass combustion technologies, and considered the nearest term low-cost option, is biomass cocombustion with fossil fuels in existing boilers. Successful demonstrations using biomass as a supplementary energy source in large high-efficiency boilers have been carried out, showing that effective biomass fuel substitution can be made in the range of 10–15% of the total energy input with minimal plant modifications and no impact on the plant efficiency and operation. This strategy is economical when the biomass fuels cost less than the fossil fuels used. For fossil fuel plant capacities greater than 100 MWe, this can mean a substantial amount of biomass and related carbon savings and emissions reductions, particularly for coal substitution.

2.3.2 Gasification

Combustible gas can be produced from biomass through a high-temperature thermochemical process. The term "gasification" commonly refers to this high-temperature thermochemical conversion and involves burning biomass without sufficient air for full combustion, but with enough air to convert the solid biomass into a gaseous fuel. The product gas, called producer-gas, consists primarily of carbon monoxide, hydrogen, carbon dioxide, and nitrogen, and has a heating value of 4 to 6 MJ per normal cubic meter (Nm^3), or 10–15% of the heating value of natural gas. The intended use of the gas and the characteristics of the particular biomass (size, texture, moisture content, etc.) determine the design and operating characteristics of the gasifier and associated equipment. After appropriate treatment, the resulting gases can be burned directly for cooking or heat supply, or can be used in secondary conversion devices such as internal combustion engines or gas turbines for producing electricity or shaft work. The systems used can scale from small to medium (5–100 kW), suitable for the cooking or lighting needs of a single family or community, up to large grid-connected power generation facilities consuming several hundred of kilograms of woody biomass per hour and producing 10–100 MW of electricity.

One technology that has generated wide interest is the biomass integrated gasification combined cycle (IGCC) technology for larger scale power and combined heat and power generation in the range of 5 to 100 MWe. An IGCC system involves sizing and drying of the feedstock, followed by thermochemical gasification to produce a combustible gas, then cooling and cleaning of the gas and combustion in a gas turbine. Steam is generated using the hot exhaust of the gas turbine to drive a steam turbine, producing additional power and/or delivering lower pressure steam for heating purposes. The cascading of a gas turbine and a steam turbine in this manner is commonly called a combined cycle. In approximate terms, the IGCC technology will enable electricity to be made at double or more the efficiency of the steam cycle, and the capital costs per installed kilowatt for commercially mature IGCC units are expected to be lower than for comparably sized steam cycles. Thus, the overall economics of biomass-based power generation are expected to be considerably better with an IGCC system than with a steam–Rankine system, especially in situations in which biomass fuel is relatively expensive.

IGCC technology is expected to be commercially available within a few years, based on current demonstration and commercialization efforts worldwide. Several of the most advanced demonstration projects are in Sweden, the United Kingdom, Italy, and Brazil. In Varnamo, Sweden, the first complete biomass-fueled IGCC system has been operating for over 1500 hours on forest residues, generating 6 MW of electricity and 9 MW of heat for the local district heating system. In Yorkshire, England, construction of the Arable Biomass Renewable Energy (ARBRE) project, an IGCC facility that will generate about 10 MW of electricity from short-rotation biomass plantations, is nearly complete. It is supported under both the THERMIE program and the United Kingdom's Non-Fossil Fuel Obligation-3. The Bioelettrica Project near Pisa, Italy, an IGCC, is also under construction and will use poplar and robina wood chips, olive residues, grape residues, and sawdust to produce 12 MWe. At a site in Bahia, Brazil, construction began in 2000 on a Global Environment Facility (GEF)/World Bank-supported demonstration project of a 32 MW IGCC power plant using plantation-grown eucalyptus for fuel. The facility will also test the use of sugarcane bagasse. It has been estimated that if IGCC technology was applied worldwide, around 25% of all current electricity generation from sugarcane-producing countries could be produced just from their available sugarcane bagasse resource.

At the intermediate scale, producer-gas from biomass gasification can be used in modified internal combustion engines (typically diesel engines), in which it can replace 70–80% of the conventional fuel required by the engine. These smaller scale biomass gasifiers, coupled to diesel/gas internal combustion engines, operate in the 100- to 200-kWe range with efficiencies on the order of 15–25%, and have been made available commercially.

The greatest technical challenge for electricity-generating gasifier systems, at all scales, continues to be cleaning the tars and oils from the producer-gas such that the system operates efficiently, is economical, and has minimal toxic by-products and air emissions.

2.3.3 Anaerobic Digestion

Combustible gas can also be produced from biomass through low-temperature biological processes called anaerobic (without air) digestion. Biogas is the common name for the gas produced either in specifically designed anaerobic digesters or in landfills, by capturing the naturally produced methane. Biogas is typically about 60% methane and 40% carbon dioxide, with a heating value of about 55% that of natural gas. Almost any biomass except lignin (a major component of wood) can be converted to biogas; animal and human wastes, sewage sludge, crop residues, carbon-laden industrial processing by-products, and landfill material have all been widely used.

Anaerobic digesters generally consist of an inlet, where the organic residues and other wastes are fed into the digester tank; a tank, in which the biomass is typically heated to increase its decomposition rate and is partially converted by bacteria into biogas; and an outlet, where the biomass of the bacteria that carried out the process and the undigested material remain as sludge and can be removed. The biogas produced can be burned to provide energy for cooking and space heating or to generate electricity. Digestion has a low overall electrical efficiency (roughly 10–15%, strongly dependent on the feedstock) and is particularly suited for wet biomass materials. Direct nonenergy benefits are especially significant in this process. The effluent sludge from the digester is a concentrated nitrogen fertilizer and the pathogens in the waste are reduced or eliminated by the warm temperatures in the digester tank.

Anaerobic digestion of biomass has been demonstrated and applied commercially with success in a multitude of situations and countries. In India, biogas production from manure and wastes is applied widely in many villages and is used for cooking and power generation. Small-scale digesters have been used most extensively in India and China. Over 1.85 million cattle-dung digesters were installed in India by the mid-1990s, but about one-third of these are not operating for a variety of reasons, primarily insufficient dung supply and difficulties with the organization of dung deliveries. A mass popularization effort in China in the 1970s led to some 7 million household-scale digesters being installed, using pig manure and human waste as feed material. Many failed to work, however, due to insufficient or improper feed characteristics or poor construction and repair techniques. Estimates were that some 3 million to 4.5 million digesters were operating in the early 1980s. Since then, research, development, and dissemination activities have focused greater attention on proper construction, operation, and maintenance of digesters. One estimate is that there were some 5 million household digesters in working condition in China as of the mid-1990s. There are in addition some 500 large-scale digesters operating at large pig farms and other agroindustrial sites, and some 24,000 digesters at urban sewage treatment plants.

Several thousand biogas digesters are also operating in other developing countries, most notably South Korea, Brazil, Thailand, and Nepal. In addition, there are an estimated 5000 digesters installed in industrialized countries, primarily at large livestock processing facilities (stockyards) and municipal sewage treatment plants. An increasing number of digesters are located at food-processing plants and other industrial facilities. Most industrial and municipal digesters are used predominantly for the environmental benefits they provide, rather than for fuel production.

2.3.4 Liquid Biofuels

Biofuels are produced in processes that convert biomass into more useful intermediate forms of energy. There is particular interest in converting solid biomass into liquids, which have the potential to replace petroleum-based fuels used in the transportation sector. However, adapting liquid biofuels to our present-day fuel infrastructure and engine technology has proved to be nontrivial. Only oil-producing plants, such as soybeans, palm oil trees, and oilseeds such as rapeseed, can produce compounds similar to hydrocarbon petroleum products, and these have been used to replace small amounts of biodiesel. This biodiesel has been marketed in Europe and to a lesser extent in the United States,

but it requires substantial subsidies to compete with diesel. Another family of petroleum-like liquid fuels that is produced from gasified biomass is a class of synthesized hydrocarbons called Fischer–Tropsch (F–T) liquids. The process synthesizes hydrocarbon fuels [C_{10} to C_{12} hydrocarbons (kerosene) or C_3 and C_4 hydrocarbons (liquid petroleum gas)] from carbon monoxide and hydrogen gas over iron or cobalt catalysts. F–T liquids can be used as a sulfur-free diesel or can be blended with existing diesel to reduce emissions, an environmental advantage, but have yet to be produced efficiently and economically on a large scale; research and development efforts are ongoing. In addition to use as automotive fuels, F–T liquids can potentially be used as a more efficient, cleaner cooking fuel, compared to the traditional wood fuels from which it is synthesized.

Other biofuel alternatives to petroleum-based fuels are biomass-produced alcohols, which can replace gasoline or kerosene. The most widely produced bioalcohol today is ethanol, derived from the fermentation of biomass. In industrialized countries, ethanol is most commonly produced from food crops such as corn; in the developing world, it is produced from sugarcane. Its most prevalent use is as a gasoline fuel additive to boost octane levels or to reduce dependence on imported fossil fuels. In the United States and Europe, ethanol production is still far from competitive when compared to gasoline and diesel prices, and the overall energy balance of such systems has not been very favorable. The Brazilian Proalcohol ethanol program, initiated in 1975, has been successful due to the high productivity of sugarcane, although subsidies are still required. Two other potential transportation biofuels are methanol and hydrogen. They are both produced via biomass gasification and may be used in future fuel cells.

Although ethanol production from maize and sugarcane, both agricultural crops, has become widespread and occasionally successful, it can suffer from commodity price fluctuation relative to the fuels market. Consequently, the production of ethanol from lignocellulosic biomass (such as wood, straw, and grasses) is being given serious attention. In particular, it is thought that enzymatic hydrolysis of lignocellulosic biomass will open the way to low-cost and efficient production of ethanol. The development of various hydrolysis techniques has gained attention in recent years, particularly in Sweden and the United States, but cheap and efficient hydrolysis processes are still under development and some fundamental issues need to be resolved. Once such technical barriers are surmounted and ethanol production can be combined with efficient electricity production from unconverted wood fractions (such as the lignin), ethanol costs could come close to current gasoline prices and overall system efficiencies could go up to about 70% (low heating value). Though the technology to make this an economically viable option still does not exist, promising technologies are in the works and there are currently a number of pilot and demonstration projects.

2.4 Implementation of Biomass Energy Systems

Raw biomass has several disadvantages as an energy source. It is bulky, has a low energy density, and direct combustion is generally highly inefficient (other than advanced domestic heaters), producing high levels of indoor and outdoor air pollution. The goal of modernized biomass energy is to increase the fuel's energy density while decreasing its emissions during production and use. Modernizing biomass energy production, however, faces a variety of challenges that must be adequately addressed and dealt with before the widespread implementation of bioenergy systems can occur. These issues include technical problems (just discussed), resource availability, environmental impacts, and economic feasibility.

2.4.1 Biomass Resources

Biomass resources are potentially the largest renewable global energy source; there is an annual primary production of around 4500 EJ with a bioenergy potential on the order of 2900 EJ, of which about 270 EJ could be considered available on a sustainable basis. The challenge is not the availability so much as the sustainable management and conversion and delivery to the consumer in the form of modern and affordable energy services. Most of the biomass used today is either a residue in a bioprocessing industry or is an opportunity fuel that is used in households for daily living needs. It is argued that if biomass is to become a major fuel in the world, as is being proposed in future energy scenarios, then residues will not suffice and energy plantations may need to supply up to 80% of the future feedstock.

The solar energy conversion efficiency of plants is low, often less than 1%. Consequently, relatively large land surfaces are required to produce a substantial amount of energy. Moreover, biomass has a low energy density (only 8 GJ/tonne of wood, 50% moisture content). For comparison, other fuels have the following energy densities: coal, 28 GJ/tonne; mineral

oil, 42 GJ/tonne; and liquefied natural gas, 52 GJ/tonne. Consequently, transportation becomes an essential element of biomass energy systems, with transportation distances becoming a limiting factor, both from an economic and energetic point of view. Although generally it has been found that for woody biomass the energy output is 10–30 times greater than the energy input necessary for fuel production and transport, the issue is less clear for the production of liquid fuels, except for ethanol from sugarcane, which does have high net energy yields.

At present, the production of biomass residues and wastes globally, including by-products of food, fiber, and forest production, exceeds 110 EJ/year, perhaps 10% of which is used for energy. Residues concentrated at industrial sites are currently the largest commercially used biomass source. Residues are not, however, always accessible for energy use. In some cases, collection and transport costs are prohibitive; in other cases, agronomic considerations dictate that residues be recycled to the land. In still other cases, there are competing nonenergy uses for residues (e.g., fodder, construction material, or industrial feedstock).

Residues are an especially important potential biomass energy source in densely populated regions, where much of the land is used for food production. In fact, biomass residues play important roles in such regions precisely because the regions produce so much food: crop production can generate large quantities of by-product residues. For example, in 1996, China generated crop residues in the field (mostly corn stover, rice straw, and wheat straw) plus agricultural processing residues (mostly rice husks, corncobs, and bagasse) totaling about 790 million tonnes, with a corresponding energy content of about 11 EJ. To put this in perspective, if half of this resource were to be used for generating electricity at an efficiency of 25% (achievable at small scales today), the resulting electricity generation would be about half of the total electricity generated from coal in China in 1996. There is also a significant potential for providing biomass for energy by growing crops specifically for that purpose. The IPCC's biomass-intensive future energy supply scenario discussed previously includes 385 million hectares of biomass energy plantations globally in 2050 (equivalent to about one-quarter of present planted agricultural area), with three-quarters of this area established in developing countries. Such levels of land use for bioenergy raise the issue of intensified competition with other important land uses, especially food production.

There are two approaches to producing energy crops. These include devoting an area exclusively to production of such crops, and commingling the production of energy and nonenergy crops, either on the same piece of land (agroforestry) or on adjacent pieces of land (farm forestry). Because energy crops typically require several years to grow before the first harvest, the second approach has the benefit of providing the energy-crop farmer with revenue from the land between harvests of energy crops. In Sweden, productive heat power generation from willow plantations has been successful, and there has also been experience in small-scale fuel wood production in India, China, and elsewhere. In Brazil, farm forestry activities have involved small farmers in the high-yield production of biomass feedstocks.

2.4.2 Environmental Impacts and Benefits

In general, renewable forms of energy are considered "green" because they cause little depletion of Earth's resources, have beneficial environmental impacts, and cause negligible emissions during power generation. Yet, although biomass is in principle renewable and can have positive environmental impacts if managed properly, it also shares many characteristics with fossil fuels, both good and bad. Biomass can be transported and stored, allowing for heat and power generation on demand, but modernized bioenergy systems can also have negative environmental impacts associated both with the growing of the biomass and with its conversion to energy.

Many bioenergy conversion technologies offer flexibility in choice of feedstock and the manner in which it is produced. In contrast, most agricultural products are subject to rigorous consumer demands in terms of taste, nutritional content, uniformity, etc. The flexibility afforded by biomass technologies makes it easier to meet the simultaneous challenges of producing biomass energy feedstocks and meeting environmental objectives. For example, unlike the case with food crops, there are good possibilities for bioenergy crops to be used to revegetate barren land, to reclaim water-logged or salinated soils, and to stabilize erosion-prone land. Biomass energy feedstocks, when properly managed, can both provide habitat and improve biodiversity on previously degraded land.

Erosion and removal of soil nutrients are problems related to the cultivation of annual crops in many regions of the world. Although, relative to a healthy natural ecosystem, bioenergy systems may increase erosion and deplete soil nutrients and quality, bioenergy production on degraded or

erosion-prone lands can instead help stabilize soils, improve their fertility, and reduce erosion. Perennial energy crops (unlike food crops) improve land cover and form an extensive root system, adding to the organic matter content of the soil. Also, removal of soil during energy crop harvest can be kept to a minimum because roots are left in place, and twigs and leaves can be left to decompose in the field, enhancing the soil's nutrient store. This helps prevent diseases and improves soil fertility and quality. Environmental benefits of biomass crops, for carbon sequestration, biodiversity, landscape enhancement, and soil stabilization, can be particularly significant if plantations are established on intensively managed agricultural land. Although energy crops can be harvested by coppicing every 3 or 4 years, the stools (rootstocks) can survive for many decades, or even centuries, becoming significant carbon sinks. In addition, there are considerable benefits to both the landscape and to biodiversity when native species are used. For example, in Europe it would be preferable to grow willows and poplars rather than eucalyptus. Willows in particular support a high biomass and diversity of phytophagous insects, which in turn can support an important food web with many bird species. Also, when feasible, the recycling of ashes from the biomass combustion can return crucial trace elements and phosphates to the soil. This is already common practice in countries such as Sweden and Austria, where some of the ashes are returned to the forest floors, and in Brazil, where stillage, a nutrient-rich remainder of sugar cane fermentation, is returned to sugar cane plantations.

Another important potential impact from bioenergy feedstock production is the introduction of agricultural inputs such as fertilizers and pesticides into the environment. Fertilizers and pesticides can adversely affect the human health, water quality, and plant and animal life. Specific effects strongly depend on the type of chemical, the quantities used, and the method of application. Current experience with perennial crops (e.g., willow, poplar, or eucalyptus) for feedstock production suggests that necessary agricultural practices meet very strict environmental standards. Compared to food crops such as cereals, application rates of agrochemicals per hectare are a factor of 5 to 20 times lower for perennial energy crops. The abundant use of fertilizers and manure in agriculture has led to considerable environmental problems in various regions in the world: nitrification of groundwater, saturation of soils with phosphates (leading to eutrophication), and problems in meeting drinking water standards. Also, the application of phosphates has led to increased heavy metal flux to the soil. Compared to conventional agriculture, energy farming with short-rotation forestry and perennial grasses requires less fertilizer. With perennials, better recycling of nutrients is obtained. The leaching of nitrogen relating to willow cultivation can be about a factor of 2 to 10 times less than for food crops and is able to meet stringent standards for groundwater protection.

Possibly the biggest concern, and often considered the most limiting factor to the spread of bioenergy crops, is the demand on available water supplies, particularly in arid or semiarid regions. The choice of a certain energy crop can have a considerable effect on its water-use efficiency. Certain eucalyptus species, for example, have very good water-use efficiency when the amount of water needed per tonne of biomass produced is considered. However, a eucalyptus plantation on a large area could increase the local demand on groundwater and thus affect the groundwater level. On the other hand, energy crops on previously degraded land will improve land cover, which generally has positive effects on water retention and microclimate conditions. Impacts on the hydrological situation, therefore, always need to be evaluated on local level.

Finally, there is the issue of biodiversity and landscape. Biomass plantations are frequently criticized because the range of biological species they support is much narrower than is found in natural ecosystems. Although generally true, this is not always relevant. It would be relevant if a virgin forest were to be replaced by a biomass plantation—a situation that would be undesirable. However, when plantations are established on degraded lands or on excess agricultural lands, as is intended to be the case, the restored lands are very likely to support a more diverse ecology compared to the original situation. The restoration of such land is generally desirable for purposes of water retention, erosion prevention, and (micro) climate control. Furthermore, a good plantation design, including areas set aside for native flora and fauna, fitting into the landscape in a natural way, can avoid the problems normally associated with monocultures. The presence of natural predators (e.g., insects) can prevent the outbreak of pests and diseases. This issue needs more research, taking into account specific local conditions, species, and cultural aspects.

2.4.3 Economic and Production Issues

A number of key areas can be identified as being essential for the successful development and

implementation of sustainable, economically competitive bioenergy systems. The main consideration—a possible barrier—is whether the energy carriers produced are competitive. This is particularly true when specially produced biomass is used. In many situations, cheap or negative-cost biomass wastes and residues are available, thus the utilization of biomass is or could be competitive and future technology development should help further reduce the costs of bioenergy. In Sweden and Denmark, where a carbon and energy tax has been introduced, more expensive wood fuels and straw are now being used on a large scale. However, on a worldwide basis, the commercial production of energy crops is almost nonexistent. A major exception is Brazil, where subsidies have been introduced to make ethanol from sugarcane competitive with gasoline.

Closely related to the cost issue are the availability and the full-scale demonstration of advanced conversion technology that combines a high-efficiency and an environmentally sound performance with low investment costs. This is essential for competition with fossil fuels when relatively high-cost energy crops are used as energy sources. Advances in the combustion and cocombustion of biomass can considerably increase the attractiveness of combustion as a conversion technology. However, the development and the application of the IGCC technology have the potential to attain higher conversion efficiency at lower costs. Demonstration and commercialization of this technology are therefore important.

Experience with dedicated fuel supply systems based on "new" energy crops such as perennial grasses and short-rotation crops (SRCs) are very limited compared to the experience of traditional food crop cultivation and forestry techniques. Improvement of yields, increased pest resistance, management techniques, reduction of inputs, and further development of machinery are all necessary to lower costs and raise productivity. The same is true for harvesting, storage, and supply logistics. Bioenergy systems are complex in terms of organization and the number of actors that can be involved in a total energy system. The biomass is most likely to be produced by farmers or foresters whereas transport and storage are likely to be the responsibility of another party, and utilities may be responsible for the energy production. The combination of the utilities on the one hand and the agricultural system on the other will create a number of nontechnical barriers that have to be dealt with for any future system to work.

2.5 Conclusions

Biomass is one of the renewable energy sources capable of making a large contribution to the world's future energy supply. Land availability for biomass production should not be a bottleneck, provided it is combined with modernization of conventional agricultural production. Recent evaluations indicate that even if land surfaces of 400 million–700 million hectares were used for biomass production for energy about halfway the next century, this could be done without conflicting with other land-use functions and nature preservation. This can be obtained in part by better agricultural practices and in part by making use of huge areas of unproductive degraded lands. Latin America, Africa, Asia, and to a lesser extent Eastern Europe and North America represent a large potential for biomass production.

The types of biomass that can be used for energy are diverse, and optimal resources, technologies, and entire systems will be shaped by local conditions, both physical and socioeconomic. Perennial crops in particular may offer cheap and productive biomass production systems with low or positive environmental impacts. Technical improvements and optimized production systems along with multifunctional land use could bring biomass close to the costs of fossil fuels.

A key issue for bioenergy is that its use must be modernized to fit into a sustainable development. Conversion of biomass to energy carriers such as electricity and transportation fuels will give biomass a commercial value and will provide income for local rural economies. In order to obtain such a situation, it is essential that biomass markets and necessary infrastructure are developed, that key conversion technologies such as IGCC technology and advanced fuel production systems for methanol, hydrogen, and ethanol are demonstrated and commercialized, and that much more experience is gained with biomass production systems in a wide variety of contexts. Although the actual role of bioenergy will depend on its competitiveness versus fossil fuels and agricultural policies, it seems realistic to expect that the current contribution of bioenergy will increase during this century.

3. WIND ENERGY

3.1 Introduction

Wind has considerable potential as a global clean energy source, being both widely available, though

diffuse, and producing no pollution during power generation. Wind energy has been one of humanity's primary energy sources for transporting goods, milling grain, and pumping water for several millennia. From windmills used in China, India, and Persia over 2000 years ago to the generation of electricity in the early 20th century in Europe and North America, wind energy has played an important part in our recorded history. As industrialization took place in Europe and then in North America, wind power generation declined, first gradually as the use of petroleum and coal, both cheaper and more reliable energy sources, became widespread, and then more sharply as power transmission lines were extended into most rural areas of industrialized countries. The oil crises of the 1970s, however, triggered renewed interest in wind energy technology for grid-connected electricity production, water pumping, and power supply in remote areas, promoting the industry's rebirth.

This impetus prompted countries; notably Denmark and the United States, to establish government research and development programs to improve wind turbine technology. In conjunction with private industry research, this lead to a reemergence in the 1980s of wind energy in the United States and Europe, when the first modern grid-connected wind turbines were installed. In the 1990s, this development accelerated, with wind becoming the fastest growing energy technology in the world, developing into a commercially competitive global power generation industry. In 1990, only about 2000 MW of grid-connected wind power was in operation worldwide, whereas by 1999, this figure had surpassed 10,000 MW, not including the over 1 million water-pumping wind turbines located in remote areas. Since 1990, the average annual growth rate in world wind-generating capacity has been over 24%/year, with rates of over 30% in the past 2 years. Today, there is more than 31,000 MW of installed wind power, double the capacity that was in place just 3 years earlier (Fig. 3). More than 6000 MW of new wind energy capacity was installed in 2002. This dramatic growth rate in wind power has created one of the most rapidly expanding industries in the world, with sales of roughly $7 billion in 2002, and predictions of 10-fold growth over the next decade. Most 2000 forecasts for installed capacity were quickly eclipsed, and wind power passed the 10,000-MW mark in early 1999 and is now three times that level.

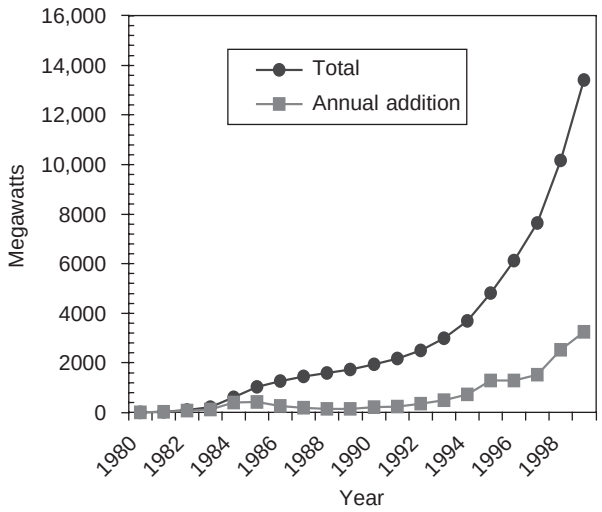

FIGURE 3 World wind-generating capacity, total and annual addition. From American Wind Energy Association (2003).

3.2 Economics of Wind Energy

Larger turbines, more efficient manufacturing, and careful siting of wind machines have brought wind power costs down precipitously, from $2600/kW in 1981 to $800/kW in 1998 and still lower today. New wind farms in some areas have now reached economic parity, or have beaten, new coal-based power plants, and as the technology continues to improve, further cost declines are projected, which could make wind power the most economical source of electricity in some countries. Market growth, particularly in Europe, has been stimulated by a combination of favorable governmental policies, lower costs, improved technology, and concern over environmental impacts of energy use. Compared to wind turbines built in 1981, modern turbines generate 56 times the energy at only nine times the cost.

Wind energy is currently one of the most cost-competitive renewable energy technologies. Worldwide, the cost of generating electricity from wind has fallen by more than 80%, from about 38¢/kWh (U.S.) in the early 1980s to a current range of 3–6¢/kWh (U.S.) levelized over a plant's lifetime, and analysts forecast that costs will drop an additional 20–30% in the next 5 years. Consequently, in the not-too-distant future, analysts believe that wind energy costs could fall lower than most conventional fossil fuel generators, reaching a cost of 2.5¢/kWh (U.S.) (Fig. 4). Wind technology does not have fuel requirements, as do coal, gas, and petroleum technologies. However, both the equipment costs and the costs of accommodating special characteristics such as intermittence, resource variability,

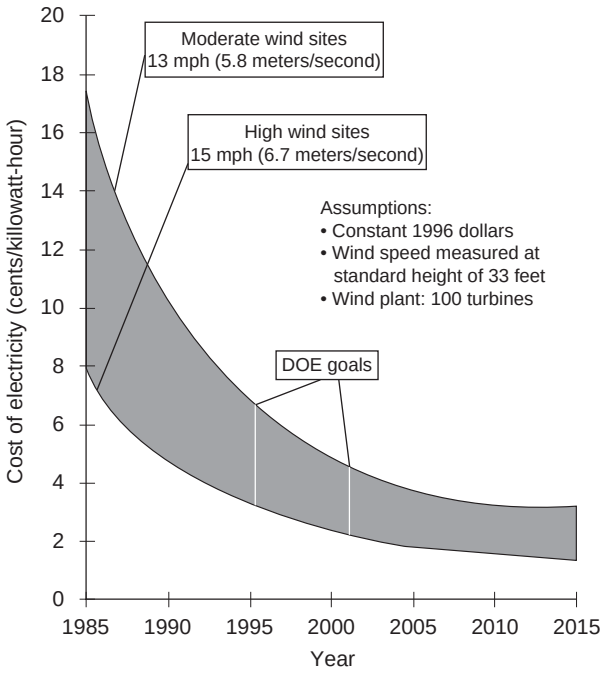

FIGURE 4 Trends in wind energy costs. From the U.S. Department of Energy (1998), (see the DOE Web site at http://www.eren.doe.gov).

competing demands for land use, and transmission and distribution availability can add substantially to the costs of generating electricity from wind.

3.3 Potential for Wind Energy: Technical, Resource, and Environmental Issues

The main technical parameter determining the economic success of a wind turbine system is its annual energy output, which in turn is determined by parameters such as average wind speed, statistical wind speed distribution, distribution of occurring wind directions, turbulence intensities, and roughness of the surrounding terrain. Of these, the most important and sensitive parameter is the wind speed (where the power in the wind is proportional to the third power of the momentary wind speed), which increases with height above the ground. As a result, vertical-axis wind turbines have mostly been abandoned in favor of the taller traditional horizontal-axis configuration. As accurate meteorological measurements and wind energy maps become more commonly available, wind project developers are able to more reliably assess the long-term economic performance of wind farms.

Some of the problems with wind power involve siting wind turbines. In densely populated countries where the best sites on land are occupied, there is increasing public resistance, making it impossible to realize projects at acceptable cost. This is one of the main reasons that countries such as Denmark and The Netherlands are concentrating on offshore projects, despite the fact that technically and economically they are expected to be less favorable, compared to good land sites. On the other hand, in countries such as the United Kingdom and Sweden, offshore projects are being planned not due to scarcity of suitable land sites, but because preserving the landscape is such an important national value. Another obstacle can be that the best wind site locations are not in close proximity to populations with the greatest energy needs, as in the U.S. midwest, making such sites impractical due to the high cost of transmission of power over long distances.

There has been a gradual growth of the unit size of commercial machines since the mid-1970s, when the typical size of a wind turbine was 30 kW installed power. By 1998, the largest units installed had a capacity of 1.65 MW, and turbines with an installed power of 2 MW are now being introduced on the market, with 3.6-MW machines now slated for construction. The trend toward larger machines is driven by the demand side of the market to utilize economy of scale, to reduce the visual impact on the landscape per unit of installed power, and to support the expectation that the offshore potential will be developed soon. Recent technical advances have also made wind turbines more controllable and grid compatible and have reduced their number of components, making them more reliable and robust.

Wind energy, although considered an environmentally sound energy option, does have several negative environmental aspects connected to its use. These include acoustic noise emission, visual impact on the landscape, impact on bird life, shadow caused by the rotor, and electromagnetic interference (influencing the reception of radio, television, and radar signals). In practice, the noise and visual impacts appear to cause the most problems for siting projects. Noise issues have been reduced by progress in aeroacoustic research, providing design tools and blade configurations that have successfully made blades considerably quieter. The impact on bird life appears to be a relatively minor problem. For instance, a research project in The Netherlands showed that bird casualties as a result of collisions with rotating rotor blades for a wind farm of 1000 MW represent only a very small fraction of birds killed from hunting, high-voltage lines, and traffic; the estimates predict a maximum level of six to seven bird

TABLE II

Estimates of Annual Total Human-Related Bird Mortality in The Netherlands[a]

Causes of death	Bird victims (× 100,000)
Road kills	20–80
Power lines	10–20
Hunting	6.5
Per 1000 MW of wind power	2.1–4.6

[a] *Source*. National Wind Coordinating Committee, Proceedings of National Avian–Wind Power Planning Meeting (1994).

collisions/turbine/year (see Table II). Avoiding endangered species habitats and major migration routes in the siting of wind farms can, for the most, part eliminate this problem.

In addition to being cost-competitive and environmentally sound, wind energy has several additional advantages over conventional fossil fuel power plants and even other renewable energy sources. First, it is modular: that is, the generating capacity of wind farms can easily be expanded because new turbines can be quickly manufactured and installed, not true for either coal-fired or nuclear power plants. Furthermore, a repair to one wind turbine does not affect the power production of all the others. Second, the energy generated by wind turbines can pay for the materials used to make them in as short as 3–4 months for good wind sites. Third, during normal operation, they produce no emissions. One estimate of wind energy potential to reduce CO_2 emissions predicts that a 10% contribution of wind energy to the world's electricity demand by 2025 would prevent the emission of 1.4 Gton/year of CO_2. Finally, there is also a strong and growing market for small wind turbines (under 100 kW), of which the United States is a leading manufacturer. Four very active U.S. manufacturers are estimated to cover a 30% market share worldwide. Small-scale turbines especially can play a significant role in rural and remote locations, particularly in developing countries, where access to the grid is either unlikely or extremely expensive.

3.4 Selected Country Profiles and Government Incentives to Promote Wind Energy

Incentives have long been viewed as a means of supporting technological developments until a new technology becomes cost-competitive. Wind-based electricity is not yet generally competitive with alternate sources of electricity such as fossil fuels. Thus, it is still dependent on nonmarket support for development to take place. Where sufficient support has been made available, wind capacity has expanded. When support has been withdrawn, or is uncertain, wind energy development has substantially slowed. The countries that have been fueling wind energy's growth throughout this decade have mainly been in the Northern Hemisphere, in particular Europe, where issues regarding the environment, fuel security, and electricity-generating diversity are a priority. Of the 10 countries with the highest installed capacity at the end of 2000, only the United States, India, and China lie outside Europe (Table III).

The stimulus for European wind energy growth continues to be regional and national policy incentives, which have facilitated the birth and development of the wind energy industry. Collectively, high energy prices, renewable energy subsidies that include investment and other fiscal incentives, and mandated purchases that include price support systems are some of the most important parameters that have encouraged wind energy development in the European Union (EU). The heightened sensitivity that Europeans have for the environment has been a determining factor in setting such policies. Another important factor, although it is less frequently mentioned, is fuel security. Developing an indigenous resource helps diminish the dependence on imported energy sources, which is of strategic importance to many countries in the EU. According to a 2003 American Wind Energy Association (AWEA) report, Europe continued to drive the engine of global wind power growth. A total of 5871 MW (worth $6.3 billion) was installed in the EU countries in 2002. Regional wind power capacity grew 33% to 23,056 MW. This volume of production offsets 20 million tons of coal burned annually in a conventional power plant, according to the European Wind Energy Association. Germany, Spain, and Denmark alone accounted for 89% of the wind power capacity installed in Europe in 2002. Non-EU European countries (such as Norway and Poland) contributed an additional 112 MW to the region's wind power growth.

3.4.1 United States

In the early 1980s, the United States accounted for 95% of the world's installed wind energy capacity;

TABLE III

Installed Wind Power in 1997 and 1998[a]

Region	Installed MW (1997)	Cumulative MW (1997)	Installed MW (1998)	Cumulative MW (1998)
United States	29	1611	577	2141

Total other continents and areas	11	57	27	83
Annual MW installed capacity	1568		2597	
Cumulative World MW installed		7639		10,153

[a] *Source*. WEA (2000). *Note*. The cumulative installed capacity by the end of 1998 is not always equal to the 1997 data plus installed capacity during 1998. Adjustments have been made by considering the amount of decommissioned/dismantled capacity.

the U.S. share dropped to 22% in 2002 and has essentially stagnated while other countries have increased their capacity. In 2001, 1600 MW of new capacity was installed in the United States. In 2002, that figure dropped to just over 4000 MW, although there are signs of steady growth resulting from the federal production tax credit [currently 1.7¢/kWh (U.S.) for utility-scale projects].

3.4.2 Germany

In contrast to the United States, Germany has increased its wind energy production consistently and dramatically throughout the past decade. In 2002, Germany installed over 3200 MW, or 55% of the total global new capacity. Germany overtook the United States in 1997 as the country with the highest installed wind capacity in the world, and Spain

followed suit in 2001 with a surge of new installations. A mixture of government incentives, including the Electric Feed-in Law, guaranteeing that renewable energy producers are paid up to 90% of the current domestic retail electricity price, and low interest loans in several regions, have helped make Germany the strongest wind market in the world. Germany passed another law that aims to double renewable energy's share of electricity to 10% in the next decade. This took effect in April 2000, replacing the Electric Feed-in law, and it provides a fixed level of support for all green power.

3.4.3 Denmark

Denmark ranks as the world's largest manufacturer and exporter of wind turbines, manufacturing over 60% of the world's turbines. They are 5 years ahead of their goal to produce 10% of their electricity from wind, and their new goal is to supply 50% of electric generation from wind by 2030, in part through a 4000-MW offshore wind initiative. The Danish government has been a consistent, strong supporter of its wind industry and, similar to the German legislation, their Windmill Law requires electric utilities to purchase output from private wind turbines at 85% of the consumer price of electricity, plus giving an ecotax break of 9¢/kWh (U.S.). Due to policies encouraging ownership of equipment, privately owned wind turbines represent 80% of the market. In addition, the electric utilities also receive a 1.5¢/kWh (U.S.) production subsidy for wind power generation. As of 2000, the wind energy market has been transformed from a fixed-price system to a renewable portfolio standard (RPS) such that by 2003, 20% of the country's electricity consumption will have to come from renewable sources; the current amount is between 12 and 14%. The plan is to achieve this through the trading of "green certificates" issued to renewable energy generators in proportion to their energy production. The United States is adopting RPS legislation on a state-by-state basis; the most aggressive standard (to date) is in Nevada, with a 20% RPS plan for 2015.

3.4.4 Developing Countries

Finally, among the developing countries, India continues to be the leader, followed by China. India had one of the fastest growing wind markets in the mid-1990s; growth has since slowed substantially due to underperformance of projects (often due to poor siting), transmission problems, and political and economic instability, all of which have affected investments in new projects. Extensive use of investment tax credits has also led to unsustainable revenue losses for the government. During the 1990s, electricity consumption more than doubled in India, and despite huge expenditures in the power industry, the country still has a 12% electricity deficit and 20% peak power shortage. Due to these conditions and the continued fast rate of growth in consumption, India continues to be considered a key market for wind developers. China remains mostly an untapped market with a huge future potential for wind energy; to date, relatively little money has been invested into projects, which remain small and donor based. It is expected that major commercial development, possibly to take place in the next decade, will be needed for strong wind energy development to occur in China.

3.5 Conclusions

For the first time, we are seeing one of the emerging renewable energy generating options—wind power—in a position to compete with the generation technologies of the past century. A variety of players are engaged in pushing forward wind projects worldwide. Enron Wind Corporation acquired German turbine manufacturer Tacke, NEG Micon of Denmark has built manufacturing facilities in the United States, Vestas of Denmark has built factories in Spain and India, and many manufacturers have developed joint ventures in various countries around the world. This globalization trend is likely to continue because financial institutions are beginning to view the wind industry as a promising investment opportunity. As more countries are added to the wind energy roster, uneven development focusing on a half-dozen key markets will most likely be replaced by more balanced growth. During the next couple of years, large-scale projects are expected to be developed in Egypt, Nicaragua, Costa Rica, Brazil, Turkey, Philippines, and several other countries, totaling thousands of megawatts of newly installed capacity, and expanding the number of countries using their wind resources.

4. SOLAR-PHOTOVOLTAIC AND SOLAR-THERMAL TECHNOLOGIES

There are two basic categories of technologies that convert sunlight into useful forms of energy, aside from biomass-based systems, which do this in a broader sense by using photosynthesis from plants as

an intermediate step. First, solar-photovoltaic (PV) modules convert sunlight directly into electricity. Second, solar-thermal power systems use focused solar radiation to produce steam, which is then used to turn a turbine, producing electricity. The following discussion provides a brief overview of these technologies, along with their current commercial status.

4.1 Solar Photovoltaics

At present, annual global PV module production is over 400 MW, which translates into a more than $2 billion/year business. In addition to the ongoing use of PV technologies in space, their present-day cost and performance also make them suitable for many grid-isolated and even grid-connected applications in both developed and developing parts of the world. PV technologies are potentially so useful that, as their comparatively high initial cost is brought down another order of magnitude, it is very easy to imagine them becoming nearly ubiquitous late in the 21st century. PV systems would then likely be employed on many scales in vastly differing environments, from microscopic cells to 100-MW or larger "central station" generating plants covering many square kilometers on Earth and in space. The technical and economic driving forces that favor the use of PV technologies in these widely diverse applications will be equally diverse. However, common among them will be the durability, high efficiency, quiet operation, and lack of moving parts that PV systems offer, and the fact that these attributes combine to provide a power source with minimum maintenance and unmatched reliability. PV system cost and performance have been steadily improving in recent years. PV manufacturing costs have fallen from about $30/W in 1976 to $5.00–8.00/W today, depending on the level of solar insolation at the site and other factors. These installed system costs are expected by some analysts to reach a range of $2.00–5.00/W by 2010, and if this is achieved, PV systems could achieve a sales level of over 1600 MW/year by that time (see Fig. 5).

PV efficiency has also increased markedly over the past few decades, as shown in Fig. 6. The best thin film cells tested in laboratories in 1980 achieved an efficiency level of about 10%. This was improved to about 13% by 1990 and to over 17% in recent years, for the best thin film cells made from copper indium diselenide ($CuInSe_2$) or cadmium telluride (CdTe). However, the modules that are currently being manufactured have somewhat lower efficiencies compared to the recent test cells, with typical values

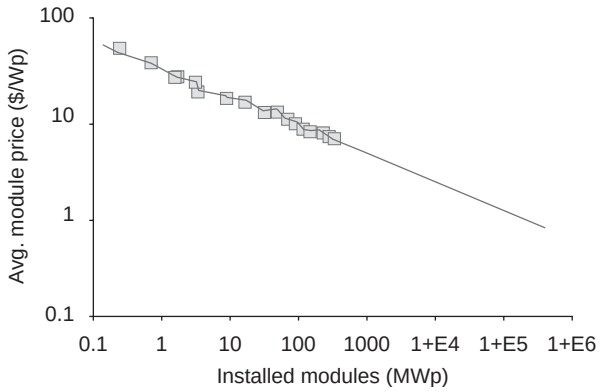

FIGURE 5 Learning curve for photovoltaics, 1976–2000. The average module price is in 1992 dollars (per watt, photovoltaic; Wp).

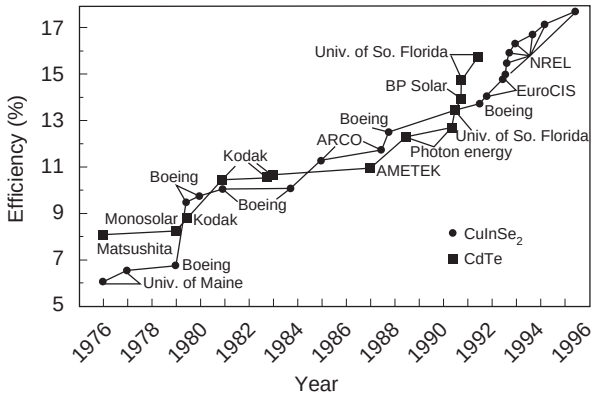

FIGURE 6 Progress in polycrystalline thin-film laboratory cell efficiencies. From the U.S. Department of Energy (1997).

in the range of 9–11% for $CuInSe_2$ and CdTe modules, and 8–10% for the more common amorphous silicon modules. The efficiency gains made over the past decade at the cell level will slowly translate into higher efficiency manufactured products, and this should combine with cell and module manufacturing cost reductions to aid in producing the reductions in per-watt installed system costs.

Figure 7 shows PV shipments by region and for the entire world, from 1976 to 1998. As can be seen, PV sales are growing rapidly; in fact, the sales growth rate throughout the 1990s was approximately 30%/year. Thus, PV systems are declining in cost, improving in efficiency, and increasing rapidly in sales. The cost of electricity produced from PV systems is still higher than it is from most other competing technologies, at about 30¢/kWh, but these costs are expected to continue to decline steadily. In fact, the U.S. Department of Energy projects that the cost of generating electricity from

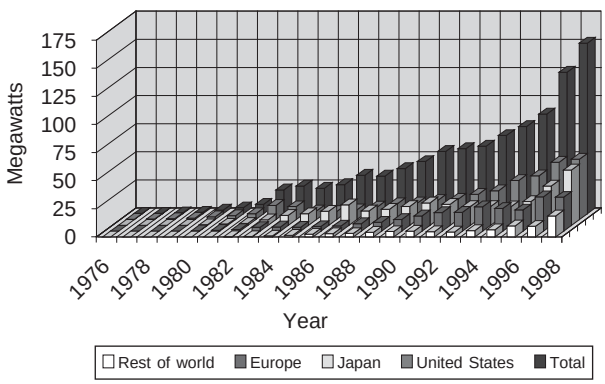

FIGURE 7 Regional and global photovoltaic shipments to different regions worldwide, 1976–2000. In 2002 (not shown), shipments reached 400 MW. From Maycock (1998).

utility-scale PV systems could be below 10¢/kWh (U.S.) by 2010, perhaps falling to about 6¢/kWh by 2020. Meanwhile, costs of electricity from residential PV systems could reach about 18¢/kWh by 2010 and 10¢/kWh by 2020. These potential reductions in cost, combined with the simplicity, versatility, reliability, and low environmental impact of PV systems, should help them to become increasingly important sources of economical premium-quality power over the next 20 to 30 years.

4.2 Solar-Thermal Systems

Solar-thermal power systems use various techniques to focus sunlight to heat an intermediary fluid, known as heat transfer fluid, which then is used to generate steam. The steam is used in a conventional steam turbine to generate electricity. At present, there are three solar-thermal power systems currently being developed: parabolic troughs, power towers, and dish/engine systems. Because these technologies involve a thermal intermediary, they can be readily hybridized with fossil fuels and in some cases adapted to utilize thermal storage. The primary advantage of hybridization and thermal storage is that the technologies can provide dispatchable power and operate during periods when solar energy is not available. Hybridization and thermal storage can enhance the economic value of the electricity produced and reduce its average cost.

Parabolic trough solar-thermal systems are commercially available. These systems use parabolic trough-shaped mirrors to focus sunlight on thermally efficient receiver tubes that contain a heat transfer fluid. This fluid is heated to about 390°C (734°F) and pumped through a series of heat exchangers to produce superheated steam that powers a conventional turbine generator, producing electricity. Nine of these parabolic trough systems, built in the 1980s, are currently generating 354 MW in Southern California. These systems, sized between 14 and 80 MW, are hybridized with up to 25% natural gas in order to provide dispatchable power when solar energy is not available.

Power tower solar-thermal systems are in the demonstration and scale-up phase. They use a circular array of heliostats (large, individually tracking mirrors) to focus sunlight onto a central receiver mounted on top of a tower. The first power tower, Solar One, was built in Southern California and operated in the mid-1980s. This initial plant used a water/steam system to generate 10 MW of power. In 1992, a consortium of U.S. utilities joined together to retrofit Solar One to demonstrate a molten-salt receiver and thermal storage system. The addition of this thermal storage capability makes power towers unique among solar technologies by allowing dispatchable power to be provided at load factors of up to 65%. In this system, molten salt is pumped from a "cold" tank at 288°C (550°F) and then cycled through the receiver, where it is heated to 565°C (1049°F) and finally returned to a "hot" tank. The hot salt can then be used to generate electricity when needed. Current designs allow storage ranging from 3 to 13 hours.

5. HYDROPOWER

5.1 Introduction

Hydropower is currently the largest renewable resource used for electricity. It plays an essential role in many regions of the world, with more than 150 countries generating hydroelectric power. A survey in 1997 by *The International Journal on Hydropower & Dams* found that hydro supplies at least 50% of national electricity production in 63 countries and at least 90% in 23 countries. About 10 countries obtain essentially all their commercial electricity from hydro, including Norway, several African nations, Bhutan, and Paraguay.

There is about 700 GW of hydro capacity in operation worldwide, generating 2600 TWh/year (about 19% of the world's electricity production). About half of this capacity and generation is in Europe and North America, with Europe the largest, at 32% of total hydro use, and North America at 23% of the total. However, this proportion is

declining as Asia and Latin America commission large amounts of new hydro capacity. Small, mini, and micro hydro plants (usually defined as plants generating less than 10 MW, 2 MW, and 100 kW, respectively) also play a key role in rural electrification in many countries. An estimated 300 million people in China, for example, depend on small hydro.

5.2 Capacity and Potential

There is vast unexploited potential worldwide for new hydro plants, particularly in the developing countries of Asia, Latin America, and Africa, but most of the best sites have already been developed in Europe and North America. There is also upgrading potential at existing schemes, though any future hydro projects will, in general, have to satisfy stricter requirements both environmentally and economically than they have in the past.

As shown in Table IV, the world's gross theoretical hydropower potential is about 40,000 TWh/year, of which about 14,000 TWh/year is technically feasible for development and about 7000 TWh/year is currently economically feasible. The last figure fluctuates most being influenced not only by hydro technology, but also by the changing competitiveness of other energy/electricity options, the status of various laws, costs of imported energy/electricity, etc. The biggest growth in hydro generation is expected in the developing countries, where there is still a large potential for hydro development, but relatively little growth is expected in most OECD countries, where more than 65% of the economic potential is already in use. Thus, at least in the near future, hydro will likely remain the main source of electricity generation in developing countries that possess adequate water resources.

Until recent years, there has been less than 100 GW (about 350 TWh/year) of new hydro capacity under construction at any one time, equivalent to less than 15% of the capacity in operation. The figure has now risen, reflecting China's vast construction program, which includes the 18.2-GW Three Gorges Project, now in its second phase of construction. Most new hydro capacity is under

TABLE IV

construction in Asia and South America. China has by far the most, with about 50 GW underway, and India, Brazil, and Russia each have more than 9 GW under construction. Brazil has the largest resources in world (800,000 GWh/year) of economically exploitable capacity and Norway depends almost entirely hydro for its electricity needs.

Hydropower continues to be the most energy-efficient way to generate electricity. Modern hydro turbines can convert as much as 90% of the available energy into electricity. The best fossil fuel plants are only about 50% efficient. In the United States, hydropower is produced for an average of 0.7¢/kWh. This is about one-third the cost of using fossil fuel or nuclear energy and one-sixth the cost of using natural gas. Hydro resources are also widely distributed compared with fossil and nuclear fuels and can help provide energy independence for countries without fossil fuel resources. There is also significant, widespread activity in developing small, mini, and micro hydro plants. At least 40 countries, particularly in Asia and Europe, have plants under construction and even more have plants planned. China, Brazil, Canada, Turkey, Italy, Japan, and Spain all have plans for more than 100 MW of new capacity.

5.3 Small Hydro

Small-scale hydro is mainly "run of river," so does not involve the construction of large dams and reservoirs. It also has the capacity to make a more immediate impact on the replacement of fossil fuels because, unlike other sources of renewable energy, it can generally produce some electricity on demand (at least at times of the year when an adequate flow of water is available), with no need for storage or backup systems. It is also in many cases cost-competitive with fossil fuel power stations or (for remote rural areas) diesel-generated power.

Small hydro has a large, and as yet untapped, potential in many parts of the world. It depends largely on already proved and developed technology with scope for further development and optimization. Least-cost hydro is generally "high-head" hydro because the higher the head, the less the flow of water required for a given power level, and so smaller and less costly equipment is needed. Although this makes mountainous regions very attractive sites, they also tend to be in areas of low population density and thus low electricity demand, and long transmission distances often nullify the low-cost advantage. Low-head hydro, on the other hand, is relatively common, and also tends to be found in or near concentrations of population, where there is a demand for electricity. Unfortunately, the economics also tend to be less attractive unless there are policy incentives in place to encourage their development.

5.4 Environmental and Social Impacts

Although hydroelectricity is generally considered a clean energy source, it is not totally devoid of greenhouse gas emissions and it can often have significant adverse socioeconomic impacts. There are arguments now that large-scale dams actually do not reduce overall GHG emissions when compared to fossil fuel power plants. To build a dam, significant amounts of land need to be flooded, often in densely inhabited rural area, involving large displacements of usually poor, indigenous peoples. Mitigating such social impacts represents a significant cost to the project, which, if it is even taken into consideration, often not done in the past, can make the project economically and socially unviable.

Environmental concerns are also quite significant, as past experience has shown. This includes reductions in biodiversity and fish populations; sedimentation, which can greatly reduce dam efficiency and destroy the river habitat; negative impacts on water quality; and contributions to the spread of water-related diseases. In fact, in the United States, several large power production dams are being decommissioned due to their negative environmental impacts. Properly addressing these issues would result in an enormous escalation of the overall costs for producing hydropower, making it far less competitive than is usually stated. As many countries move toward an open electricity market, this fact will come into play when decisions regarding investments in new energy sources are being made. If the large hydro industry is to survive, it needs to come to grips with its poor record of both cost estimation and project implementation.

5.5 Conclusions

Hydropower is a significant source of electricity worldwide and will likely continue to grow, especially in the developing countries. Although large dams have become much riskier investments, there still remains much unexploited potential for small hydro projects around the world. It is expected that growth of hydroelectricity will continue but at a slower rate than that of the 1970s and 1980s. Thus, the fraction of hydroelectricity in the portfolio of

primary sources of energy, which is today at 19%, is expected to decrease in the future. Improvements and efficiency measures are needed in dam structures, turbines, generators, substations, transmission lines, and environmental mitigation technology if the role of hydropower as a clean renewable energy source is to continue to be supported.

6. GEOTHERMAL ENERGY

6.1 Introduction

Geothermal energy, the natural heat within the earth, arises from the ancient heat remaining in Earth's core, from friction where continental plates slide beneath each other and from the decay of radioactive elements that occur naturally in small amounts in all rocks. The amount of geothermal energy is enormous. Scientists estimate that just 1% of the heat contained in the uppermost 10 km of Earth's crust is equivalent to 500 times the energy contained in all of Earth's oil and gas resources. Yet, despite the fact that this heat is present in practically inexhaustible quantities, it is unevenly distributed, seldom concentrated, and often at depths too great to be exploited industrially and economically.

Geothermal energy has been produced commercially for 70 years for both electricity generation and direct use; its use has increased rapidly during the past three decades. From 1975 to 1995, the growth rates worldwide for electricity generation and direct use of geothermal energy were about 9%/year and about 6%/year, respectively. In 1997, geothermal resources had been identified in over 80 countries and there were quantified records of geothermal utilization in at least 46 countries.

6.2 Capacity and Potential

The worldwide use of geothermal energy amounts to about 44,000 GWh/year of electricity and 38,000 GWh/year for direct use, as shown in Table V. Although geothermal accounts for only about 0.3% of the total electrical power generated worldwide, among renewable sources (excluding hydro) it ranks first, at around 80% of the total. It is currently estimated that the geothermal potential of the world for electricity production is 12,000 TWh/year, and for direct use it is estimated to be even larger, at 600,000 EJ. A very small fraction of the geothermal potential has therefore been developed so far, and an accelerated use of geothermal energy in the near future is certainly feasible. In addition, the technology for both electricity generation and direct application is mature and accessible. Thus, the question of future geothermal development depends on whether it is economically competitive with other energy sources in the different markets around the world. Currently, the electric generation cost is variable, but averages around 4¢/kWh (U.S.); direct utilization production costs, though highly variable, are commonly under 2¢/kWh.

TABLE V

[a] Data From the International Geothermal Association.

Table VI shows the installed geothermal electricity generation capacity in 1990, 1995, and 1998 for a selection of countries. The growth of the total generation capacity from 1990 to 1995 was about 16% and from 1995 to 1998, about 17%. The largest additions in generation capacity from 1990 to 1998 (in megawatts of electricity, MWe) were in the Philippines (957), Indonesia (445), Italy (224), Japan (315), Costa Rica (120), Iceland (95), United States (75), New Zealand (62), and Mexico (43). The most progressive of these countries, the Philippines, plans to add some 580 MWe to their installed capacity through 2008.

In the industrialized countries where installed electrical capacity is already very high, geothermal energy is unlikely in the near-term future to account for more than 1% of the total. On the other hand, in developing countries, with still relatively limited electrical consumption, but with good geothermal prospects, electrical generation from geothermal energy could make a significant contribution to the total installed electrical capacity. For example, 18% of the electricity in the Philippines already comes from geothermal sources; geothermal production is currently 17% in Nicaragua, 12% in El Salvador, 11% in Costa Rica, and 6% in Kenya.

TABLE VII

Top 10 Countries in Direct Utilization of Geothermal Energy[a]

France	309	1359
Italy	314	1026
Russia	210	673

[a] *Source*. WEA (2000).

Direct application of geothermal energy can involve a wide variety of end uses employing mostly existing technology. The technology, reliability, economics, and environmental acceptability of direct use of geothermal energy have been demonstrated throughout the world. In comparison with electricity production from geothermal energy, direct utilization has several advantages. It has higher energy efficiency (50–70% as opposed to 5–20% for conventional geothermal electric plants), generally a much shorter development time, and normally less capital investment is needed. In addition, direct application can use both high- and low-temperature geothermal resources and is therefore much more widely available in the world. Direct application is, however, much more site specific for the market, because steam and hot water are rarely transported long distances from the geothermal site. The longest geothermal hot water pipeline in the world, 63 km, is in Iceland. Space heating is the dominant (33%) type of direct geothermal use in the world; the various other types of direct use of geothermal energy include bathing/swimming/balneology (19%), greenhouses (14%), heat pumps (12%) for air cooling and heating, fish farming (11%), and industry (10%).

Table VII shows installed geothermal capacity and production in the top 10 direct-use countries in the world. It is worth noting that the two countries with the highest energy production, Japan and Iceland, are not the same as the two with the highest installed

capacities, China and the United States. The reason for this is the variety in the load factors for the different types of use.

6.3 Environmental Impacts

Geothermal fluids contain variable concentrations of gases, largely nitrogen and carbon dioxide, with some hydrogen sulfide and smaller proportions of ammonia, mercury, radon, and boron. Most of these chemicals are concentrated in the disposal water that is usually reinjected back into the drill holes, so that there is minimal release into the environment. The concentrations of the gases are usually low enough not to be harmful and the abatement of toxic gases can be managed with current technology. Carbon dioxide is the major component of the noncondensible gases in the steam, but its emission into the atmosphere per kilowatt-hour is well below the figures for power plants fired by natural gas, oil, or coal. Hydrogen sulfide is the pollutant of greatest concern in geothermal plants, yet even the sulfur emitted, with no controls, is only half of what is emitted from a coal-fired plant. Overall, with present technology able to control the environmental impact of geothermal energy development, it is considered to be a relatively benign source of energy.

6.4 Conclusions

Geothermal energy is generally cost-competitive with conventional energy sources and is produced by well-proved conventional technology. It is reliable and has been used for the more than half of the past century to heat large municipal districts, as well as to feed power plants generating hundreds of megawatts of electricity. It has strong potential to continue to expand, especially in the developing countries, and is a clean energy source that can help contribute to reducing our greenhouse gas emissions. It is felt that in the near term, the development of geothermal energy could help fulfill a bridging function during the next few decades, as other more modern clean fuel technologies and renewables mature enough to provide a meaningful share of the world energy supply.

7. RENEWABLE ENERGY SYSTEM COST AND PERFORMANCE

7.1 Recent Progress

There has been significant progress in cost reduction made by wind and PV systems, and biomass, geothermal, and solar-thermal technologies are also experiencing cost reductions that are forecast to continue. Figure 8 presents forecasts made by the U.S. Department of Energy (DOE) for the capital costs of these technologies, from 1997 to 2030. Of course, capital costs are only one component of the total cost of generating electricity, which also includes fuel costs and operation and maintenance costs. In general, renewable energy systems are characterized by low or no fuel costs, although operation and maintenance costs can be considerable. It is important to note, however, that operation and maintenance costs for all new technologies are generally high, and can fall rapidly with increasing familiarity and operational experience. Renewable energy systems such as photovoltaics contain far fewer mechanically active parts than do comparable fossil fuel combustion systems, and therefore are likely in the long term to be less costly to maintain. Figure 9 presents U.S. DOE projections for the levelized costs of electricity production from these same renewable energy technologies, from 1997 to 2030. Given these likely capital and levelized system cost reductions, recent analyses have shown that additional generating capacity from wind and solar energy can be added at low incremental costs relative to additions of fossil fuel-based generation. These incremental costs would be further offset by environmental and human health benefits. Furthermore, a U.S. National Renewable Energy Laboratory (NREL) analysis shows that geothermal and wind energy could actually become more economic than coal in the next 15 years.

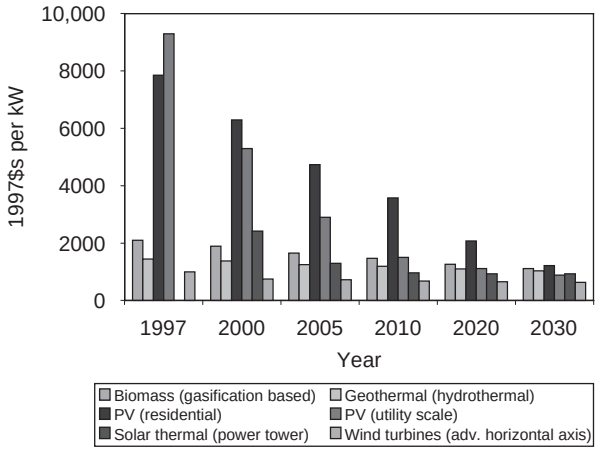

FIGURE 8 Capital cost forecasts for renewable energy technologies. PV, Photovoltaic. From the U.S. Department of Energy (1997).

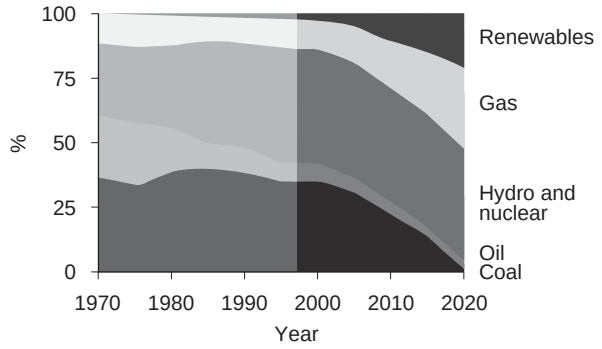

FIGURE 11 Electricity mix in Organization for Economic Cooperation and Development countries. From Shell Petroleum (2000).

Another analysis conducted by the Renewable Energy Policy Project (REPP) shows that adding 3050 MW of wind energy production in Texas, over a 10-year period, would entail only modest additional costs to residential customers. REPP estimates these additional costs to be about 75¢/month for a household using 1000 kWh/per month, or about $9 annually. The economic case for renewables looks even better when environmental costs are considered along with capital and operating costs. As shown in Fig. 10, geothermal and wind can be competitive with modern combined-cycle power plants, and geothermal, wind, and biomass all have lower total costs compared to advanced coal-fired plants, once approximate environmental costs are also included. Shell Petroleum has made one of the highest profile projections of future renewables growth. As shown in Fig. 11, Shell projects that renewables could constitute about 15% of the OECD's energy production by 2020, and that renewables and natural gas combined could account for about 50% of total production.

As already noted, the remarkable difference between the setting for renewable energy today, relative to the past 30 years, is that renewable and other clean energy technologies are now becoming economically competitive, and the push to develop them is no longer being driven solely by environmental concerns. With regard to prospects for investing in companies developing clean energy resources, Merrill Lynch's Robin Batchelor recently stated that "This is not an ethical investment opportunity, it's a straightforward business opportunity." Batchelor also noted that the traditional energy sector has lacked appeal to investors in recent years because of heavy regulation, low growth, and a tendency to be highly cyclical. He has identified 300 companies worldwide whose aim is to develop wind, solar, and wave power technologies and to advance capabilities in energy storage, conservation, and on-site power generation. Further evidence of the impending transition to renewable energy systems can be found in recent corporate reorganization among the world's largest oil companies. Corporate giants such as Shell and BP/Amoco, which would now like to be known as "energy companies" rather than "oil companies," have recently reorganized into a broader array of business units, including those exclusively focused on renewables. Such subsidiary units now include "Shell Renewables," and "BP Solar."

7.2 Lessons Learned in Developing Countries

In developing nations, renewable energy technologies are increasingly used to address energy shortages and to expand the range of services in both rural and urban areas. In Kenya, over 120,000 small

(20–100 Wp) (Wp, photovoltaic-derived watts) solar-PV systems have been commercially financed and installed in homes, battery charging stations, and other small enterprises. Meanwhile, a government program in Mexico has disseminated over 40,000 such systems. In the Inner Mongolian autonomous region of China, over 130,000 portable windmills provide electricity to about one-third of the non-grid-connected households in this region. These examples demonstrate that the combination of sound national and international policies and genuinely competitive markets—the so-called level playing field—can be used to generate sustainable markets for clean energy systems. They also demonstrate that renewable energy systems can penetrate markets in the developing world, even where resources are scarce, and that growth in the renewables sector need not be limited to applications in the developed world. Just as some developing countries are bypassing construction of telephone wires by leaping directly to cellular-based systems, so too might they avoid building large, centralized power plants and instead develop decentralized systems. In addition, to help mitigating the environmental costs of electrification, this strategy can also reduce the need for the construction of large power grids.

In the absence of policy interventions, we may remain locked-in to existing technologies, even if the benefits of technology switching overwhelm the costs. There are numerous examples, however, of an entrenched or locked-in technology being first challenged and ultimately replaced by a competing technology. This process is generally enabled by a new wave of technology, and it is sometimes achieved through a process of hybridization of the old and the new. Technological "leapfrogging" is another possibility, but this seems to occur relatively rarely. A prime example of the hybridization concept is in the case of the competition between gas- and steam-powered generators, dating back to the beginning of the century. From about 1910 to 1980, the success of steam turbines led to a case of technological lock-in, and to the virtual abandonment of gas turbine research and development. However, partly with the aid of "spillover" effects from the use of gas turbines in aviation, the gas turbine was able to escape the lock-in to steam turbine technology. First, gas turbines were used as auxiliary devices to improve steam turbine performance, and then they slowly became the main component of a hybridized, "combined-cycle" system. In recent years, orders for thermal power stations based primarily on gas turbines have increased to more than 50% of the world market, up from just 15–18% in 1985.

7.3 Leveling the Playing Field

As was shown in Fig. 10, renewable energy technologies tend to be characterized by low environmental costs. In an ideal world, this would aid them in competing with conventional technologies, but of course many of these environmental costs are "externalities" that are not priced in the market. Only in certain areas and for certain pollutants do these environmental costs enter the picture, and clearly further internalizing these costs would benefit the spread of renewables. The international effort to limit the growth of greenhouse emissions through the Kyoto Protocol may lead to some form of carbon-based tax, and this could prove to be an enormous boon to renewable energy industries. However, support for the Kyoto Protocol among industrialized countries remains relatively weak, particularly in the United States, and any proposed carbon-based taxation scheme will surely face stiff opposition.

Perhaps more likely, concern about particulate matter emission and formation from fossil fuel power plants will lead to expensive mitigation efforts, and this would help to tip the balance toward cleaner renewable systems. In a relatively controversial move, the U.S. Environmental Protection Agency (EPA) has recently proposed new ozone and particulate matter (PM) standards that are even more stringent than the current standards that remain unattained in some U.S. urban areas. The EPA has justified these new regulations with analysis that shows that new standards are necessary to provide increased protection against a wide range of potential health impacts. For example, the EPA estimates that even if Los Angeles County (California) were to meet the existing PM standards, 400 to 1000 deaths per year would still occur as a result of exposure to very fine PM (under 2.5 μm in diameter), which presently is not regulated. The combination of increased pressure to attain ozone and PM standards will further complicate siting of new fossil-fueled power plants in some areas of the United States, particularly where it is now required to find "offsets" for pollution impacts. This will indirectly but surely benefit renewable energy technologies, which do not typically face these difficulties in obtaining siting permits.

7.3.1 Public and Private Sector Investment Issues

A fundamental problem with any new technology is that, by definition, it does not have the track record

of performance that exists for older, more established systems. Proponents of existing technologies in mistaken arguments against technological change often cite this fact. New technologies and operational procedures do present greater risks, but at the same time present greater opportunities for innovation and profit. Emerging energy systems were long seen as an area of risky investments, with the history of renewable energy systems seen as the primary illustration of that "fact." It has been argued that this pattern is not only illusory, but is largely a self-fulfilling prophecy. Larger gains, both to individual companies and to society, typically stem from carefully targeted but consistently pursued avenues of research, innovation, and implementation. Renewable energy systems offer this same combination of increased uncertainty, great promise, and the potential for significant innovations and profits.

There are two principal rationales for government support of research and development to develop clean energy technologies (CETs). First, conventional energy prices generally do not reflect the social cost of pollution. This provides a rationale based on a well-accepted economic argument, for subsidizing research and development for CETs as potential alternatives to polluting fossil fuels. Second, private firms are generally unable to appropriate all the benefits of their research and development investments. Consequently, the social rate of return for research and development exceeds available private returns, and firms therefore do not invest enough in research and development to maximize social welfare. Thus, innovation "spillover" among CET firms is a form of positive externality that justifies public research and development investment. The conventional wisdom is that government should restrict its support to research and development and let the private sector commercialize new technologies. Failed CET commercialization subsidies (e.g., the U.S. corn ethanol and synfuels programs) bolster this view. Nonetheless, there are compelling arguments for public funding of market transformation programs (MTPs) that subsidize demand for some CETs in order to help commercialize them. Further, the argument that it may not be worthwhile for firms to invest in new technologies because of the spillover effects is generally false as well. Early investment in new technologies in promising market sectors has proved to be the best strategy for firms interested in long-term (and not simply short-term) profitability.

A principal motivation for considering MTPs is inherent in the production process. When a new technology is first introduced, it is invariably more expensive than established substitutes. There is, however, a clear tendency for the unit cost of manufactured goods to fall as a function of cumulative production experience. Cost reductions are typically very rapid at first, but taper off as the industry matures. This relationship is called an "experience curve" when it accounts for all production costs, and it can be described by a progress ratio (PR), where unit costs fall by $100 \times (1-\mathrm{PR})$ percent with every doubling of cumulative production. Typical PR values range from 0.7 to 0.9 and are widely applicable to technologies such as toasters, microwave ovens, solar panels, windmills, and essentially any good that can be manufactured in quantity. For example, Fig. 12 presents PRs for photovoltaics, windmills, and gas turbines. All three have initial PRs of approximately 0.8, which is a typical value observed for many products. After 1963, the gas turbine PR increased substantially, however, indicating an attenuation of experience effects.

The benefits of production experience may accrue primarily to the producing firm, or they may spill over to its competitors. Among other channels, "experience spillovers" could result from hiring competitors' employees, reverse engineering rivals' products, informal contacts among employees of rival firms, or even industrial espionage. If firms retain the benefits of their own production experience, they have an incentive to consider experience effects when deciding how much to produce. Consequently, they will "forward price," producing at a loss initially to bring down their costs and thereby maximize profit over the entire production period. It has been shown that, in each period, firms maximize profit by setting marginal revenue equal to their true marginal cost (TMC). For a firm with a discount rate of zero, TMC is defined as the cost of the last unit the firm plans to produce. If the firm has a positive discount rate, its TMC will be somewhat higher. However, due to experience effects, the TMC is always lower than current marginal cost (except

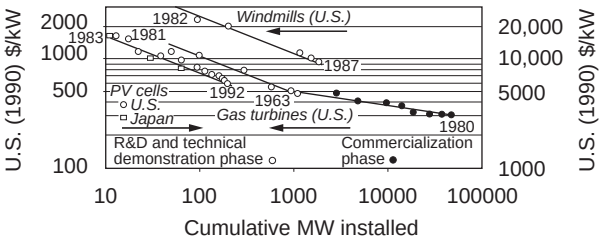

FIGURE 12 Progress ratios for photovoltaics (PV), windmills, and gas turbines. R&D, Research and development. From IIASA/WEC (1995).

for the very last unit produced). In addition, unless there is 100% spillover, the first-best social optimum requires regulating a single firm such that it produces in every period up to the level where price equals true marginal cost. This policy would require subsidizing the monopolist because it would be selling units for less than their current marginal cost in every period except the last. Absent regulation, when experience spillover is low, cumulative production experience gives incumbent firms widening cost advantages over potential entrants. Thus, early entrants can cut back their output and raise prices above the competitive level without prompting other firms to enter. The incentive to forward price partially mitigates the problem, but output remains below the social optimum. When experience does spill over substantially, firms still do not produce enough to maximize social efficiency. This follows because experience becomes a positive externality, analogous to the research and development appropriability problem. Thus, firms insufficiently forward price because they do not value the portion of their experience benefits that accrue to other firms.

To summarize, regardless of the level of spillover, strong experience effects imply that output is less than the socially efficient level. That is, some consumers would be willing to pay more than the cost of additional production, but the market fails to facilitate these mutually beneficial trades. Market transformation programs can improve social welfare by correcting the output shortfall associated with these experience effects. Moreover, as with research and development, MTPs also help to promote the use of clean energy technologies as alternatives to polluting fossil fuel technologies, and thereby reduce the social costs of pollution. When politically possible, the first-best policy is to internalize pollution costs fully (e.g., through pollution taxes set at the marginal social cost of the pollution externality or through tradable emissions permits set at the socially optimal pollution level). Governments chronically fail to achieve this, however, providing another clear rationale to support market transformation programs.

When evaluating MTPs, it is essential to account for positive feedback between the demand response and experience effects. An MTP increases the quantity produced in the first year and, due to experience effects, year 2 unit costs are lower than they would have been without the additional production from the MTP. These lower costs, in turn, imply that the quantity demanded in year 2 is higher. This "indirect demand effect," in turn, adds to cumulative production experience and further lowers unit costs in future years. This process continues indefinitely, though it gradually dissipates once the MTP is discontinued. Accounting for these indirect demand effects substantially raises the benefit–cost ratio (BCR) of typical MTPs. Even without accounting for environmental benefits, the case studies of MTPs targeting photovoltaics and efficient lighting show positive BCRs of 1.05 and 1.54, respectively.

These results suggest a role for MTPs in national and international technology policies; however, the costs of poor program design, inefficient implementation, or simply choosing the "wrong" technologies can easily outweigh cost reduction benefits. This suggests that MTPs be limited to emergent CETs with a steep industry experience curve, a high probability of major long-term market penetration once subsidies are removed, and a price elasticity of demand of approximately unity or greater. The condition that they be clean technologies mitigates the risk of poor MTP performance by adding the value of displaced environmental externalities. The other conditions ensure a strong indirect demand effect. Finally, as with energy research and development policy, public agencies should invest in a portfolio of new clean energy technologies in order to reduce overall market transformation program performance risk through diversification.

8. CONCLUSIONS

In conclusion, it is clear that the promise of renewable energy has now become a reality. Both solar photovoltaics and wind energy are experiencing rapid sales growth, declining capital costs and costs of electricity generated, and continued performance increases. Because of these developments, market opportunity exists now both to innovate and to take advantage of emerging markets, with the additional assistance of governmental and popular sentiment. The development and use of these sources can enhance diversity in energy supply markets, contribute to securing long-term sustainable energy supplies, make a contribution to the reduction of local and global atmospheric emissions, provide commercially attractive options to meet specific needs for energy services (particularly in developing countries and rural areas), and create new employment opportunities.

Glossary

fixed feed-in tariff An offer by government or a utility to purchase electricity from renewables producers at a fixed price, regardless of the producers' costs of production.

green (renewables) certificate A certificate, provided by a regulator to renewables producers for specified units of their electricity output; can be traded to other electricity producers who need it to meet their obligation to produce a minimum percentage of renewable electricity under the renewable portfolio standard.

quantity-based policy A policy that specifies a quantity outcome (as opposed to a price-based policy such as an environmental tax or subsidy); an example is the renewable portfolio standard policy, which requires production of a specific quantity of electricity.

renewable energy Forms of energy (sunlight, wind, geothermal heat, wave power, tidal energy, hydropower, and organic matter) that flow through Earth's biosphere, available for human use indefinitely, provided that the physical basis for their flow is not destroyed.

The renewable portfolio standard (RPS) is a policy instrument to force greater production of electricity from energy sources (usually renewable) that have desirable social and environmental characteristics. By requiring market participants to deliver a minimum amount of electricity, typically as a percentage of total sales, from specific fuels and/or technologies, the RPS is a "quantity-based policy." In Europe, the policy is often referred to as "green certificate" trading. Renewable energy sources are normally defined as sunlight, wind, geothermal heat, wave power, tidal energy, hydropower, and organic matter, but the definition used in a given jurisdiction's RPS may be narrower or broader, depending on local views of the social and environmental characteristics of each technology and fuel.

1. RATIONALE

Renewables appear to have lower social and environmental impacts and risks when compared with electricity derived from conventional sources, such as fossil fuels and nuclear power. Environmental benefits may include reduced emissions contributing to smog or producing acid rain and greenhouse gases relative to a total reliance on fossil fuels, and zero risk of radiation exposure or nuclear weapons proliferation relative to nuclear power. Greater use of renewable sources may also enhance energy security by increasing supply diversity and the use of indigenous fuels, thereby reducing vulnerability to supply disruptions and volatile fuel prices. Renewables can also support economic development through reducing payments for imported fuels (increasing local multiplier effects) and fostering the development of local technical expertise.

Renewables are usually more expensive than conventional electricity sources when compared on a financial cost basis. Because of this, both monopoly and competitive electricity producers have concentrated their investment on conventional electricity technologies, with renewables usually accounting for only a small percentage of the generating stock. The only countries dependent on renewables for electricity generation are those with substantial, low-cost hydropower endowments, such as Brazil, Norway, New Zealand, and Canada. But because many large hydropower facilities disrupt ecosystems, sometimes dramatically, hydro plants exceeding a threshold of, say, 20 MW may be excluded from RPS eligibility.

 © 2004 Elsevier Inc. All rights reserved.

There are three arguments for why the financial comparison of renewables and conventional generation sources does not reflect the full costs and benefits to society of the alternative sources:

1. Some jurisdictions provide greater subsidies to conventional generation fuels and technologies.
2. The full costs of pollution (externalities) are not included in the financial costs of conventional electricity sources, and are usually much greater than pollution costs for renewables.
3. Although humans have used some renewables (such as wind) for millennia, renewables are today associated with new technologies, the relative costs of which will fall with widespread commercialization because of economies of learning and economies of scale in manufacture.

Thus, although from a strict financial cost perspective (Fig. 1, left side) most renewables are more expensive compared to conventional electricity, the situation may be reversed when these three additional factors are taken into account (Fig. 1, right side). Inclusion of these three factors is referred to as the "long-run, social cost perspective." Whereas it is not certain that renewables are always less expensive on a social cost basis, they are nonetheless recognized as desirable sources of electricity that will have difficulty penetrating the market given the pressure on electricity investors to focus on financial considerations. This constraint is exacerbated if electricity markets continue the current trend toward independent electricity production, mostly by privately owned companies.

In recognition of the possible advantages of renewables on a social cost basis, governments have developed policies to improve the financial competitiveness of renewables. There are four broad categories of measures to support renewables:

1. Assist the commercialization of renewables with indirect support. This may include funding of demonstration projects, audits, evaluations, resource assessments, research and development support, and training.
2. Provide direct financial support to renewables. This may include capital grants, preferential purchase prices, tax advantages, or low-interest loans. Energy price subsidies can be in the form of preferential fixed-price tariffs (feed-in tariffs), a fixed premium on the prevailing electricity price, or a premium payment to renewable electricity producers determined by a "competitive bidding" process.
3. Increase the cost of polluting sources of supply. This may include the reduction or elimination of subsidies to conventional sources, higher energy or pollution taxes (externality taxes), stronger technology regulations, or emission cap regulations.
4. Foster voluntary or mandatory minimum market shares for renewables. This may include voluntary agreements with producers, green tariffs that allow consumers to pay extra for renewables, and the RPS.

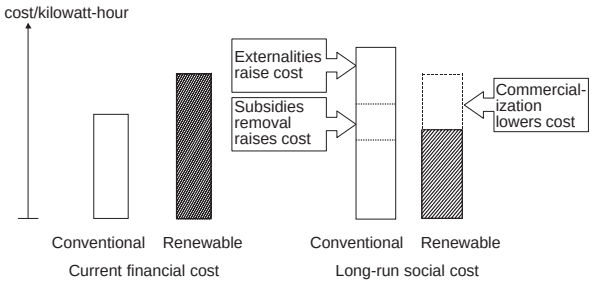

FIGURE 1 Conventional versus renewable electricity: financial and social cost comparison.

Since the energy crisis of the 1970s, governments have especially relied on the first two mechanisms to support renewables. Various indirect support policies (e.g., research and development subsidies) have been in place throughout the past 30 years. But the dominant policy in terms of impact has been direct financial support. Many governments have provided tax credits for renewables. Electric utilities and governments have offered above-market, fixed-tariff prices to acquire electricity from renewables producers. In the United States, the Public Utility Regulatory Policy Act of 1978 required utilities to purchase renewables and other independent electricity at prices that reflected the long-run cost of new, high-cost nuclear and fossil fuel plants. In Europe, fixed-tariff price support was implemented through direct government subsidy (e.g., in Denmark) or cross-subsidy from other utility customers (e.g., in Germany). In the 1990s, however, interest in the third and fourth approaches has increased as governments have explored policies that raise the cost of polluting sources of supply. Europe has focused on pollution regulations and externality taxes, and the United States has focused on regulations and systems that involve emissions caps and tradable permits. Industrialized countries, and increasingly developing countries (e.g., China), have also reduced subsidies to conventional fossil fuel and nuclear energy producers. Voluntary green tariffs and the RPS

emerged in the late 1990s in Europe, the United States, and Australia.

Three characteristics help explain the emerging interest in the RPS: First, an RPS maintains continuous incentives for renewable producers to seek cost reductions (economic efficiency) and can be designed to ensure that these cost reductions are passed on to consumers (equity). This is achieved by mechanisms that establish continuous cost competition among renewable producers for their share of the RPS. Second, because an RPS ensures the attainment of a specific market share, it can be directly linked to government policy objectives. Governments can set an RPS target as part of a package of policies to meet an environmental target such as CO_2 reduction. Third, an RPS minimizes government involvement relative to other measures. The government's budget is not implicated because customers pay producers directly the extra financial cost of renewables, and the selection of winning bids can be left to market forces (competitive bidding) instead of government evaluation. Because the RPS has only recently emerged as a policy tool, there is insufficient experience to provide an empirical evaluation of its performance relative to key alternatives, such as subsidized feed-in tariffs and competitive bidding for subsidies. However, critical issues in its design have already emerged.

2. DESIGN CONSIDERATIONS

Many considerations influence the design of an RPS. Major categories include selection of the target, determining resource eligibility, determining where and to whom the policy is applied, designing flexibility mechanisms, and setting administrative responsibilities. Although these are presented individually here, they cannot be considered in isolation from each other in the design process. A clear set of policy objectives is required for navigating these considerations. These include standard policy objectives, such as effectiveness, economic efficiency, equity, political acceptability, and administrative feasibility, but also the specific environmental and perhaps social goals that are the motivation for the RPS in the first place. For example, the RPS has been linked to the greenhouse gas reduction goals of several jurisdictions. The following discussion of design considerations assumes that the policy objectives include the standard list, as well as those environmental objectives that tend to favor renewables relative to fossil fuel- and nuclear-generated electricity.

2.1 Target Selection

The main challenge of the RPS is determination of the binding target or quota for renewable energy production. There are several aspects to this determination.

2.1.1 Target Size

Setting target size requires consideration of impacts on different objectives, including anticipated costs. These impacts will depend in part on the local cost and availability of renewables and the price of conventional electricity sources. From a political acceptability perspective, the target would be large enough to move the industry toward the environmental objective, but not so large that it results in a dramatic increase in electricity prices. The size of the target can also affect the level of competition among fuels or technologies. For example, if targets could be achieved with a relatively small number of large projects, there may be less competition and little pressure to innovate. Some knowledge of the potential costs and quantities of renewables is therefore important in establishing targets.

2.1.2 Target Timing

Another consideration in selecting the target is timing. Some lead time may be required to permit cost-effective responses to the RPS target. The length of the lead time will depend on the magnitude of the target and the characteristics of eligible resources. If existing facilities are not eligible for meeting targets, sufficient lead time will be required for investments in new facilities. A phase-in period would enable the government to conduct interim evaluations in order to assess impacts and make target adjustments where necessary, thereby maintaining fairly stable compliance costs. However, duration and stability of targets can also be important so that buyers and sellers can more easily negotiate long-term supply contracts. Long-term commitments that guarantee a revenue stream are important for securing low-cost project financing, especially for capital-intensive technologies such as renewables.

2.1.3 One or Multiple Renewables Targets

An issue in target setting is whether there should be one target for which all renewables compete, or a separate target for different classes of renewables. Under the first approach, the lowest cost options would be developed to meet the aggregate target. This approach should advance environmental goals more cost-effectively, but it might do less well in

furthering other objectives, such as greater supply diversity or increased support for newly emerging, but still expensive, types of renewables. Perhaps one renewable (e.g., wind) will capture the entire RPS market even though other renewables would eventually become competitive were they assisted in achieving commercialization and production thresholds. The state of Connecticut designed its RPS with separate targets for Class 1 renewables (solar, wind, landfill gas, and sustainable biomass) and Class 2 renewables (hydropower and municipal solid waste), the intent being to limit the share of hydropower and municipal solid waste within the RPS.

2.1.4 Target Adjustment and Other Cost Cap Measures

If the RPS is set too high, it could substantially increase the price of electricity, with perhaps significant political acceptability and economic performance impacts. There are several ways in which the government (or RPS administrator) could deal with this challenge. First, the RPS target could be voluntary (as in The Netherlands in its initial policy), or converted to voluntary status as higher-than-anticipated costs emerge. Second, the government could adjust the target downward as evidence of high cost emerged. Third, the government could set a modest penalty that participants would pay to the extent that they failed to comply completely with the RPS. This penalty provides assurance to participants that costs will not rise above the penalty level. Fourth, if the RPS includes a system of tradable renewable certificates (green certificates in Europe), the government could offer to sell an unlimited number of these at a modest price, in effect providing a price cap (e.g., The Netherlands). These measures all ensure that costs will not exceed a given level, but at the possible expense of not achieving the RPS target, and the corresponding environmental target associated with it. On the negative side, adjusting targets could jeopardize the credibility and predictability of the program, with serious consequences for its long-term success.

2.2 Eligible Resources

In addition to specific targets, the RPS must establish resource eligibility. This will depend on the objectives for the RPS and the local viability of different types of resources.

2.2.1 Renewables vs Other Desired Technologies

A key eligibility decision is whether the RPS should be limited to renewable sources of electricity or can include other energy/technology combinations. This depends on the objectives and, in some sense, on the comfort level with using the term "renewables" to symbolize the broader concept of environmentally desirable technologies. In Italy, only truly renewable forms of energy are included in the RPS definition. In some jurisdictions, however, fossil fuel-driven cogeneration or fuel cell technology is included because of the higher energy efficiency and lower local emissions of these mechanisms. In proposing its RPS, Australia included solar water heaters that displace electric water heaters that use electricity from fossil fuel plants.

2.2.2 Existing Renewables vs New Investments

Another eligibility consideration is whether the RPS should apply to all renewable resources or only to new investments in renewable resources. Applying it to new investment helps advance the new technology commercialization intent of the RPS, as adopted in the Italian RPS. However, this may increase administrative complexity by requiring ongoing monitoring and regulatory rulings as to whether a given expenditure is just maintenance and refurbishment of an existing facility or a truly new investment (a problem experienced in a different context with the U.S. Clean Air Act). Is a complete reconstruction of a small hydropower facility a new or old investment? If new, what if only the turbines are replaced? If, however, the policy goal is simply to expand output from renewables at the lowest cost, the government may be indifferent regarding investments for reconditioning or for totally new facilities.

2.2.3 Grid-Connected Renewables vs All Renewables

The RPS may apply only to grid-connected facilities or to both grid-connected and off-grid facilities. Although the simplest approach is to focus the policy on changing the grid-transmitted market share of renewables, some would argue that environmental objectives are equally served by the development of renewables anywhere, including off grid. However, administrative realities must be considered. It would be difficult to verify the annual production of a myriad of small off-grid generators, leading to high administrative costs.

2.2.4 Facility Size

The size of resources may also be part of the RPS eligibility determination. Size limits can affect the number of potential projects required to meet the

overall target. They can also indirectly affect objectives such as diversity and the location of projects. The RPS of the state of Maine in the United States had an upper limit of 100 MW, which applied to both existing and new facilities. A limit of 10 or 20 MW is sometimes suggested as the maximum size that should be allowed for hydropower projects to be included in the RPS.

2.2.5 Imports vs Domestic Renewables

External, renewable electricity producers may wish to sell into a jurisdiction with an RPS standard. Again, determination of eligibility depends on the policy objectives. If the expansion of domestic resources is key, imports of renewables may be limited or excluded from the RPS, which does not prevent them from competing in the non-RPS market against conventional generation facilities. In many jurisdictions, external participation in the RPS will require some consideration of existing trade agreements and commercial law, which may limit policymakers' ability to discriminate between domestic supplies and imports. Both Europe and North America are working toward electricity trade rules that should make external participation easier.

2.3 Applicability

The applicability of the RPS target is another important design consideration. Key issues include the geographic coverage of the standard, the applicability of the standard to specific market participants, and whether it should be applied to capacity or energy.

2.3.1 Geographic Coverage

In terms of geographic coverage, the RPS may be most effective if the breadth of its application is matched to the breadth of environmental and other objectives. This explains why the European Union (EU), which sees renewables as a component of its greenhouse gas emission reduction objective, is seeking to achieve an EU-wide RPS. However, the physical limitations to trade must be considered. In some countries, the lack of grid interconnection makes implementation of even a national RPS problematic, unless some form of credit trading is permitted. In these cases, it may be easier initially to set an RPS for each major grid area.

2.3.2 Market Participants Regulated by the RPS

The RPS must specify the market participants to which it applies. Possible participants include producers, wholesale customers or brokers, retail suppliers, distribution utilities, and consumers. Some jurisdictions want the RPS to be associated with final consumption, hoping that the public will better understand its link to environmental or other policy objectives. Denmark's proposed RPS applies to consumers, although distribution utilities or retail suppliers would presumably represent the interests of small consumers. Others believe that the administrative ease of regulating producers is important. Italy has size restrictions so that the standard applies to only about 100 producers nationwide.

2.3.3 Energy Production vs Installed Capacity

The RPS may apply to energy production or installed capacity. Capacity may be easier to verify, but energy production is directly connected to environmental objectives. An energy-determined RPS provides the incentive for producers to maximize production from individual projects, and thereby lower costs.

2.4 Flexibility Mechanisms

An RPS can be less costly to implement, yet still achieve the same target, if there is flexibility in how it is applied both to individual producers and across the entire market.

2.4.1 Account-Balancing Mechanisms for Individual Producers

One way to increase flexibility is to allow those to whom the policy is applied to have some flexibility in the choice of calendar year and in the period for achieving their annual RPS. This is known as an "account-balancing mechanism." For example, the inherent output variability of some types of renewables, such as wind, hinders accurate fulfillment of the RPS target each year. The electricity provider can be given extra months to meet the previous year's commitment as long as the full RPS requirement is achieved on average over a period of years. The Australian RPS has a 3-year balancing mechanism for electricity providers.

2.4.2 Trading Mechanisms between Producers

Another way to increase flexibility is to allow trade among electricity providers so that the RPS target is met in aggregate, even if some providers exceed the RPS and others fail to achieve it. This approach can significantly decrease the total cost of the

RPS because it allows the maximum electricity production from those renewables generators with the lowest costs. This trading can be facilitated by the creation of tradable certificates, hence the European term "green certificate" trading for the RPS. As of 2003, The Netherlands, Italy, England, Australia, and some U.S. states (Texas) had such certificates. The creation of certificates is not essential, however, for trading to occur. The RPS administrator could allow electricity providers to use a variety of instruments to demonstrate achievement of the RPS target in aggregate while they trade among themselves. Contracts between providers could be filed with the administrator and these would be verified against actual inputs to the grid.

2.5 Administrative Responsibilities

There are several administrative responsibilities in implementing a RPS. These could all be handled by one RPS administrator or delegated to specialized agencies.

2.5.1 Setting the RPS Target

The RPS target would likely be set at a senior level of government because it involves critical trade-offs between environmental targets, economic development goals, and concerns about electricity prices.

2.5.2 Certification of Renewables

Certification of renewables could be delegated to the operator of the grid, subject to periodic review by the government agency responsible for administering the RPS. Environmental regulators could help with the definition of what is a renewable resource, although, again, this may be a high-level policy decision.

2.5.3 Compliance Monitoring

Compliance monitoring could be delegated to the operator of the grid, because this entity will already have information on production of connected facilities. If nongrid production is also eligible for the RPS, compliance verification will be much more difficult and may require some other entity.

2.5.4 Setting and Collecting Penalties for Noncompliance

Penalties for noncompliance may be set at senior levels of government, for consistency with other public policies, but could then be administered by the grid operator or environmental agency.

3. EARLY ADOPTERS

The renewable portfolio standard is a new policy tool. Many jurisdictions (national, regional) are studying it, and several have RPS legislation under consideration. But as of 2003, only a few jurisdictions (and only in industrialized countries) have enacted RPS legislation. Although it is too early to assess the effectiveness of the RPS relative to alternative policies, a survey of early adopters provides an initial indication of the preferences of policymakers when trading-off implementation objectives and constraints. Because the RPS legislative situation is so dynamic, this survey is limited to general policy developments, and even some of these may soon change.

3.1 United States

The United States Congress has considered several RPS legislative proposals. In the spring of 2003, the U.S. Senate passed a bill requiring new renewables to provide an additional 1% of U.S. electricity by 2005 and 10% by 2020. The RPS would include a credit trading mechanism between producers to reduce the cost of compliance. The bill also sustains a production tax credit for renewable generators. In 2003, just over 10 U.S. states had enacted an RPS, but many additional states were considering legislation. States with an RPS enacted or in final consideration included Maine, Massachusetts, Connecticut, Pennsylvania, New Jersey, Minnesota, Wisconsin, Iowa, Texas, New Mexico, Arizona, Nevada, and California. Most RPS legislation has been associated with electricity sector reform toward greater generation competition, with RPS targeting electricity retailers. Almost all programs envision flexibility mechanisms (tradable credits), although these are mostly in the development stage. State-level electric utility regulators are usually charged with the responsibility for program administration. Urban waste and landfill gas are often included as eligible resources, and sometimes technologies such as fuel cells and cogeneration.

Variation in the RPS from one state to another reflects the unique circumstances and objectives of each state. At 30%, Maine's RPS target appears ambitious, but the RPS includes all currently operating renewables and the state already generates 50% of its electricity from eligible hydro and biomass resources. RPS advocates hail the Texas RPS as the best-designed and most ambitious policy in the

country. It envisioned the development of an additional 2000 MW of mostly wind power by 2009, which, in combination with existing renewables, would provide about 3% of total state electricity provision. Wind power has expanded rapidly since the inception of the RPS.

3.2 European Union

As part of its effort to establish a liberalized internal electricity market, the EU has been developing harmonized rules on the treatment of renewables in order to avoid distortion of trade and competition in electricity from renewable sources. In 1997, the EU issued a White Paper setting a goal for a minimum 12% share of renewable electricity supply by 2010. In 2000, the EU issued a directive proposal for a community-wide policy. To date, the directive proposal is not binding, nor does it specify the policy that should be used. Nonetheless, interest in the RPS at the EU-wide level is strong, and several countries have implemented the policy and several are close to implementation.

In Italy's RPS, operators who produce and import more than 100 GWh are obliged, from 2001, to provide at least 2% of the electricity produced and imported (net of cogeneration, exports, and self-consumption) from new, renewable generation. Renewables generators earn green certificates, which they can use or trade to nonrenewables producers in a tradable certificate market. The goal of the RPS is to triple electricity production from renewable sources by 2010.

The government of The Netherlands initially negotiated a voluntary RPS with the country's major utilities, but participants behave as if it were mandatory because meeting their RPS quota allows them to avoid an environmental tax. Producers of renewable electricity (utilities and independent power producers) receive for each kilowatt-hour provided to the grid a subsidy, which is financed by an environmental tax throughout the country on conventional energy consumption. Producers and utilities can also trade green energy certificates among themselves to meet their obligation under the RPS.

England has recently implemented an RPS with tradable certificates (called the Renewables Obligation). This replaces its system of the past decade, which involved competitive bidding by potential renewables generators for funds collected from all customers in a tariff charge called the Non-Fossil Fuel Obligation. That system did not stimulate as much renewables production as did the feed-in tariffs for producers of Denmark, Germany, and Spain, but it did lead to declining bid prices for electricity offers to the grid from renewables producers. Sweden, Belgium, and Austria implemented RPS policies in 2003 and several other European countries are close to implementation. Denmark has been known for its generous feed-in tariffs that have fostered the dramatic growth in wind power in that country. But the subsidies are a substantial drain on public resources (100 million Euros in 1998), and the Danish parliament recently developed legislation to create an RPS, slated for implementation in the 2004–2005 period.

3.3 Australia

The Australian federal government enacted a nationwide RPS in 2001 to operate within its competitive electricity market. The policy includes a certificate trading scheme.

4. PRELIMINARY ASSESSMENT

The RPS is a policy tool to expand production of renewable-generated electricity to reflect what its role would be if long-run social costs instead of short-run financial costs were the determinant of electricity generation investment. By establishing a guaranteed market share for renewables producers, the RPS provides a strong incentive for new renewable investment, an ongoing motivation for current and new renewable producers to reduce costs, and a relatively sure means of attaining environmental targets while reducing the requirement for government financial and managerial involvement. The RPS can be applied both to electric utilities that are regulated monopolies and to competitive independent producers, but it is generally associated with jurisdictions that have reformed their electricity sector to increase competition in electricity generation. Several European countries, several U.S. states, and Australia have thus far implemented the RPS, but it is under active consideration in many other jurisdictions. Legislation and implementation are underway for an EU-wide RPS in Europe and a federal-level RPS in the United States.

It is too early to provide an empirical evaluation of the RPS relative to alternative mechanisms. However, the survey reported in here provides

information on the critical considerations in designing an RPS and a general sense of the choices being made by different jurisdictions. A few generalizations can be offered at this early stage in the development of the RPS.

The selection of the RPS target involves a three-way trade-off between environmental improvement, long-term technology strategy, and short-run cost. Jurisdictions that are especially focused on getting the greatest environmental improvement at the least cost will have only one standard for all renewables and may even include technologies that are not renewables. Jurisdictions that are interested in long-term development of advanced renewables technologies will tend to have categories of renewables (and perhaps environmentally desirable technologies that use fossil fuels), ensuring a more diverse mix of renewables and associated clean technologies. Most jurisdictions are concerned with the uncertainty of cost, so cost caps or equivalent mechanisms are common.

In terms of eligibility, most jurisdictions are starting out conservatively, limiting the scope to local renewables, excluding off-grid renewables, and trying to make sure that truly new renewable resources result from the RPS. Geographic application of policies is usually limited to individual electricity jurisdictions. However, with Australia's federal system as an example, there are efforts at the U.S. federal level and the EU level for multi-jurisdictional application. The general tendency is to apply the standard to providers rather than to consumers of electricity. The standard is almost universally applied to energy production rather than to capacity, which is consistent with environmental objectives.

Flexibility mechanisms are widely accepted as desirable. Their implementation is slowed by the administrative complexity that they can entail. Administration of the RPS in the United States and Australia is conducted through a combination of government and delegation to electricity regulators. In Europe, it is more in the domain of government at this point, but various institutional reforms are being undertaken. Thus far, all jurisdictions implementing a RPS have continued with at least some of the other policies that support renewables, whether these be research and development and demonstration projects, tax credits, or subsidized feed-in tariffs. This final point reintroduces the more fundamental concern about how the RPS compares to alternative policies, given the public objectives it was meant to serve. Critiques have argued that the RPS is inevitably flawed because it forces the adoption of particular forms of energy, even though these are but indirect means to an end, such as environmental improvement. In so doing, the RPS may delay or prevent the development and commercialization of technology innovations that would more economically achieve the same objective. If, for example, a key motive for the RPS is to reduce greenhouse gas emissions, a policy focused directly on these emissions—such as a greenhouse gas tax or emission cap and tradable permit system—would open the door to technologies such as the production of hydrogen from coal with capture and permanent storage of all potentially harmful by-products in geological formations. Conceivably, this or other alternatives to renewables could meet all of the public objectives behind the creation of the RPS at a much lower cost, freeing resources for other social objectives.

Advocates of renewable energy have countered that nonrenewable resources such as "clean coal" cannot possibly outperform renewables in providing affordable energy while also satisfying long-term environmental, security, and social objectives. A less exclusionary argument in favor of the RPS is that renewables are likely nonetheless to be part of a future energy mix that might one day also include cleaner fossil fuel and nuclear technologies, but that renewables need special help at this stage to pass critical commercialization thresholds.

In particular, the RPS has several attractive features for driving long-run technological change in renewables. It can provide an incentive that influences the contribution of renewables to new electricity generation investment without changing the costs and economic viability of existing facilities; thus, it produces technological change at a pace consistent with the natural rate of equipment stock turnover and does not force economic obsolescence on existing equipment. For consumer prices, the higher costs of new renewables are blended with the lower costs of existing, conventional generation; price changes are therefore negligible and the likelihood of political acceptability is greater. The RPS ensures that renewables attain critical commercialization thresholds that should enable them to achieve economies of learning and economies of scale, with their costs of producing electricity falling accordingly. If the RPS includes tradable certificates and other flexibility mechanisms, it reduces the policy cost and again increases the likelihood of political acceptability. The RPS can be closely linked to environmental objectives because it provides a higher

level of confidence of the environmental outcome than do price-based policies. The RPS does not require government subsidies, and can even allow a reduced role for government in the policy's administration, because this role is delegated to electricity regulators. Finally, RPS targets can be set and adjusted to ensure that the costs of renewables expansion are not significantly greater than those of alternative means of achieving the slate of policy objectives they are intended to satisfy.

Glossary

altricial When offspring are hatched or born at an early stage of development.
basal metabolic rate (BMR) Resting metabolic rate of a homeotherm measured at thermoneutrality.
energy budget Partitioning of energy expenditure into the competing demands of maintenance, growth, reproduction, and storage.
gestation Period of embryonic development in live-bearing vertebrates.
iteroparous More than one reproductive event per lifetime.
lactation Period of milk production in mammals.
life history trade-offs Constraining relationships among life-history traits (e.g., current reproduction and survival, current reproduction and future reproduction, number and size of offspring).
life history traits Traits that define the life cycle of an organism (e.g., size at birth, growth pattern, mode of reproduction, age and size at reproductive maturity, size of offspring, fecundity, reproductive life span, longevity).
oviparous Egg laying; offspring develop within eggs outside a female's body.
precocial When offspring are hatched or born at an advanced stage of development.
production energy Energy allocated to growth (e.g., lean somatic tissue), storage (e.g., lipid deposition), and reproduction (e.g., gonadal recrudescence, gametogenesis, egg production).
reproductive effort Proportion of total energy devoted to reproduction within a biologically meaningful time interval.
reproductive success Number of offspring produced by an individual.
semelparous One reproductive event per lifetime.
viviparous Live-bearing; offspring develop fully or partially within the female reproductive tract.

The amount of energy that an animal can devote to reproduction is limited. The habitat in which an animal lives may contain limited food and/or water resources (e.g., deserts, high altitudes), environmental conditions may limit energy acquisition by reduced foraging activity (e.g., predation, daily or seasonal weather extremes), and there are morphological and physiological constraints on the rates at which food can be obtained and processed. Within an individual, energy must also be allocated to physiological processes and behavioral activities associated with survival and growth (e.g., foraging, thermoregulation, predator evasion). Thus, the total energy that an animal obtains must be allocated in such a way that balances maintenance, growth, reproduction, and survival.

1. INTRODUCTION

Life history traits largely determine how the energy intake of an animal is allocated to reproduction, growth, and survival. Some life history traits include the size of an animal at birth (or at hatching), the age and size at which an animal reaches reproductive maturity, how it reproduces (oviparous or viviparous), how often it can reproduce (semelparous or iteroparous), the length of time it is reproductively

 © 2004 Elsevier Inc. All rights reserved.

active, the number and size of offspring produced, and its expected age-specific mortality and longevity. Constraints or trade-offs exist among life history traits, many of which are physiological and relate to energy management. A classic example of such a trade-off is size versus number of offspring. The allocation of energy by an adult female to produce larger offspring may improve the offspring's chances of survival, but it also can reduce the number of offspring that the female can produce. Another trade-off is between the energy allocated to current reproduction and future survival. If an animal allocates too much energy to reproduction, not enough energy will be available for maintenance or vice versa. After fat reserves are depleted, other body tissues (muscle mass) are metabolized for energy and body condition declines. Deterioration in body condition and immune function contributes to susceptibility to predators, parasites, and disease, eventually leading to death. In semelparous species (e.g., salmon), this is exactly what happens; an individual allocates all available energy to a single burst of reproduction and then dies (termed "big bang" reproduction). Iteroparous species are those that have a long enough life span that they have a high probability of surviving to reproduce more than once, and their life history traits tend to balance energy allocated to current reproduction and maintenance. Iteroparous species also illustrate another important life history trade-off: current reproduction versus future reproduction.

Longevity, age-specific mortality schedules, and reproductive life span also have a strong influence on the patterns of energy allocation to reproduction as individuals age. For example, some species invest less energy in reproduction when they are young and relatively small in body size than when they are older and larger. Smaller individuals have fewer energy reserves than do larger individuals, they have less space in their body cavity (limiting the number of eggs or offspring they can produce), and they have a narrower pelvic canal that limits egg or offspring size. Thus, smaller individuals are constrained both energetically and anatomically and, thus, produce fewer and/or smaller offspring rather than more and/or larger individuals. By allocating less energy to reproduction, smaller individuals can allocate more energy to growth—building up body condition and attaining larger body size more quickly than if they allocated less energy to growth. When individuals are older and larger, they can better afford to allocate a greater proportion of their energy to reproduction and do so when it enhances their reproductive success. The question arises as to why young and small iteroparous animals should reproduce at all. Why not allocate energy to growth and delay reproduction until they are larger? In fact, many species do delay reproduction when they are young, even though they are physiologically mature and able to reproduce. The age-related schedule of energy allocation to reproduction in a given species is part of a suite of life history traits that coevolve to optimize the balance of energy allocated to maintenance, growth, reproduction, and survival.

Reproductive energetics is also a central aspect of theories that explain sexual selection and the evolution of mating systems. Bateman's concept of anisogamy (differential investment by each sex in gametes) and Triver's concept of parental investment are at the root of the relationship among reproductive energetics, sexual selection, and the evolution of mating systems. In general, females allocate energy to relatively few, but energetically expensive, eggs. In some species, females make a substantial energy investment in gestation, lactation, and other forms of parental care. Thus, the reproductive output of females is limited primarily by energy resources. Because variance in female reproductive success is relatively low, the influence of sexual selection on females is relatively weak. In contrast to females, males allocate minimal energy for the production of sperm; thus, male reproductive success is not usually limited by the amount of energy available for gamete production. Instead, male reproductive success is limited by the ability to compete for and successfully mate with females. As a consequence, males often invest a considerable amount of energy in activities and traits associated with mating success (e.g., advertisement displays, territorial defense, agonistic encounters, courtship, large body size, structures used for courtship or intermale combat). In addition, males that are emancipated from parental care typically invest time and energy in defending or pursuing multiple mates, contributing to a polygynous mating system, and engaging in intense intermale competition for mates. For other species, both males and females (or, in rare cases, males alone) are required to invest time and energy in caring for offspring. Caregiving males rarely have the time and energy to pursue multiple mates; thus, a monogamous mating system usually results. Although monogamous males also expend energy to compete for mates, their reproductive success does not vary as much as that of polygynous males; thus, intermale competition and the influence of sexual selection on males are not as intense as in polygynous systems.

2. HOW ENERGY IS EXPENDED FOR REPRODUCTION

Because of wide variation in life history traits, reproductive biology, and mating strategies, the ways in which energy is expended for reproduction differ greatly among species and between the sexes. Because most vertebrate species breed seasonally, they do not typically produce gametes year-round, and many species maintain nonreproductive gonadal tissues in a reduced state. Thus, the initial investment of energy into reproduction actually begins prior to mating when energy is expended for gonadal recrudescence. Once hormones are produced, they stimulate the development or enlargement of the testes, ovaries, and oviducts or uterus. Once the reproductive organs are ready, energy is expended to produce gametes. For males, this includes spermatogenesis and production of seminal fluids. For females, egg production starts with oogenesis but goes beyond the simple production of sex cells. Oviparous reptiles and birds allocate a considerable amount of energy to egg production; eggs are provisioned with a large mass of energy-rich lipids or yolk, egg white (water and albumen), and a calcified eggshell. In comparison, viviparous (live-bearing) mammals produce eggs that contain little stored energy but allocate a large amount of energy to carry and nourish developing embryos—and for lactation to nourish offspring for all or part of the period of postnatal growth.

In addition to physiological investment in reproduction, a large amount of energy is expended for reproductive activities. Examples of reproductive activities include finding and defending a suitable territory or nest site, fighting or repelling competitors, collecting nest materials and building a nest or excavating a burrow, and finding, choosing, and courting a mate. The act of copulation is a reproductive activity, as is the laying of eggs, giving birth to live offspring, and guarding, burying, incubating, or carrying eggs. Males of some species actively guard their mates prior to and/or after copulation to ensure paternity. For crocodilians as well as many bird and mammal species, reproductive activities in the form of parental care may continue long after offspring are hatched or born. These activities include feeding the offspring while they are unable to forage for themselves, guarding them from predators, and tutoring them in social and survival skills. In some cases, it may be difficult to draw the line as to whether a particular activity should be classified as reproductive. Nonbreeding types of activities that occur during the breeding season may occur more frequently to support reproduction. For example, some animals might need to forage and feed more often prior to or during the breeding season to support reproduction, and males might forage to provide nuptial gifts to impress prospective mates or to feed nest-bound mates that incubate eggs or guard offspring. Many animals (mostly birds and mammals) exert some degree of thermoregulation to survive, but reproductive females might need to maintain higher than normal body temperatures and basal metabolic rates (BMRs) to promote the optimal development of offspring or to increase the rate of digestion, assimilation, and egg or milk production.

3. TECHNIQUES USED TO STUDY REPRODUCTIVE ENERGETICS

Because energy is expended for reproduction in so many different ways, quantifying this energy is often complicated and difficult. As a result, many studies examine only part of the energy expended for reproduction. One of the easiest components of reproduction to determine is the energy allocated to the storage of fat and the production of eggs. Lipid extraction is used to separate body fat from lean tissue and to quantify the energy contained in body fat. Bomb calorimetry is used to determine the energy content of eggs and lean body tissues (Table I). Changes in body mass and body composition observed in a cohort of individuals over time, and the energy content of fat and lean tissue, can be used to calculate the amount of energy allocated to storage and/or growth (Fig. 1).

Another technique used to examine reproductive energetics is laboratory respirometry (Table I). Respirometry is used to measure metabolic rates (in milliliters O_2 consumed per hour or CO_2 produced per hour) of inactive animals held at species-typical body temperature(s). BMRs (in mammals or birds) and standard metabolic rates (SMRs) (in reptiles) of fasted sleeping animals are the lowest rates of energy metabolism and represent the amount of energy expended for basic body functions. Resting or maintenance metabolic rates (RMRs) are determined in inactive or sleeping animals digesting food and so include the cost of digesting and assimilating food (specific dynamic action). Some studies have determined metabolic rates of animals engaged in various activities. Laboratory metabolic rates have frequently been used to extrapolate the amount of total energy expenditure, with extrapolated values then being used

TABLE I

Analytical Techniques Used to Study Reproductive Energetics of Terrestrial Vertebrates

Activity profiles: Time budgets detailing the amount of time spent in various activities. They may be combined with respirometry to calculate the amount of energy allocated to activity and maintenance.

Lab respirometry: Measures the metabolism (in milliliters O_2 consumed and/or CO_2 produced per hour, converted to joules of energy) of inactive animals under laboratory conditions.

Doubly labeled water: Determines the daily energy expended or consumed (in milliliters CO_2 per day, converted to joules of energy) by free-ranging animals. Isotopes of oxygen (O–18) and hydrogen (deuterium or tritium) are injected into an animal, blood samples are taken over two or more intervals of time, and then the turnover rate in isotopes is used to calculate the amount of energy consumed during that time by oxidative metabolism.

Lipid extraction: Used to separate and quantify the energy contained in whole body lipids. An animal carcass is dried to a constant mass and macerated, and solvents are used to extract the lipids for further analysis.

Bomb calorimetry: Determines the energy content of organic substances (e.g., body tissues, eggs). Dried material is incinerated in high-pressure oxygen in a stainless steel container at a constant volume. The heat produced by the reaction is absorbed by water surrounding the container, and the change in water temperature indicates the amount of energy released.

Energy budgets: Where data from several different techniques are combined to partition total metabolizable energy into that allocated to competing categories of resting maintenance, activity maintenance, and production.

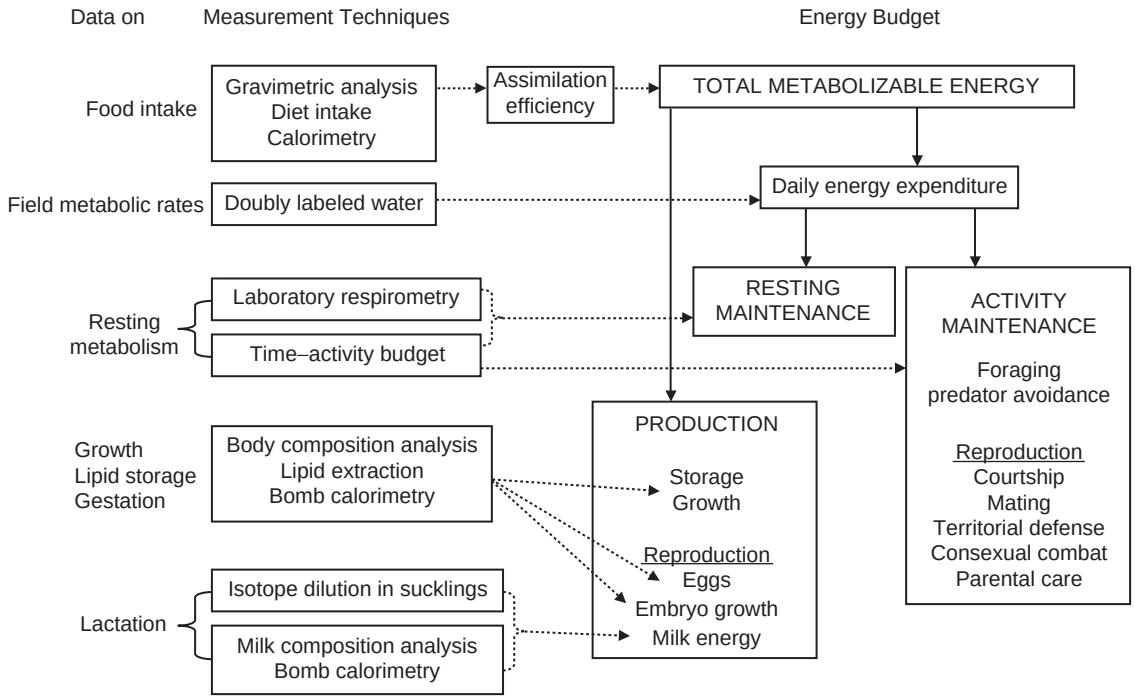

FIGURE 1 Schematic diagram of a generalized energy budget used to examine reproductive energetics, including the type of data used, measurement techniques and definitions of energy budget components, and methods used to construct an energy budget. Modified from Kunz and Nagy (1988)

to construct energy budgets (Fig. 1). Similarly, RMRs combined with time–activity budgets can be used to estimate the energy allocated to maintenance or resting metabolism for a fixed interval of time.

The doubly-labeled water (DLW) method (Table I) is used to determine the total daily energy expenditure (DEE) (in kilojoules per day) of free-ranging animals under field conditions. The DLW method is the only energy measurement technique that includes the energy allocated to activity under natural conditions. Thus, the DLW technique can be used in combination with other techniques (Fig. 1) to examine the energy allocated to reproductive activities.

Energy budgets combine several techniques to partition total energy expenditure into compartments of maintenance, growth, reproduction, storage, and export (as milk). The construction of an energy budget requires several different techniques (Table I): (1) the DLW method to determine daily energy expenditure, (2) laboratory respirometry and time–activity budgets to calculate energy expended for maintenance, (3) bomb calorimetry to measure the energy content of eggs (for birds and oviparous reptiles), (4) quantification of energy accumulated prior to breeding (fat), and (5) the amount of energy exported as milk by mammals. If one can quantify the total energy expended by an animal, the energy expended for maintenance metabolism, the energy allocated to egg production in reptiles and birds and to embryonic growth and milk production in mammals, and energy allocated to growth, the energy that is allocated to activity can be estimated by subtraction. The energy expended for reproductive activities can then be estimated based on time–activity profiles and the amount of energy stored in fat or exported in milk.

A difficult part of examining reproductive energetics is determining the appropriate temporal schedule of reproduction. Although a few species are semelparous and reproduce only once before they die (e.g., salmon, spiders, many insects), this is not a typical reproductive pattern in vertebrate animals. Most species are iteroparous (reproducing more than once) and may reproduce once per year for several years in succession or even multiple times per year, whereas others may skip years. A reproductive period or season may be relatively short for some species (a few weeks or months), whereas other species may spend several months or years providing parental care to ensure the survival of their offspring (e.g., alligators, primates, elephants). In some iteroparous species, the amount of energy allocated to reproduction varies greatly with age. Thus, for some species, it may be necessary to investigate the reproductive energetics of a cohort of individuals over their entire life span.

4. REPRODUCTIVE ENERGETICS OF REPTILES

4.1 Territorial and Courtship Activities

There are many different types of mating strategies exhibited by reptiles, but most fall within two basic patterns of behavior: territorial (most lizards and crocodilians) and nonterritorial (most snakes and turtles). In territorial species, one or both sexes (usually males) actively defend a fixed area to monopolize the resources (food, shelter, or nest sites) and/or the mates (usually females) residing within it and to prevent intrusion or takeover by consexual competitors. Territoriality should evolve when the benefits (e.g., access to resources such as space, food, and females) exceed the costs incurred (e.g., energy expenditure, risk of injury). A large amount of energy is expended for territorial activities, including visual and/or chemical signals used to advertise the territory holder's presence and territorial boundaries, aggressive interactions and/or combat with consexuals, and territorial patrol to detect and repel intruders.

Nonterritorial reptiles may stay within a well-defined or loosely defined home range that is not defended, or they may roam widely in search of mates. Although nonterritorial reptiles often use chemical signals to find mates, they do not typically invest energy in the conspicuous and frequent visual signaling and patrol activities characteristic of territorial males. However, it is typical of both territorial and nonterritorial reptiles to invest energy in aggressive conflicts and combat with consexuals, especially if males are competing for a territory or a female.

During agonistic encounters, male lizards of many species typically perform head-bob or push-up displays accompanied by size-enhancing displays and body postures, mouth gapes that convey the threat to bite, and ritualized circling and jaw sparring with opponents. Males in some snake species also exhibit ritualized combat. Male rattlesnakes wrap around each other and raise their upper bodies off the ground, and then each attempts to wrestle and pin its opponent's head to the ground. Even some male turtles (e.g., snapping turtles, wood turtles, gopher tortoise) inhabiting the same area may fight each other to establish their position in a dominance hierarchy to gain the privilege of mating with females.

Most reptile species invest energy in some type of courtship behavior. Because females are typically choosier than males about their mating partners, it is usually the males of the species that do most of the courting in an attempt to persuade females to mate with them. Courtship in reptiles typically consists of species-specific visual displays (e.g., lizard head-bob displays, display of colored skin patches), acceptance or rejection behaviors (usually given by females), and/or tactile behaviors (e.g., licking, stroking, biting, chin rubbing) exchanged between the sexes. Reptiles do not exhibit the elaborate courtship rituals often observed in birds.

The amount of energy that reptiles allocate to copulatory activity varies greatly with the type of mating system. Some reptile species copulate only once or a few times during a breeding season, whereas others copulate repeatedly, especially polygynous males. For example, males of the green anole (*Anolis carolinensis*) expend energy to court and mate with an average of three females residing within their territory, mating repeatedly with each female roughly once each week for the duration of a 4-month breeding season. Because the purpose of territorial behavior is to exclude male competitors, territorial males do not usually guard their females directly after mating. Nonterritorial species may be polygynous, promiscuous (both sexes mate with multiple individuals), or even monogamous. In some nonterritorial species, males expend energy to guard their mates following copulation to prevent them from mating with other males. Guarding their mates may also preclude males from mating with other females (hence, they are monogamous), and a few species form long-term pair bonds that span multiple reproductive seasons (e.g., snow skinks [*Niveoscincus microlepidotus*], sleepy lizards [*Tiliqua rugosa*]). The duration of copulations, and thus the amount of energy allocated to copulation, also varies widely, even among closely related species. Some *Anolis* lizards have copulations lasting for several seconds, whereas males of *A. carolinensis* average approximately 25 to 30 min for a single copulation. In many vertebrate taxa, the duration and frequency of copulations are related to the intensity of sperm competition in a species, although studies addressing this issue in reptiles are currently lacking.

Four studies on lizards have quantified the energy expended for activities during the breeding season, and all of the species examined are territorial and polygynous (Table II). For a single reproductive season, the proportion of energy expended for activities during the breeding season ranged from 23 to 57% of total energy expended during that time. For males of *A. carolinensis,* nearly all of their activity is devoted to reproduction (e.g., only 1–2% of their day is spent foraging) and nearly half of their total energy expenditure is allocated to reproductive activity (Table II).

4.2 Gamete Production

Reptiles are similar to most vertebrate species in that males typically allocate little energy to producing sperm. The amount of energy that gonadal recrudescence and sperm production requires has not been

[a] Key to mating system: T, territorial; NT, nonterritorial; P, polygynous; PR, promiscuous.

[b] Reproduction: energy allocated to breeding season activity by males, and to breeding season activity + eggs for females.

[c] TME: Total metabolizable energy, calculated as daily energy expenditure during the breeding season + energy allocated to eggs.

[d] TME/body mass$^{0.8}$: TME adjusted for interspecific differences in body size, to facilitate interspecies comparisons.

quantified, but it is likely to be a very small amount relative to the energy expended for other aspects of reproduction. In contrast, nearly all female reptiles allocate a considerable amount of energy to producing large eggs that contain energy-rich yolk. The size and number of eggs produced by different species varies considerably. However, the amount of energy contained in egg materials is very similar among reptile species, averaging approximately 6 calories per milligram of dry egg mass. The amount of energy allocated to eggs by lizards ranges from 13 to 48% of total energy expended during the breeding season (Table II) and from 7 to 13% of total annual energy expenditure. Similarly, the painted turtle (*Chrysemys picta*) allocates approximately 14% of its annual energy to eggs.

4.3 Nest-Related Activities, Incubation, and Parental Care

Because most reptiles produce precocial and independent offspring that develop and hatch from shelled eggs (ovipary), reptiles rarely allocate energy to parental care activities. Instead, reptile species provide a form of nutritional parental care by provisioning their eggs with "extra" yolk that nourishes the hatchling for days or weeks after emergence from the egg. Female reptiles may also allocate energy to digging holes or nest cavities in which they lay eggs and then cover them with substrate (e.g., most turtles, many lizards). In crocodilians and some snake species, females construct a nest mound made from soil or vegetation in which to lay eggs, where decaying organic matter provides heat for optimal incubation temperatures. In species with relatively small eggs and/or clutches (e.g., *Anolis* lizards lay single-egg clutches), burying eggs may require a relatively minor amount of energy relative to other reproductive activities. In species with large eggs, large clutch sizes, and/or long travel distances to find nest sites (e.g., sea turtles travel many miles to lay eggs on natal beaches), the energy expended for nest-related activities may constitute a substantial energy investment.

In addition to nest construction, some reptile species guard their nest of eggs for all or part of their development (e.g., king cobras, crocodilians, pythons, some lizards). Female alligators construct and guard their nest of eggs and then protect their young for up to 2 years. Female Burmese pythons (*Python molurus*) actually incubate their eggs by coiling around them and rhythmically contracting their body muscles, generating metabolic heat to maintain the optimal incubation temperature of 30°C. The increase in energy expenditure associated with incubation for female pythons is 2 to 20 times higher than that for females that are not incubating, with an inverse relationship between ambient temperature and the rate of energy expended; that is, it takes more energy to keep the eggs warm at cooler ambient temperature.

4.4 Egg Retention and Gestation

Most reptiles (chelonians, crocodilians, tuataras, and most lizards and snakes) are oviparous. They lay eggs with relatively undeveloped embryos and a large yolk mass containing enough energy to support embryonic development. For the most part, oviparity excludes the energetic costs of gestation. However, as many as one-fifth of squamate species (snakes, lizards, and amphisbaenids) exhibit various degrees of viviparity that require some amount of energy expended for gestation. At one end of the ovipary/vivipary continuum, there are many oviparous squamates that retain developing eggs in the oviducts for some length of time. Further along this continuum, ovoviviparous females provide eggs with yolk for embryo development, but eggs are enclosed by a noncalcified shell or membrane and remain in the oviduct until completely developed (e.g., *Boa constrictor*). Various intermediate states include some species providing both a yolk mass and some type of placental nutrition of embryos (e.g., garter snake [*Thamnophis sirtalis*]) or a highly vascularized oviduct (e.g., common lizard [*Lacerta vivipara*]). At the other end of the continuum, a few species exhibit extremely reduced yolk mass, and offspring are attached and nourished by a placenta formed from uterine tissue and extra-embryonic membranes (euvivipary) (e.g., skinks [*Mabuya heathi* and *Chalcides chalcides*]).

In addition to nutrition that may be provided directly to offspring, there are a number of energetic costs for egg retention and embryo gestation that do not occur with strictly oviparous species. Egg-retaining/Gestating females must expend energy to behaviorally thermoregulate and maintain optimal body temperatures for developing embryos. In addition, if egg-retaining/gestating females maintain higher than normal body temperatures (and studies show that many do), this in turn increases their own temperature-dependent maintenance metabolism. Energy is also expended to carry around the bulk and mass of the eggs and/or developing embryos. Other types of costs for egg retention and embryo gestation include decreased mobility and greater

susceptibility to predators, smaller offspring and/or clutch sizes, and lower rate of offspring production. Given all of the potential costs, there must be tremendous selective pressure on some species to evolve toward some degree of viviparity. The potential benefits of egg retention or gestation include optimal temperatures for embryonic development, delayed oviposition (or birth of live offspring) when environmental conditions (e.g., moisture, temperature) are unfavorable to embryonic development within eggs, and protection of eggs from predators, bacteria, and fungi. There is a strong trend for egg retention and viviparity to occur in squamates at high elevations, where extremes in temperature, humidity, and low atmospheric oxygen concentration inhibit or preclude embryonic development if eggs were subject to these conditions. Clearly, egg retention and various forms of gestation have both costs and selective benefits in terms of energy allocation and mortality risk versus increased offspring survival and reproductive success, making the evolution of egg retention and viviparity an example of another life history trade-off.

5. REPRODUCTIVE ENERGETICS OF BIRDS

5.1 Territoriality, Courtship, and Mating

The vast majority of bird species (>90%) have a monogamous mating system in which individuals (typically males) compete with each other for access to mates and resources critical to mating. When mates or resources are economically defendable, individuals monopolize mates and/or resources through territorial behavior. The area defended may be large and contain mates or resources important to reproduction (e.g., food, mating, nest sites), or it may be small and encompass only the space immediately surrounding the nest to protect the offspring, nest, nest site, and/or nesting materials (e.g., colonial nesting species). Song is one of the most conspicuous and energetically demanding aspects of territorial behavior of birds. Birds (mostly males) use species-specific songs to advertise their presence in a territory, to repel potential intruders, to find and attract potential mates, and to stimulate female reproductive physiology and behavior. Studies have shown that normal males rendered mute experimentally are far less effective at repelling intruders and/or maintaining their territory and mates than are vocal males. Laboratory respirometry was used to determine the energy expended for singing in captive male Carolina wrens (*Thryothorus ludovicianus*). Their metabolic rates while singing were 2.7 to 8.7 times higher than their RMRs. Another example of energetically demanding territorial behavior is the rapid and loud drumming of woodpeckers (males rapidly tap their beaks on hollow trees or other resonant structures) and grouse (males beat their wings in the air or on their breasts while standing on logs, boulders, or tree roots).

In addition to advertising a male's presence in a territory, the frequency and/or intensity of bird song or drumming may indicate male body condition and/or energy reserves and may be a signal used by males to assess competitive ability or used by females to make mate choice decisions. In addition to singing and drumming, some birds expend energy for territorial patrol of their territory to detect and repel conspecific and/or heterospecific intruders, using visual threat displays and/or chasing to protect resources and/or offspring. When threat displays and chasing fail to oust intruders, escalated aggression can involve direct combat and the risk of physical injury. It has been estimated that some males expend up to a third of their daily energy expenditure, or up to 2.4 times the cost of BMR (in house martins [*Delichon urbica*]), for territorial activity. Perhaps because territorial advertisement is energetically costly and attracts the attention of predators, females of many bird species do not sing or call for territorial reasons or they do so much less frequently than do conspecific males. Although females do not advertise their territory, they too may chase off conspecific females to protect their offspring or resources important to reproduction.

As a result of competition among males for mates, sexual selection results in male birds expending energy for conspicuous traits and behaviors used to influence female mate choice. Males of many bird species exhibit colorful and/or modified feathers and/or structures (e.g., "red-wing" blackbirds, yellow- or orange-crested cockatoos, multicolored macaws, greatly elongated and colorful tail feathers of peacocks, wattles and combs of roosters). The conspicuous ornaments of male birds may require a minor amount of energy to produce relative to total energy expended for reproduction, but these traits may also be costly to males because they attract the attention of predators or reduce a male's ability to evade predators (e.g., long tail feathers). In addition, the quality and/or size of these traits may reflect the energy stores, body conditions, and general health of individuals and could be an important signal to male competitors and

potential mates. For instance, bright and intensely colored traits could indicate that males are free of parasites and/or disease that could otherwise compromise their ability to defend their territory or that could be transmitted to mates or offspring. Quality of male ornaments may also indicate the genetic quality of individuals, that is, parasite and/or disease resistance that will be passed to offspring or inherited traits preferred by females that confer reproductive success to those males and their future offspring.

Males expend a considerable amount of energy to show off their conspicuous ornaments, using complex and ritualized behaviors or activities to court females. Courtship displays may consist of aerial dances or ritualized sequences of behaviors performed on the ground, in trees, or on the water (e.g., head bows; fluffed feathers; erected crests; fanned, waved, or flapped wings; choreographed hops or steps), and all of these displays may be combined with vocalizations. Male bowerbirds build elaborate bowers out of vegetation, often decorating them with feathers, paper, string, or other colored objects, and then use the bowers as performance stages or backgrounds for their ritualized courtship dances. In some bird species, several males congregate in "leks" and simultaneously display and exhibit their ornaments to observing females, who evaluate them and their performances before choosing their mates. Male jays, cardinals, terns, and other species also expend energy to forage for food items presented to prospective or current mates as nuptial gifts. Courtship displays and activities often require a large investment of energy to perform, especially if performed repeatedly. The daily energy expended by male sage grouse (*Centrocercus urophasianus*) performing strut displays toward females may be twice that of nondisplaying males and positively correlated with the number of struts performed per day. In many species, the frequency or intensity of courtship behaviors is correlated with the displayer's condition (i.e., sufficient energy intake to support the activity and maintain body condition) and/or with female mating preferences. Researchers have found that female sage grouse that choose among displaying males on a lek preferred those with the highest strut rates, and a positive correlation between male foraging distance and strut rate suggests that display vigor indicates male endurance and foraging skill.

Female birds rarely exhibit the bright colors, elaborate structures, or ritualized courtship behaviors and activities observed in conspecific males, possibly because these traits are selected against in females and are costly in terms of energy expenditure and susceptibility to predators. However, in some cases, females participate in male courtship rituals, especially when they are receptive to the courting males.

Although a single copulation is generally very brief in birds, the energy expended for copulatory behavior varies considerably. Some species copulate only a few times during the breeding season, whereas other species copulate hundreds of times. The frequency of copulations and the energy expended in this activity are related to sperm competition and paternity. Although the vast majority of bird species are socially monogamous, extra-pair copulations are common in most species. In general, the less assured a male is of paternity, the more frequently he will copulate with a female. For species in which a male guards the female before and after copulation and until her eggs are laid, the male has a reasonable assurance that the female has not mated with other males and that only one or a few copulations are required for him to fertilize her eggs. For a male that leaves his mate for extended periods of time, either to forage for food or to copulate with other females (a polygynous male or a monogamous male seeking his own extra-pair copulations), it is possible (or in some cases probable) that his female has copulated with one or more other males. Because males in many bird species invest a large amount of energy in parental care to raise offspring, it is crucial to a male's reproductive success to ensure that his sperm fertilizes his mate's eggs. Frequent copulations with a female may increase a male's paternity by inseminating a greater quantity of sperm, and/or by providing fresh sperm, to compete with sperm inseminated by other males. Studies using DNA markers have revealed that paternity in birds is influenced by copulation frequency, sperm number, fertilizing capacity of sperm, and the timing of insemination relative to other inseminations and to oviposition. Frequent copulations require greater sperm production, and many studies on birds have documented that large testes produce greater numbers of sperm than do smaller testes. Therefore, it is not surprising that copulation frequency is positively correlated with testis size in many vertebrate taxa, including birds. Because large testes may evolve in response to sperm competition, relative testis size provides a measure of the intensity of sperm competition in various species.

5.2 Gamete Production

Because most birds are seasonal breeders that produce gametes only during the reproductive season, energy

is allocated to gonadal recrudescence prior to the breeding season for both sexes. However, the increase in testes size equates to roughly 2% of the cost of male BMR, and the increase in ovary and oviduct mass constitute 2 to 9% of the cost of female BMR. Thus, females expend more energy than males for gonadal recrudescence, but for both sexes it is a relatively trivial amount compared with the amount of energy expended for other aspects of reproduction.

Although the amount of energy allocated to sperm production varies depending on copulation frequency, males still allocate a very small amount of energy to sperm and ejaculate production. For example, the energy that male chickens require to produce semen accounts for less than 1% of the amount expended for BMR. In contrast, females allocate a tremendous amount of energy to egg production. The total amount of energy allocated to egg production in a reproductive season depends on the number of eggs produced, egg size, and the amount of energy contained in the eggs, and these factors are influenced by female body size, energy availability, and the particular life history traits of the species. Although the total amount of energy allocated to egg production varies among individuals and species, the amount of energy contained in the eggs themselves generally is proportional to the developmental stage of the offspring at hatching (Fig. 2). The eggs of birds that produce altricial offspring tend to contain a relatively small proportion of yolk (24% of wet egg mass) and less energy (4.7 kJ/g of wet mass) in comparison with most precocial species (40% of wet egg mass). The eggs of extremely precocial species (e.g., Australian megapodes such as the brush turkey [*Alectura lathami*]) contain the greatest proportion of yolk (up to 65% of wet mass) and the greatest amount of energy (12.3 kJ/g of wet mass). Altricial offspring also tend to have the least amount of energy remaining in yolk sacs after hatching (used for development and growth [average 8% of hatchling body mass]), whereas precocial species tend to have a greater amount of energy left in yolk sacs after hatching (average 15% of hatchling body mass). The total energy allocated to egg production in various bird groups has been estimated at 40 to 170% of the energy expended for BMR.

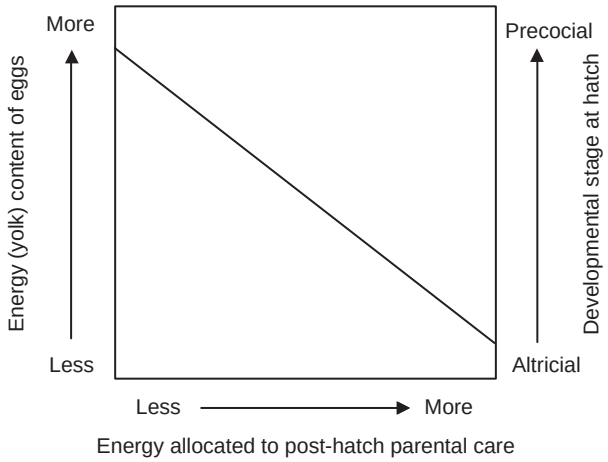

FIGURE 2 General trends in the relationships between the energy content of eggs, the energy allocated to post-hatch parental care, and the developmental stage of avian offspring at hatch.

5.3 Nest Building and Incubation

Because all birds are oviparous, nearly all species expend energy to collect nest materials, construct or excavate nests, and incubate eggs. Exceptions to this generalization include several species of parasitic birds (e.g., cowbirds) that lay their eggs in the nests of other species (or, more rarely, in the nests of conspecifics), leaving eggs to be incubated and cared for by the nest owners. Although birds invest a substantial amount of time and effort in constructing nests, the energetic cost of this effort has not been examined.

Egg incubation in birds consists of maintaining a clutch of eggs at the optimal temperature for embryonic development until they are hatched. Most birds use their own body heat to maintain egg temperatures (except megapodes, which bury and tend eggs in mounds of organic matter and depend on external sources of heat such as solar radiation, plant decomposition, and geothermal heat). The transfer of body heat to eggs and the monitoring of egg temperature are facilitated by a highly vascularized and bare patch of skin called a brood patch. In many monogamous species, each sex takes its turn incubating the eggs while the other mate forages for food. In some species, the female continually incubates the eggs while her mate provides her with food. Egg incubation may also be performed by only one parent (usually the females, although a polyandrous male may also incubate), but that parent must either forgo feeding during incubation or occasionally leave the eggs to find food. When environmental temperatures are near the thermoneutral zone of a species, the eggs may require little incubation time or metabolic heat to maintain their optimal temperature. When environmental

temperatures drop below the incubating bird's thermoneutral zone, birds may have to raise their metabolism to provide enough heat to maintain egg temperature, thereby expending energy specifically for incubation. Studies indicate that incubating birds have RMRs that are 19 to 50% higher than those of nonincubating birds at the same environmental temperatures.

5.4 Parental Care

Birds invest a considerable amount of time and energy in caring for their offspring and do so in a number of different ways. Hatchlings must typically be fed, so one or both parents must find or capture enough food to support the maintenance and growth of their offspring and to support their own maintenance and reproductive activities. Parents may also process food prior to feeding it to offspring; many birds partially digest and regurgitate food, and pigeons and doves of both sexes produce crop milk secretions to nourish hatchlings. Parental care also includes brooding offspring, that is, protecting them from extremes in temperature or other types of inclement weather. Brooding is essential to offspring survival because most chicks are poikilothermic (body temperature fluctuates with environmental temperatures) for days or weeks after they hatch because they do not have the muscle mass to produce sufficient metabolic heat for homeothermy (constant body temperature) and/or because they lack insulating down or feathers to retain body heat that is produced. Thus, species that reproduce in cold regions (e.g., penguins) invest more time and energy in brooding their young than do those that inhabit warmer tropical regions. Birds often protect offspring from predators, for example, by using alarm calls to warn offspring about the presence of predators, attacking and mobbing predators to chase them away, or luring predators away by faking injuries (e.g., the broken wing act used by killdeer [*Charadrius vociferus*]). Some bird species also teach their offspring survival skills such as leading them to food sites and demonstrating how to find and capture prey and how to evade predators.

The amount of time and energy that birds expend for parental care depends on many factors, including (but not limited to) the developmental stage of hatchlings, the number of offspring in a clutch, and the abundance and distribution of food resources. To some extent, the amount of parental care provided is inversely proportional to the hatchling developmental stage; the more developed the offspring are at hatching, the less time and energy are required for parental care. Thus, the amount of time and energy required for parental care tends to be counterbalanced by the energy invested in eggs (Fig. 2). The amount of time and energy required to raise offspring is a strong limiting factor for the number of offspring that can be raised successfully. Experiments have found that artificially increasing brood size in house martins (*D. urbica*) decreases both the size and number of offspring fledged and proportionally increases the daily energy expenditure of savannah sparrows (*Passerculus ssnwichensis*). An increase in energy expenditure in savannah sparrows was correlated with both brood size and the number of feeding visits to the nest. Similar experiments that increased brood size in Eurasian kestrels (*Falco tinnunculus*) found that males (which provide most of the food to offspring) were able to increase the number of voles caught to support the entire brood. However, when prey abundance was artificially reduced, male kestrels compensated by expending more energy to bring back food. When prey abundance was decreased and brood size was increased at the same time, kestrel offspring grew more slowly and had higher mortality rates, and the parents lost body mass and had increased mortality. The amount of energy that birds expend while raising broods has been determined in several species to be about three times their basal rate of metabolism.

In some species of birds, the energetic expense associated with parental care may be alleviated in part by conspecific "helpers" that provide alloparental care or assistance in raising and/or protecting the offspring of other birds. Helpers are usually related to the breeding birds. Most often, young adults from previous broods help to raise their younger siblings. Helpers usually delay their own reproduction due to limited breeding resources (e.g., territory space, nest sites, food). The breeding birds benefit from the assistance of helpers by successfully producing a greater number of offspring than they could produce on their own. In one study, the mortality of offspring in the pied kingfisher (*Ceryle rudis*) was 61% when parents were unassisted, decreased to 22% when there was one helper, and decreased to nearly 0% when there were two helpers. Helpers also benefit by gaining skill and experience in providing parental care, making them more successful at raising their own offspring later. In addition, by helping to raise related individuals, they increase their genetic contribution to the next generation.

6. REPRODUCTIVE ENERGETICS OF MAMMALS

6.1 Territoriality, Courtship, and Mating

Most mammal species (~95%) have a polygynous mating system in which males typically compete with each other for access to mates and resources. Males of polygynous species defend territories (or female groups) so as to acquire multiple mates, and the energy investment in this activity can be substantial. Males may spend a considerable amount of time patrolling boundaries of their space, vocalizing, scent marking, and making visual displays. In some instances, the displays require a relatively small investment in energy because once a territory is established, neighbors are conditioned and need only occasional reminders to keep out. Still, economic defendability is the most important determinant of when a territory or group of females should be defended. For example, male arctic ground squirrels (*Spermophilus parryii*) defend territories against other reproductively active males, and paternity analysis has revealed that the first male to mate with an estrous female sires her offspring. Male short-nosed fruit bats (*Cynopterus sphinx*) construct tents in which they roost by modifying leaves and other plant parts and then defend these roosts against intrusions of conspecific males. Different numbers of females join these males, but it is unknown whether females choose the males based on quality of the resource (tent) or on some quality of the males. Still, paternity analysis has revealed that females sometimes move among adjacent tents; thus, the resident males might not always sire the pups produced by the female occupants of their tents. If males defend females instead of some habitat, this is referred to as female defense polygyny. However, as in other mammal species, it is not always clear whether a male defends a territory or defends the female that occupies it.

Three general types of polygynous mating systems occur in mammals: resource defense polygyny, female defense polygyny, and leks. Resource defense polygyny occurs when males defend areas that contain the feeding, nesting, or roosting sites that are critical for reproduction. Female choice is generally influenced by the quality of the male and the area that he defends. Female defense polygyny commonly occurs in situations where females are gregarious for reasons unrelated to reproduction, for example, when females form herds for protection from predators (e.g., musk oxen [*Ovibos moschatus*]) or when they assemble near food, nesting, or roosting sites (e.g., greater spear-nosed bat [*Phyllostomus hastatus*]). In the latter situation, females become gregarious because roost sites in caves are limited and males then monopolize the females for breeding. Polygynous mating systems usually lead to intense competition among males, and this can result in marked sexual dimorphism and large variations in reproductive success. In the greater spear-nosed bat, resident males sire from 60 to 90% of the pups born to the females in a harem.

The sac-winged bat, *Saccopteryx bilineata,* is characterized by a female defense mating system in which males defend females in a harem territory. Courtship and harem defense in this species includes energetically costly flight maneuvers and hovering displays. A doubly labeled water experiment revealed that the mass-specific field metabolic rate of harem males increased with harem size. Males typically scent mark the boundaries of their territories and defend these areas against intrusions by other males. Adult males attempt to attract females into their harem territories using acoustic, visual, and olfactory displays. In daytime roosts, which are often located in well-illuminated buttress cavities of large trees around buildings in the Neotropics, females are aggressive toward one another as well as toward males. One of the most distinguishing displays of this species is a hovering flight during which odor is fanned toward roosting females. Males perform hovering displays throughout the year, although copulations occur only during 2 months of the year. Males that roost on the periphery of harems father some of the offspring, but harem males on average are the most successful. Thus, although harem males are not the exclusive fathers of the harem offspring, male reproductive success is on average correlated with harem size.

Intense competition among males can also be observed in a lek mating system, where males congregate and display communally to attract females. The only resource that a male defends on a lek is the space where courtship and mating occurs. Males arrive early in the breeding season and, through highly ritualized combat behaviors, compete for and establish their territories. Males of lekking mammals have evolved elaborate ornaments such as horns, antlers, and vocalizations that they use in intermale competition to attract females and to influence female choice. Females move through the arena (lek) in which males are displaying and mate with one or more males based on the quality of their leks (and resources within it) or on the relative qualities of the

males. Lek mating systems have been observed in at least five species of African ungulates, including the Uganda kob (*Kobus kob*) and white-eared kob (*Kobus kob leucotis*), and four species of fruit bats, including the hammerheaded bat (*Hypsignathus monstrosus*) and Wahlberg's epauletted bat (*Epomophorus wahlbergi*). These and other lek mating species occur when males are unable to economically defend either the females or the resources they require. Such a situation can arise when females exploit widely dispersed resources such as grasses (ungulates) and fruit (bats). At high female density, males of the Uganda kob form leks and display to females, but they defend harems (resource-based territories) at low density when defense is presumably economically feasible. Male hammerheaded bats display from calling roosts located in gallery forests along rivers. They emit series of sharp "honks," and when females approach, they vigorously shake their wings and increase the rate of vocalizations. Once a female chooses a particular male, they mate and the male continues to call. As in other polygynous mating systems, some males have greater success in attracting females than do others. In one study, 6% of male hammerheaded bats achieved approximately 79% of the matings in a single year. Courtship displays in species that form leks are fueled by body reserves that allow high instantaneous increases in metabolic rates (up to 20 times BMR). The short-term increase in metabolism that males incur during displays contrasts with the long-term or sustainable metabolic scope that reflects the upper limit of metabolism over a longer period of time.

Polygyny also is common among carnivores where dominant males typically roam over larger areas and seek females in estrous (e.g., felids). Although energetically costly, this strategy appears to contribute to their high reproductive success. A roaming strategy is energetically more profitable for a dominant male because the probability of taking over other females is related to his social status. When females are concentrated in patches, a dominant male can increase the number of potential matings by including a second patch within his range.

Mating systems among canids vary in relation to body size, but the pervasive mating system is monogamy. Smaller species such as red foxes (*Vulpes vulpes*) and bat-eared foxes (*Otocyon megalotis*) are usually monogamous but are sometimes polygynous. The largest canids, such as the African hunting dog (*Lycaon pictus*), are generally monogamous but with a tendency toward polyandry (several females monopolize a single male). In some situations, a polygynous mating system may change depending on the density and dispersion of females, or it may change from polygamy to monogamy depending on the abundance of (and ability to monopolize) females. When mating is restricted to only one season of the year, the preferred resources for males may differ during the mating and nonmating seasons because the two resources (receptive females and available food) tend to have different characteristics. Where males cannot monopolize feeding, nesting, or roosting resources, monogamy becomes possible. Where habitats are characterized by having clumped resources that can be defended economically, polygyny tends to be favored.

In general, variation in mating behavior in mammals can be attributed to four characteristics of females: (1) the extent to which female reproductive rate can be increased by assistance with offspring, (2) the size of female ranges, (3) the size and stability of female groups, and (4) the density and distribution of females in space. A male is better able to monopolize several females when male care of offspring is not needed and when females have small ranges or when they occur in small stable groups. Alternatively, when females are solitary in large ranges or occur in large unstable groups, or when female density is high, it is uneconomical for males to defend several females at once.

6.2 Gamete Production

As in most other vertebrates, mammals are seasonal breeders and produce gametes only during the reproductive season. Energy is generally allocated to gonadal development prior to the breeding season in both sexes. In comparison with female mammals, males allocate a relatively small amount of energy to the production of sperm and ejaculate. The size of testes, expressed relative to body mass, is a standard method for comparing the investment among different species of mammals and birds. The variation in relative testes size in mammals ranges from 0.02 to 0.75% in primates, from 0.15 to 8.40% in rodents, and from 0.12 to 8.40% in bats. Among terrestrial mammal species that have been studied, bats have the widest range of variation in relative testes size. In fact, the relative testes size of the insectivorous Rafinesque's long-eared bat, *Corynorhinus rafinesquii,* exceeds that of all other mammal species. Still, the investment made by both sexes is a relatively trivial energy investment compared with the energy allocation to other aspects of reproduction and to the

investment that oviparous (egg-laying) vertebrates make in reproduction.

Sexual selection by sperm competition has been postulated as the mechanism that contributes to the wide range and maximal size of testes in mammals. Species in which multiple males mate with multiple females (promiscuity) have the largest testes, whereas the smallest testes occur in species where single males mate with single females (monogamy) or multiple females (polygyny). Thus, the mating system appears to be an important variable that explains testes size in mammals. In bats, sperm-storing species also have larger relative testes size than do non-sperm-storing storing species. Among rodents that breed two or more times per year, males allocate more resources to sperm production.

6.3 Nest Construction/Excavation and Nest Guarding

Nest construction varies widely among terrestrial mammals, with females in colder climates commonly investing more in nest construction than those in moderate to warm regions. Females of many small terrestrial mammals (e.g., shrews, rodents, lagomorphs) frequently excavate burrows or runways near the surface or create deeper cavities in the ground and construct nests made of vegetation (leaves, grass, and tree branches) where young are cared for until they are weaned. The excavated burrows and nest cavities provide protection from many would-be predators and provide insulation for the occupants, especially altricial young and their mothers. Insulation provided by nest material helps to reduce maintenance costs (for thermoregulation) of both the mother and her young, making it possible for the female to allocate more energy to reproduction. Medium-size terrestrial mammals (e.g., foxes, woodchucks, badgers) also construct burrows and nest spaces below the ground, but because they have a greater body mass and thus thermal inertia, they do not need to invest as much time and energy in actual nest construction. The Canadian beaver (*Castor canadensis*), a medium-size monogamous mammal, invests extensively in nest construction, which typically involves constructing lodges from vegetation (tree branches and grasses). Both males and females engage in nest-building activity. Before construction of a lodge, which includes the natal nest, beavers may first construct dams to increase the depth of the water so that the only access to the lodge is from an opening beneath the water. Such lodges, with additional nest material, provide not only insulation but also protection from predators.

With the exception of large arboreal primates (e.g., chimpanzees, orangutans), most large mammals and bats do not construct nests. Instead, large mammals seek shelter from inclement weather by forming tightly spaced social groups (e.g., musk oxen, elephants) or seek shelter beneath trees (e.g., many bovids and cervids) or under rock overhangs in treeless habitats (e.g., asses, mountain sheep). Because most large mammals produce precocial offspring, extensive natal nests are not needed. Although bat species are altricial at birth, the parents do not construct shelters or nests but rather use existing structures such as tree cavities, caves, mines, buildings and similar spaces, and roost beneath foliage. In contrast to some mammals (mostly rodents) that seek shelter in similar places and use nesting material from grass and leaves, bats do not use any such material. Sites selected by female bats for rearing young are often physically confined spaces (cavities in trees and caves) that are warmer than alternative locations and, thus, provide conditions that reduce maintenance costs and promote milk production by females and growth of their young. Because females often return to these same roosts year after year, little energy is invested in finding these sites. Energetic benefits accrue to both the mothers and their young by occupying shelters in which metabolic heat can be trapped, thereby reducing heat loss to an otherwise cool environment. However, a few species of bats construct shelters by modifying leaves, other plant parts (roosts and vines), bird nests, and nests of ants and termites that, in turn, often become occupied by females to give birth to young. These so-called "tents" are constructed by single males that recruit females with whom they have a high probability of mating. Because these shelters are constructed by males that are chosen by females to rear their young, tent construction can be considered as a form of paternal investment.

Natal nests of many mammals are often strongly defended from predators and conspecific intruders by both males and females. Many colonial species (e.g., prairie dogs, marmots, bats) use a variety of signals to alert nest or group members to threats from such predators, and these may include vocalizations (e.g., chirps, howls), visual signals (e.g., flashes of white or black tails by prairie dogs, wing displays by bats), and olfactory signals (e.g., production of scent from specialized glands, secretion into the urine). Some rodents secrete substances into their urine when they are stressed, and this acts as a pheromone that may cause others to escape or avoid an area. Skunks and

other mustelids are well known for the use of visual and scent displays that they use when threatened by conspecifics and would-be predators.

6.4 Gestation and Size at Birth

Gestation in mammals occurs in the uterus; however, the development of the uterus and its role in gestation differs considerably among different mammalian taxa. In placental (eutherian) mammals, an intimate physical, nutritive, and endocrine association develops between the fetus and the uterus via a chorioallantoic placenta, which nourishes the fetus for the duration of gestation and helps to regulate the duration of gestation. In contrast, the uterus of marsupial (metatherian) mammals and associated choriovitelline (yolk sac) placenta plays a relatively minor role in embryonic development. No intimate physical or endocrine association is established, and the young are born in an extremely altricial state. However, in either case, the requirements for gestation depend on the amount of energy and matter retained by the gravid uterus and the enlarging mammary glands and the increased maintenance costs of these structures. Altricial marsupials are instead nourished throughout most of their "fetal" period from highly specialized mammary glands and nipples.

Embryonic development incurs the greatest cost to the female during gestation. In eutherian mammals, fetal growth is curvilinear, with most of the increase in embryonic mass occurring after 50 to 60% of the gestation period has elapsed. In general, the length of the gestation period and the birth mass of eutherian neonates increase as a power of maternal mass, with smaller species having shorter gestation periods than larger ones and with smaller species having smaller offspring than larger ones. However, carnivores, primates, and most bats have longer gestation periods than can be predicted from maternal body mass, whereas marsupials and red and giant pandas have shorter gestation periods than can be predicted from maternal mass. Exceptions to predictions in length of gestation occur predominantly among marsupials that have a choriovitalline placenta and have unusually short gestation periods and among eutherian mammals that undergo delayed embryonic development (e.g., mustelids, pinnipeds, some bats). For example, the gestation length of an 18-g rodent is approximately 21 days, whereas the gestation period of comparable size bat species can range upward from 2 to 6 months. Bats and bears best exemplify exceptions to the predicted trend in size at birth among eutherian mammals. Newborn little brown bats (*Myotis lucifugus*) are larger at birth than predicted, weighing about 2 g and representing nearly one-fourth of the mother's body mass. By contrast, newborn black bears (*Ursus americanus*) are smaller than predicted, ranging in mass from 200 to 450 g and averaging 1/250th of the mother's mass.

In general, birth mass is a reflection of the metabolic body mass of the mother, with larger species producing offspring that represent a smaller proportion of adult mass. The energy cost of gestation can be estimated using birth mass to maternal mass relationships, a maternal mass to gestation period regression, the composition and growth characteristics of the gravid uterus, and an estimate of the oxygen consumption of the gravid uterus per kilogram of tissue. Several studies have shown that the maintenance cost of the gravid uterus is the major cost of gestation in eutherian mammals. In general, gestation is far less costly and stressful in larger mammals than in smaller mammals because the relatively smaller neonate of larger species is produced over a much longer period. However, when one compares the total cost (maintenance and production) of a gravid uterus with that of the gestation period, the cost is proportional to maternal metabolic body mass ($M^{0.77}$). In eutherians, protein accumulates curvilinearly in the gravid uterus and mammary glands during gestation. In general, because of longer gestation periods in larger species, protein accumulates at a decreasing rate per kilogram of fetus. Changes in fetal size of gestation length are far more complex than simply comparing relative growth rates. Pregnant females can benefit by lengthening the gestation period if protein (or minerals) is limiting, but they gain nothing by prolonging the gestation period if energy is limiting. Some mammals ingest nutrients in excess of the actual costs of gestation, and because lactation is more costly than gestation, females of larger species (but not small species) can accumulate reserves during gestation when food is available and can mobilize it later for milk synthesis. Mammary glands begin to enlarge during the final trimester of gestation and, thus, can be considered as a cost of pregnancy and lactation.

6.5 Lactation

The production and secretion of milk is a trait that distinguishes mammals from all other vertebrates, although some birds (e.g., pigeons, doves, penguins, flamingos) feed crop secretions, or "crop milk," to

hatchlings during their first few days of life. Among mammals, the milk produced by a postpartum female provides an important dietary buffer between the dependent fetus and the weaned and nutritionally dependent young. Milk is produced by mammary glands that vary in position from the thoracic to the inguinal region of the body. Mammary glands generally vary from a single pectoral pair in primates, elephants, and bats up to 12 pairs located in the abdominal and inguinal regions in some rodents and marsupials. The young of placental and marsupial mammals obtain milk from nipples by a sucking action that stimulates milk letdown (the neural–hormonal release of milk from the mammary glands). Nipples are absent in monotremes (egg-laying mammals), and milk is secreted from mammary glands directly onto the ventral surface of the skin of females so that the beaked young can lap up the milk with their tongues.

Female mammals typically provision their offspring with milk for varying amounts of time. Factors known to influence the length of lactation is adult body size relative maturity of their young at birth (altricial or precocial) as well as the quantity and quality of milk. The quantity and quality (energy and nutrient content) of milk can vary according to a particular species, the type of food that is ingested by the mother, the availability of water, and the type of habitat in which they live. Terrestrial mammals that have a high-fat diet (those that live in arid regions) often produce milk with high lipid content. In contrast, mammals that feed on fruit and nectar or fleshy aquatic vegetation generally produce milk that is high in water content and carbohydrates but low in protein. Carnivorous and insectivorous species more commonly produce milk that is high in protein and fat but low in carbohydrates. The milk composition may also change over the course of lactation in many mammals. The first milk produced during a lactation cycle is called colostrum. Colostrum has a high concentration of antibodies and active phagocytic cells, each of which are thought to be important for the development of an effective immune system in neonates.

The major nutrient constituents of milk are water, minerals, protein (casein and whey), fat, and carbohydrates. Protein concentration ranges from less than 2% in primates to nearly 16% in the eastern cottontail (*Sylvilagus floridanus*). Fat content in the milk of terrestrial mammals also varies among species, ranging from a mean of 2.3% in lemurs (*Lemur* sp.) to 18.5% in the brown bear (*Ursus arctos*). The milk composition of bats also appears to be influenced by diet. For example, the milk composition of insectivorous species generally has a greater amount of dry matter, fat, and protein content than that of omnivorous and frugivorous species. The relatively low fat, protein, and dry matter content of milk of frugivorous species is consistent with the relatively low fat and protein content of available fruit. Insectivorous species produce milk with percentages of fat and protein that often exceed values reported for other small mammals, an observation that is consistent with evidence that small mammals produce milk of higher energy content than do most large mammals.

Some females suckle their young on demand (e.g., marsupials, primates, some ungulates, some bats), whereas others suckle their young on a schedule (e.g., lagomorphs, most rodents, most carnivores, many artiodactyls, some bats). As their young increase in size, so do the energy and nutrient demands on the mothers to produce more milk. Thus, the composition of milk often changes over the course of lactation. For example, in the Brazilian free-tailed bat (*Tadarida brasiliensis*), fat content of milk changes from a mean of 17.3 to 25.8% from early to peak lactation. Large mammals such as carnivores, bovids, and cervids also deposit fat reserves during pregnancy and mobilize them during lactation to either support the production of milk or support the increased demands for energy of the mother to secure food. During peak lactation, when energy demands are the highest, females may mobilize their other body reserves to supplement daily food intake. This is especially the case during periods of food shortages but also in small mammals that do not have the capacity to store large fat reserves.

As energy demands increase due to lactation, maintenance costs also increase because more time is invested in locomotor activity to secure food. The amount of time and energy that mammals allocate to foraging can increase more than twofold compared with that allocated to pregnancy. For example, female little brown bats (*M. lucifugus*) and Brazilian free-tailed bats (*T. brasiliensis*) more than double their nightly intake of insects from early to peak lactation. As lactation progresses, the energy cost of milk synthesis increases, corresponding to the increased energy demands of the growing young. Milk production generally increases until peak lactation and then begins to decrease as infants become more independent and begin to feed on other foods.

Estimates of milk intake by maternally raised young, when combined with estimates of milk composition, provide data necessary for determining

requirements for maternal production and requirements for neonatal growth. Methods used for estimating milk intake by suckling young include weighing the neonate before and after a controlled nursing period, hand milking a lactating female after a controlled period of neonate removal, and using the dilution of isotopes (usually deuterium or tritium oxide) to quantify the dilution of the body water pool by ingested milk. The isotope dilution method offers the only available method for estimating milk intake in free-ranging mammals. Thus, milk intake can be directly estimated from measurements of neonatal water kinetics. Because milk is the only source of water to a suckling before it takes solid food, measuring the daily water flux of such a neonate using isotope dilution and estimating the proximate composition of milk (energy content of the dry matter) makes it possible to estimate the amount of energy that a mother invests in her offspring in a given 24-h period or over the course of lactation. The energy expenditure of free-ranging female mammals during lactation can be quantified using a combination of time budget analysis and laboratory respirometry or from estimates of energy expenditure using the doubly labeled water technique.

Energy requirements for pregnancy and lactation are proportional to the productive process involved—synthesis of fetal, placental, uterine, and mammary tissue during pregnancy and milk production during lactation. In one study, metabolizable energy requirements for domestic ruminants and horses increased by 28.2 and 23.2% above maintenance levels, respectively, during late pregnancy and by 37.2 and 41.5% from late pregnancy to early lactation. In free-ranging golden mantled ground squirrels (*Spermophilus lateralis*), the amount of metabolized energy allocated to reproduction by females into newborn young and milk export increased by 17.7% over nonreproductive levels in one study. The total energy budget of a lactating female includes loss or storage of body reserves and the amount of energy that is produced and exported as milk (Fig. 1). In free-ranging little brown bats (*M. lucifugus*), average daily energy requirements during lactation (litter size of one) exceeded requirements during late pregnancy by a factor of 1.2 in one study. However, when milk output was included, energy required by females during lactation nearly doubled from early (33.8 kJ/day) to peak lactation (60.3 kJ/day).

Among terrestrial mammals, most young are weaned by the time they have reached approximately 40% of adult size. In contrast, lactating female bats typically nurse their young until they have nearly reached adult size. Because bats cannot fly until they are nearly adult size, mothers must continue to suckle their young until such time that they have achieved approximately 90% of adult wing dimensions and can secure food on the wing. The lactation period for most small (<60 g) insectivorous bats is 6 to 8 weeks. Larger mammals (>10 kg) have disproportionately longer lactation periods (several months) and distribute their total costs over a far greater period of time. Because larger species tend to produce relatively low levels of milk at peak lactation and during the prolonged end of the lactation cycle, the average daily cost as a function of BMR is lower in larger species. Thus, lactation costs are high but are of relatively short duration in small mammals, as compared with a relatively lower cost but longer duration in large mammals.

Because most mammals are polygynous, males assume little or no role in the care of the young they have fathered. However, among monogamous species, females suckle their young but may be assisted by fathers who provision their young with food (e.g., many carnivores). In general, male mammals do not lactate; however, recent observations have shown that some male mammals do produce milk, perhaps as a trait in some monogamous species or possibly as a consequence of eating leaves high in phytoestrogens or eating food that has been exposed to pesticides that have estrogenic properties. Males of at least two species of Old World fruit bats (*Dyacopterus spadiceus* and *Pteropus capistratus*) are known to produce milk, although it has not been determined that they actually suckle their offspring. Because the mating system of these two species is not known, any relationship between a monogamous mating system and male lactation remains unclear.

In addition to productive processes (fetal growth and lactation) associated with pregnancy and lactation in mammals, other energy costs include the establishment and maintenance of territories associated with courtship and mating, gamete production (relatively small in mammals), the increased locomotor activity associated with food acquisition, nest construction and guarding, and other forms of parental care.

6.6 Parental Care

Because of constraints imposed by polygynous mating systems and female lactation, parental care in mammals generally is largely the responsibility of females. However, in some species that breed cooperatively, offspring from previous litters help

care for members of the subsequent litter. Events and activities associated with parental care in mammals cover gestation, parturition (birth), lactation, grooming, feeding, and tutoring of young. During or before the gestation period, nest construction and nest defense are the primary energy-demanding activities that extend above maintenance costs. Parturition is an energy-demanding activity, but because this period is relatively short (minutes to hours), the overall impact on the energy budget of a female is trivial. During lactation, thermoregulation and grooming are the primary activities. Among these, lactation is the most energetically demanding. The energy demands associated with lactation will depend on the duration of lactation, the number and size of offspring, the body size of the mother, the local microclimate, and the availability of food resources. For species in which there is a prolonged postnatal period of growth and development (e.g., primates, elephants), tutoring exacts additional energy costs.

Among monogamous mammals, males invest in their offspring both indirectly and directly. For example, a dominant male gray wolf (*Canis lupus*) or dominant male coyote (*Canis latrans*) will bring food to a lactating female in its den, and when the young approach the age of weaning, he will offer them partially chewed food. Males may defend burrows that contain neonates from potential predators, either by giving alarm calls, signaling with visual displays, or distracting potential predators away from nest area. Paternal care that is most often associated with monogamy is relatively rare in placental mammals, averaging less than 5% of all species that have been studied.

Alloparental care has also been observed in several species of mammals. Among these are highly social and cooperative breeding species. For example, alpine marmots (*Marmota marmota*) live in colonies that include a territorial pair, subordinates, yearlings, and young of the year. Subordinates cluster with newborns, groom them, and cover them with grass, behaviors that improve the survival of offspring. A special case of alloparental behavior has been observed in eucocial mammals, including the naked mole rat (*Heterocephalus glaber*) and Damara mole rat (*Cryptomys damarensis*). Colonies of naked mole rats consist of one reproductive female, several males; and several nonreproductive female workers. Reproductive maturity of subordinate females is suppressed pheromonally by the presence of a dominant "queen" who mates with and gives birth to offspring fathered by a few resident males. The reproductively suppressed females construct burrows and nest chambers and assist the queen by bringing her food and grooming her. The dominant female suckles all of the offspring. Alloparental behavior also extends to assistance during the birthing period. Female Rodrigues fruit bats (*Pteropus rodrigues*) have been observed assisting other females during the birthing period. In one instance, when a female was having a difficult (breech birth), another female approached the expecting mother and groomed her pup as it was emerging from the vagina. She also tutored the mother in the correct birthing position and wrapped her wings around the mother and pup during the birth process. Similar observations of helper-assisted births have been observed in the common marmoset (*Callithrix jacchus*), African elephant (*Elephas maximus*), Afghan hunting dog (*Canis familiaris*), and spiny mouse (*Acomys cahirinus*). Sharing of a blood meal with roostmates, including young, has been observed in the common vampire bat (*Desmodus rotundus*). This behavior appears to be practiced mostly by mothers who provision their own young, but it has also been observed between adults as well as between adults and related but nonfilial young. This altruistic behavior appears to be based on reciprocity and kin selection in this highly social and communally breeding species. Parental care in mammals, especially in highly social species (e.g., primates, some rodents, bats), also involves social grooming and protecting young from extremes in temperature or inclement weather. The latter may also involve clustering and huddling to reduce energy expenditure.

7. CONCLUDING REMARKS

This article has provided a brief overview and a few glimpses of how various factors influence the reproductive energetics of terrestrial reptiles, birds, and mammals. The amount of energy allocated to various phases of reproduction (courtship and mating, incubation, gestation, lactation, parental care, and the pre- and postfledging or postlactational periods) is, in part, influenced by the type of reproduction (oviparity vs. vivaparity), different types of mating system (monogamy, polygyny, and polyandry), rates of posthatching and postnatal growth, competitive interactions with members of the same or different species, and extrinsic factors such as habitat quality, food availability, and climate. In general, costs of courtship and mating are higher for males that typically compete for females by developing elaborate structures or behaviors used in

courtship display to show females that they are fit and by defending either mating territories or females. The energy investment that male vertebrates make in the production of gametes is relatively small compared with that made by females, and female reptiles and birds typically invest more in egg production (both size and number) than do female mammals.

Apart from the production of a relatively large number of eggs, few reptiles exhibit maternal care once the young hatch. In contrast, birds and mammals often invest extensively in their young once they hatch or are born. Female birds allocate large amounts of energy to brooding and feeding their young until they have reached or exceed adult size. Some species invest further in their offspring by tutoring them once they have fledged. In contrast, mammals typically produce a relatively small number of eggs that are fertilized internally, the fetus develops in the uterus that is protected from environmental extremes, young are born alive, and females nurse their young with milk for variable periods of time and in many species may provide extended care to their offspring. Among males, courtship and mating are the most energetically expensive activities in reptiles, birds, and mammals. The production of nutrient- and energy-rich eggs is the most energetically expensive phase of reproduction in female reptiles. Production and incubation of eggs and feeding of nestlings comprise the most energetically expensive phase of reproduction in female birds. Lactation is the most energetically expensive period of reproduction in female mammals.

Glossary

development A stage of the innovation process during which basic research findings are applied to the development of new materials, devices, or processes for practical use.

energy restructuring Often referred to as energy deregulation or liberalization, the process of opening the energy industries (e.g., electricity, gas, oil) to market forces and competition; in many countries, the process involves the dismantling of large, integrated state monopoly energy companies and the privatization of all, or of large parts of, the industries.

energy technologies Materials, devices, and processes for the location, recovery, preparation, storage, transport, conversion, and use of energy resources and for the treatment of associated waste products.

innovation The systematic practice of research and development and the creation of new technologies, usually through a linked network of scientists, engineers, and research sponsors at university, private sector, and government-owned research facilities.

research The initial stage of the innovation process where new knowledge of the natural world is sought through experiment and observation without specific motivation for the application of findings to particular practical problems or to the creation of new technologies.

Energy research and development (R&D) is often defined in a manner similar to that in which a U.S. Supreme Court justice defined pornography: "I know it when I see it." That is, most of those concerned with energy R&D believe that there is a common tacit definition, yet attempts at explicit definition usually reveal significant differences in understanding among researchers, analysts, and those who support energy innovation. Accepting that there are few explicit definitions of energy R&D provided in the literature, and that no extant definition is regarded as constituting a standard one, this article adopts the following definition based on that of the U.S. President's Committee of Advisors on Science and Technology:

> *Energy R&D refers to a series of linked processes by which technologies for energy supply, end use, or carbon management move from theoretical conceptualization to feasibility testing and, ultimately, to small-scale deployment. Energy R&D encompasses both basic and applied research, technology development, and demonstration associated with each phase of the energy life cycle, including production (e.g., mining, drilling), energy conversion and power generation (e.g., nuclear fission and fusion, fossil and renewable energy systems, bioenergy, hydrogen production), transmission, distribution, energy storage, end use and energy efficiency, and carbon management. Carbon management technologies aim to manage anthropogenic releases of greenhouse gases, such as those associated with the combustion of fossil fuel use, in an effort to mitigate the potential impacts of these emissions on climate systems. Carbon management technologies include advanced agroforestry practices aiming to enhance the capacity of soils, trees, and other standing biomass to absorb atmospheric carbon dioxide; engineered pre- and postcombustion carbon capture systems; and technologies for geologic and ocean carbon sequestration.*

This definition is an extension of one first put forward by the U.S. President's Council of Advisors on Science and Technology in 1999. Although this constitutes a useful and comprehensive working definition of energy R&D, it is important to note that it is descriptive rather than prescriptive in

 © 2004 Elsevier Inc. All rights reserved.

nature; no government agency or private organization uses such a definition as a guide in planning its energy R&D investments. Although many commercially available technologies, such as low-emissivity windows, are the result of established energy R&D programs, other projects and technologies are often classified as the fruit of energy R&D investments *ex post facto*. For example, the use of natural gas turbines for electric power production has been one of the most important energy technology advances of the past few decades, yet the investments that led to this breakthrough were largely made by the U.S. Department of Defense during the 1960s and 1970s under the rubric of aircraft engine research. That this work led in the long run to the technology's application in the electric power industry raises taxonomical questions about its retroactive classification as "energy R&D." Thus, defining energy R&D remains a malleable enterprise.

1. THE IMPORTANCE OF ENERGY R&D

Energy technologies are the primary determinants of energy availability, fuel choice, end use efficiency, and the degree and nature of by-product emissions, and energy research and development (R&D) is the vehicle by which new technologies become available. To the extent that energy technologies augment or diminish society's range of energy choices, energy R&D is a matter of high importance. Over the past half-century or so, awareness of energy use and its implications for economic growth, national security, and environmental quality have at times held prominence to an unprecedented degree. To a large degree, these three societal goals have formed the underlying rationale for investments in energy R&D across the globe over this period. The relative emphasis placed on each of these goals has varied from country to country and even within countries over time.

For example, two of the three founding treaties of the European Union focused on the coordinated management of energy resources and energy R&D for reconstruction and economic growth. Moreover, virtually all industrialized countries created domestic agencies for energy technology development during the post-World War II period. For energy resource-poor countries such as Japan, the fact that energy R&D continually receives a sizable percentage of government's total outlays for all kinds of R&D (more than 10% of all government R&D expenditures consistently over the past 25 years or so) is a testament to the importance of this activity. At other times and in countries such as the United States, Canada, and most of the European Union, the importance of energy and energy R&D has received relatively little attention, and as a result, public and private sector investments in energy R&D have suffered. Energy R&D tends to be a near- to midterm beneficiary of energy crises.

Energy considerations are central factors in several policy areas, including environmental, economic, and defense policy. Energy resources have served both as a cause for and as a weapon of war, and the consequences of energy use have manifest themselves in a host of environmental problems, ranging from local air pollution to global climate change. Consequently, energy R&D and the technologies that the R&D process yields broaden or narrow the portfolio of choices available to policymakers on a number of important issues.

2. ENERGY R&D PERFORMERS AND SPONSORS

Energy R&D has historically been the province of large industrialized countries with limited domestic energy resources and high levels of energy imports. Most of the world's energy R&D is funded and performed by a small group of industrialized countries: the United States, Canada, Japan, Germany, France, Italy, The Netherlands, Switzerland, the United Kingdom, and countries comprising the European Union. According to the International Energy Agency (IEA), these countries alone account for more than 90% of the industrialized world's energy R&D. Although these countries are clearly the "energy R&D-intensive" leaders, only in the case of Japan does energy R&D account for more than 1.5% of a nation's overall R&D enterprise.

The performance of energy R&D in the private sector is similarly concentrated in large industrial firms. For example, in the United States in 2000, firms that had more than 10,000 employees performed 89% of industrial energy R&D. Although it is clear that these companies are the leading performers of energy R&D, it is also clear that the performance of R&D is not a significant aspect of their business. The energy industries are among the least R&D intensive in the industrialized world. In comparison, the most R&D-intensive industries, such as medical equipment and information technology, invest 12 and 8% of annual

sales, respectively, in R&D. Although a few specialized oil and gas exploration service companies have R&D/sales ratios in excess of 7%, this level of investment is the exception within the energy industries that typically invest less than 1% of sales in R&D.

Neither of these observations is meant to exclude the possibility (indeed the cerainty) that smaller countries and smaller firms are not conducting important energy R&D. Rather, it seems clear that the performance of energy R&D is limited to this select set of large industrialized countries and large firms by the often times significant research infrastructure requirements. (It is hard to imagine a very small firm conducting all of the research needed to bring about a new fission reactor from conception to pilot scale testing.) The successful performance of energy R&D often depends on the existence of a large cadre of scientists and engineers, the availability of specialized laboratories and user facilities, funding mechanisms for sustained research support, and programs for technology commercialization and adoption. A relatively small set of countries and large firms have these capabilities; therefore, it is these entities that constitute the bulk of the global energy R&D enterprise.

Governments have historically been the principal sponsors of energy R&D, whereas the private sector has played an important but secondary role from the perspective of overall investment levels. Governments have historically been the main supporters of long-term, higher risk R&D in particular, whereas private sector investments have focused more on short-term research and technology commercialization efforts. In several industrialized countries, including the United States, Germany, and Japan, the gap between public and private sector investments has widened over the past 15 years or so. For example, whereas government and industry investments were roughly equal in 1990, government now invests approximately 50% more than the private sector in the United States. Similarly, whereas the German government invested 30% more than did industry in 1990, by 2000 its energy R&D investment was more than double that of the private sector.

3. MOTIVATIONS FOR ENERGY R&D

As noted previously, in most countries, public sector energy R&D has been closely tied to domestic policy priorities such as efforts to bolster national security, to enhance economic productivity, and to remedy specific local- to regional-scale environmental problems. Because policy priorities change continually, so too have the focus and intensity of R&D efforts in performing countries over the past half-century. For example, the oil supply shocks of the 1970s and the related economic crises were among the strongest drivers of energy R&D efforts in industrialized countries. Between 1973 and 1981, government investments in energy R&D rose to their highest levels as new programs and new institutions formed in response to oil supply interruptions initiated by the Organization of Petroleum Exporting Countries (OPEC). Domestic policy programs, such as Project Independence in the United States, and agencies with significant energy R&D missions, such as the U.S. Department of Energy (DOE), Britain's Department of Energy, and the Organization for Economic Cooperation and Development's (OECD) IEA, grew out of Western policymakers' ambitions to reduce exposure to future energy supply interruptions. Nuclear fission and fusion research programs, energy efficiency, and renewable energy research all received substantial funding increases in the interest of reducing the energy security risks associated with high levels of fossil fuel import dependence. In real inflation-adjusted terms, energy R&D investments hit their high-water marks during this period and have been on a steady decline, for the most part, since the late 1970s and early 1980s. For example, U.S. energy R&D expenditures in 1980 were nearly three times what they are at the turn of the 21st century.

These investments in energy R&D have yielded significant economic benefits. For example, over the 20-period between 1973 and 1993, energy productivity—the amount of energy required to produce $1 of gross domestic product (GDP)—rose by 1.7% annually on average in the United States and by as much as twice that rate in Japan and Europe. The decoupling of energy consumption from economic growth also dismissed a widely held belief regarding the tight interdependence of these two factors. In addition, overall levels of energy import dependence in industrialized countries declined for more than a decade, although they have since rebounded to historically high levels.

Although improvements in energy productivity over this period cannot be attributed exclusively to investments in energy R&D, these investments were an important factor. As the National Research Council found in its 2001 study of DOE-sponsored energy efficiency and fossil fuel R&D programs, real economic benefits were realized from DOE and private sector investments between 1978 and 2000.

Although other factors, including structural changes in the U.S. economy, fuel prices, and changes in the fuel mix, also played important roles, the National Research Council panel found that a small group of government programs exercised tremendous leverage in the U.S. economy. For example, government-sponsored programs addressing building efficiency and fossil fuel-related NO_x emissions realized benefits in the form of avoided energy and environmental costs that were orders of magnitude larger than the associated R&D investments.

In the private sector, profitability and the need to meet ever tighter environmental regulations have been the prime motivators for investment in energy technology development. Private energy R&D efforts intensified during the 1970s and 1980s in response to the higher market prices that made energy production more profitable for those firms that were energy producers and provided a significant motivation for energy users to find ways in which to conserve energy as a cost-cutting measure. For example, for oil and gas companies, the prospect of higher profits prompted major new investments in exploration and production technology aimed at bringing to market energy resources that had been considered uneconomical at lower prices. Important technological advances, such as three-dimensional seismic imaging and directional drilling, occurred during this period and have continued to buoy the profitability of energy companies through subsequent and prolonged periods of low energy prices.

For gas and electric utilities in many countries, the motivation for energy R&D stemmed from energy providers' "regulatory compact" with government. Typically, regulated utilities were guaranteed a geographically isolated market and a fixed rate of return on their capital and R&D investments, minimizing the risks associated with those investments. Moreover, in some cases (e.g., the United States), utilities were required to invest a specified portion of annual revenues in common associations that served as industry-wide R&D pools. The Electric Power Research Institute and the Gas Research Institute derived their existence largely from the mandated "wires and pipeline charges" paid by power and gas suppliers in the regulated energy marketplace. However, the process of energy deregulation has usually included the repeal of government-mandated R&D contributions. As a result, collective R&D institutions have seen their annual revenues fall by more than 50%.

The deregulation of the energy industries raises lingering questions about the current and future motivations for energy R&D investments. Although major problems such as climate change and energy security are indicative of the significant energy challenges that lie ahead, the structure of market and policy incentives have shifted in ways that motivate public and private sector decision makers to forgo higher overall levels of energy R&D investment. Arguably, the most pressing problem facing energy R&D sponsors and performers today is the sharp dislocation between current incentives for energy R&D investment and the likely future societal demands for new generations of cleaner and more efficient energy technologies.

4. TRENDS IN ENERGY R&D INVESTMENTS

According to the IEA, the industrialized world's overall investment in energy R&D declined by approximately 17% during the 1990s (Fig. 1). The IEA's 1999 aggregate estimate of world energy R&D investment, $7.4 billion, reflects a decrease of 50% from the high-water mark of $14.7 billion in 1980.

Of the group of nine countries that constitute the world's leading energy R&D sponsors (the United States, Japan, France, Germany, Italy, Canada, The Netherlands, Switzerland, and the United Kingdom), seven have reduced their expenditures over the past decade or more. In each of these countries, overall R&D spending has increased significantly in real terms. Some areas, such as health and biomedical research and information technology, have experienced large and sustained R&D investment increases, reflecting the major advances in these fields over the past two decades or so and the widely held belief that the private and public returns on additional investments in these areas will be significant. The absence of acute energy crises and perceptions of shortage, such as those that characterized the 1970s and early 1980s, have discounted the value of government-sponsored energy R&D in the eyes of policymakers and the general public. Thus, as a research priority, energy R&D has lost ground in both relative and absolute terms as an element of the broader research portfolios of most industrialized countries. Only France and Japan have increased their energy R&D investments in real terms since 1991 (Table I).

Although the aggregate trend data reveal steadily waning investments, individual energy technology areas are flourishing in some countries. For example, because hydrogen and fuel cells are widely regarded

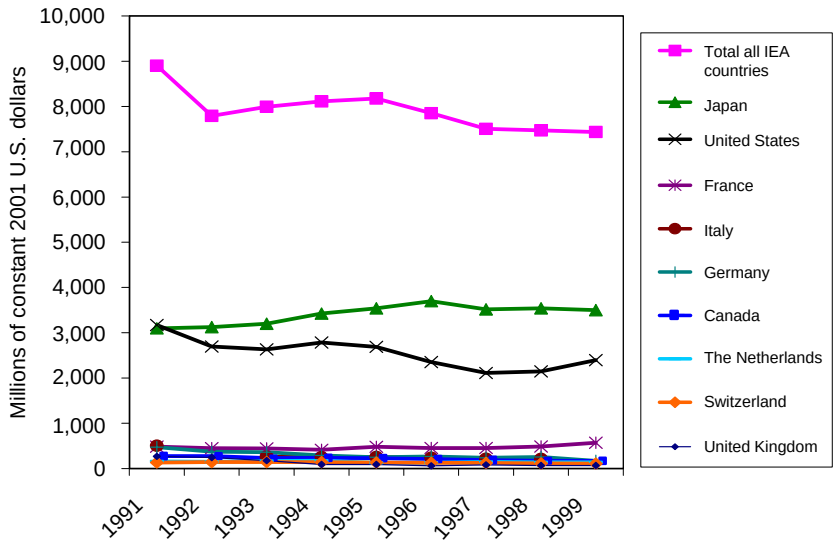

FIGURE 1 Energy R&D investment trends in major performing countries during the 1990s, as reported to the International Energy Agency (IEA). Note that currency conversions in the figure are based on market exchange rates rather than on purchasing power parities. Because energy R&D is largely a nontraded good (i.e., funded and produced within national borders rather than across them), the use of market exchange rates in converting local currencies to constant U.S. dollars may distort the real values of countries' R&D investments.

TABLE I

Real Growth in Energy R&D Investments, 1991–2001 (Percentages)

Country	Change in energy R&D investment, 1991–2001
United States	−13
Japan	+15
France	+17.8
United Kingdom	−71
Italy	−50
Germany	−46.5
Canada	−43
The Netherlands	−14
Switzerland	−11

Note. The majority of major performing countries made large cuts in energy R&D support during the 1990s. As the table shows, restructuring and deregulation of the energy industries have been strongly correlated with energy R&D funding cuts. France and Japan are the only major energy R&D-performing countries that have not yet restructured their energy industries.

as holding significant promise as a future alternative to fossil fuel-based energy systems, investment in these areas has risen sharply during recent years. In Germany, fuel cell research has grown by 400% since 1998. In the United States and Canada, hydrogen programs have nearly doubled over the same period. The European Union and Japan also sponsor major public and private sector hydrogen fuel cell programs. Similarly, government-sponsored biomass/biofuels, energy efficiency, and carbon sequestration programs have grown moderately in the United States, Japan, Germany, and Australia. Yet even with significant growth in these selected technology areas, emerging energy technology programs still constitute just a small share of energy R&D budgets.

Assessing private sector energy R&D trends has always presented difficult challenges because most energy R&D-performing firms consider these investment data sensitive and proprietary. The private sector data that are available are usually gathered via a brief survey instrument by industry associations or government agencies and are published only at an industry aggregate level. Trend data from these sources reveal that private energy R&D investments have declined even more precipitously over the past decade or so than have public sector energy R&D investments in several countries, including the United States (−63%), Germany (−70%), the United Kingdom (−90%), and Canada (−40%).

The energy R&D sponsored by the private sector is largely short term focused, aiming to develop new products or improve existing ones so as to bring them to the marketplace quickly. Long-term energy R&D, which entails larger financial risks and uncertain time horizons, has generally been supported by government agencies. In the United States, government currently sponsors more than 60% of

long-term energy R&D, whereas industry supports more than 80% of short-term research.

5. ASSESSING R&D TRENDS: METHODOLOGICAL CHALLENGES

It is important to note that all of the preceding data are based on surveys that use the term "energy R&D" in a conventional and narrow sense. The term is used to describe R&D activities that were explicitly carried out by governments or industry primarily to increase or create new energy supplies or to use energy more efficiently and cleanly. This means that these data sets will exclude R&D whose main and *a priori* purpose was to create something like a new military system, even though at times strictly defined "military R&D" has spilled over to benefit the energy industry. The most obvious example of this spillover phenomenon is the aforementioned combined cycle gas turbines, which have had a profound impact on the energy industry and are largely derivative of military jet engines.

The exclusion of these ancillary R&D efforts is driven by practicality and a desire to keep some temporal integrity to the data set being examined here. That is, only in an *ex post facto* sense can one identify these technologies that spill over into "energy R&D," and the selection of these technologies is an inherently subjective exercise. It is more feasible to track R&D expenditures that were initiated due to their relevance to energy. Analysts and decision makers who rely on energy R&D statistics need to understand this important nuance in the data on which they are relying.

Another important methodological issue that analysts must consider in assessing energy R&D data across countries concerns the exchange rate mechanism used to convert the data to a common (typically U.S. dollars) currency. Many publicly available, multicountry energy R&D data sets use market exchange rates rather than purchasing power parities for their conversion to U.S. dollars. This method can introduce significant distortions into the data, often inflating actual energy R&D investments. Given that energy R&D is nearly exclusively funded and performed within—rather than across—national borders, exchange rates based on purchasing power parity yield more accurate estimates than do market exchange rates, which are more appropriately used for internationally traded goods and services.

It is also important to note that the use of brief survey instruments, by the IEA and others, as a primary mechanism for energy R&D data gathering should instill a measure of caution in analysts working with data sets compiled in this manner. Such survey instruments typically contain questions regarding a country's or firm's overall spending levels on energy R&D in selected program areas but offer little detail below aggregate levels. The use of survey instruments in this manner also raises questions regarding data accuracy and reliability given that survey participants are usually given few if any guidelines regarding their responses. Consequently, investments in fossil energy efficiency could, for example, be classified as "fossil energy R&D" by one participant and as "energy efficiency R&D" by another. Finally, verification of energy R&D statistics provided to international agencies via surveys is not possible. Thus, although these statistical data sets may be some of the best available, they must nonetheless be used and interpreted with caution.

6. CONCLUSION

Energy R&D is an important vehicle for the achievement of a wide variety of societal and policy goals. Because energy technology and fuel choices are critical determinants of economic prosperity, environmental quality, and national security, energy R&D is an important public policy vehicle. Moreover, the relative strength of energy R&D support is also a useful metric for the assessment of a number of public goods. The extent to which firms and government agencies view energy R&D as a priority activity and fund it accordingly may be regarded as a proxy indicator of political interest in selected policy areas such as climate change mitigation, national energy security, and overall environmental stewardship.

In this regard, it is important to note that available energy R&D data sets provide an important, but limited, measurement of inputs into energy R&D and offer little insight into R&D outputs—new technologies, their deployment, and their impacts on the environment as well as the economy and other policy concerns. Other common proxy measures of R&D efforts, including statistics on patent grants and applications, doctoral degrees awarded, and trends in energy intensity, can serve as useful pieces of the broad mosaic of energy R&D data but can be difficult to interpret outside a broader analytical context. Like statistics on energy R&D expenditures, these data are used as proxy measures because energy

R&D statistics are relatively easy to collect and have the appearance of being easy to interpret. In fact, output measures such as energy intensity (i.e., energy input per unit of GDP) are notoriously difficult to interpret because the number of variables influencing observed trends is potentially large and the isolation of individual variables is often impossible. For example, given data limitations, it might not be possible to determine definitively whether improvements in industrial energy intensity are due to the introduction of more fuel-efficient energy technologies, to broader changes in production methods, to structural changes in the economy, or to any number of other factors.

Most recent studies of trends in energy R&D have documented significant reductions in the overall level of support and a concomitant redistribution of remaining energy R&D funds in favor of less risky, short-term evolutionary R&D with clear commercial applications rather than longer term, higher risk projects with potentially revolutionary impacts. Many analysts have interpreted this trend as inherently dangerous given the likelihood that such funding patterns are likely to delay or prevent the attainment of many energy policy goals such as climate change mitigation. On the other hand, some analysts have pointed out that a reduction in the amount spent on energy R&D in itself cannot always be interpreted as a step backward for a firm or for society at large. For example, it is possible that energy R&D-performing laboratories might have become more efficient in their delivery of energy R&D results due to the increasing use of computer modeling or due to mergers between firms with large and redundant R&D capabilities that are subsequently consolidated—a frequent occurrence in the oil and gas industries. In either case, energy R&D statistics would reflect the fact that smaller amounts are invested in energy R&D, yet the implications of these events for energy technology innovation would remain indeterminate.

A final caution concerns forward-looking statements regarding future patterns of energy R&D investment and performance. As all investors are warned, past performance cannot be relied on as a predictor of the future. Many factors, including economic downturns, unforeseen energy crises, or environmental surprises can and have affected energy R&D investment in significant and unpredictable ways. Likewise, policy rhetoric regarding energy R&D priorities often remains disjointed from actual R&D expenditures. For example, during the 1990s, many governments issued numerous white papers, policy briefs, and press releases about the importance of reorganizing their energy R&D portfolios to focus on climate change or to put more emphasis on renewable energy R&D. However, the historical budget data that detail how these governments actually allocated their energy R&D funds reveal modest changes in overall energy R&D emphasis. Thus, for the energy R&D policy analyst, *caveat emptor* remains sound advice. Analysts are advised to seek out multiple sources of qualitative and quantitative data on energy policy and energy R&D before drawing conclusions about the health and direction of the energy R&D enterprise.

Glossary

crowding out Where one sector manages to secure first call on resources, preventing access to those resources for other sectors.

developmental state A country in which the government espouses an ideology of development and tries to create the capacity to implement policies to promote development.

Dutch disease As a result of large oil or gas revenues, the real exchange rate appreciates, causing imports to rise and non-oil or gas exports to fall. The result is a contraction in the non-oil or gas tradable sector.

oil fund An institution whose function is to receive the revenues from oil or gas projects and to control their use in terms of both investing and spending.

predatory state The opposite of a developmental state; the government is a kleptocracy in which the ruling elite is out to plunder the wealth of the country for its own selfish purposes.

rent seeking Where managers in an enterprise—state or privately owned—seek to absorb resources to improve their own working environment and lifestyle. This is not the same as corruption since rent seeking is viewed as normal and legal behavior.

terms of trade The amount of goods or services that have to be exchanged for other goods or services; for example, the number of agricultural products that must be exchanged for an amount of manufactured goods.

Large revenues from natural resources should generate wealth, promote economic progress, and reduce poverty. The logic behind this may be based on common sense (more money may be better than less) or economic development theories, including capital fundamentalism, dual-gap analysis, or the big push argument to break out of a self-feeding circle of poverty. Thus, large windfalls from oil or gas projects should overcome capital and foreign exchange constraints and generate the required "push." However, for many years casual empiricism and more formal investigation suggest the opposite. Many resource-rich countries have experienced a worse performance in economic progress and poverty reduction than countries without such apparent benefits. In the economics literature, this has become known as the resource curse thesis. However, it should be noted that although many suffered a "curse" from the influx of large natural resource revenues, others did not. Thus, resource curse is by no means the default situation.

1. A HISTORY OF INTEREST IN RESOURCE IMPACT

Concern regarding the impact of natural resources dates back many centuries, most obviously with Spain's wealth from the New World. Concern emerged among development economists such as Raul Prebisch and Hans Singer in the 1950s and 1960s. They argued that primary product exporters (the periphery) would find themselves disadvantaged in trading with the industrialized countries (the center) because of deteriorating terms of trade.

Concern was focused on primary products and natural resources generally. However, in the 1970s, attention focused on the oil exporters following the oil

 © 2004 Elsevier Inc. All rights reserved.

shocks. Their aftermath caused speculation that large-scale revenues might be bad for their development prospects. The experience of The Netherlands following the discovery of the Groningen gas field gave rise to concern regarding Dutch disease. This was defined explicitly as the contraction in the nonhydrocarbon-traded sector following a real appreciation of the exchange rate. For The Netherlands, this meant a decline in manufacturing. However, economists also began to observe that for oil-exporting developing countries, it was agriculture that took the hit.

In the 1990s, it was the impact on government behavior that attracted attention. Large windfall revenues from oil or gas projects appeared to change government behavior, damaging growth and development. This ran parallel to the wider developments in economic theory on the economic theory of politics, theories of public choice, and principal-agent analysis that laid the ideological basis that government involvement in the allocation of resources would lead to misallocation.

Recently, several factors revived interest in the subject and also brought resource curse to a wider audience. For some time, nongovernmental organizations (NGOs) have expressed concern that oil or gas projects in poor developing countries have negative effects. The World Bank Group set up an "Extractive Industry Review" to consider the bank's role in such projects. The larger, more responsible oil and mining companies are also considering their impact on host countries and how to mitigate negative consequences. This is driven by concern for reputation in a world in which ethical considerations of investment are becoming paramount. It is also driven by a view that negative effects could threaten the economics of the project.

Another cause of this revival of interest is that a number of countries—Azerbaijan, Angola, Chad, Kazakhstan, Papua New Guinea, and numerous others—will soon receive large-scale oil or gas revenues. There is general concern about the impact and use of these revenues and what should be done to maximize the benefits and minimize negative effects.

Finally, many institutions financing such extractive projects realize that the potential for resource curse from the projects threatens the viability of the projects and, hence, ultimately the value of their investments.

2. THE PRESENCE OF RESOURCE CURSE

A large body of work has attempted to establish a negative relationship between the abundance of natural resources and poor gross domestic product (GDP) performance. For the most part, the evidence appears to support the negative link. However, such work is sensitive to the period chosen and there is evidence that before the 1970s resource-abundant countries grew faster than resource-deficient ones. Also, because of price fluctuations certain periods are likely to distort results.

There are a few dissenting voices to this empirical work based on methodology rather than the overall conclusions, although some challenge both methodology and conclusions, arguing that there is little long-term evidence that natural resource-abundant countries generally underperform. Rather, natural resources have played an integral role in the success of many industrialized countries. Oil exporters have also provided support for resource curse. For example, Mikesell identified Saudi Arabia, Mexico, and Venezuela as having lower than average annual growth rates of GDP.

Apart from a negative growth impact, another aspect is the prevalence of poverty and the observation that oil- or gas-rich economies have a poor record in poverty alleviation. This is a central theme of much of the literature. Another dimension is that oil or gas projects are associated with greater conflict in a society. Large-scale resource revenues create a pot that is worth fighting for. Whoever is in power is better able to plunder that pot. Such revenues also generate higher levels of military spending. The projects often alienate local populations, especially if separatist tendencies already exist. Conflict is also linked to poverty. War and strife (e.g., inflation) are regressive since they hurt the poor more than the rich because the poor cannot mitigate against the effects. Fighting or expectations of fighting also absorb resources that could go to improving economic performance and alleviating poverty.

Another characteristic linked to resource curse is that natural resource abundance slows political change and entrenches regimes. Thus, as Auty noted, an abundance of resources significantly weakened nascent democratic institutions, repressing political parties so that power is weakly contested, public finances are opaque, and corruption by both the elite and the bureaucracy is rampant.

A final dimension is the regional impact of the projects. Although the effect at a national level might be debated, because of the local impact, damage is often done especially in terms of both the environment and human rights. Meanwhile, the benefits appear to flow to central rather than regional authority.

However, although evidence of the presence of resource curse appears convincing, there are examples of countries for which there appears to have been a "blessing" rather than a curse, including Botswana, Chile, Malaysia, Norway, Indonesia before 1997, Australia, and Canada. A study by Stevens provides strong support for the fact that these countries avoided the curse. Thus, there is a case for dropping the automatic use of the term resource curse and instead using the term resource impact and considering whether the outcome was a curse or a blessing.

3. TRANSMISSION MECHANISM BETWEEN LARGE RESOURCE REVENUES AND POOR PERFORMANCE

There is a huge literature on why countries might suffer a curse rather than a blessing following a large inflow of oil or gas revenues.

3.1 Long-Term Decline in Terms of Trade

This argues that over time, the revenue would buy less imports of capital goods, thereby inhibiting development-creating investment. However, this is controversial and the empirical and theoretical arguments have been much contested. Also, it is difficult to understand how a slow decline in prices would explain the sort of deterioration in economic performance associated with resource curse. Economies constantly face changing relative prices. If they take place gradually, economies might be expected to adjust unless other factors are at work.

3.2 Revenue Volatility

Oil or gas revenues are very volatile, especially driven by wide fluctuations in prices over relatively short periods of time. Certainly, there is plenty of empirical support for the existence of such volatility. Thus, Mikesell found that between 1972 and 1992, regions with high primary export shares experienced periods of trade volatility two or three times greater than those of industrial countries during the same period. Fluctuating revenue profiles make it difficult to pursue a prudent fiscal policy. This creates problems ranging from aggravating investor uncertainty to "stop go" spending policies. There is also concern that windfall revenues would be consumed rather than invested, although empirical evidence throws doubt on this since the permanent income hypothesis argues that windfall gains would be more likely to be saved and invested than consumed. However, intuitively it is easy to imagine fluctuating revenues, in the absence of effective stabilizing measures, creating problems for government fiscal policy and macroeconomic management more generally.

3.3 Dutch Disease

Originally, this referred to the appreciation of the real exchange rate as a result of inflation from spending the revenues plus an appreciation of the nominal exchange rate as the domestic currency attracted higher demand. The result was a contraction in the non-oil or gas sector. However, over time, the meaning has become wider to encompass all negative macroeconomic effects associated with resource curse.

These changes of meaning are reflected in the differing theoretical approaches. Corden and Neary split the impact of an oil boom into a resource movement effect and a spending effect. In the former, a higher marginal product in the booming resource sector draws resources from other sectors. Thus, factors move into oil, bidding up wages and causing other sectors to contract. The spending effect occurs when, as a result of the windfall, demand rises in both tradables and nontradables. Since prices of tradables are determined by the international market, greater demand is met by higher imports. However, prices of nontradables increase relative to tradables and so resources shift from tradables to nontradables. This approach forms the basis for much of the subsequent analysis in the literature.

Over time, other dimensions of Dutch disease—defined simply as a contraction of the tradable sector—have emerged. Thus, one argument is that subsidies used to protect nonresource tradables that are weakened by the boom aggravate the sector's problems and eventually become unsustainable. Another is the "leapfrog effect," in which governments tend to miss the labor-intensive phase of industrialization and move straight to the heavy, capital-intensive phase with negative effects for the tradable sector. It has also been suggested that resource-poor countries accumulate social capital faster than resource-rich countries. One explanation for this is that limited natural resources promote early industrialization forcing earlier urbanization.

In addition to the controversy regarding the exact nature of the theory of Dutch disease, there is also

controversy regarding whether empirical evidence supports its existence. A number of country studies provide support, including studies on Bolivia, Venezuela, Mexico, Brazil, Peru, Algeria, Ecuador, Indonesia, Nigeria, and the United Kingdom. However, often the situation is complicated by extraneous factors. For example, in Botswana a Dutch disease effect on agriculture was complicated by two serious droughts in the 1980s. Others conclude that Dutch disease was not the major factor explaining the growth pattern and that some deindustrialization may be the result of adjustment toward a new equilibrium. Furthermore, for oil-exporting countries, after the oil boom of the 1970s, although agriculture did contract, manufacturing tradables actually expanded in most cases.

3.4 Crowding Out Effects

This is a variation of the resource movement effect of Dutch disease in which the project, which is large relative to the rest of the economy, stakes first claim on scarce resources. The rest of the economy finds it difficult to secure the factors needed to develop. This is especially relevant in smaller countries when the size of the investment project is large or where there are strong regional dimensions to an economy and the project is focused in one region. It is also important in the transition economies, in which transition has destroyed the old productive base and a new and private tradable sector is struggling to emerge.

3.5 Increasing the Role of the State

If the "Washington consensus" is believed, then greater government intervention in an economy is a bad thing. Given that in most legal regimes the revenues accrue to the government, this inevitably invites greater government intervention. Many of those writing on resource curse view a major part of the explanation of the phenomenon as relating to the role of the government. Also, many argue that it was good government decisions that enabled a few countries to avoid the worst excesses of resources curse. As with crowding out, the issue is especially sensitive in the transition countries simply because the objective of transition is to reduce government intervention in the economy.

However, although many would agree with these sentiments, why oil- or gas-exporting countries appear more vulnerable to policy failure requires further explanation. Several strands of argument are possible. The first argues that large windfalls lead to poor general decision-making by governments. The development of such projects raises expectations. This pressures government to "do something" that encourages speedy responses. Often, quick, ill-coordinated decisions are bad decisions. Also, spending revenues too quickly is more likely to introduce distortions into the economy, if only because there is less chance for the economy to adjust naturally. Having more money to play with weakens prudence and normal procedures of due diligence. Thus, making the "right choices" seems somehow less important. Of particular relevance is when governments decide on capital spending without consideration of the recurrent spending implications. Finally, because in the first instance the revenues accrue to government, decision-making is concentrated in fewer hands than if a greater number of economic agents are involved in decisions regarding how to spend any windfalls.

Another strand of explanation concerns corruption and rent seeking. Having large amounts of money to play with increases the temptation for corruption and rent seeking on the part of the decision makers. However, this is a complex and controversial area. Some argue that corruption evolves from a clash between traditional values and foreign norms. Thus, in Africa, bureaucrats are under an obligation to share the benefits of their office with their kin, a characteristic common to a great many other societies. If this is the case, then because the oil or gas projects in developing countries almost invariably involve foreign companies, this alone helps explain why resource-rich countries may experience greater levels of corruption.

Rent seeking concerns how people compete for "artificially contrived transfers." The result is that the expenditure creates no social value and, arguably more important, distorts markets and hence the way the economy operates. There are several explanations for why rent seeking is greater in countries with large oil or gas revenues. Most obvious, the larger the public purse, the less noticeable the leakage to interest groups, although this may not be true if the result is a "feeding frenzy." Also, rent seeking is greater because wealth is concentrated in the public sector or possibly a small number of companies. Thus, most of the rents created are channeled by bureaucrats, most of whom are members of the politically dominant group. There is general agreement that rent-seeking behavior produces undesirable results for the economy and imposes significant losses on many economies. Such behavior distracts attention from goals of long-term development

toward maximizing rent creation and capture. Also, rent seeking creates powerful lobby groups that block much needed economic reforms. Rent seeking also makes it more difficult for governments to adjust spending when faced with revenue fluctuations.

However, such issues are far from clear-cut. An important aspect is what happens to the rewards of corruption and rent seeking once they have been secured. If used for productive investment within the economy, the outcome will be different than if used for conspicuous consumption or to enhance foreign bank accounts. After all, at the risk of being simplistic, the whole point of capitalism is for a few greedy, selfish, and unscrupulous individuals to "grab" resources and put them to productive use to secure even more resources. The "robber barons" who developed the U.S. economy in the 19th century (very resource rich by any definition) indulged in some very dubious business practices, not least in the oil sector.

Often, the nature of investment decisions following large windfall revenues creates problems for economic progress. This is in part explained by the bad decision-making previously discussed. Also, often investments made by resource-rich governments fail to develop the productive base of the economy. Furthermore, if borrowing funds these investments, this compounds the problem since the loan must be serviced and repaid. It has been argued that much of the link between resource abundance and negative growth may be attributed to the aftereffects of a borrowing spree by natural resource exporters in the 1970s.

A specific area that combines poor decision-making and bad investment decisions in many resource-rich countries concerns the industrial policy adopted. Resource-rich countries tend not to promote a competitive manufacturing sector. Rather, they adopt an industrial policy based on import substitution involving subsidy and protectionism. Often, resource revenues prompt the introduction of heavy subsidies, usually based on an infant industry argument. These become unsustainable when revenues decline. However, their creation and the subsequent rent seeking create powerful interest groups that oppose their removal. Regarding protectionism, there is a positive correlation between dependency on primary products and a closed trade regime. Once these elements of policy—subsidy and protection—are in place, continuing resource revenues reduce the incentive to create competitive manufacturing industries. Since many development economists regard competitive manufacturing as a principal source of technological progress, this has serious implications for economic progress.

3.6 Sociocultural and Political Impacts

The sociopolitical dimension is central to the discussion, although its role is much disputed. It has been suggested that resource-rich countries have weaker institutional capacities, and that the endogenously determined institutional capacities are key determinants of growth. In contrast, others argue that although differences in income can be explained by the effectiveness of institutions, this is a legacy of colonialism and there is no discernable impact from natural resource abundance.

Previous explanations related to the macroeconomic causes of the curse. Countries that avoided the curse did so by the adoption of specific policies to minimize damage. Of key interest is why such policies were or were not adopted and why the various political elites allowed them. The answer lies in the nature of the society and its politics and, as such, is a crucial part of the explanation of the transmission mechanism.

Some of the discussion revolves around rentier societies in which there is no connection between reward and effort. Thus, easy access to riches bred idleness and provided no incentive to accumulate or innovate. Although this explanation seems attractive, it is not conducive to analytical rigor and smacks slightly of stereotyping that, apart from any other potential problems, condemns the recipients to a life with no hope of redemption.

A particularly fruitful area of sociopolitical enquiry concerns the categorization of states as developmental or predatory. A developmental state has two elements—an ideological and a structural component. The ideological component involves the ruling elite adopting developmentalism as its prime objective. Legitimacy is derived from the ability to deliver development, implying both growth and poverty reduction. This elite establishes a form of ideological hegemony—via the ballot box or less desirable means—over the rest of the society. The structural component involves the capacity to implement policies "sagaciously and effectively" that will deliver development. Apart from technical capabilities, this also requires a strong ruling elite that can resist pressure from powerful, short-sighted private interests and/or some form of "social anchor" that restrains any temptation to use its autonomy in a predatory manner. A key element is the realization that developmental states can still fail. Despite the

"right" ideology and the limits of predation in place, the capacity to implement effective policies might not be enough to manage certain problems, especially if these are exogenous. Such problems may be driven by external shocks, mistakes, or bad luck.

In contrast, in the predatory state, the ruling elite only have interest in feathering their own nests. They are "takers," not "makers," who have little or no interest in promoting economic development. Thus, their objective is to plunder the state's resources to benefit the few, as opposed to a developmental state in which the objective is to benefit the many. There are no checks and balances to inhibit plundering the national wealth. Indeed, the less constraints on the ruling elite, the more they can plunder. This process becomes self-reinforcing. The greater the wealth accumulated, the more resources they have to inhibit, buy off, or control any potential checks and balances.

Large-scale oil revenues encourage predatory states by a number of mechanisms. As with rent seeking and corruption, they make the pot larger and therefore more attractive to take. The more there is to steal, the greater the temptation to do so. Revenues generate resources to suppress opposition to the predation either by the use of force or by simply buying off potential problems. Finally, the major powers, dependent on oil, may provide support and legitimacy for predatory regimes to ensure the continued flow of oil, thereby protecting the regime both from internal problems and from threats from neighbors. Iraq is a classic example.

It is tempting to attribute poor performance by resource-rich countries to a lack of democracy. However, the argument is debatable. Thus, as Mikesell suggested, democracy does not ensure good government, nor are all oligarchies poorly governed. Furthermore, the democratic credentials of countries that avoided the curse—Malaysia, Indonesia, Pinochet's Chile, and indeed Botswana—are highly debatable.

This lack of clarity on the transmission mechanisms presents a serious challenge. If it is not clear what causes the problem, then treatment is likely to prove equally elusive. However, this is important if investment in oil and gas projects under consideration is to go forward.

4. HOW RESOURCE CURSE MAY BE AVOIDED: THE THEORY AND THE PRACTICE

The literature presents a number of options for avoiding resource curse.

4.1 Leave It in the Ground

Although this cannot be regarded as a serious option since a less ethical company will always be willing to make money, irrespective of damage or reputation, it does raise issues about the speed of the project and hence the consequent production/revenue profile.

Conventional project economics argues that from a commercial standpoint, the faster the development, the better. The slower the production, the lower the total present value of the revenue stream. However, common sense argues that a slow, steady trickle of revenues should be easier to handle than a sudden surge. If revenue management problems are easier to deal with, the resource movement effect and crowding out are likely to be less severe. Furthermore, slow development allows the development of a service industry to maximize backward linkages from the project, whereas swift development must be based on imports. The problem is persuading investors to slow development. Although this goes against conventional project economics, if rapid development generates a curse and if this threatens the project because of the political fallout, slower development may well be justified on purely commercial grounds. There is a major gap in the literature on resource curse regarding how the phenomenon might affect the economics of a project. One obvious connection is that insofar as the curse embodies increased conflict within a country, this may directly physically threaten the project's equipment and infrastructure. This would be especially relevant where the curse had a strong regional dimension as a result of the local impact of the project.

A variant on this theme is the nature of the revenue flow. Differing forms of extractive agreements—concession based on royalty and taxes, joint ventures, production-sharing agreements, service agreements, etc.—will create differing profiles of revenue flow. Thus, although development of the project may still be rapid, the revenue flow could be controlled by the agreement rather than leaving it to the vagaries of some sort of stabilization fund. An example is the case in which a project is expected to create a short-lived revenue peak for the government. In this case, the project may flatten the peak by providing revenue upfront before the project is fully operational and afterwards when the project is finished. Of course, this implies that it is the company that controls the revenue flow rather than the government, which raises issues of sovereignty.

4.2 Diversification

One obvious solution is to reduce the importance of the oil or gas sector in the economy by diversifying the economy. Since the early 1970s, oil-exporting countries have paid lip service to diversification away from dependence on crude oil exports. However, the record in general has been very poor, with huge amounts of public money being poured into inefficient and uncompetitive industries.

Several factors explain these failures. Dutch disease and crowding out cause a contraction of an existing non-oil or gas tradable sector. It is not surprising if the mechanisms that destroy do not also inhibit the rise of a new tradable sector. Another explanation favored by countries is that trade restrictions imposed by the Organization for Economic Cooperation and Development exclude their outputs. Although both arguments have validity, there is a third explanation. In most cases, the diversification policy has consisted of governments trying to pick winners. Thus, much of the new economic activity has been government-owned enterprises. Governments are generally very bad at picking winners, although there have been exceptions.

The only effective diversification derives from private sector investment, although governments can play an important role in this process, as can be seen from the experience of the Asian tigers. Thus, one solution to the problem of diversification is to maximize the revenue flow to the private rather than the public sector (discussed later). This was certainly an important part of the explanation for why Australia, Canada, and the United States avoided the curse. Of course, this raises important issues of income distribution and private economic power leading to concentrations of political power. This in turn is associated with the complex and controversial issue of how much political repression is worth accepting for an improved standard of living—a constant theme of more general literature for centuries.

Another means to encourage successful diversification relates to trade policy. Countries that avoided the curse pursued a policy of trade openness with the rest of the world coupled with a deliberate policy of exchange rate depreciation to ensure the competitiveness of non-oil or gas exports.

4.3 Revenue Sterilization

A key factor is the macroeconomic policy adopted by the government, specifically the policy adopted to try to neutralize the impact of the large windfall revenue inflow on the rest of the economy. This has several dimensions. The first is the need for fiscal prudence to prevent the revenues from translating immediately into greater aggregate demand and inflation. This requires the government to resist spending pressures and either accumulate budget surpluses or channel the revenues into some form of fund. An important subissue is that the government should avoid using promises of more revenue to increase borrowing.

Another important strand to macropolicy is to avoid exchange rate appreciation. Several options are available. The first is to avoid a fixed exchange rate policy when domestic inflation of any magnitude exists. The second is to encourage currency devaluation. However, this has no effect on the real exchange rate without appropriate demand management policies. One option is for the central bank to purchase foreign exchange to hold down the nominal rate. One common factor in the case of countries that recently avoided a curse is that they all experienced significant depreciation of the real exchange rate as a result of explicit policy choices.

4.4 Stabilization and Oil Funds

There is general agreement that trying to stabilize spending to ensure stable and moderate growth is important. This can be done in several ways. Trying to stabilize the international price is no longer a serious option and probably never was despite a large literature on commodity stabilization schemes. One possible solution is to stabilize prices by using futures markets to lock in price stability. However, there are problems. For very large producers, the danger is that their involvement would simply swamp the markets. Also, such insurance costs. Although having guaranteed prices in a falling market would result in praise for the decision makers, in a rising market there is bound to be criticism. Another solution might be to use the extractive agreement to smooth revenue flows, as previously suggested.

Another mechanism is to create an oil fund. These can fulfill three functions. They can be used to insulate the economy from large revenue windfalls by investing them outside the domestic economy. The fund can also be used to stabilize revenues by setting a price assumption for budgetary purposes. If prices exceed this, then the fund absorbs the windfall. If prices are lower, then the fund's assets are used to meet the budget. Finally, such funds can be used to put assets aside for future generations. Thus, the

revenue is accumulated and only the earned income is spent, leaving the capital sum intact to allow future generations to benefit from a depletable resource.

In recent years, the role of such funds has become extremely controversial, especially within and between the World Bank and the International Monetary Fund. There are two schools of thought. One argues that the conditions for such funds to work are such that if they are present, the revenue windfall can be managed within the normal budgetary process. Hence, the funds are not needed. The other argues that even if conditions are not ideal, the creation of such funds makes some contribution to avoiding the worst excesses of resource curse if only because of the role of the fund in dampening spending expectations.

4.5 Investment Policy

The investment policy adopted by the government for the revenues will play a crucial role both in avoiding many of the macroeconomic pitfalls described previously and in encouraging the process of economic diversification by creating alternative sources of value added to the depleting resource sector. Ideally, investment is best carried out by the private sector. Although, as previously noted, the experience of the robber barons in the United States in the 19th century illustrates that this does not guarantee everyone lives happily ever after. However, private sector investment is more likely to be sustainable than when the government tries to pick winners.

4.6 Political Reforms Needed to Carry Out the Corrective Politics

A key component of any solution is the need to remove corruption and contain rent seeking. However, this is far from straightforward. For example, any cleanup campaign must start with an agreement on a common standard of morality. Options to solve problems of corruption include incorporating controls in legal codes and encouraging independent (and fearless) enquiries. Another solution is to reduce rent-seeking opportunities by depoliticizing resource allocation. Thus, deregulation allows free markets, taking politicians and bureaucrats out of the resource-allocation process. The theory with empirical support is that competition squeezes out illicit margins. Although this is probably true, it still requires the creation of competition, and often simple deregulation and privatization is not sufficient to achieve this.

Much is also made of the need for transparency as an aide to reduce corruption. Although this can have a role, there is a danger that its effectiveness can be overstated. For example, many have called for the oil companies to disclose how much money they provide to the government so the public can see how much money is being "diverted." This neglects the fact that often very large sums accrue to the national oil company as a result of the agreements, especially joint ventures and production sharing agreements. It also bestows upon both the public and the local media a degree of sophistication that may be misplaced. For example, a major problem is that because the cash flow associated with projects is uneven over time, considering only a few years could give the impression that the oil companies are taking a huge share of the proceeds, ignoring the earlier years of negative cash flow. This could revive the "obsolescing bargain" and lead to unjustified pressures to renegotiate terms. This is not to argue that there is no place for transparency, just that it is far from a sufficient condition to reduce corruption.

There is also the issue discussed previously that from an economic standpoint, it is not so much the presence of bribes and rent that is the problem. Rather, it is how they are used. Leaving aside moral issues and issues of income distribution, bribes and rent productively invested result in a successful capitalist economy. Economic problems arise when these are diverted into conspicuous consumption or foreign bank accounts.

Following from previous discussion, a key issue relates to securing a developmental rather than a predatory state as a way of minimizing the risk of suffering a curse. Developmental states require two components: a strong elite with an ideology that is conducive to economic development and whose interests are aligned with the population and also the institutional capacity to implement the necessary policies without being captured by narrow private interests. In contrast, a predatory state lacks the linkages to the population or any other constraint that prevents the elite from ransacking the economy.

Securing an alignment of interests is crucial. One route to achieve this alignment is democracy in which the government must satisfy public interests or be voted out. However, although this may seem to be the optimal route morally, as argued previously, it is not the only route. Thus, for example, Chile under Pinochet and Malaysia, Indonesia, and indeed Botswana as a "one-party democracy" managed the alignment quite well.

Of course, what constitutes an ideology that is conducive to economic development is also a moot point. Clearly, simple mantras based on "leave it all to the market" are inappropriate. However, the experience of those countries that avoided a curse suggests that although their governments did intervene extensively, they did so to push the economy toward a market-based system linked into the global economy and toward the encouragement of a vibrant private sector.

The ability of the elite to translate this ideology into effective policies is a function of institutional capacity. Clearly, both international financial institutions (IFIs) and investing companies have a role to play in training those elements of the bureaucracy that could play a key role in policy making. This can be done using a combination of seconding expertise (assuming acceptance by the governments) and training nationals using short professional training courses and more long-term basic provision of university postgraduate training.

All this is feasible and can be made to work such that the economy progresses. The real problem arises when the ruling elite lacks any social anchor and alignment with the public and the state has become predatory. Insofar as the state may be dependent on IFI good will for financing and debt management, the IFIs can be in a position to provide the constraints required to reign in predatory behavior, although this obviously raises sensitive issues of sovereignty. However, such an outcome has the seeds of its own destruction since once the resource revenues begin to flow, the IFI leverage seeps away and with it the constraint. One possibility is that the strengthening of civil society might begin to provide both the constraints and the alignment necessary to switch the state from being predatory to developmental. Again, the IFIs and companies can help strengthen civil society, but this means more than just giving the NGOs more money, although what precisely it does mean is uncertain and needs further thought and analysis. Also, it assumes the predatory state will tolerate the growing influence of civil society, which for obvious reasons of its own survival it may not. Another option is for the oil company to exert pressure on the government to curb predation, but this would only be effective if all the main oil companies were willing to take the same stance.

Of course, one solution is for the international community to refuse to invest in predatory states. However, this raises the prospect of an unethical portion of the industry investing to add further to the plunder of an economy by its own elite. It also raises the prospects of creating ever more failed states harboring resentment against the West.

5. CONCLUSION

Clearly, the issue of what causes a curse rather than a blessing and how to enjoy the latter and avoid the former is extremely complex. The literature is divided on both causes and cures, although there is a growing consensus that essentially it has something to do with governance and the answer lies more in political economy than macroeconomic analysis. Hence, the key question is not what was done in terms of policy decisions but, rather, why was it done? The outcome of the debate will be of crucial importance in terms of determining the future magnitude, type, and direction of investment in the oil and gas sector.

Glossary

improved material management Intentional actions that lead to a reduced amount of material that is used to fulfill the same function. Since materials require a large amount of energy in production, this often leads to energy savings.

material cascading Improved material management measure. It is a form of material recycling but differs due to the reduction in product quality that can be produced with the secondary material. An example of material cascade is paper used for printing and writing that is recycled for newsprint.

material recycling Improved material management measure; reuse of materials. The original product is destroyed in order to reuse the materials for new products. This can be the same type of product or a new type of product. Energy savings often occur since the manufacturing of virgin materials often requires more energy than producing recycled materials.

product reuse Improved material management measure. This is a type of material recycling, but it leaves the original product intact. The major advantage is that energy used in the construction of a product is not lost due to destruction of the product. It is the material management measure with the highest carbon reduction potential in the packaging sector.

Since the use of fossil fuels is an important cause of increased greenhouse gas concentrations, many strategies for reducing human greenhouse gas emissions focus on a reduced use of fossil fuels. To reduce the use of fossil fuels, a wide range of options can be applied: (i) improvement of energy efficiency, leading to a reduction of the energy consumption per unit of activity or product; (ii) development and application of renewable energy sources, such as biomass, hydropower, solar, and wind energy; (iii) a shift in the use of fuels from resources with a high carbon content (coal) to resources with lower or even no carbon content (natural gas and uranium); (iv) decarbonization of fuels and flue gases, for example, by recovering carbon dioxide from energy conversion processes and storing it outside the atmosphere; and (v) improvement of material management.

This article focuses on reuse of materials, which can be categorized as an improvement of material management.

1. RELATIONSHIP BETWEEN ENERGY AND MATERIALS

Improvement of material management is not commonly incorporated in greenhouse gas reduction policies. This is strange since several studies indicate that this option has a large potential and is often economically attractive. Before the results of these studies are described in more detail, the reason why material efficiency may lead to reduced greenhouse gas emissions is discussed.

Materials are produced in the industrial sector and a major portion of fossil energy consumption is used in this sector. The industrial sector (excluding refineries) consumed approximately 33% of the total primary energy use in 1995 for developed countries. When materials are used more efficiently, less materials need to be produced and, therefore, less energy is needed in the production stage. Consequently, more efficient material management is likely to lead to reduced emissions of greenhouse gases.

A limited number of studies have been performed on the subject of improved material management and climate change. A few case studies from Utrecht

 © 2004 Elsevier Inc. All rights reserved.

University on plastic packaging and fertilizers show that a significant greenhouse gas emission reduction is possible by more efficient material use. Patel studied a limited amount of material management options for the plastics sector in Germany. He showed that these options may lead to a 24% reduction of CO_2 emissions from the German plastics-producing industries. Furthermore, the U.S. Environmental Protection Agency showed that management of waste materials presents many opportunities for greenhouse gas emission reduction. Elliott showed that recycling, an improved material management option, may lead to major savings in industrial energy use. In The Netherlands, the MATTER project, involving the Dutch Energy Research Centre and several universities, was started to model the Western European energy and materials system and determine, based on technological improvement options, the greenhouse gas emission potential in these systems in the period 1990–2050. Gielen concluded, based on these model results, that "the potential for emission reduction in the materials system seems to be of a similar magnitude as the emission reduction potential in the energy system." The importance of these studies for understanding the potentials for greenhouse gas emission reduction is stated by the United Nations Department of Policy Coordination and Sustainable Development. Based on these studies, one may conclude that the potential of improved material management on greenhouse gas emission reduction seems to be significant, and obtaining more insight into the exact potential and the ways to utilize this potential is important.

2. PRODUCT REUSE IN PERSPECTIVE

The environmental pressure that is related to a product or a material is the sum of the environmental pressures related to the production of that material or product as well as the other stages in the life cycle of the product, such as production of raw material and waste management.

Climate policy should therefore focus on greenhouse gas emissions at all stages of the product life cycle: raw material extraction, material production, product manufacturing, product use, and disposal of products and waste management.

Changes in any of these stages can lead to reduced product-related greenhouse gas emissions. However, it is important to realize that measures that lead to reduced emissions in one part of the product life cycle may lead to increased emissions elsewhere: In order to reduce product-related greenhouse gas emissions, the whole life cycle needs to be taken into account.

Figure 1 gives an overview of the different life-cycle stages and the measures that can be taken to improve the efficiency of material production and use.

Figure 1 shows that in all stages of the life cycle, measures can be taken to increase material efficiency. The improvements can be categorized in many different ways. Here, the following classification is used:

1. Technical measures in the individual life-cycle stages
2. Management of the entire material product chain

Technical measures in the individual life-cycle stages include measures such as increasing the efficiency of processes (where innovations in technological development and process design can be used to reduce the amount of materials used in the process), improved product design [where using innovative production methods facilitates the use of thinner material (layers) and using other materials in the product manufacturing stage may lead to reduced emissions; important substitution criteria are the use

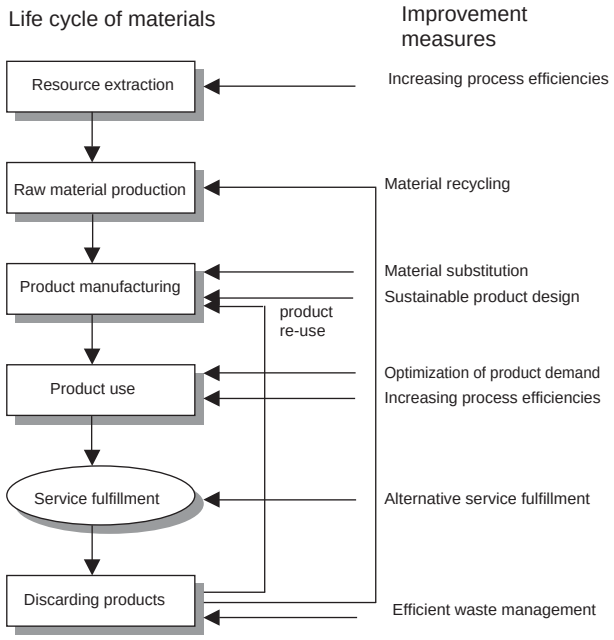

FIGURE 1 Material life cycle and improvement measures.

of energy-extensive materials, materials with a long lifetime, and materials that are suitable for reuse], and more efficient waste management (where there is optimal energy recovery from waste materials).

Management of the entire material product chain covers measures such as material recycling, material cascading (using discarded materials for the highest possible functions), extension of the useful life of products (modular design and increased fitness for repair and maintenance), sustainable product service systems (measures that lead to more efficient service fulfillment due to the substitution of products by services or combinations of products and services), and reuse (e.g., refillable plastic or glass bottles).

Reuse involves the collection and cleaning of products in such a way that they can be used again in the same form and shape as they were used in the previous life cycle. In such a way, both the structural properties of the material and the energy required for shaping the product are preserved. Therefore, to make a clear distinction between reuse and recycling, it is more appropriate to speak of product reuse and material recycling. In the case of material recycling, only the structural properties of materials are used again in new product life cycles. In this case, it is not necessary to use the recycled material for the original product. For example, polyethylene theraphtalate (PET) bottles can be collected and recycled in two different ways. The first is to clean the PET bottle and reuse it as a bottle (product reuse). The second is to shred the bottle and recycle the PET material for a different product, such as crates or fleece jackets (material recycling). Material reuse and material recycling differ from material cascading by the fact that in a material cascade the product that is made out of recycled material is always lower in quality than that of the original product. Optimal material cascading policy tries to optimize the required material characteristics for a product and the factual material characteristics. An example of a material cascade is to produce a solid wooden beam for construction purposes from a tree, then recycle the material after its product lifetime as wooden floorboards or window frames, and recycle the material again after this life cycle as fiberboard. In this case, the required wood quality of the products declines over the consecutive life cycles. Another example is the use of virgin wood pulp for the production of high-quality printing and writing paper, reuse of the wood fibers for lower quality printing and writing paper, and finally use of the fibers for newsprint production.

3. EXAMPLES OF PRODUCT REUSE

To make product reuse possible, a good working collection system is necessary. Traditional waste collection systems are not sufficient since the original products are damaged and contaminated. Therefore, separate collection systems are necessary. There are a few examples in which these systems have been set up successfully.

The first example is the reuse of beverage bottles in several European countries. In The Netherlands, several types of beverage bottles are separately collected, cleaned, and reused. Examples are the reuse of 0.33-liter beer bottles (88% of the beer volume packed), 1- and 1.5-liter soda bottles (56% of the volume packed), and 1-liter milk bottles (10% of milk volume packed). The beer bottles are made out of glass, the soda bottles are made out of PET, and milk bottles are produced from polycarbonate (PC). In packaging terminology, every time a bottle is reused it is called a trip. Thus, the trip number is the number of times a bottle is reused. On average, these trip numbers are approximately 20 for beverage bottles, implying that 20 times less material is needed to fulfill the same packaging function.

The second example is the reuse of transport packaging, also popular in many European countries. Transport packaging is defined as packaging that is used to bundle and protect multiple products for transport purposes. Examples are corrugated transport boxes, crates, and pallets. The latter two are often reused.

Crates and boxes are normally used to pack loose products, such as fruit and vegetables, meat, and product parts. (Crates are also used for transportation of bottles. No improvements for these crates have been modeled.) The crates and boxes can be used for one-way shipping or function as a returnable (reuse) package. The one-way crate is mostly made out of wood or corrugated board and is normally used to pack fruit and vegetables. One-way boxes are always made out of corrugated board. This box has an average volume of 40 liters and weighs 0.8 kg. Multiple-trip plastic crates can be used instead of one-way crates and boxes. The plastic multiple-use crate is made from high-density polyethylene (HDPE), weighs 2 kg, and has a volume of 40 liters. Using plastic returnable crates requires a closed-loop transport system. A third party often manages the logistics of this transport system. The crates currently used have a lifetime of 5–10 years and the average trip rate is 25/year.

Pallets are also used as single-trip packaging and in reuse systems. A vast majority of the pallets used in

Europe are made out of wood. Wooden pallets are popular because they are cheap, have a large carrying capacity, and are easy to repair. Moreover, they are very suitable for production of small series with deviating sizes. Approximately one-third of the pallets used in Europe are returnable. A single-use pallet weighs approximately 17 kg and a multiple-use pallet weighs approximately 25 kg. On average, returnable wooden pallets make 20 trips. Obviously, much material saving occurs when returnable pallets are used instead of single-use pallets.

In addition to wooden pallets, plastics pallets are also used. They are often used in the food industry because they are easy to clean due to their smooth surface. The most common material for plastic pallet production is PE, but sometimes PC is used. Pallets made out of PC are stronger than PE pallets. Plastic pallets are especially suitable as multiple-use pallets. They weigh approximately 30 kg. There is no consensus about the number of trips that can be made with a multiple-trip plastic pallet; it varies between 30 and 100 trips.

The shift from one-way pallets to returnable pallets requires major changes in pallet administration and management. The use of multiple-trip pallets requires a pallet pool. A pallet pool is an organization that manages the transit of the pallets between the various users. Standard sizes for pallets are introduced to make the pallet applicable for many users. In Europe, several organizations are active in the management of pallet pools, of which Europool and Chep have the largest market shares.

A third example is the reuse of product components of machinery such as televisions and copy machines. When the product has reached the end of its lifetime, it is collected and taken to a deconstruction facility, where the reusable parts are separated from the other components. The reusable parts are transported to the production facility and can be reused in new televisions and other equipment.

Two types of collection systems are generally used. The first system is completely organized by the producer. In order to make such a system work, the product is sometimes leased and not sold. The advantage is that the producer remains the owner of the product. When the product is not desired anymore by the customer, the producer (and owner) collects the product. This arrangement is typical for large, expensive products such as copy machines. In the second system, the collection is organized by either municipalities that collect electrotechnical products or retail traders that collect old products when selling new products. In The Netherlands, the latter system exists. When buying new products, a tax is paid to cover the expenses of dismantling the old products.

The success of both systems in terms of product reuse is strongly dependent on the efforts made by the producer to take back old products and reuse product parts. When this responsibility is low, the chances that product parts are actually reused are slim. In these cases, the maximum benefit is that the collection of these products offers potential for material recycling (plastic and metal recycling).

Producers that take product responsibility very seriously include Xerox, which takes back and dismantles its copy machines, and Bosch, which is making efforts to reuse the motors from returned machinery. The lifetime of a motor in electrical equipment is generally much longer that the lifetime of the total product. Reuse of motors is therefore a very good option.

4. ENVIRONMENTAL BENEFITS OF PRODUCT REUSE

The environmental benefits of reuse can be calculated. To do so, the original life cycle needs to be compared with the reuse life cycle. Specifically, all extra processes necessary to make reuse possible need to be analyzed (e.g., separation, cleaning, and transport of used products) and compared to all the processes that do not take place any longer in the reuse life cycle (e.g., material production, material transport, and product manufacturing). The environmental benefit can then be calculated by subtracting the environmental impacts of the obsolete processes from the environmental impact of the additional processes. The environmental benefits of reuse are often quite large since the environmental impact of the separation, cleaning, and transport of used products is often much smaller than the impact of material production, material transport, and product manufacturing. This is emphasized by Table I, which gives an estimate of energy use data for typical processes that occur in the production and use of PET bottles used for packaging of soft drinks. Here, it is assumed that the environmental effects of energy use are a good indicator of the total environmental effects. Table I shows that the dominant processes in terms of energy use are material production and product manufacturing. Since, product reuse leads to reduced material production and product manufacturing, the environmental benefits of reuse are easily explained.

Hekkert *et al.* analyzed a number of improvement options to reduce the environmental impacts of packaging materials. Product reuse was taken into account as an important improvement option. The results of their analyses indicate the potential environmental benefits of product reuse in relation to other options to improve a material cycle, such as material recycling, material substitution, and more material-efficient product design. In these analyses, the scope of studying environmental benefits is reduced to studying carbon emissions. In Fig. 2, the results of the analysis for packaging products are depicted.

Figure 2 needs to be read as follows. Each horizontal line represents one specific improvement option. Specifically, it represents the carbon emissions that are saved by replacing a traditional package with an improved packaging concept. Every horizontal line is numbered and the numbers relate to Table II, in which the traditional packaging concept and the improved packaging concept are listed. The length of each line indicates the size of the reduced carbon emissions, and the position of the line in relation to the vertical axis gives information on the life cycle costs associated with this improvement option. Figure 2 shows that the costs of many options have a negative value, which means that over the complete life cycle, costs are saved when the option is implemented.

TABLE I

Use of Energy for Typical Processes in the Production and Use of PET Bottles

Process	Energy use (GJ/1000 bottles)
Material production	8.50
Product manufacturing	1.22
Filling of bottle	0.20
Cleaning of bottle	0.45
Transport of bottle	0.10

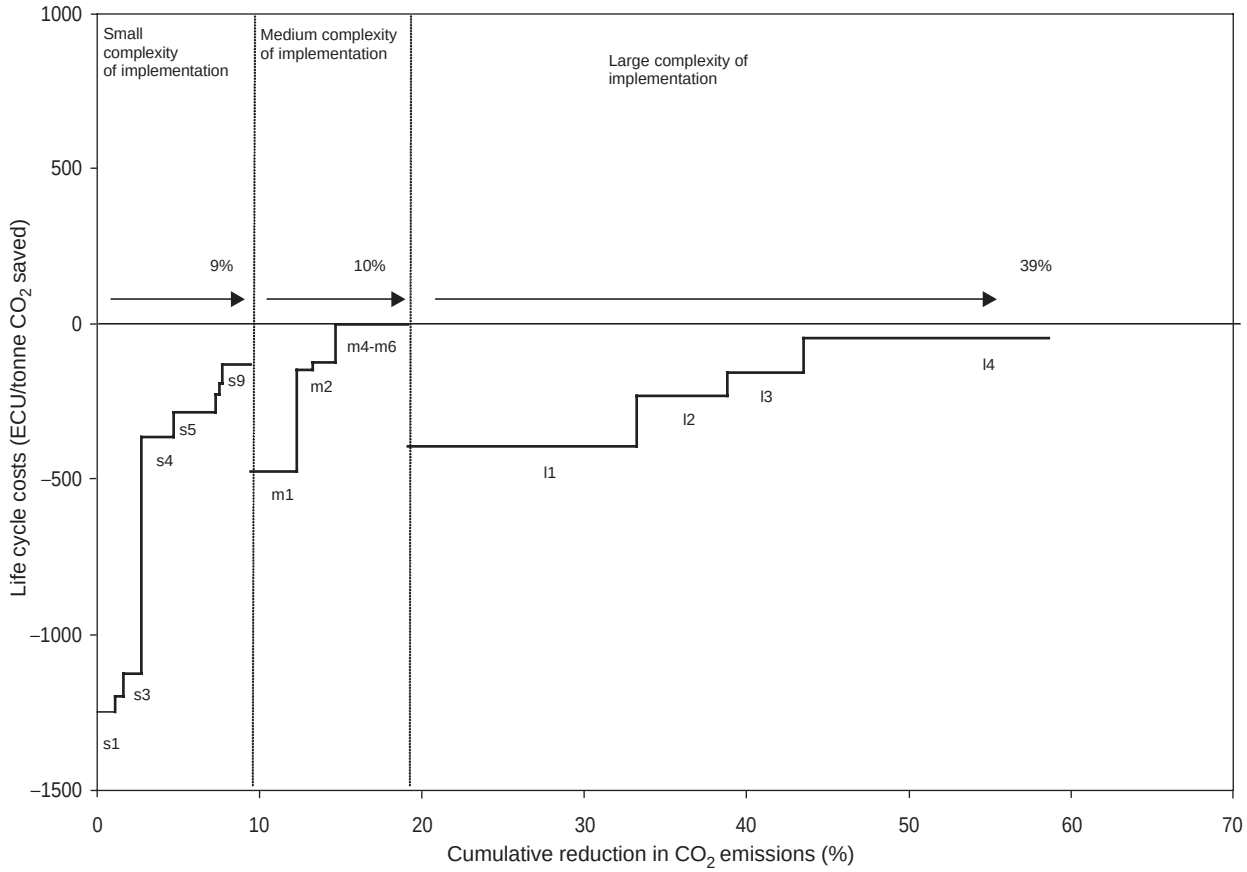

FIGURE 2 A supply curve for the reduction of CO_2 emissions by improved use of materials for primary packaging in Europe. The data refer to Table II.

TABLE II

Potential CO_2 Emission Reduction and Costs of Improved Material Management for Packaging in Western Europe[a]

No.	New packaging concept	Old packaging concept	CO_2 emission reduction (%)	Cost (ECU/tonne CO_2 saved)
S1	PP film thin	PP film	1.1	−1200
S2	Cardboard box, light	Cardboard box	0.5	−1200
S3	LDPE film thin	LDPE film	1.1	−1100
S4	Honeycomb food can	Steel food can	2.0	−360
S5	Light glass bottle, large	Glass bottle, large	2.4	−280
S6	Glass jar, light	Glass jar	0.2	−280
S7	Steel beverage can, light	Steel beverage can	0.2	−230
S8	Aluminum beverage can, light	Aluminum beverage can	0.2	−190
S9	Light HDPE bottle	HDPE bottle	1.8	−130
M1	PET bottle, one way	Glass bottle, large	5.2	−470
M2	Steel beverage can, light	Aluminum beverage can	1.1	−150
M3	PP cup	PS cup	1.4	−120
M4	PET bottle to be recycled	PET bottle, one way	1.0	0
M5	Recycled HDPE bottle	Light HDPE bottle	2.9	0
M6	Cardboard blister	PVC blister	2.2	0
L1	Pouch	Liquid board	14.1	−390
L2	Glass bottle, small refillable	Glass bottle, small	5.6	−230
L3	Pouch	HDPE bottle	4.7	−160
L4	PET bottle reuse, recycled	PET bottle, one way + PET bottle to be recycled	15.1	−40

[a] Abbreviations used: HDPE, high-density polyethylene; LDPE, low-density polyethylene; PET, polyethylene theraphtalate; PP, polypropylene; PS, polystyrene; PVC, polyvinyl chloride.

Figure 2 is divided into three parts. The first part indicates the options that can categorized as easy to implement; it contains mostly options that use a different product design to use lighter or less materials in packaging design. The second part contains options that are more difficult to implement, such as material substitution options. The final part is dedicated to reuse options and product substitution, which are the most difficult options to implement. The figure clearly shows that the total carbon emissions that can be expected from reuse (measure l2 and l4) are very large compared to the other measures. Thus, these results indicate that product reuse can be a very efficient option to reduce the environmental impacts of material life cycles compared to competing measures.

5. IMPLEMENTATION BARRIERS OF PRODUCT REUSE

It was previously mentioned that product reuse can be categorized as a rather difficult measure to improve a material life cycle. The reason for this is the fact that product reuse requires an additional infrastructure to return the products to the manufacturer or distributor. In this respect, product reuse can be seen as an ultimate form of extended producer responsibility. However, since manufacturers often strive to distinguish themselves from competitors, in every product group a whole range of different product designs can be found. This requires an extremely intense separation and returning system in which all individual products can be traced back to a certain manufacturer. In practice, this is likely not feasible.

Two types of systems do seem feasible. The first system was discussed previously. Here, products are not sold but leased and the manufacturer remains the owner of the product. In this case, the manufacturer knows the location of the product at all times and can take the product back at the end of its lifetime. Typical products for such a system are large, expensive (electronic) equipment for the professional market, such as copy machines. An important drawback of this system is that the speed of technological change in these product types is very high. This

results in a situation in which recycled product parts are often outdated. In these cases, material recycling is the second best option. However, one might question whether for material recycling, returning the product to the owner is preferable to a general collection system. The latter is much easier to organize and can benefit from scale issues.

The second system uses the concept of standardization to create an efficient returning system. In this case, several manufacturers and distributors agree on a standardized product that is manufactured by these parties. Examples are returnable beer and soda bottles in several European countries that do not differ in size, material, or design but only differ in the type of labels used. This system makes it possible for all bottles to be distributed over all manufacturers. This simplifies the setup of the returning system, but it requires the commitment of all major producers and distributors and it decreases the capabilities of the individual producers to develop new competitive product designs. The difficultly in developing this type of returning system is that it requires a large amount of companies (retail organizations, distributors, and manufacturers), the details of the system need to be agreed on by all parties, and much administration is necessary to keep the system going. This leads to transaction costs, which companies prefer to keep as low as possible.

One way to decrease the transaction costs is to make one party responsible for the complete setup and maintenance of the system. Other parties only have to join the system. Such an example is the use of returnable pallets in Europe. In this case, supranational standards have led to fixed pallet sizes, which makes it possible to rotate pallets over distributors throughout Europe. The pallet pools are organized by pool companies that own and maintain the pallets. Detailed tracking systems have been set up to calculate the pallet costs for each company in the pallet pool. The advantage for the distributors is that they do not need to own a large amount of pallets, which saves investment costs and space.

6. CONCLUSION

This article has shown that product reuse is an important method for improved material management, in addition to other methods such as material recycling, improved product design, and improved waste management. Important examples of current reuse practices can be found in the packaging and electronics sectors. The environmental benefit of product reuse seems quite large due to the fact that major environmental impacts from material production and product manufacturing are largely reduced. The problem with product reuse is that it requires a new and often additional distribution system that requires the involvement of many parties that need to align their actions. Transaction costs are regarded to be high, which can be seen as an important barrier for implementation.

Glossary

aversion A feeling of repugnance toward something with a desire to avoid or turn from it. Risk aversion plays a part in setting environmental standards.

perception Quick, acute, and intuitive cognition. In terms of risk analysis, it has been noted that perception often varies from objective studies.

pollution Environmental contamination with man-made waste. Air pollution is a major source of energy-related risk; water pollution is less so.

radiation Energy radiated in the form of waves or particles. This is a prime concern in terms of nuclear power risk.

risk Possibility of loss or injury.

risk per unit energy or electricity production To put different energy or electricity forms on an equal footing in terms of risk, analysts often divide the risks by a unit energy output, such as a megawatt-year. Other units can and are used. A large fossil fuel or nuclear plant might have a capacity of 1000 MW. If it operated without interruption for 1 year (highly unlikely), it would produce 1000 MW-years during that time.

uncertainty This may range from a falling short of certainty to an almost complete lack of conviction or knowledge. Risk analyses often contain more uncertainty than policymakers desire.

The production of electricity from any form of primary energy has some, in certain cases substantial, risks to human health and environmental effects. A balanced assessment of different forms of energy requires comparison of their environmental effects with those of their alternatives.

1. HISTORY OF RISK ASSESSMENT

Clearly, our prehistoric ancestors had some appreciation of risk, even in terms of energy. Fire, the main energy source of the time, could destroy unless it was carefully watched and controlled. In a broader context, staying far away from a saber-tooth tiger was safer than having it close at hand. However, until some numerical measure was used, what our ancestors experienced was not what we would call risk analysis. Thus, the phrase implies a type of calculation, from the simplest to the Monte Carlo probabilistic techniques of advanced risk studies.

The Babylonians were apparently among the first to use numbers extensively, often in conjunction with astronomical events. Consequently, it is little surprise that in approximately 3200 BC they apparently had the first risk assessors. These assessors did not deal with health or environmental issues. Although periodic flooding by rivers is now regarded as environmental, the Babylonians believed that these events were created by the gods and not amenable to any

 © 2004 Elsevier Inc. All rights reserved.

type of quantitative analysis. Issues such as health, death, food supply, and the like were planned by the supernatural, not to be interfered with by humans.

Rather, these forerunners of modern consultants offered advice on other risky decisions, such as deciding where to locate important buildings and when and whom to marry. These areas were clearly not energy related but have some resonance with modern life. Newspaper horoscopes, claimed by their developers to be based on mathematical formulae, are still read by tens of millions of people. In many areas of the world, the dates of major events such as marriages or contract signings are regulated by mathematics. In the United States, it has been claimed that President Ronald Reagan had the dates of some of his decisions set by the same formulae. The purpose of these calculations is to avoid risk—marrying the wrong person or losing money on a business decision.

In the Western world, the industrial revolution generated new diseases or caused the increased spread of old ones. It was realized that some diseases could be prevented or alleviated by human intervention. The scientific study of scrotum cancer in chimney sweeps by Percival Potts in Britain in the late 18th century was perhaps the first epidemiological study. This study has been cited in the first chapter of many books on risk. Since fireplaces were the main source of home heating in Britain at the time, the study was obviously energy related and perhaps the first scientific risk study dealing with energy. Epidemiology has undergirded many energy risk studies since then.

Curiously, however, although detailed in gruesome detail in books by Charles Dickens and others, the terrible diseases and accidents suffered by coal miners of the early 19th century, often children, apparently did not receive the same scientific scrutiny despite the fact that the total loss of health and life by coal miners was much greater than that of chimney sweeps. Chimney sweeps visited the homes of the wealthy, who never saw the suffering coal miners.

This omission still holds a lesson for modern energy risk analysis: The largest sources of risk for a given energy technology are sometimes ignored or glossed over as "common knowledge." This point will be illustrated later.

By the late 19th century, industrial hygiene, epidemiology, and toxicology were established as scientific areas. However, general application of this research to factories and industrial enterprises had to wait a number of decades as social consciousness grew. By the 1930s, considerable evidence on the relationship between occupational toxins and human health had accumulated. However, the Great Depression prevented widespread use of these results in regulation. Only certain large firms, such as DuPont, whose social consciousness dated back to its gunpowder manufacturing days, made use of these results.

At that time, it was known that air pollution could cause health problems. Pittsburgh, Pennsylvania, was known as the "smoke city" for the heavy pall it often endured. However, smoke was associated with industrial prowess and jobs, so little was done. During a visit to India in the 1970s, I was given a matchbook showing a factory belching smoke. It is unlikely that such a matchbook would be printed today.

The next era in risk assessment occurred indirectly with the advent of the atomic bomb in 1945. It was quickly recognized that the power of destruction could be harnessed for peaceful purposes, and major governments adopted nuclear power programs. However, the risks associated with producing this form of energy were unlike those calculated in the past. This in turn led to vast research on nuclear risks, much more than for other energy technologies. To date, more has been spent on analysis of nuclear risks than on all other energy sources combined—probably at least an order of magnitude greater.

It was quickly recognized that a major accident at a nuclear reactor could have significant consequences for health, causing cancers and perhaps other diseases. A 1957 study by Brookhaven National Laboratory for an extreme case predicted hundreds of immediate and long-term deaths from radiation. However, defenders of the nuclear industry pointed out that these large numbers were not representative of likely operation.

In the 1970s, drawing on experience from the National Aeronautics and Space Administration, the concept of probabilistic risk analysis (PRA) for complex systems such as nuclear power plants was developed. The methodology was incorporated in the so-called Rasmussen Report of 1974–1975, which showed that the average risk to health from nuclear reactors was extremely small. As in many phases of life, the average is considerably different from extreme events or conditions.

Since that time, dozens of PRAs have been performed for nuclear reactors (as well as for chemical and other large industrial facilities). In addition, because energy has assumed such a major role in modern life—the famed economist Julian Simon once called it the "master resource"—thousands of studies on various aspects of energy risk

have been completed. It would take far too much space to even list, let alone discuss, them here.

2. RISK COMPARISONS

Risk comparisons are used extensively in risk analyses for a simple reason: Lay audiences often have difficulty understanding the complex terminology and mathematics of many energy risk studies. This has been shown in both psychological studies and public meetings on energy. In this section, the reasons for risk comparisons are discussed in a general way. Later, specific comparisons are evaluated.

Regulations in the United States and many other industrialized countries require public meetings to be held to discuss new energy projects. When the subject of risk arises, observers have noted that there is little, if any, substantive contribution from the public. When roentgens, rems, and parts per billion are mentioned by speakers, the relatively low level of scientific understanding by the public becomes apparent. To remedy this, risk comparisons are often used. These comparisons can be divided into two categories: (i) comparisons between different substances and activities and (ii) comparisons between different technologies.

The first category cuts across different aspects of life and exposure. For example, a widely used comparison devised by Richard Wilson of Harvard University states that each of the following activities presents the same risk, measured as the increased risk of death within 1 year by 1 in 1 million. This means, for example, that cycling the specified distance will increase that person's chances of death within a year by one in a million, a very small chance:

- Smoking 1.4 cigarettes
- Riding 10 miles by bicycle
- Eating 40 tablespoons of peanut butter
- Drinking 30 12-ounce cans of diet soda containing saccharine
- Living within 5 miles of a nuclear reactor for 50 years

It is evident that calculating each of these risks contains a wide variety of data and assumptions. For example, nonsmokers (approximately three-fourths of the population) who smoke one or two cigarettes almost certainly will not develop lung cancer as a result. The estimate of one chance in a million of death is based on smokers. Peanut butter by itself will not cause death; any aflatoxin it contains might.

Some risk experts have objected to these types of comparisons, claiming that the activities specified have little or nothing to do with each other. Peanut butter has no known connection to nuclear power. They state that comparing the risks of different forms of energy is more illuminating to the public than contrasting the risks of smoking with nuclear power. The problem is reduced to ensuring that the entire fuel or energy cycle for each energy technology is used to allow for a fair and reasonable comparison.

3. VOLUNTARY VERSUS INVOLUNTARY ENERGY RISKS

Chauncey Starr was one of the first to quantify the difference between voluntary and involuntary risks. It is self-evident that risk, at least per hour of activity, is greater for hang-gliding and mountain climbing than for driving an automobile or sitting behind a desk. Starr estimated that voluntary activities were between two and three orders of magnitude more risky than involuntary ones, depending on the precise activities considered.

How does this translate to energy? With some difficulty. The problem is that the line between voluntary and involuntary activities, which is clear in other contexts, is often unclear in the energy situation. For example, consider a coal miner in Wales or China. He may be descended from a long line of miners and is expected to go into the mines when he reaches working age. In principle, coal mining, with its known high risks, should be a voluntary activity. Those who do not wish to accept its risks are able to take up other less risky occupations. However, in the example cited, it is not completely clear that it is voluntary.

In terms of public risk, again the line is often indistinct. Certain areas of the nation have higher levels of air pollution, mostly due to energy activities, than others. Los Angeles has its infamous smog. Again, in principle, residents who know about these air pollution risks and are concerned about them can move to other more bucolic areas of the nation, making this air pollution exposure voluntary. Some do. However, many are confined by employment and family ties to the polluted region, suggesting that the risk is more involuntary.

The question becomes more acute with regard to nuclear power, clearly the most highly publicized form of energy risk. When a new nuclear reactor is to be built, residents have the option of moving away if

their concerns about risks are great. No doubt some have done so in the past, although there do not seem to be sociological studies indicating the percentage of those who depart. It is likely to be small for the reasons mentioned previously as well as others, such as difficulty in selling a home and sheer inertia.

Thus, although using the dichotomy of voluntary versus involuntary risks can be useful in other aspects of risk analysis, it is difficult to employ in the energy context.

4. EARLY AND LATE FATALITIES

Deaths from energy technologies can be characterized as early or late. The division applies primarily to nuclear power. For other energy technologies, such as coal- or gas-fired electricity, deaths occur almost immediately after an accident or air pollution incident. For example, construction and mining accidents, which are shown elsewhere in this article to be a substantial part of some energy technology risks, produce deaths either immediately or within a few days. The effects of air pollution from fossil fuels are often calculated by the increase in deaths after a pollution alert. When a dam fails, deaths are immediate.

Nuclear power is different in the sense that if a major accident occurs, the release of radiation could cause deaths from cancers in three or four decades. The Three Mile Island (TMI) accident in 1979 did not produce enough radiation to generate this effect. Although the radioactive release from Chernobyl in 1986 was substantially greater than that of TMI, the World Health Organization and International Atomic Energy Agency calculate that the late fatalities will be small. However, they will be nonzero.

It is evident that both early and late fatalities from a nuclear reactor accident should be combined. The Rasmussen Report was criticized for not including late fatalities with its estimates of early deaths from a reactor accident.

5. DIMENSIONS OF RISK EFFECTS

Decision makers want one or two numbers in a risk comparison. Scientists would prefer to have many dimensions of a subject quantified. The tug-of-war between the two viewpoints has persisted in the past and is likely to continue indefinitely.

These generalities can be made concrete by specific examples. Inhaber determined that the risks of the energy systems he considered could be divided into two categories: public and occupational. This division is described by some as involuntary and voluntary, respectively, As noted earlier, the division is not so clear-cut. He then noted that some risk estimates were in deaths and others were in nonfatal diseases and accidents. A number of studies estimated the loss of life expectancy for fatalities, accidents, and diseases due to energy production. The data for both occupational and public effects could then be combined into man-days lost.

The next step was to provide a common denominator for the amount of energy or electricity produced by the 11 systems he considered. He chose a megawatt-year, but in principle any multiple of this could have been used.

Since he was aiming his research at decision makers, he combined the occupational and public risks, both in man-days lost per megawatt-year, into a total risk. For this, he was criticized by some for oversimplification and combining two dissimilar entities.

One of the valid criticisms of risk analyses of that era was that they did not take into account the ages of victims of accidents or diseases. Clearly, someone of age 80, perhaps already in poor health, has fewer days lost if felled by an air pollution spike than a vigorous 21-year-old killed in a mine accident. Because governments have an interest in the efficacy of health interventions, health scientists have devised the "quality days of life lost," which takes into account the previous points concerning relative ages of victims of energy risk as well as their state of health. This measure provides a more accurate view of energy risk effects.

Researchers at Clark University in Massachusetts took another approach. They attempted to characterize technologies on a scale that encompassed 12 descriptors, including social, physical, and biological aspects of risk: intentionality, spatial extent, concentration, persistence, recurrence time, population at risk, delay of consequences, annual mortality, maximum potentially killed, effects across generations, maximum potential nonhuman mortality, and experienced nonhuman mortality. Although some of the descriptors are self-explanatory, others would require a lengthy discussion of their assumptions.

However, the problem still remains: Is there a rational and defensible method of combining 2 or 12 measures, or should they be presented separately? For example, if technology A has a lower risk than technology B on 3 of 12 measures but also has a higher risk than technology C on 5, how do we rank

A, B, and C? It is unlikely that decision makers would have the skill or patience to sort through all the possible permutations and combinations. For this reason, at least some risk researchers will continue to combine different measures of risk into one or two easily understood numbers.

6. OCCUPATIONAL VERSUS PUBLIC RISK

In the energy risk studies discussed elsewhere in this article, risk to workers tends to be higher than risk to the public. In a completely rational world, emphasis should be on reducing worker risk, with less concern about public risk reduction.

Al Hoskin of the U.S. National Safety Council evaluated the relative risks to workers and the public in Superfund (abandoned waste) sites. He found that the risk to workers for the cleanup was higher than the existing risk to the public.

In reality, developed nations place the emphasis on public risk. As noted later, this may be due to the media's concentration on disasters, real or potential, affecting the public. Occupational risk to individual workers in the United States tends to receive little attention, except by the agencies devoted to the problem or when a disaster occurs, as in the case of the Pennsylvania coal miners trapped below the surface in water in 2002. The miners were rescued with no loss of life. At the same time, news came of major coal mine disasters in China, where scores were killed. Little attention was paid to these incidents.

7. RISK PERCEPTION

The following is one of the oldest questions in philosophy: If a tree falls in a forest and nobody hears it, does it make a sound? Like many philosophical issues, there is no simple answer. The analogous question in risk analysis is, If a study shows that chemical or toxin has a high (or low) risk, and this study is either unknown to the public or ignored by it, what then is the risk?

As Slovic, Fischhoff, and Lichtenstein (SFL), three of the founders of risk perception studies, have noted, subjective judgments, by both experts and lay people, are a major component of any risk assessment. Expert judgments are often obscured in impenetrable mathematics. Judgments of lay people are considerably easier to detect.

In a classic study that went from the social science literature to popular magazines, SFL noted the divergent risk estimates of four groups: members of the League of Women Voters (LWV), college students in Oregon, a business and professional club, and risk experts. SFL considered 30 sources of risk, from nuclear power to lawn mowers and vaccinations. Many of these activities rarely appear on risk lists, but they all produce some hazards. Only a few of the categories related to energy risk.

The two largest divergences between estimates of the lay group and experts were in nuclear power and X-rays. The experts rated nuclear energy as 20th riskiest of the 30 activities, the LWV and college students rated it highest, and the business and professional people rated it 8th. X-rays were rated approximately 20th in riskiness by the laypeople but 7th by the experts. The rankings of many of the other risk sources were approximately the same for laypeople and experts.

Although there are many possible explanations for why the estimates varied so much, the variation results from the benefits received from the two activities. X-rays are viewed as having considerable benefits in medical diagnosis that outweigh the risks of radiation. The benefit of nuclear power is electricity generation, but there are other ways of producing this energy form, such as coal, gas, and oil. In the United States, approximately 80% of electricity is nonnuclear. (Admittedly, there are methods other of detecting internal diseases besides X-rays, such as nuclear magnetic resonance, but these were not included on the SFL list.) Thus, the benefits and risks of nuclear energy must be compared not to those of swimming or lawn mowers but to those of other ways of generating electricity.

One aspect of the SFL study that deserves mention is the ranking of technologies as opposed to concentration on absolute values of risk, either real or perceived. Because the values in their studies ranged over many orders of magnitude, it was clearer to rank technologies rather than to discuss the absolute values.

Experts measure risk as *X* deaths or diseases per activity, but risk is perceived according to SFL by whether it is voluntary, controllable, certain to be fatal, catastrophic, immediately manifested, and unfamiliar. Some of these are discussed elsewhere in this article.

Most of the perception aspects of risk can be described by two factors: dread (related to aspects

such as certain to be fatal and catastrophic) and how unknown the risk was (related to involuntariness and newness). On these scales, nuclear power had relatively high scores for both factors, even among the experts.

How are risk perceptions formed? The media clearly plays a major role. For example, pesticides ranked approximately eighth in the list of 30 activities noted previously. Some years ago, concerns about the pesticide Alar were expressed on a widely watched television show. Would a repeat of the poll have shown higher perceived risk for pesticides? Risk assessors sometimes talk about "risk of the week" in reference to the media publicizing a seemingly new hazard on a regular basis. On the other hand, editors of newspapers and television news shows would respond that they are merely reporting on what interests the public.

8. THE ZERO–INFINITY DILEMMA

Students of mathematics know that multiplying zero by infinity produces an indeterminate value—that is, no number that can be identified. What relationship does this have to energy risk?

The problem arises in only one energy technology—nuclear. It is acknowledged by the nuclear industry that in the most extreme conditions, a reactor accident can emit considerable radiation, thus producing deaths from disease. The number of deaths is clearly not infinite but can be high.

The industry points out that, at least according to probabilistic risk analyses, the chance of such an accident occurring is extremely small, perhaps one in tens or hundreds of thousands of years of reactor operation. The chance is not zero, but very small. Thus the zero–infinity question: If one multiplies a very small number by an enormous one, what is the product?

Simple calculation shows that the result is a small risk. However, the estimate—and both the "zero" and "infinity" are no more than estimates—is conditioned more by risk perception than by mathematical analysis. Many people think of the risks of nuclear power primarily in terms of the quasi-infinite number. They tend to ignore or disregard the other factor in the product—the estimate of likelihood. Thus, the risks of nuclear power may be, in some minds at least, overestimated.

Curiously, the catastrophic risks of a renewable resource, hydroelectricity, do not seem to be weighed in the same scale. The vast majority of hydro dams are as safe as any structure on Earth. However, there have been major failures over the years of some dams, in some cases causing hundreds of deaths in the valleys below. The zero–infinity dilemma does not seem to be applied to this energy form, although the deaths it has caused are real, not hypothetical.

9. STORAGE AND BACKUP

No energy system operates at 100% capacity all the time. Even in the best run systems, parts have to be adjusted and replaced, and unforeseen accidents can occur. On average, nuclear and fossil fuel systems generally operate in the 80–90% capacity range. That is, approximately 10–20% of the time a given plant in this group is unavailable for refueling, maintenance, or other reasons.

The vast majority of these shutdowns are planned. If fossil fuel and nuclear plants generally stopped on a random or arbitrary basis (these types of shutdowns can occur but are comparatively rare), it would be extremely difficult to have a reliable electricity grid.

The situation is different for at least some renewables. They require some combination of energy storage and backup—the supply of conventional energy when the sun does not shine and the wind does not blow. Consumers generally demand highly reliable electricity service. The proof of this is the torrent of phone calls that a utility receives from irate customers when their power is temporarily cut off due to weather-related accidents.

For hydroelectricity, categorized as a renewable energy source by the U.S. Energy Information Administration and other agencies, the entire system is storage. Thus, no further storage or backup is necessary. Using wood to produce electricity also does not require backup since enough wood can be gathered to provide as reliable fuel supply as fossil fuels. Transportation using corn-based fuels also does not require backup since the sun's energy is stored in the corn.

However, the variability of the sun and wind require some combination of storage and/or backup. Some quotations from the literature on solar and wind make the point:

"Natural gas serves as the backup heat when the solar energy is unavailable or insufficient."

"A global solar-energy system without fossil or nuclear backup would also be dangerously vulnerable to drops in solar radiation from volcanic events such as the 1883 eruption of Krakatoa, which caused

widespread crop failure during the 'year without a summer' that followed."

"Luz (solar thermal) units are hybrid systems with natural gas firing capacity added as backup. … PV systems (and wind systems as well) can be used in hybrid configurations with natural gas-based backup power, as in the case of solar thermal units."

"A wind-driven generator to convert wind energy to electrical energy, backup diesel generators (for when there is no wind). …"

"The principal disadvantage of solar is the dependence on variable sunshine hours and the resulting short capacity utilization as well as the need for energy storage and backup systems."

Thus, the question is, what fraction of backup and/or storage should be required for an intermittent system? Estimates have varied up to 20% of the original system for backup. This implies that up to 20% of the risk associated with conventional energy systems is attributable to solar or wind systems. Other estimates of storage and backup are lower.

Electricity cannot be stored, except in expensive batteries impractical for an electrical grid. It is true that over a sufficiently large area, the wind is always blowing somewhere, suggesting that wind power is continuous, not intermittent. However, no technology can instantaneously transfer wind power from North Dakota to Florida, for example. If and when such technology is developed, the need for backup and storage will disappear.

10. OTHER FORMS OF RISK: CLIMATE CHANGE

The risks discussed in this article are primarily to health, in the form of accidents or diseases. However, there is another less apparent form of risk—that of climate change. The greenhouse effect refers to the effect of certain trace gases in the earth's atmosphere so that long-wave radiation, such as heat from the earth's surface, is trapped. Much of the greenhouse effect is due to carbon dioxide. An increase from 280 to 350 parts per million has occurred since the beginning of the industrial revolution.

If the connection between increased concentrations of carbon dioxide and rising world temperatures is valid, it has been stated by many climatologists that the result will be more hurricanes, tornadoes, droughts, and other extreme events. In this sense, risks to humans will be greater, if the chain of assumptions is valid.

Renewables and nuclear electricity produce no carbon dioxide directly. However, there are indirect effects, albeit much less than the direct combustion of fossil fuels to produce electricity. The electric car is sometimes held up as an example of a system emitting no carbon dioxide, which is correct in a direct sense. However, approximately 70% of the electricity used to charge its batteries in the United States derives from fossil fuels. The carbon dioxide is emitted at the plants, not on the street.

The global climatic effect of increasing CO_2 levels is a factor in the comparison of different forms of energy. Worldwide emissions of CO_2 from burning fossil fuels total approximately 25 billion tonnes per year. Approximately 38% is from coal and approximately 43% from oil. Every 1000-MWe power station running on black coal produces CO_2 emissions of approximately 7 million tonnes per year. If brown coal (a less energy-intensive type) is used, the amount is much greater.

Figure 1 shows the estimated production of CO_2, both direct and indirect, for different energy sources. As noted elsewhere in this article, there are often wide variations in estimates of energy risk and their subcomponents. Also, the significant figures listed later for some of the data points should be treated with caution.

Coal has by far the highest values, and almost all reports on the subject confirm this result. The maximum direct production of CO_2 for coal is approximately 1000 g/kWh. Indirect production (coal mining, equipment used in mining and electricity production, etc.) is approximately 300 g/kWh, for a total of 1300 g/kWh. The minimum of the range is approximately 1000 g/kWh.

The range for gas is approximately half that of coal. The other four energy sources do not have

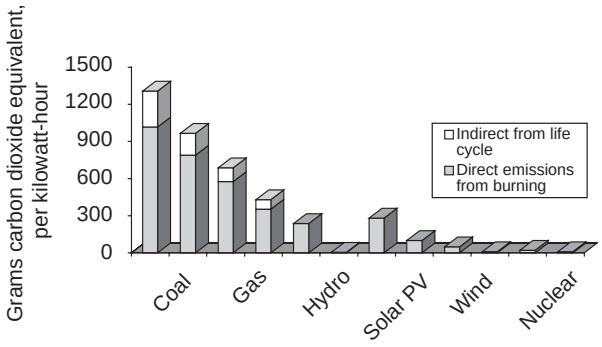

FIGURE 1 Greenhouse gas emissions from electricity production. Modified from the International Atomic Energy Agency (2000).

direct emissions. Hydroelectricity has values ranging from 4 to 240 g/kWh. One reason for the wide range of almost two orders of magnitude may be that the lower values refer to solid-earth hydro dams. Many hydro dams in developed countries are exemplified by the Hoover Dam, built in the 1930s near Las Vegas, Nevada. Much of the dam is concrete and steel, the making of which generates CO_2.

Earthen dams require soil and rock from the surrounding countryside, the transport of which generates only small amounts of CO_2. To give a representative value for hydro, indirect CO_2 production from dams built during approximately the past generation would have to be averaged.

Solar photovoltaic systems have values ranging from 100 to 280 g/kWh primarily because of the large amount of materials used per unit energy output in their construction. The values are substantially higher than those for hydro, by far the largest renewable energy system used throughout the world to generate electricity.

Wind energy has values from 10 to 50 g/kWh. Its lower range is thus higher than that of hydro, but its upper range is lower.

Nuclear has a range of 9–20 g/kWh. It is possible that the variability in nuclear data is lower than that of most other energy systems because so many studies have been performed in this area. Although nuclear, like the three other renewable systems described in Fig. 1, emits no direct CO_2, substantial amounts of metals such as steel and zirconium are used in construction of reactors. Also, given the extremely thick walls of most Western-built reactors, large volumes of concrete are used. In many countries (excluding those using the Canadian CANDU system), enrichment of the uranium for fuel rods employs fossil fuels for the required electricity.

These sources of CO_2 production are divided by the large amounts of electricity produced by typical reactors. Thus, nuclear has CO_2 values comparable to those of wind and considerably better than those of the other systems, both renewable and fossil fuel, considered in Fig. 1.

In summary, coal and gas have substantially higher emissions of CO_2 compared to renewables and nuclear. Of the renewables, solar photovoltaic seems to be highest and wind the lowest. Nuclear has values comparable to those of wind. There are considerable uncertainties regarding all the values.

11. AIR POLLUTION RISK

The largest source of risk to the public associated with fossil fuels has been air pollution effects. These effects can range from death to asthma attacks and other breathing difficulties.

However, a report in a 2002 issue of the Canadian *National Post*, quoting an article in the journal *Nature*, suggests that the estimate of 5000 Canadians (mostly elderly) dying each year from air pollution is too high by at least 1200 deaths and very likely by 3000–4000. This implies that air pollution deaths may be overestimated by approximately 30% and possibly by 150–400%. It is clearly too soon to determine the validity of these claims. Most comparative risk studies suggest that fossil fuels have higher risks per unit energy output than renewables and nuclear. If the study is validated, it would make fossil fuels closer on an absolute scale to renewables and nuclear per unit energy output. However, the relative position of these former fuels compared to their competitors probably would not change.

12. RISK AVERSION

There is a wide range of attitudes toward risk, as shown by surveys and other indirect devices. Risk-seeking individuals drink heavily, drive fast sports cars with unbuckled seat belts, smoke, sky-dive, climb mountains, and engage in other well-known risky behaviors. Risk-averse individuals read the newspapers avidly for the next food or activity to avoid, try vegetarian diets, wash their vegetables and fruits twice, bundle up heavily for cold weather, eat an apple every day, take their medicine when prescribed, move away from nuclear reactors if one is built nearby, stay away from people with colds, and try to elude all risks.

Some individuals are risk seeking for certain hazards and risk averse for others (e.g., smoking while practicing vegetarianism). Most people are somewhere in the middle, steering clear of the obvious risks but not having enough time to study and avoid all hazards.

Policymakers must account for both ends of this spectrum. If most people were risk seeking, there would be little need for any government regulation of energy or any other activity. If most were risk averse, virtually all economic activity would halt. Ironically, this would probably increase societal risk dramatically as society retreated to preindustrial age conditions.

Although many risk calculations are publicly available, there is little evidence that those who are risk averse and risk seeking make use of these data. Risk-averse people are unlikely to take more risks if they are told that they are concerned about infinitesimal hazards. Conversely, risk seekers know that climbing mountains is risky without information from a study. The inclination to join either group is a function of personality, not the results of risk assessments that people have read.

The risk averse and risk seekers seem to coexist happily in most situations. One situation in which they come together is when a waste site is being proposed nearby. Although risk estimates may indicate that the hazards of these sites are extremely small when regulations are satisfied, risk-averse and even risk-seeking citizens generally show strong concerns at siting meetings. As a result, most of these proposed sites are either abandoned or take many years to complete.

13. UNCERTAINTY

To paraphrase the poet, risk analysis, thy name is uncertainty. From the first energy risk analysis, uncertainty has made the results less convincing than they might have been. Some energy risk analyses have not discussed their uncertainties at all. Most others have done so, but sometimes the final results do not reflect the detailed uncertainty calculations in appendices. For example, in the Rasmussen Report, uncertainties were discussed in great detail in the body of the work. However, in the executive summary, which was read by far more people than were the elaborate calculations, uncertainties were downplayed. This led to criticisms.

On the other hand, the Slovic study on risk perception apparently did not show uncertainties at all. That is, if one or another group were ranking nuclear power or lawn mowers in terms of their risk, there would certainly be a statistical distribution. These distributions were never shown in the many reprints and reworkings of the Slovic study. Curiously, the work was not criticized for this omission, although it dealt with many of the risk issues that the Rasmussen Report and many other analyses dealt with.

It would take considerable space to discuss all the uncertainties associated with energy risk analyses, from data to statistical distributions and variations in assumptions. It is sufficient to state here that one of the main charges leveled at risk analyses is that the uncertainties are sometimes glossed over or not discussed at all.

14. CATASTROPHIC VERSUS NONCATASTROPHIC RISK

Many members of the public tend to think of energy risk in terms of catastrophes, those that kill or injure many at a time. However, at least for industrialized countries, most energy risk is noncatastrophic—that is, occurring to perhaps less than five people at a time.

Nonetheless, there have been catastrophes associated with energy production. Some of the major ones from 1977 to 1993 are shown in Table I. (A full listing to the present would take too much space.) Even for risk experts, many of the listings are likely to be unknown or, at best, barely recalled. In terms of coverage by Western news media, the reports tend to appear somewhere on page 13 of newspapers, with perhaps a 5-s news clip on television. Because many of them occur in Third World countries, the disasters are rarely followed up by stories explaining why they took place.

A number of comments can be made about Table I. First, many major accidents occurred prior to 1977. For example, the Vajont dam accident in Italy killed 2600–3000; The St. Francis dam failure in the United States in 1926 killed more than 400. A complete table would occupy many pages.

Second, many of the accidents took place in Third World countries, as noted previously. Because safety and environmental controls are usually better in industrialized nations, this is to be expected.

Third, although the Chernobyl nuclear accident undoubtedly received more media coverage than all the other accidents combined, it is clear from the table that the vast majority of catastrophic deaths were due to two major energy systems: fossil fuels (mostly gas and coal) and hydroelectricity. Because of their small size, renewables, with the notable exception of hydroelectricity, are unlikely to have catastrophic accidents. The largest recorded in the table was the Indian Machhu II dam failure in 1979.

Fourth, the question arises, can catastrophic and noncatastrophic risk be added in a reasonable way to produce an overall risk value for each technology? There is no simple answer to this question. However, it should be noted that catastrophic risk is small compared to ordinary risks for virtually all energy technologies. Thus, whether or not the catastrophic aspects are added is unlikely to change the comparative energy risk rankings.

TABLE I

Energy-Related Accidents, 1977–1993[a]

Location	Year	No. killed	Comment
Machhu II, India	1979	2500	Hydroelectric dam failure
Hirakud, India	1980	1000	Hydroelectric dam failure
Ortuella, Spain	1980	70	Gas explosion
Donbass, Ukraine	1980	68	Coal mine methane explosion
Israel	1982	89	Gas explosion
Guavio, Colombia	1983	160	Hydroelectric dam failure
Nile River, Egypt	1983	317	LPG explosion
Cubatao, Brazil	1984	508	Oil fire
Mexico City	1984	498	LPG explosion
Tbilisi, Russia	1984	100	Gas explosion
Northern Taiwan	1984	314	Three coal mine accidents
Chernobyl, Ukraine	1986	31 +	Nuclear reactor accident
Piper Alpha, North Sea	1988	167	Explosion of offshore oil platform
Asha-ufa, Siberia	1989	600	LPG pipeline leak and fire
Dobrnja, Yugoslavia	1990	178	Coal mine
Hongton, Shanxi, China	1991	147	Coal mine
Belci, Romania	1991	116	Hydroelectric dam failure
Kozlu, Turkey	1992	272	Coal mine methane explosion
Cuenca, Equador	1993	200	Coal mine

[a] From the Uranium Information Centre (2000).

15. COMPARATIVE ENERGY RISK

15.1 Can We Learn from Comparative Energy Risk?

In principle, comparing the risks of different forms of energy can guide both the public and decision makers to more valid decisions and attitudes. In practice, the conclusions are not so simple to draw.

Some observers, such as Andrew Stirling, have suggested that there is so much overlap between the results of energy risk analyses that few if any conclusions can be drawn. Figure 2 shows the results of approximately 30 energy risk analyses that he compiled. Certainly, the wide overlap between each technology suggests considerable uncertainty in conclusions.

Nonetheless, some crude inferences can be drawn even from Fig. 2. The fossil fuels generally have maximum values substantially higher than those of nuclear and the three renewables shown. Hydroelectricity is in the middle range.

In 1996, the Health Physics Society suggested that below a lifetime dose of 100 mSv (10 rem) (a unit of radioactive dose), "risks of health effects are either too small to be observed or are nonexistent." If this is correct, it is likely that the maximum value assigned to nuclear fission in Fig. 2 would be substantially lower than the corresponding value for hydroelectricity, making it comparable to the renewables.

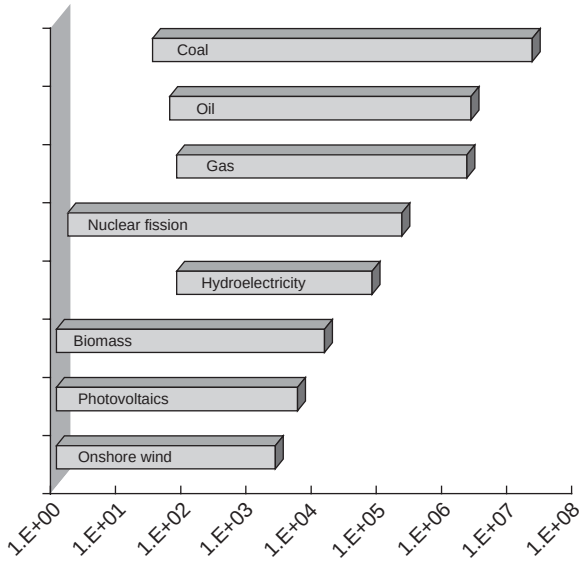

FIGURE 2 Total risk costs for selected energy systems in 1995 U.S. dollars per gigawatt-hour. Modified from Stirling (1999), illustrating ambiguities in the environmental ranking of contending options.

The problem with figures of this type is that they compare vastly different studies, with often strongly disparate assumptions. If similar studies are compared, the overlap may be substantially less. An analogy may be drawn about the heights of men and women. On average, men are taller than women. However, in a random group of perhaps 100 of each gender, the tallest woman will almost certainly be taller than the shortest man. The overall conclusion that men are taller than women is not disproved by this observation. Applying this to Fig. 2, the overlap may not be as great as it appears if like studies are compared.

15.2 Being Comprehensive

If comparisons are to be made between energy systems, great care must be taken to include all the sources of risk, from mining of the raw materials to disposition of waste, if any. This generalization can be difficult to implement in practice. Should the risks associated with building the machinery to do the mining be included? Should storage and backup, if necessary, be included as well? There has been considerable debate in the literature on these and other topics of comprehensiveness, without final resolution.

One way of solving at least some of these difficulties is the use economic input–output (I–O) tables, which show how different inputs to a system result in outputs. The risks associated with the inputs and outputs can, in principle, be calculated. Although the I–O system has been used by a number of investigators, it has not been generally adopted in the risk arena. Most investigators use a system approximately as shown in Fig. 3.

The top of Fig. 3 refers to occupational risks and the bottom to public risks. Clearly, there is considerable simplification in such a figure. For example, waste disposition, one of the greatest public concerns about nuclear power generation, is not shown. At least a rough estimate, given the fact that nuclear waste can pose some risks for thousands of years, is included in many studies of this technology.

Nonetheless, a figure of this type, with its defects, is useful. It shows decision makers, who rarely have time to sort through risk analyses of many volumes, the conceptual basis of comparative risk analysis.

15.3 The Hauptmanns Study

In 1991, Hauptmanns in Germany attempted to summarize more than a decade of major energy risk studies. He considered a wide variety of sources. Rather than develop a statistical distribution, he tabulated the maximum and minimum for 15 energy and electricity sources. Some of them, such as nuclear fusion, are mostly speculative and are not shown in Fig. 4.

In the interests of brevity, only occupational risks are discussed. Hauptmanns also estimated public risks for these technologies. Only fatalities are indicated in Fig. 4. As noted elsewhere in this article, an overall measure of occupational or public risk would also include injuries and diseases attributable to energy systems.

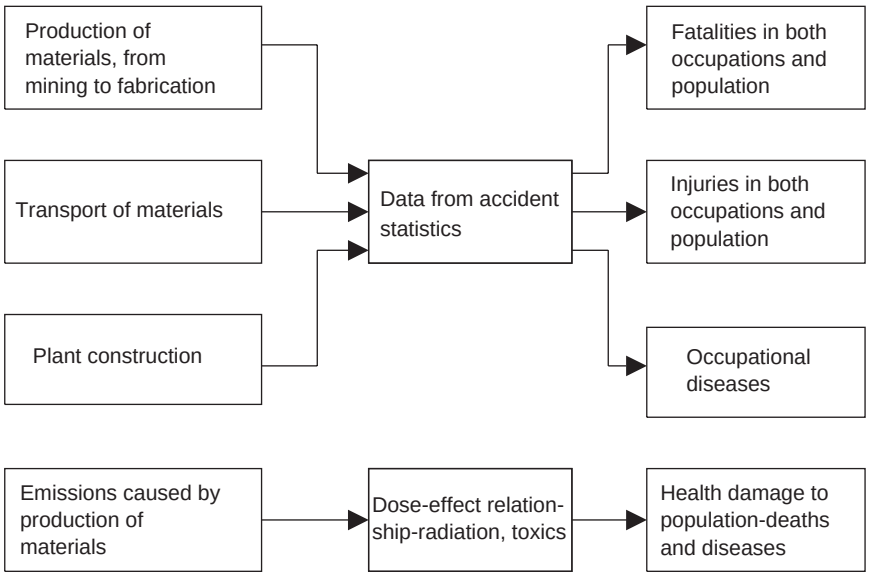

FIGURE 3 Sources of overall risk for energy systems. Modified from Hauptmanns and Werner (1991).

Although there is clearly overlap for many of the ranges shown, it is somewhat less than indicated by Stirling. The highest value seems to be for methanol, beyond the range of the 10 other systems. The fast breeder reactor apparently has the lowest value. However, the upper part of its range overlaps with that of a number of other systems, such as coal, oil, solar photovoltaic, and wind.

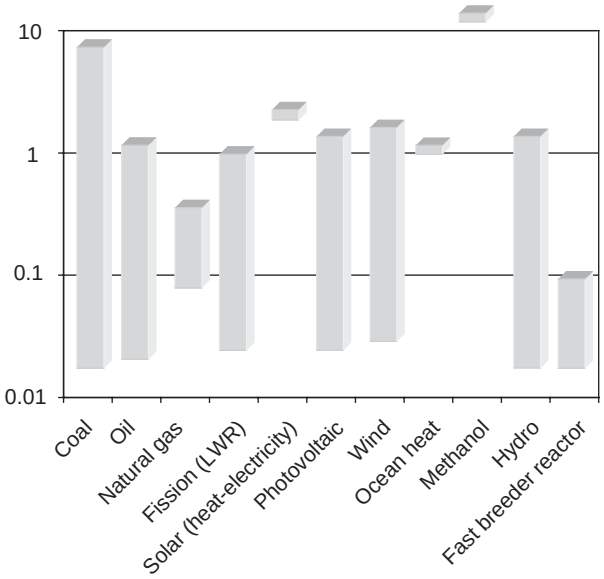

FIGURE 4 Employee (occupational) fatalities per 2.2×10^{16} J for 11 energy systems. A similar graph can be prepared for public risks. Modified from Hauptmanns and Werner (1991).

The next highest value is for coal, at least judging from its maximum. Its minimum, however, is among the lowest. This may be attributable to assuming so-called strip mining, for which occupational risks are substantially lower than those for underground mining. A fair estimate of coal occupational risks would allocate appropriate percentages to underground and surface mining.

15.4 The ExternE Project

After the Hauptmanns effort, the European Union, through the ExternE project, and the International Atomic Energy Agency, through its DECADES project, supported the largest schemes ever to estimate the relative risk of different energy and electricity systems. Taken as a whole, they are the most comprehensive set of energy risk studies to date.

Results are mostly applicable to Western Europe and, to some extent, the United States. Although evaluating the risks of energy in Third World countries would be useful as they industrialize,

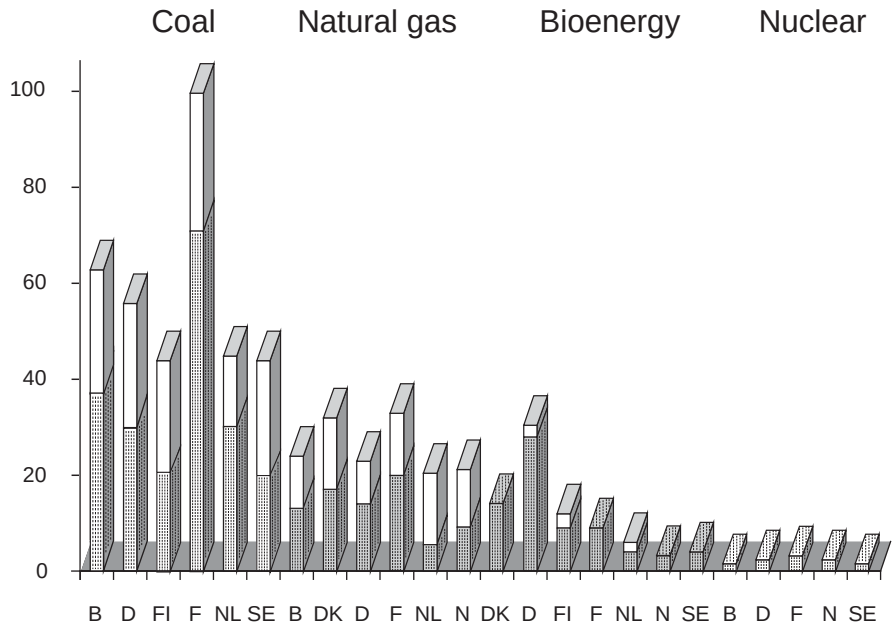

FIGURE 5 External costs of the entire fuel cycle, including global warming, in mECU per kilowatt-hour. B, Belgium; D, Germany; A, Austria; F, France; NL, The Netherlands; SE, Sweden; DK, Denmark; FI, Finland; N, Norway. The shaded portions of each column show the total environmental costs, including global warming, at a relatively low cost per ton of carbon dioxide emitted; the unshaded portions show the total costs at a higher value per ton of carbon dioxide emitted. Modified from Starfelt (1998).

there has been comparatively little written on the subject.

Starfelt attempted to draw general conclusions for the ExternE work. Results are shown in Fig. 5. He considered four systems: coal, natural gas, bioenergy, and nuclear. Different studies were performed for a variety of European Union countries. All costs, risks to human health and the environment, were put on a fiscal scale. The European Community Unit (ECU, commonly known as the euro) was at a level of approximately $1.20 in December 2003.

Note that this is similar to the calculations of Stirling noted previously. In effect, human risks per assigned a monetary value, requiring an estimate of how much a human life is worth. Although this estimate is required for the ExternE calculations, it is so buried in the voluminous calculations that no easy extraction is available. The reduction of all costs to money also implies estimates of the financial effects of climate change, which are not completely known. Thus, the ExternE results require more assumptions than the standard risk calculations for energy, which have already been criticized for having too many assumptions.

In Fig. 5, the shaded areas show the external costs, including global warming at an estimated cost of 19 ECU per ton of CO_2. Note that this is not a direct measure of potential economic costs of global warming but rather an estimate of the price that firms might pay to emit one extra ton of CO_2 in the future. The columns including the blank areas assume a cost of 46 ECU per ton of CO_2.

Despite substantial variations, coal had by far the greatest external costs, regardless of the estimated cost per ton of CO_2. French coal had the highest values, perhaps because coal from this nation is riskier to mine than elsewhere. The added cost of 46 ECU/ton made coal substantially higher than the other three systems, but it would have retained its most costly rank even if the lower value had been used.

Second was natural gas, with not as much variation as in the coal case. Values were approximately half those of coal. Using the higher value of cost per ton of CO_2 approximately doubled the values of natural gas.

Bioenergy was third, with average values approximately half those of natural gas. At approximately 33 mECU/kWh, German bioenergy was substantially higher than that of the other six nations in the survey. Lowest was that of The Netherlands, at approximately 5 mECU/kWh.

Nuclear was the lowest of the four. Most values were approximately 2 mECU/kWh. France seemed to have the highest value. The effect of valuing CO_2 at different costs played little role with regard to the relative external costs of bioenergy and nuclear, although all energy systems generate CO_2 either directly or indirectly.

16. CONCLUSION

Many conclusions can be drawn from the hundreds of studies on most aspects of energy risk. Perhaps the most remarkable is the divergence between public perception of energy risk, often centered on the hazards of nuclear power technology, and its often low relative rank in terms of comparative analysis.

Energy risk analysis is highly complex. The subjects discussed in this article represent only part of the field. Energy risk analysis is also somewhat different from other subjects in the field of energy in that much of it is highly contentious, with public debates over assumptions and results. These debates indicate the importance of the field to both policymakers and the public.

Glossary

bipropellant Propellant system consisting of both an oxidizer and a fuel.

characteristic exhaust velocity A reference term relating achievable chamber pressure to the propellant type and nozzle throat diameter. It is a figure of merit for the propellant and efficiency of combustion.

impulse The total force imparted to a vehicle over the course of the burn time, with units of N-s. The impulse per unit mass is the specific impulse.

nozzle Thrust chamber component comprising converging and diverging sections. The minimal nozzle area is the throat, at which point the speed of the combustion gas is approximately equal to the speed of sound in the gas. The ratio of the nozzle exit area to the throat area is the expansion ratio.

propellant The working fluid in a rocket. The chemical energy contained in the propellant is converted first to thermal energy during the combustion process and then to kinetic energy during expansion in the nozzle.

thrust The reaction force imparted to a rocket primarily due to the change in momentum of propellants as they expand in the thrust chamber.

thrust coefficient The ratio between the thrust and the product of chamber pressure and throat area. It is a figure of merit for the nozzle design.

velocity increment The change in velocity of a vehicle due to its acceleration by thrust (also called ΔV).

Rockets are devices that contain all the elements necessary for propulsion within themselves. They are most useful for space travel and when high thrust rapid acceleration is required. Applications include boosting payloads to low-earth orbit, missiles, satellite station-keeping and orbit transfers, and interplanetary missions. Rockets are typified by the high velocity of the gas that is accelerated through a supersonic nozzle to generate thrust. They can be further classified according to the propellant state, the thrust level, and the type of engine cycle that is used.

1. INTRODUCTION TO ROCKET PROPULSION SYSTEMS

1.1 Rocket Propulsion

Propulsion is the means by which a force is imparted to change the velocity of a vehicle, affecting both its speed and its direction. In aerospace vehicles, this force is typically called thrust. The thrust applied to a rocket is due to a reaction from the momentum of a high-speed jet directed opposite the direction in which the vehicle is being accelerated. The thrust is proportional to the product of the mass flow rate, $\dot{m}$, and velocity, V, of the jet (i.e., $F = \dot{m}V$). These propulsive forces are used to overcome gravity and drag and to steer the vehicle.

Both rocket and jet engines use jet propulsion to develop thrust. Rocket propulsion differs from its air-breathing cousin mainly in that rockets have self-contained propellants. This feature allows operation at high altitudes and in space. Rockets are typically classified according to the energy source that is used to accelerate the working fluid. Energy sources include pressurized gas, chemical, electric, and nuclear. More exotic types, such as nuclear, solar sails, or beamed-energy approaches, may be feasible in the future, but their consideration is beyond the scope of this article.

Cold gas propulsion comprises a controlled, pressurized gas source and a nozzle and represents the simplest form of rocket engine. Cold gas has many applications in which simplicity is more important than high performance, for example, the

 © 2004 Elsevier Inc. All rights reserved.

Manned Maneuvering Unit used by astronauts. Nuclear and electric propulsion can be separated into two general categories: thermal and electrostatic/magnetic. Thermal systems work by a transfer of heat generated by the nuclear or electric energy source to a working fluid. Electrostatic/magnetic systems work by accelerating ions through an electrostatic or combined electromagnetic potential. Although some development has occurred, there are no operational nuclear rocket systems. There are operational systems that use electrothermal and electrostatic propulsion.

1.2 Chemical Rockets

The main focus of this article is chemical rockets, whereby the energy that is stored in the chemical bonds of the propellants is first converted to thermal energy through the process of combustion and then converted to kinetic energy by expanding the high-temperature combustion products through a supersonic nozzle. Since the attainable thrust is proportional to the exhaust velocity, and the exhaust velocity is proportional to the square root of the kinetic energy of the exhaust gas, it is readily seen that the chemical energy content of the propellants that can be converted to thermal energy provides a fundamental limit on the thrust that can be achieved.

Chemical rocket propulsion can be categorized according to the original state of the propellant. Rockets that use solid propellants are called solid rocket motors (SRMs), and those that use liquid propellants are called liquid rocket engines (LREs). A hybrid rocket uses liquid oxidizer and solid fuel. LREs and SRMs are the focus of this article.

A general schematic of a pump-driven LRE is shown in Fig. 1. A single gas generator (GG) is used to provide hot gas to turbines that drive the fuel and oxidizer pumps. The pressurized propellants are sent to the GG and the thrust chamber assembly (TCA), which comprises an injector, the main combustion chamber, and the supersonic nozzle. The effluent from the GG is shown to be expanded through separate nozzles; in some configurations, it is injected into the TCA nozzle at an axial location where the gas is the same pressure as that of the GG effluent. Figure 1 depicts a specific LRE cycle—the GG cycle. Other types of cycles are discussed later.

The SRM is one of the most common types of rocket propulsion systems and has a wide variety of applications. An SRM is conceptually a very simple device with very few moving parts. The entire propellant charge, the propellant grain, is contained within a pressure vessel generally called the motor case. The case is protected from hot combustion gases by internal insulation. The nozzle serves to convert the thermal energy of the combustion gases to thrust and may be moved (vectored) to provide a directional force for steering. The polar boss provides a means of connecting the nozzle assembly to the motor case, whereas the thrust skirt provides a mechanism to transmit thrust loads to an upper stage or payload.

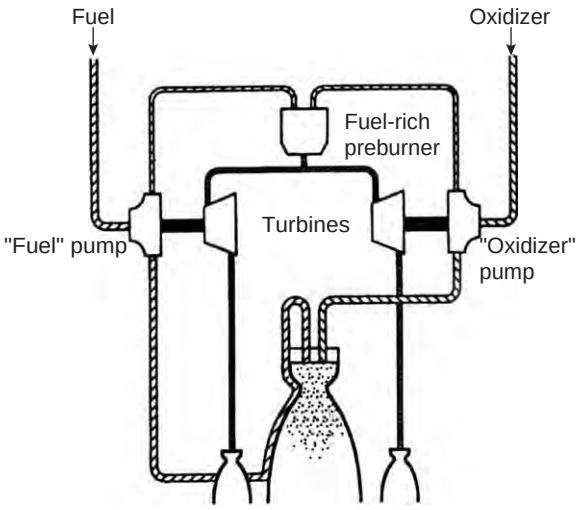

FIGURE 1 Liquid rocket engine schematic. The pump-fed engine shown uses a fuel-rich gas generator to produce turbine drive gases. The turbines provide power to pump the oxidizer and the fuel to high pressures. The high-pressure propellants enter the combustion chamber through the injector and react to form a high-temperature gas. The high-temperature, high-pressure gas is expanded through a supersonic nozzle, in which it reaches a very high velocity.

Other distinguishing features of chemical rocket propulsion include high operating pressures and high rates of propellant consumption. Operating pressures can be up to 50 MPa for LREs, and flow rates may be >4000 kg/s for high-thrust SRBs. A pump on the Space Shuttle main engine (SSME) could drain an average backyard swimming pool in 25 s, and the energy released by the three SSMEs is equivalent to the output of 23 Hoover Dams. The high energy density of the rocket provides a 100-fold increase in thrust over air-breathing engines of similar size.

1.3 Chemical Rocket Requirements

The energy requirements of a rocket are typically stated in terms of velocity increment or ΔV. The flight velocity required to escape from Earth's gravitational

field (the escape velocity, u_{esc}), neglecting the rotation of the earth, frictional drag, and the attraction of other celestial bodies, can be calculated as $u_{esc} = \sqrt{2g_e r_e} = 11.2$ km/s, where g_e is the acceleration due to gravity at the earth's surface ($g_e = 9.81$ m/s^2), and r_e is the radius of the earth ($r_e = 6.38 \times 10^3$ km). Launching an object into space at this initial velocity would not be practical because the object could not withstand the severe aerodynamic heating and dynamic pressures that it would experience in the earth's atmosphere.

For a rocket launched from the surface of the earth where the goal is to put an object into an orbit, the overall velocity increment is the difference between the velocity at the surface and the velocity required for a stable orbit, whereby the centrifugal force of the satellite balances the earth's gravitational field. A circular orbital velocity can be calculated by $u_c = \sqrt{\mu/r_c}$, where μ is the gravitational constant (3.99×10^5 km^3/s^2 for Earth), and r_c is the distance between the centers of the two bodies. The altitude above the earth surface corresponding to low Earth orbit (LEO), which serves as a stable orbit for many satellites as well as a staging point for acquisition to higher orbits, is on the order of 180 km or approximately 100 nautical miles. A typical ideal ΔV requirement for placing an object in LEO, neglecting the earth's rotation and also gravitational, steering, and drag losses, is approximately 8 km/s. Adding these real effects increases the ΔV requirement to approximately 9 km/s. Launching a rocket into an eastward trajectory near the Equator provides the maximum initial velocity and reduces the ΔV requirement. The overall flight velocity budget for a typical Space Shuttle LEO mission launching from Cape Kennedy is shown in Table I. Higher orbits require more velocity increment. Round-trips to the moon and Mars require a ΔV of approximately 18 and 27 km/s, respectively.

TABLE I

Typical Velocity Increment Budget for Space Shuttle

Circular orbit velocity at 110-km altitude	7790 m/s
ΔV gravity loss	1220 m/s
ΔV turning loss	360 m/s
ΔV aerodynamic drag loss	118 m/s
Orbit injection	145 m/s
Deorbit maneuver for reentry and aerobraking	60 m/s
Correction maneuvers	62 m/s
Initial velocity provided by Earth's rotation at 28.5° latitude	−408 m/s
Total ΔV required	9347 m/s

Other applications for chemical rockets include missiles and orbit transfer vehicles. Ballistic missiles spend most of their flight time in a ballistic trajectory in which only gravity forces are active. Ballistic flight is defined as a "zero-lift" trajectory in which the missile always flies at a zero angle of attack (i.e., the axis of the missile is aligned with its velocity vector). The ΔV for a ballistic missile is determined by its range requirement. Other missile applications include interceptors (e.g., air-to-air and surface-to-air missiles) that must close in on a moving target with high initial acceleration rates and therefore high thrust-to-weight requirements. Orbit transfer propulsion provides transfers from LEO to higher orbits [e.g., geosynchronous orbits (GEOs)] and inclination changes. The Hohmann transfer ellipse is a well-known maneuver between two circular orbits that provides a minimum velocity increment requirement. A LEO-to-GEO maneuver using the Hohmann transfer requires a ΔV of approximately 4 km/s.

2. FUNDAMENTAL PRINCIPLES OF CHEMICAL ROCKET PROPULSION

2.1 The Thrust Equation

The performance of a chemical rocket is governed by the thermal energy contained within the combustion products and the efficiency of the nozzle in converting this thermal energy into kinetic energy and thrust. Figure 2 shows a simple schematic of a chemical rocket. The thrust, F, is the reactive force applied to the rocket and is the sum of the momentum thrust and the pressure thrust:

$$F = \dot{m} V_e + A_e [P_e - P_\infty],$$

where A_e is nozzle exit area, P_e is the gas pressure at the nozzle exit, and P_∞ is the ambient pressure. The momentum thrust is much larger than the pressure thrust. When the pressure in the chamber is sufficiently higher (at least twice) than the ambient pressure, supersonic flow can be achieved in a properly designed nozzle. In a supersonic flow, the velocity increases and the pressure decreases with increasing nozzle cross-sectional area. This process of expansion is the means through which high V_e is obtained.

Although the thrust equation suggests that additional thrust can be obtained when the exit pressure

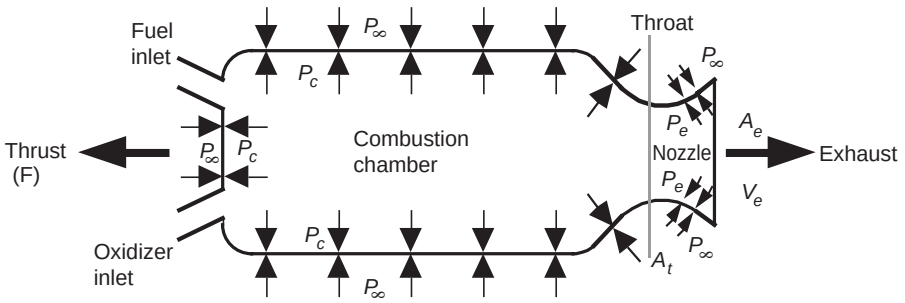

FIGURE 2 Simplified diagram of a chemical rocket. Reaction between the fuel and oxidizer in the combustion chamber produces hot gases, which are then expanded in a supersonic nozzle to high velocity.

TABLE II

Applications and Typical Performance

Propulsion technology	Launch vehicles	Orbit insertion		Orbit maintenance and maneuvering	Attitude control	Typical I_{sp} (s)
		Perigee	Apogee			
Cold gas				X	X	30–70
Solid	X	X	X			280–300
Liquid						
Monopropellant				X	X	220–240
Bipropellant		X	X	X	X	305–325
Dual mode		X	X	X	X	313–330
Hybrid		X		X		250–340
LO_2/kerosene	X	X				320–340
H_2O_2/kerosene	X	X				310–330
LO_2/H_2	X	X				405–460

is greater than the ambient pressure, the loss in the momentum thrust term is greater than the gain in the pressure thrust term. Rocket exhaust nozzles are often designed with an exit pressure equal to the ambient pressure; when P_e is equal to P_∞, the nozzle is "optimally expanded." The highest thrust for a given flow rate is achieved when the nozzle flow is expanded to pressures approaching zero in a vacuum environment. Some space engines have nozzle expansion ratios (ε, the ratio of nozzle exit area to throat area) exceeding 100. Practically, the expansion ratio is increased until the additional weight of the longer nozzle and the increase in internal nozzle drag losses result in an overall penalty. The physical envelope provided by the launch vehicle also sets limitations on the space engine nozzle expansion ratio.

If the ambient pressure (P_∞) is greater than the pressure at the exit of the nozzle, the pressure thrust term is negative. This loss in thrust is most severe at low altitudes for first-stage engines with exit nozzles that are configured to produce a maximum amount of thrust over the entire launch profile.

2.2 Rocket Performance Parameters

Mission requirements are often stated in terms of total impulse, I_t, which is a measure of the thrust imparted to the vehicle over the thrusting interval, $I_t = \int F dt$, and has the dimensional units of force-time. Performance is the figure of merit for a specific propellant combination and thrust chamber configuration and is usually related in terms of effective exhaust velocity or specific impulse (Table II). The effective exhaust velocity, c, is defined as $c = V_e + A_e[P_e - P_\infty]/\dot{m}$ and is equivalent to the actual exhaust velocity at optimally expanded conditions. The specific impulse, I_{sp}, with dimensional units of seconds, is the total impulse divided by the amount of propellant that produced that amount of impulse. It is also the ratio of the thrust to the propellant flow rate, $I_{sp} = F/\dot{m}$. The first definition is useful for

SRMs and the second definition is useful for LREs because for SRMs only the total amount of propellant that was burned is typically known, whereas for LREs precise measurements of propellant flow rate at any given time can be made.

Specific impulse is a measure of how efficiently the energy content of the propellants is converted into thrust and can also be defined as the product of the characteristic exhaust velocity, C^*, and the thrust coefficient, $C_f : I_{sp} = C^* C_f$. Definition in this way separates the physical effects occurring in the combustion chamber (C^*) and the exhaust nozzle (C_f). Characteristic exhaust velocity is a parameter primarily dependent on the propellant combination and how effectively the chemical energy contained in the propellant bonds is converted to thermal energy, whereas the thrust coefficient is a measure of how efficiently the thermal energy produced by the combustion reaction is converted to kinetic energy.

Characteristic velocity can be calculated as $C^* = f(\gamma)\sqrt{T/\mathrm{MW}}$, where T and MW are the temperature and molecular weight of the combustion products, respectively, and $f(\gamma)$ is a function dependent on the specific heat ratio, γ. The thrust coefficient is an expression that relates the magnification of the momentum thrust due to expansion in the supersonic nozzle, which can be written as $C_f = F/P_c A_t$ and which is dependent only on the specific heat ratio, the ratio of chamber pressure to nozzle exit pressure, P_c/P_e, and the expansion ratio, ε, of the nozzle exit area to nozzle throat area, A_e/A_t. These relationships show that high specific impulse is partially attainable by high-combustion gas temperatures and low-combustion gas molecular weights. Further examination of the fundamental thrust coefficient equation would show that higher values of pressure ratio coupled with higher values of ε, along with lower values of γ, lead to higher values of C_f.

2.3 The Rocket Equation

For most rocket propulsion applications, the primary requirement is the velocity increment, ΔV, that must be achieved, as discussed previously. The relationship between propulsion system performance parameters and mass fraction is the so-called rocket equation:

$$\Delta V = gI_{\mathrm{sp}} \ln\left(\frac{m_0}{m_0 - m_p}\right) = gI_{\mathrm{sp}} \ln(m_0/m_f) = gI_{sp} \ln(1/MR),$$

where $m_f = m_0 - m_p$ is the final vehicle mass, m_0 is the initial vehicle mass, m_p is the mass of the propellant consumed, and $\mathrm{MR} = m_f/m_0$ is the mass ratio. This equation allows one to calculate the mass of propellant required to reach a certain ΔV based on engine performance and the final mass of the rocket, which is very close to the dry weight of the rocket.

3. ROCKET PROPELLANTS

3.1 Thermodynamics

In a chemical rocket, the propellant serves the dual functions of energy source and the working fluid that provides the momentum thrust. The energy source is the exothermic reaction that occurs between fuel and oxidizer or during the decomposition of a monopropellant. In an exothermic reaction, the products have lower heats of formation than do the reactants, and the amount of energy that is released, the enthalpy of reaction, ΔH_{rxn}, is proportional to their difference,

$$\Delta H_{\mathrm{rxn}} = \sum_{\mathrm{products},i} n_i \Delta H_i^0 - \sum_{\mathrm{reactants},j} n_j \Delta H_j^0,$$

where ΔH_i^o is the molar heat of formation of the ith component, and n_i is the number of moles of the ith component. The heats of formation of elemental molecular species such as oxygen and hydrogen are zero by convention, the heats of formation of typical products such as steam and carbon dioxide are negative, and the heats of formation of unstable molecules such as hydrogen peroxide and hydrazine are positive.

The liberated chemical energy takes its sensible form by heating up the products of combustion. An energy balance between the reactants and products provides the adiabatic flame temperature, T_{ad}; this is the temperature that the combustion products would reach according to

$$\Delta H_{\mathrm{rxn}} = \sum_{\mathrm{products},i} \int_{T_{\mathrm{ref}}}^{T_{\mathrm{ad}}} n_i C_{p,i} dT,$$

where T_{ref} is a reference temperature (typically 298.2 K) and equal to the reference temperature for the heat of formation data. It can be seen that the desirable propellant has a high positive heat of formation and reacts with the opposite propellant to form low-molecular-weight and low-heat-capacity products of reaction. Table III summarizes thermodynamic properties of some common propellants and products of combustion.

The equation of conservation of energy may be written for an ideal flow as $h_o = h + V^2/2$, where h is

TABLE III

Chemical Thermodynamic Properties of Common Propellants and Products of Combustion

Substance	Phase	MW (g/mol)	$\Delta H_{form}{}^{o}$ (kJ/mol)	C_p (J/mol K)
Al_2O_3	L	102.0	−1620.6	79.0
CO_2	G	44.0	−394.4	37.1
H_2O	G	18.0	−228.6	33.6
N_2H_4	L	32.0	50.6	98.8
N_2O_4	L	92.0	−19.6	142.5
NH_4ClO_4	S	117.5	−295.8	128.1

the specific enthalpy, and h_o is the stagnation enthalpy, which is equal to the sum of the heat of reaction and the sensible enthalpy carried in with the propellants. As the flow is accelerated through the supersonic nozzle, the static temperature decreases. As the temperature approaches zero, h approaches zero. Thus, the stagnation enthalpy sets the limit on the velocity that can be achieved by an infinite expansion through a supersonic nozzle.

3.2 Liquid Propellants

Liquid propellants can be categorized as oxidizers and fuels and as monopropellants and bipropellants. An oxidizer plus fuel is a bipropellant system. Some oxidizers and fuels can act either as part of a bipropellant system or as a monopropellant. Monopropellants generate propulsive energy through the exothermic decomposition of a single molecule or formulated mixture of fuel and oxidizer. Monopropellants allow simple systems but offer low performance. Only three monopropellants have been used in actual flight vehicles: hydrazine, hydrogen peroxide, and propyl nitrate. Monopropellant thrusters are used primarily for attitude control devices and GGs for turbine drive.

The most commonly used monopropellant is hydrazine (N_2H_4). Hydrazine is also a bipropellant fuel hypergolic with nitric acid, nitrogen tetroxide, and hydrogen peroxide. Hydrazine derivatives include unsymmetrical dimethylhydrazine (UDMH) and monomethylhydrazine (MMH), which are more stable than hydrazine with a wider liquid range but slightly lower specific impulse values. MMH is extensively used as a fuel in small attitude control engines. Hydrogen peroxide can also be used as a bipropellant. As a monopropellant, it can be decomposed to form hot water and oxygen.

A bipropellant engine introduces the complexity of a propellant feed system but allows higher performance. Oxygen and fluorine are the strongest oxidizers but must be stored in a cryogenic state. Oxygen is the most commonly used oxidizer in liquid bipropellant rocket propulsion systems. It has a normal boiling point of 90 K with a density of 1.32 g/cm^3. Its critical temperature is 155 K and critical pressure is 5.0 MPa. Nitrogen tetroxide is a common storable oxidizer that is hypergolic with many fuels. The Occupational Safety and Health Administration lists a ceiling exposure limit of 5 parts per million with possible health hazards primarily to the lungs and irritation to the eyes, nose, and throat.

The most commonly used storable liquid fuels are RP-1 and hydrazine and its derivatives. RP-1 is a petroleum derivative with a H/C ratio of 1.953, a specific gravity of 0.8, and a MW that ranges from 165 to 195 g/mol. It is typically used with liquid oxygen (LOX) in launch stages because of its combination of high density, low toxicity, and reasonable performance.

Hydrogen is the most common cryogenic fuel. It provides high performance and is an excellent regenerative coolant. However, at its normal boiling point of 20 K, its specific gravity is approximately 0.07; thus, it requires heavy insulation and large tanks. It is especially favored for high-performance, expander cycle upper-stage engines.

In addition to performance characteristics (Table IV), a number of other factors enter into the selection of a propellant for a specific propulsion application. Most of these considerations are highly mission dependent and include propellant density, handling, stability, and transport properties.

3.3 Solid Propellants

The propellant in an SRM must burn at the proper rate to maintain the desired thrust profile and must

TABLE IV

Characteristics of Liquid Propellant Combinations[a]

Propellant	O/F	Bulk density (kg/m^3)	C^* (m/s)	T (K)	I_{sp} (s)
LO_2/LH_2	4.83	320	2385	3250	455.3
LO_2/RP-1	2.77	1030	1780	3700	358.2

N_2O_4/N_2H_4	1.42	1220	1770	3260	343.8

[a] $P_c = 6.9$ MPa; $\varepsilon = 40$; $P_\infty = 0$.

have structural continuity to withstand the pressure and acceleration loads introduced during flight. Most physical characteristics cannot be predicted analytically, so heavy use of empirical data is required. Solid propellants are classified into two general categories. In double-base propellants, fuel and oxidizer are mixed on a molecular level. These propellants generally contain a nitrocellulose type of gun powder dissolved in nitroglycerine with additional amounts of minor additives. Both these primary ingredients are explosives containing fuel and oxidizer within their molecular structure. Double-base propellants have been used most frequently in military applications (primarily in ballistic missiles), but their use has declined due to an increased emphasis on safety.

The other general type of solid propellant is called composite propellant to highlight the fact that it is a heterogeneous mixture of fuel, oxidizer, and binder. Fuels for composite propellants are generally metallic powders, with aluminum being the most common. Oxidizers are usually crystalline materials; ammonium perchlorate (NH_4ClO_4), also known as AP, is the most popular. The binder is a rubber-based material that serves to hold the powder/crystal mixture together in a cohesive grain. Current binders include hydroxyl-terminated polybutadiene (HTPB) and polybutadiene nitrile (PBAN). Occasionally, small amounts of very energetic ingredients such as "Her Majesty's Explosive" (HMX) are added to improve performance.

Solid propellant burning rates are a function of chamber pressure. Most designers assume a burning rate dependence according to St. Robert's law, $r_b = ap_c^n$, where r_b is the burn rate (cm/s), a is the burn rate coefficient, and n is the burn rate exponent. The constants a and n are determined empirically. Table V summarizes characteristics of some propellant formulations.

TABLE V

Characteristics of Composite Propellants Used in Solid Rocket Motors

Combination[a]	Density (kg/m^3)	C^* (m/s)	T (K)	P_c range (MPa)	a	n
A	1840	1541	3636	2.75–7.0	0.415	0.31
B	1800	1527	3396	2.75–5.0	0.399	0.30
C	1760	1568	3392	2.75–7.0	0.561	0.35

[a] A: TP-H-1202, 21% Al, 57% AP, 12% HMX, 10% HTPB; Star 63D; B: TP-H-1202, 18% Al, 71% AP, 11% HTPB—Star 48, Star 37; C: TP-H-1202, 16% Al, 70% AP, 14% PBAN—RSRM, Titan IV.

4. ROCKET ENGINE CYCLES

The liquid propellant must be transported to the LRE TCA by some means of force. The more simple method relies on gas pressure to force the rocket propellant through one or more main propellant tank feed valves or directly into the TCA (as in the case of solid rocket motors). The other method is to use engine-mounted hot gas-powered turbopumps to feed the propellant from its tank into the TCA. All large liquid booster engines for all launch vehicles, worldwide, that have ever flown or are flying today are turbopump driven, whereas pressure-fed systems are typically used for smaller propulsion systems, such as spacecraft attitude and velocity control propulsion systems and smaller upper stages.

Pressure-fed systems can be either blowdown or regulated. In the simple blowdown configuration, the propellant tanks are initially pressurized with a finite amount of gas, and the tank pressure decreases as the propellant is consumed. In regulated systems, a constant tank pressure is maintained by controlling the pressurant flow from separate high-pressure gas tanks.

Pressure-fed systems are inherently closed cycles but are limited in performance because of the achievable chamber pressures and hence the velocity to which nozzle flow can be accelerated. The pressurant supply typically ranges from approximately 1 to 4 MPa. The low-pressure range corresponds roughly to the low-pressure limitation of minimum-gauge wall thickness tanks. The high-pressure limit corresponds roughly to the point at which the weight penalty of high-pressure gas supply tanks overcomes the added complexity and weight of a pump-driven system.

Engine power cycles for pump-fed systems include the GG cycle, the expander cycle, and the staged combustion cycle. Generally, the pump-fed cycles require that the work required by the pump be provided by the turbine. The required pump work is related to the flow rate, $\dot{m}_p$, the liquid propellant density, ρ, the required pressure rise, Δp, and the pump efficiency, η_p:

$$W_p = \frac{\dot{m}_p \Delta p}{\rho \eta_p}.$$

The delivered turbine work is related to the turbine flow rate, $\dot{m}_t$, the turbine pressure ratio, TPR, the turbine inlet temperature, T_{ti}, turbine drive gas properties R and γ, and the turbine

efficiency, η_t:

$$W_t = \dot{m}_t \left[\frac{\gamma}{\gamma - 1}\right] RT \left[1 - \left(\frac{1}{TPR}\right)^{\frac{\gamma-1}{\gamma}}\right] \eta_t.$$

Balancing the work flows with the propellant flows can be quite challenging, particularly during engine transients, and requires a significant amount of preliminary analysis and engine system testing.
