The external energy P_0V, energy as "ambient heat" T_0S, and energy as "ambient substances" $\mu_{i0}n_i$ are the product of an intensive quantity of the environment and an extensive quantity of the system. This is the expression of the available work from system A when it is brought to equilibrium with the environment, system A_0—that is, when all contrasts have been reversibly transformed into work. This expression is composed of four different terms. First, U is the energy carried within the system, which is also called internal energy. However, part of this energy is useless as work (i.e., exergy). The value of this useless part is handled by the last two terms. P_0V is the work as a volume V that occupies a space of the environment of pressure P_0. This is pure work. Thus, by reducing the volume of the system A work can be extracted. These two terms are positive contributions to the work. The energy or internal energy unfortunately also carries two parts of useless energy or disorder, which must be deducted. T_0S is the part of the energy U that is useless due to lack of order, disorder, or entropy S (i.e., heat at ambient temperature T_0). Similarly, the last term is another useless part of the energy U; in this case, as substances completely identical to substances in the environment (i.e., substances at ambient states). Obviously, these two terms are not in contrast to the environment; thus, they cannot generate work. The energy that is carried by substances can only be used "down to" the level that is given by the environment (cf. with the available potential energy of a waterfall or the carrying capacity of a ship, which is the total capacity minus the ballast).

In summary, exergy expresses the maximum available work, in this case with reference to a specified environment (i.e., to what extent the contrast that is carried by the system can be used as work). Work and heat are concepts related to a process (i.e., that something is happening). They are not state variables. They are phenomena of time; that is, the existence of time is necessary in order to experience these phenomena. When it is said that work and heat are stored in a body, this means that the ability to create work and heat is stored. What is stored is exergy as some form of time-independent contrast.

By using the so-called Gibbs relation,

$$U = ST - VP + \sum_i n_i\mu_i, \tag{10}$$

the following expression is derived from Eq. (9):

$$E = S(T - T_0) - V(P - P_0) + \sum_i n_i(\mu_i - \mu_{i,0}), \tag{11}$$

from which it is seen that E vanishes at equilibrium with the environment; that is, when $T = T_0$, $P = P_0$, and $\mu_i = \mu_{i0}$. This is the same as saying that with no contrast there is no exergy and no potential of action.

Analogously, the exergy of a flow can be written as

$$E = H - T_0S - \sum \mu_{i,0}n_i, \tag{12}$$

where H is the enthalpy.

Exergy is the most general expression of work. Other, less general but more common expressions of thermodynamic potentials (e.g., Gibbs and Helmholz free energies and enthalpy) are special cases of exergy as described in Table III. From Eq. (9) and the limitations specified in Table III, the equivalences

TABLE III

Relations between Differences in Exergy and in Other Thermodynamic Potentials

Limitations	$\Delta E = \Delta X$	Definition of X	Usually named
$\Delta n_i = 0$, $P = P_0$, $T = T_0$	$\Delta E = \Delta G$	$G = U + PV - TS$	Gibbs free energy
$\Delta n_i = 0$, $\Delta V = 0$, $T = T_0$	$\Delta E = \Delta F$	$F = U - TS$	Helmholtz free energy
$\Delta n_i = 0$, $\Delta S = 0$, $P = P_0$	$\Delta E = \Delta H$	$H = U + PV$	Enthalpy

between the difference in exergy and the difference in these other potentials can be derived.

1.2 Reference States

The major conceptual issue is the choice of reference state to which the chemical reactant under consideration is to be compared. Usually, the standard state of each element is defined as its pure elementary state, such as C for carbon, O_2 for oxygen, N_2 for nitrogen, and so on. The pure elements are normally assigned zero values in Gibbs free energy.

The standard exergies of chemical substances are often calculated on the assumption that the environment consists of a number of reference substances, one of each chemical element, with standard concentrations based on the average concentration in the natural environment. The reference substances selected are classified into three groups: gaseous compounds of the atmosphere, solid substances from the lithosphere, and both ionic and nonionic substances from the oceans. These groups are not in thermodynamic equilibrium, neither internally nor externally. Minor deviations of the actual environment from the standard environment only occasionally introduce significant errors to the exergy values.

It should also be noted that exergy may well be defined with reference to any other state (i.e., not necessarily a reference state). Thus, a locally defined environmental state is sometimes preferred. However, such a definition will imply a less general applicability of its use.

2. COMMON FORMS OF EXERGY

2.1 Work

Since exergy is defined as the maximum work potential, they are equivalent in every respect:

$$W = E - T_0 \Delta S. \tag{13}$$

It is stated in the second law that ΔS is always positive. Thus, from Eq. (13) it is obvious that exergy gives an upper limit to the work that is extractable from the process. The maximal amount of work is achieved when ΔS is minimal.

2.2 Pressure

Exergy is work, which is force F times distance S (FS) or pressure P times volume V (PV). This is illustrated by the movement of a piston in a cylinder in Fig. 1.

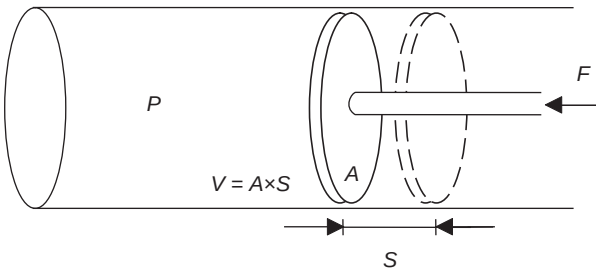

FIGURE 1 Pressure P is acting on a piston with area A that is moved the distance S by applying the force F.

2.3 Heat and Cold

An expression can be derived for the exergy of systems at different temperatures than that of the environment, both higher and lower. This will generate heat transfer when they are allowed to interact with each other or with the environment.

In Fig. 2, heat Q is transferred between two reservoirs at temperatures T and T_0, and $T > T_0$. A reversible heat engine (i.e., a Carnot engine) working between the temperatures T and T_0 gives the maximal available work. By assuming that the heat is completely lost (i.e., maximum entropy production), the exergy being lost (i.e., the available exergy that is able to be utilized) can be calculated. The ambient temperature is T_0 (Fig. 2).

When $T > T_0$, the following familiar relation holds:

$$E = T_0 S^{\text{tot}} = T_0 \left(\frac{Q}{T_0} - \frac{Q}{T} \right) = Q \left(1 - \frac{T_0}{T} \right). \tag{14}$$

If the temperature $T < T_0$, this only changes the direction of the heat flow Q, which then goes from T_0 to T; the exergy becomes

$$E = T_0 \left(\frac{Q}{T} - \frac{Q}{T_0} \right) = Q \left(\frac{T_0}{T} - 1 \right). \tag{15}$$

The ratio between the exergy E and the energy of the transferred heat Q is the exergy factor E/Q. Thus, exergy is obtained by multiplying the energy by the exergy factor. The exergy factor of heat from a heat reservoir (i.e., at a constant temperature T that differs from the ambient temperature T_0) is

$$\frac{E}{Q} = \left| \frac{T - T_0}{T} \right|. \tag{16}$$

This is a generalization of Eqs. (14) and (15) that holds at both $T > T_0$ and $T < T_0$. This expression is

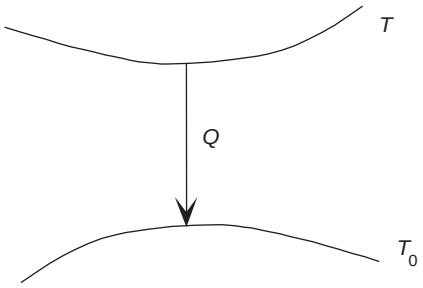

FIGURE 2 Heat Q is transferred between two reservoirs at temperatures T and T_0.

valid for heat from phase changes, i.e.,

$$E = Q\left|\frac{T_P - T_0}{T_P}\right| = L\left|\frac{T_P - T_0}{T_P}\right|, \qquad (17)$$

where T_P is the temperature during the phase change and L is latent heat, which depends on the substance and type of phase change.

Figure 3 shows how E/Q varies with temperature T according to Eq. (16). When $T < T_0$, energy is often regarded as negative, but the exergy is still positive. Figure 3 shows that E/Q strongly increases with low temperature. When T tends to absolute zero temperature (i.e., 0 K or -273.15°C), E/Q tends to infinity. This explains the difficulty in reaching absolute zero temperature. At high temperature, the E/Q comes closer to 1, which means that the exergy (E) and energy (Q) of the heat become almost the same. Higher temperatures (i.e., larger temperature differences) generate more work in a heat engine, which was stated by Carnot in 1824. This equation is useful to describe the exergy needed to maintain the temperature in hot spaces (e.g., furnaces, stoves, ovens, or houses) as well as in a cold storage (e.g., a refrigerator or a freezer) or to keep a pleasant indoor climate by air-conditioning on a hot summer day. Exergy reflects better than energy that heat or cold are more "expensive" when they are needed most. Thus, it is easier and less costly to generate cold in winter and heat in summer, and the storage of ice from winter to summer was once a profitable business. Also, waste heat to the environment carries a higher exergy together with a higher environmental impact in winter than in summer.

The exergy of a body with temperature T (i.e., exergy as sensible heat) is slightly more complicated to calculate since the temperature of the body as well as the delivered heat decrease when heat is transferred. Assume that the heat capacity of the body is C

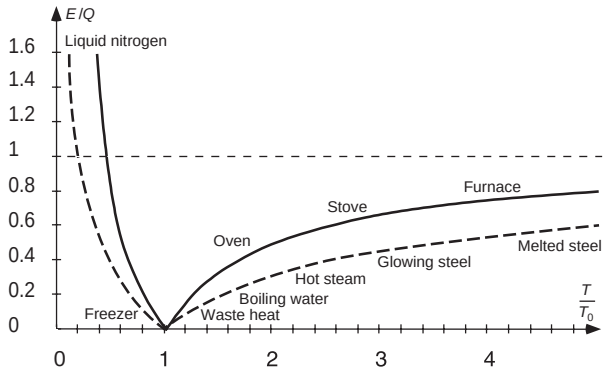

FIGURE 3 E/Q of heat as a function of its temperature; the solid line relates to Eq. (16), and the dashed line relates to Eq. (18).

(i.e., constant); the exergy becomes

$$E = C(T - T_0)\left(1 - \frac{T_0}{T - T_0}\ln\frac{T}{T_0}\right)$$

$$= C\left(T - T_0 - T_0\ln\frac{T}{T_0}\right). \qquad (18)$$

This relation is plotted in Fig. 3, and a number of examples are given, such as waste heat and melted steel. In many cases, such as for melted steel, the total exergy at different temperatures is a combination of latent heat due to phase changes and sensible heat (Eqs. 16 and 18, respectively). Assume that a power station produces 1000 MW of electricity and 2000 MW of waste heat as energy power at a temperature of 310 K by using cooling water at a local ambient temperature of $T_0 = 300$ K. From Eq. (18), the exergy of the waste heat in the cooling water is

$$E = Q\left(1 - \frac{T_0}{T - T_0}\ln\frac{T}{T_0}\right)$$

$$= 2000\left(1 - \frac{300}{310 - 300}\ln\frac{310}{300}\right)$$

$$\approx 2000 \times 0.0165 = 33\ \text{MW}.$$

The discharge of 33 MW waste heat as slightly warmed water causes an increase in the local environmental temperature, which gradually changes the local ecosystem. Most likely, the more exergy that is discharged into the environment, the more damage will be done to the local environment. Thus, exergy is also a suitable environmental indicator.

2.4 Light

The exergy per unit area of light (i.e., black body radiation, which is radiating from a body of temperature T and received by a body of temperature

T_0) can be derived as

$$\dot{e} = \dot{u}\left[1 + \frac{1}{3}\left(\frac{T_0}{T}\right)^4 - \frac{4}{3}\frac{T_0}{T}\right], \tag{19}$$

where $\dot{u}$ is energy emission per unit area and $\dot{u} = \sigma T^4$, where $\sigma = 5.67 \times 10^8\,\mathrm{WK^{-4}\,m^{-2}}$; this is the Stefan–Boltzmann constant.

Sunlight supports life on Earth. The temperature of the surface of the sun is estimated to be approximately $T_{\mathrm{sun}} = 6000\,\mathrm{K}$ and that of the earth approximately $T_{\mathrm{earth}} = T_0 = 300\,\mathrm{K}$. The exergy factor of the sunlight on the earth (i.e., the ratio of the exergy flux to the total energy flux) is

$$\left(\frac{\dot{e}}{\dot{u}}\right)_{\mathrm{sunlight}} = 1 + \frac{1}{3}\left(\frac{300}{6000}\right)^4 - \frac{4}{3} \times \frac{300}{6000} \approx 0.933.$$

Similarly, by considering the temperature of space that is assumed to be 3 K, the exergy factor of the earth's radiation to space is approximately 0.987. Strangely, more exergy leaves the earth with reference to space than is received on the earth as sunlight. However, to our knowledge, this radiated exergy is not part of any life-support system. Transmission through the atmosphere changes the spectral distribution of solar radiation due to the selective absorption of radiation. It also varies with the composition of the atmosphere and the length of the path through the atmosphere, which is determined by the position of the sun. The total solar energy and exergy power to the earth are approximately 1.7×10^{17} and $1.6 \times 10^{17}\,\mathrm{W}$, respectively; that is, the solar energy and exergy power at right angles to the inflow are approximately 1367 and $1275\,\mathrm{W/m^2}$, respectively, before entering the atmosphere.

If the ambient temperature on the earth increases due to the greenhouse effect (i.e., from the accumulation of gases such as carbon dioxide in the atmosphere), this implies a loss of solar exergy. For every higher degree in ambient earth temperatures the loss is approximately 1.5 times the total exergy use in society or approximately $2.5 \times 10^{13}\,\mathrm{W}$. This exergy will now, instead, add to the exergy of the heat radiation from the earth into space.

2.5 Material Substances

Equation (11) gives the following relation if the pressure P and the temperature T are constant (i.e., $P = P_0$ and $T = T_0$):

$$E = \sum_i n_i(\mu_i - \mu_{i,0}). \tag{20}$$

Furthermore, assume that the substance only departs from the environment in terms of chemical potential μ and concentration c. Also, assume that the chemical potential can be written as

$$\mu_i = \mu_i^0 + RT_0 \ln c_i, \tag{21}$$

where μ_i^0 is the chemical potential for the material i in relation to its standard state, obtained from chemical tables, usually the pure element in solid, liquid, or gas phase. Then the exergy becomes

$$E = \sum n_i(\mu_i^0 - \mu_{i0}^0) + RT_0 \sum n_i \ln\frac{c_i}{c_{i0}}, \tag{22}$$

where μ_{i0}^0 is the chemical potential for the material in the environment in relation to its standard state. Data on the chemical potential of different substances are found in the chemical literature. For only one material, the following relation holds:

$$E = n\left[\mu^0 - \mu_0^0 + RT_0 \ln\frac{c}{c_0}\right]. \tag{23}$$

Chemical reactions occurring in combustion processes often result in extensive exergy destruction. Evidently, no energy losses occur in the reaction. Only exergy calculations show that the production of entropy can cause a large percentage of potential work to be destroyed in the reaction. This indicates that an electrochemical membrane reactor, such as a fuel cell, could reduce exergy losses dramatically.

For pure reference components, which exist in the environment, exergy consists of the exergy that can be obtained by diffusing the components to their reference concentration. For gases and when the ideal gas law is applicable, this can be written as

$$E = nRT_0 \ln\frac{P_i}{P_{i0}}, \tag{24}$$

where P_i and P_{i0} are the partial pressures of the gas in the emission and in the environment, respectively.

Assume a power plant is fueled by pure carbon, C, with the exergy content of $410\,\mathrm{kJ\,mol^{-1}}$. Thus, at complete combustion and with no exergy losses besides waste heat, approximately $7.3\,\mathrm{kmol\,s^{-1}}$ of CO_2 is produced as exhaust gases. From Eq. (24), this emission of CO_2 carries an exergy into the environment as waste of

$$E = nRT_0 \ln\frac{P_i}{P_{i0}} \approx 7300 \times 8.31 \times 300 \times \ln\frac{1}{300 \times 10^{-6}} \approx 148\,\mathrm{MW},$$

where the concentration of CO_2 in the atmosphere is assumed to be 300 ppm. Thus, this is a considerable part of the exergy use that also reduces the efficiency

of the process. This emission will cause environmental effects such as global warming by influencing the heat radiation from the earth. When a substance does not exist in the reference environment, it often reacts to reference substances in order to get in equilibrium with the environment.

2.6 Nuclear Fuel

When the nuclear particles (i.e., nucleons) regroup into lower energy levels, exergy is released. In fission, this occurs by splitting heavy atoms, and in fusion it occurs by combining light atoms to form heavy atoms. Since a part of the transformed exergy in most cases appears as neutrinos, which can be regarded as invisible and noninteractive (i.e., not able to convert to work), nuclear exergy may be written as

$$E = \Delta mc^2 - E_{\text{neutrino}}, \tag{25}$$

where c is the speed of light in a vacuum (approximately $3 \times 10^8\,\text{m}\,\text{s}^{-1}$). The exergy of the neutrinos is often approximately 5% of the totally transformed exergy; thus, the exergy factor of nuclear energy is approximately 0.95.

2.7 Information

Exergy appears in daily life basically as three different phenomena: energy, matter, and information. Of these, energy and matter dominate in terms of amount of exergy, whereas information is exergy of a different magnitude, often several magnitudes lower than that of the energy. The exergy of a sheet of paper that carries a written message consists of the exergy of the paper and the exergy of the message (i.e., the information that it represents). The exergy of the paper (i.e., a material substance that may be combusted) amounts to approximately 50 kJ for an A4 sheet weighing 3 g (i.e., 17 MJ/kg). If this sheet carries a message of 5000 alphabetic characters (e.g., an English text), the exergy of this information is approximately 1.5×10^{-20} kJ (Eq. 8) since each character in reality only carries approximately 1 bit of information due to redundancy, which will be explained later. Exergy as material substances amounts to more than 10^{21} times the exergy as information on this sheet of paper. Thus, if it were possible to give an exact figure for the total exergy of this printed paper, the exergy of the information would not appear until in the 21st digit. Thus does not account for the exergy of the ink, which will also exceed that of the information by several magnitudes. This indicates that exergy of information should be treated differently than exergy of energy and matter. Therefore, special attention is given to the exergy of information.

Thermodynamics deals with the physical laws of systems containing many identical particles. From a macroscopic standpoint, the systems may be as small as $10^{-21}\,\text{m}^3$, but from a microscopic standpoint they are still large. $10^{-21}\,\text{m}^3$ contains approximately 10^9 atoms. Thus, it is impossible to have a detailed knowledge of the motion of each individual particle. In statistical mechanics, which provides the theoretical basis for the understanding of thermodynamics, advantage is taken of the large number of particles and statistical methods are used to describe macroscopic properties as average properties resulting from the motion and interaction of many particles.

Information theory deals with systems of incomplete information. The general problem of how to take into account, in an unambiguous way, the available and incomplete information was successfully dealt with by Jaynes in 1957. As Jaynes showed, statistical mechanics is a special case of information theory. Conversely, powerful concepts and methods, developed in statistical mechanics, may be extended into other fields through information theory. In 1961, Tribus bridged the gap to thermodynamics in his classic book, *Thermostatics and Thermodynamics*. Thus, the theory of thermodynamics survived the breakthrough of quantum physics and was incorporated as a special branch of information theory through statistical mechanics. Reality will now be approached from this microscopic view (i.e., where everything is built up from discrete energy quanta). Thus, a system can only appear in a limited number of discrete states, and if energy is added to the system this will occur step by step with not less than one energy quantum at the time.

Assume that the total number of possible states of the system is Ω. The probability that the system is in the jth state is indicated by P_j and the sum of all probabilities is normalized to 1:

$$\sum_{j=1}^{\Omega} P_j = 1. \tag{26}$$

In statistical mechanics, the entropy S is defined as

$$S = -k \sum_{j=1}^{\Omega} P_j \ln P_j, \tag{27}$$

where k is the Boltzmann constant. This gives a completely new insight into the concept of entropy.

From classical thermodynamics, entropy is just a state variable with no physical interpretation, which for generations of students made entropy a mysterious concept. Now it may be regarded as disorder and related to a lack of information or knowledge.

If the system is known to be in a specific state, the probability for this state is equal to 1. Then, the probability for all other states must be equal to 0 since the sum of all probabilities is set at 1 according to Eq. (26). The knowledge of the system is complete and from Eq. (27) the entropy becomes 0: $S=0$ $[0\times\ln(0)=0$ and $1\times\ln(1)=0]$. The state of the system is known. On the other hand, suppose nothing is known about the possible states in which the system is in—the knowledge is nil. All possible states are then equally probable. Since the number of possible states is Ω, then the probability of each state must be $1/\Omega$ in order to sum up to 1, according to Eq. (26). The entropy of the system now reaches its maximum value (i.e., $S=k\ln\Omega$). From our knowledge, the system is in complete disorder, like a library in which all the books are placed randomly. In 1896, Ludvig Boltzmann realized this expression of entropy for a thermodynamic system in equilibrium. Tragically, he never gained recognition for this fundamental relation during his lifetime.

The probabilities at equilibrium P_j^0 are those that maximize entropy S, under whatever constraints on the system that may be given

$$S_{\text{eq}}=S_{\max}=-k\sum_{j=1}^{\Omega}P_j^0\ln P_j^0. \tag{28}$$

The entropy difference between a given state and the equilibrium state of a system then becomes

$$S-S_{\text{eq}}=-k\left(\sum_{j=1}^{\Omega}P_j\ln P_j-\sum_{j=1}^{\Omega}P_j^0\ln P_j^0\right), \tag{29}$$

which then becomes a negative number since $S\le S_{\text{eq}}$. Therefore, the concept of negentropy is sometimes defined as $S_{\text{eq}}-S$, which instead becomes positive and increases with order.

According to information theory, the information content or information capacity of a system is, in binary units (bits),

$$I=\frac{1}{\ln 2}\left(\sum_{j=1}^{\Omega}P_j\ln P_j-\sum_{j=1}^{\Omega}P_j^0\ln P_j^0\right). \tag{30}$$

From Eqs. (29) and (30), it is seen that entropy, or rather negentropy, is very closely linked to information:

$$S_{\text{eq}}-S=k'I, \tag{31}$$

where $k'=k\ln 2\approx 1.0\times10^{-23}$ J/K. Thus, 1 bit of information is equivalent to 1.0×10^{-23} J/K of negentropy.

Assume a system of N different particles with two possible states each (e.g., 0 or 1). Then, $\Omega=2^N$. If there are no other restrictions, then all P_j^0 must be 2^{-N}; see Table IV, in which different particles are indicated by boxes in a row that can carry either 0 or 1.

Total information about the system (i.e., when one of P_j equals 1 and all the others equal 0) gives $I=N$, according to

$$I=\frac{1}{\ln 2}\left[0-\sum_{j=1}^{2^N}2^{-N}\ln(2^{-N})\right]$$
$$=\frac{1}{\ln 2}\left[-2^N\frac{1}{2^N}(-N)\ln 2\right]=N.$$

For every particle, there is information corresponding to a "yes" or "no" to a specific question. Every such answer corresponds to 1 bit of information. Equation (6) (i.e., $E=T_0\Delta S^{\text{tot}}$) gives

$$E=T_0(S_{\text{eq}}^{\text{tot}}-S^{\text{tot}}), \tag{32}$$

where tot is the total system, which in this case is only the system. Equations (31) and (32) give the following relation between exergy and information:

$$E=k'T_0I. \tag{33}$$

Thus, $k'T_0\approx 2.9\times10^{-21}$ J is the amount of exergy connected to 1 bit of information at room temperature. It should be noted that information is a measure not necessarily of actual meaningful information but rather of information capacity. It can also be thought of as a measure of order or structure.

The net flow of information capacity to the earth from the sun may now be calculated from Eq. (33) and the fact that the net inflow of exergy as sunlight (i.e., after reduction for reflection) is approximately

TABLE IV

Number of Possible States and Probabilities of a System of N Different Particles with Two Possible States Each

N	Boxes	Possible states	$\Omega=2^N$	P_j^0
1	□	0, 1	$2^1=2$	$\frac{1}{2}$
2	□□	00, 01, 10, 11	$2^2=4$	$\frac{1}{4}$
3	□□□	000, 001, 010, 100, 011, 101, 110, 111	$2^3=8$	$\frac{1}{8}$
etc.	…	…	…	…

1.1×10^{17} W. This gives an enormous amount of information, or

$$E = \frac{I}{k'T_0} = \frac{1.1 \times 10^{17}}{2.9 \times 10^{-21}} \approx 3.8 \times 10^{37} \text{ bits/s}.$$

Of this, man only uses a tiny fraction, approximately 5×10^{13} bits/s. Thus, the relation between used and available information capacity is approximately 10^{-24}. The same relation for energy conversion is approximately 10^{-5}. Therefore, most of the information flow from the sun (i.e., the exergy of sunlight) remains to be used.

3. EXERGY TOOLS

3.1 Exergy Losses

Energy is always in balance; however, for real processes exergy is never in balance. This unbalance is due to irreversibilities, which are usually called exergy destruction. The exergy output consists of the used output and the nonused output (i.e., exergy of waste output E_{waste}). It is very important to distinguish between exergy destruction caused by irreversibilities and exergy waste due to unused exergy (i.e., exergy flow to the environment). Both represent exergy losses, but irreversibilities have, by definition, no exergy and, thus, no environmental effects. However, due to high exergy losses from irreversibilities, more exergy is used to compensate for this loss, and this in turn may have an environmental impact (i.e., an indirect effect). In the literature, exergy destruction is commonly referred to as availability destruction, irreversibility, and lost work.

Exergy destruction is related to the entropy production by

$$E_{\text{in}}^{\text{tot}} - E_{\text{out}}^{\text{tot}} = T_0 \Delta S^{\text{tot}} = \sum_i (E_{\text{in}} - E_{\text{out}})_i, \qquad (34)$$

where ΔS^{tot} is the total entropy increase, $E_{\text{in}}^{\text{tot}}$ is the total exergy input, $E_{\text{out}}^{\text{tot}}$ is the total exergy output, and $(E_{\text{in}} - E_{\text{out}})_i$ is the exergy destruction in process i.

By definition, an exergy balance only exists for reversible processes. Thus, for real processes [i.e., irreversible processes ($\Delta S^{\text{tot}} > 0$)], exergy is never in balance because the total exergy input always exceeds the total exergy output (i.e., $E_{\text{in}}^{\text{tot}} > E_{\text{out}}^{\text{tot}}$).

By calculating the exergy loss (i.e., destruction and waste), possible process improvements are visualized. In general, when the exergy loss is high, this part should be considered for improvement first. However, this "tackle the biggest loss first" approach is not always appropriate because every part of the system depends on the others, so an improvement in one part may cause increased losses in other parts. As such, the total losses in the modified process may in fact be equal to or even larger than those in the original process configuration. Also, the use of renewable and nonrenewable resources must be considered. Therefore, the problem needs a more careful approach, which is described later.

3.2 Exergy Efficiencies

Exergy efficiency, which is also called second law efficiency, effectiveness, or rational efficiency, is usually defined as utilized exergy divided by used exergy. This must be a number between 0 and 1 since all real processes involve exergy destruction. This is in distinction to energy efficiency, which may well exceed 1. However, there are several ways to define the utilized exergy and used exergy, which add ambiguity to the application of this concept. Also worth noting is that exergy efficiency is often also defined as utilized exergy divided by the exergy that is theoretically possible to utilize due to, for example, time constraints. The faster a process operates the more exergy is lost due to increased irreversibility.

A simple definition of efficiency expresses all exergy input as used exergy and all exergy output as utilized exergy. So the exergy efficiency $\eta_{\text{ex},1}$ becomes

$$\eta_{\text{ex},1} = \frac{E_{\text{out}}}{E_{\text{in}}} = 1 - \frac{E_{\text{in}} - E_{\text{out}}}{E_{\text{in}}}, \qquad (35)$$

where the definition of exergy destruction given previously is added. However, this efficiency does not always provide an adequate characterization of the thermodynamic efficiency of processes, such as heat transfer, separation, and expansion. Often, there exists a part of the output exergy that is unused (i.e., an exergy waste E_{waste} to the environment). Thus, the utilized exergy is given by $E_{\text{out}} - E_{\text{waste}}$, which is called the exergy product E_{pr}. The output consists of two parts:

$$E_{\text{out}} = E_{\text{pr}} + E_{\text{waste}}. \qquad (36)$$

The exergy efficiency $\eta_{\text{ex},2}$ now instead becomes

$$\eta_{\text{ex},2} = \frac{E_{\text{out}} - E_{\text{waste}}}{E_{\text{in}}} = \frac{E_{\text{pr}}}{E_{\text{in}}} = \eta_{\text{ex},1} - \frac{E_{\text{waste}}}{E_{\text{in}}}. \qquad (37)$$

Sometimes, part of the exergy going through the system is unaffected. This part has been called transit exergy E_{tr} (Fig. 4).

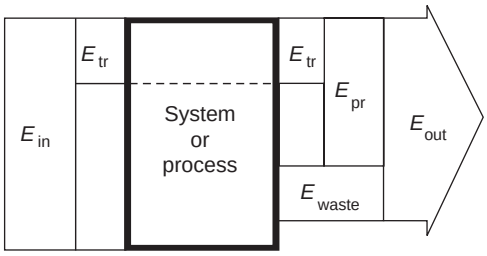

FIGURE 4 The input and output of exergies for a system.

If the transit exergy E_{tr} is deducted from both the input and the output exergy (or, rather, from the exergy product), the exergy efficiency $\eta_{ex,3}$ becomes

$$\eta_{ex,3} = \frac{E_{out} - E_{waste} - E_{tr}}{E_{in} - E_{tr}} = \frac{E_{pr} - E_{tr}}{E_{in} - E_{tr}}. \quad (38)$$

Due to the difficulties of calculating transit exergy and its lack of recognition, the exergy efficiency $\eta_{ex,2}$ is normally used:

$$\eta_{ex} = \eta_{ex,2} = \frac{E_{out} - E_{waste}}{E_{in}} = \frac{E_{pr}}{E_{in}}. \quad (39)$$

These latter definitions are compared by applying them to a system with two different processes A and B (Fig. 5). The exergy efficiencies for process A are $\eta_{ex,2} = 91\%$ and $\eta_{ex,3} = 10\%$, and those for process B are $\eta_{ex,2} = \eta_{ex,3} = 50\%$. Thus, determining which is the most efficient process is a matter of defining efficiency. However, from Fig. 5, it is seen that the exergy destruction of process A is larger than that of process B (9 vs 5); thus, process A should really be improved first.

From this comparison it is seen that a better insight is offered by using exergy flow diagrams. From an exergy flow diagram, one can learn

- the exergy efficiencies of the various parts of a system
- the different exergy inputs and outputs
- where the various exergy flows come from and go to
- the amount of transit exergy
- how much exergy is destroyed in each processes

This often leads to a better insight and understanding of the system and its characteristics, which implies a better basis for improvement considerations.

3.3 Exergy Flow Diagrams

From the previous discussion, it is known that ambiguity reduces if an exergy flow diagram is used to demonstrate an exergy transfer instead of a ratio. In engineering, these diagrams are often used to describe the energy or exergy flows through a process (Fig. 6).

Figure 6 shows a typical power plant, its main components, and the energy and exergy flows of the plant. This diagram shows where the energy and exergy losses occur in the process and also whether exergy is destroyed from irreversibilities or whether it is emitted as waste to the environment. This information is very useful when considering the ecological effects of an activity. It also gives a hint

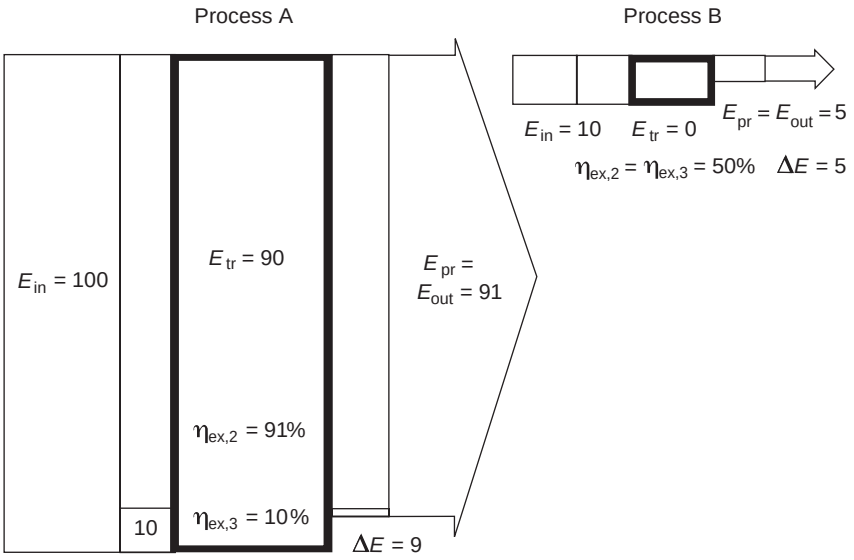

FIGURE 5 Comparison of efficiencies of exergy flows for two processes, A and B.

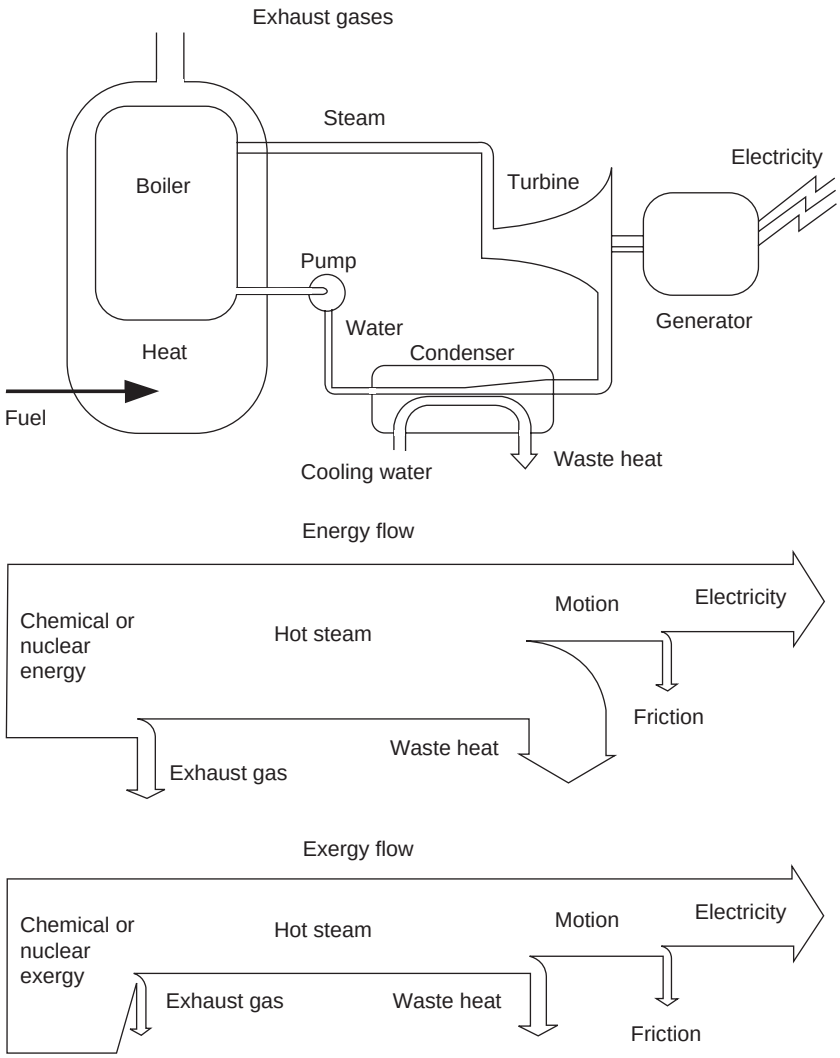

FIGURE 6 Energy and exergy flow diagrams of a condensing power plant.

about the possibilities of improving the process and where to direct efforts for improvement. In the energy flow diagram, energy is always conserved, as stated by the first law of thermodynamics. The waste heat carries the largest amount of energy into the environment, far more than is carried by the exhaust gases. However, in the exergy flow diagram the temperature of the waste heat is close to ambient so the exergy becomes much less. The exergy of the exhaust gas and that of the waste heat are comparable. Energy and exergy losses from friction have little direct impact on the environment. The ecological effects are more related to the exergy flows than to the energy flows, which makes exergy flows better ecological indicators.

The widths of the inflows and outflows in the energy and the exergy diagrams are almost equal because both the inflows and the useful outflows are very high-quality energy forms, and for them energy and exergy are almost equal. For electricity, the energy and the exergy values are identical since electricity does not carry any entropy. The losses in the two diagrams, however, are quite different. First, there are losses in the furnace, where fuel is converted into heat. In an oil- or coal-fueled power plant the flame temperature is approximately 2000°C, but in a nuclear power plant the temperature is only approximately 300°C due to safety regulations. The heat is then transmitted through heat exchangers to boil water (i.e., produce steam in what is often called a steam generator). The pressure is high to make the water boil at high temperatures. Through the walls of the furnace, and through pipes, heat is lost to the environment. Heat is also lost with the exhaust gases,

usually in order to keep the chimneys free from condensed water. These losses represent only a minor part of the total energy flow. However, from the exergy diagram, we see that more than one-third of the exergy is lost at this stage. We also see that exergy disappears and only a small fraction leaves the plant. The exergy flow literally shrinks. Large quantities of entropy are created because the steam that leaves the boiler has a relatively low temperature and pressure due to limitations in the fatigue strength of the components in the process, principally the boiler and the turbine blades. In a nuclear power plant, more than half the converted exergy is lost during this stage of the process.

The energy and exergy of hot steam in Fig. 6 differ a great deal. In the energy diagram, major losses occur in the condenser as waste heat in the cooling water. The waste heat in this case, however, is heat at a temperature slightly above the ambient temperature and its exergetic value is therefore very low. This is obvious from the exergy diagram, in which the waste heat is a minor flow. Thus, for a conversion of waste heat into work by an ideal process (i.e., a Carnot engine), only the amount indicated in the exergy diagram would become work, and the loss would be waste heat at ambient temperature (i.e., exergy equals zero). It is not possible to produce any more work or electrical energy from the steam, or from any other energy form, than what is determined by its exergy content.

When converting mechanical energy into electrical energy, both of which have an exergy factor of 1, small losses arise from friction. These losses are on the whole equally small in both diagrams. Part of the friction losses is due to mechanical fatigue (i.e., wearing out of shafts and bearings).

Figure 7 illustrates the energy and exergy flows of an oil furnace, an electric heater, an electric heat pump, and a combined power and heat plant (i.e., a cogeneration plant). In the oil furnace, the energy efficiency is assumed to be approximately 85%, with losses due mainly to the hot exhaust gases (Fig. 7). The exergy efficiency is very low (approximately 4%) because the temperature difference is not utilized when the temperature is decreased to a low of approximately 20°C, a comfortable indoor climate.

Electric heating by short-circuiting in electric resistors has an energy efficiency of 100% by

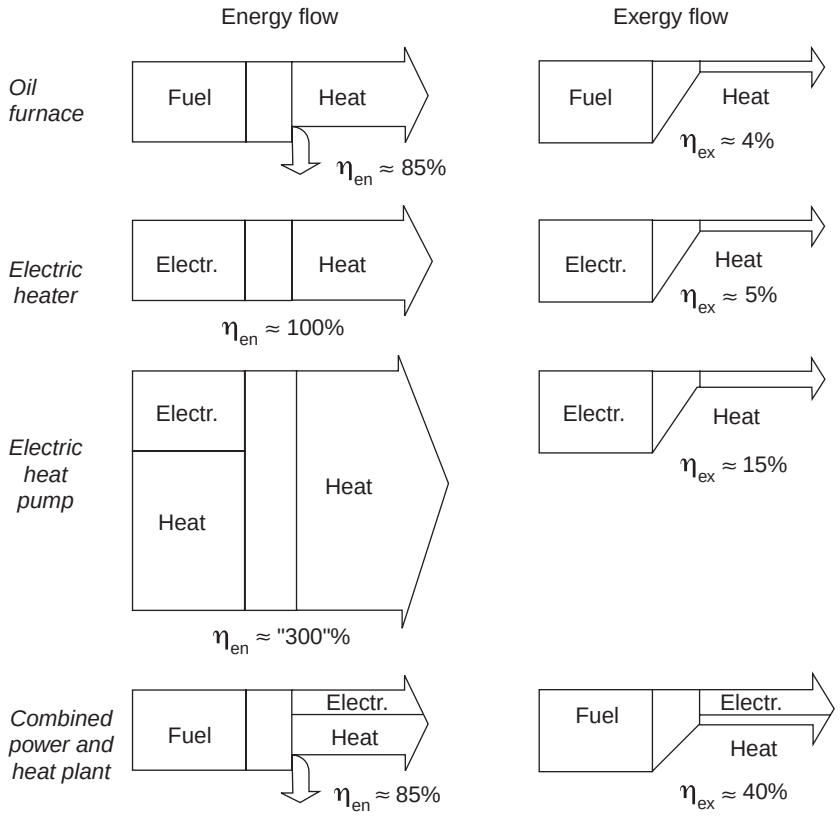

FIGURE 7 Energy and exergy flows through some typical energy systems.

definition of energy conservation. The energy efficiency of an electric heat pump is not limited to 100%. If the heat originating from the environment is ignored in the calculation of the efficiency, the conversion of electrical energy into indoor heat can be well over 100% (e.g., 300% as in Fig. 7). The exergy flow diagram of the heat pump looks quite different. The exergy efficiency for an electric heater is approximately 5% and for the heat pump 15%.

In Fig. 6, the energy and exergy efficiencies are the same because the inflow of fuels and the outflow of electricity both have an exergy factor of approximately 1. For a combined power and heat plant (Fig. 7), the exergy efficiency is about the same as that for a condensing power plant (Fig. 6). The main exergy loss occurs in the conversion of fuel into heat in the boiler. Since this conversion is practically the same in both the condensing and the combined power plants, the total exergy efficiency is the same (i.e., approximately 40%). The maximum energy efficiency of an ideal conversion process may be more than 100%, depending on the definition of efficiency. The exergy efficiency, however, can never exceed 100%.

Exergy flow diagrams may also include the total use of physical resources (i.e., energy and other resources for a system). Figure 8 shows the main conversions of energy and materials in Swedish society in 1994. The flows of resources go from left to right in the diagram (i.e., from the resource base to the consumption sector). Thus, the diagram basically represents the resource supply sector in which resources, such as crops and minerals, are turned into consumer goods, such as food, transport, and thermal comfort. The width of the flows is defined by their exergy content and the unit of the flows is Joules. The accuracy of the flows varies a great deal between the different areas. For the electricity system, the accuracy is quite high, whereas for

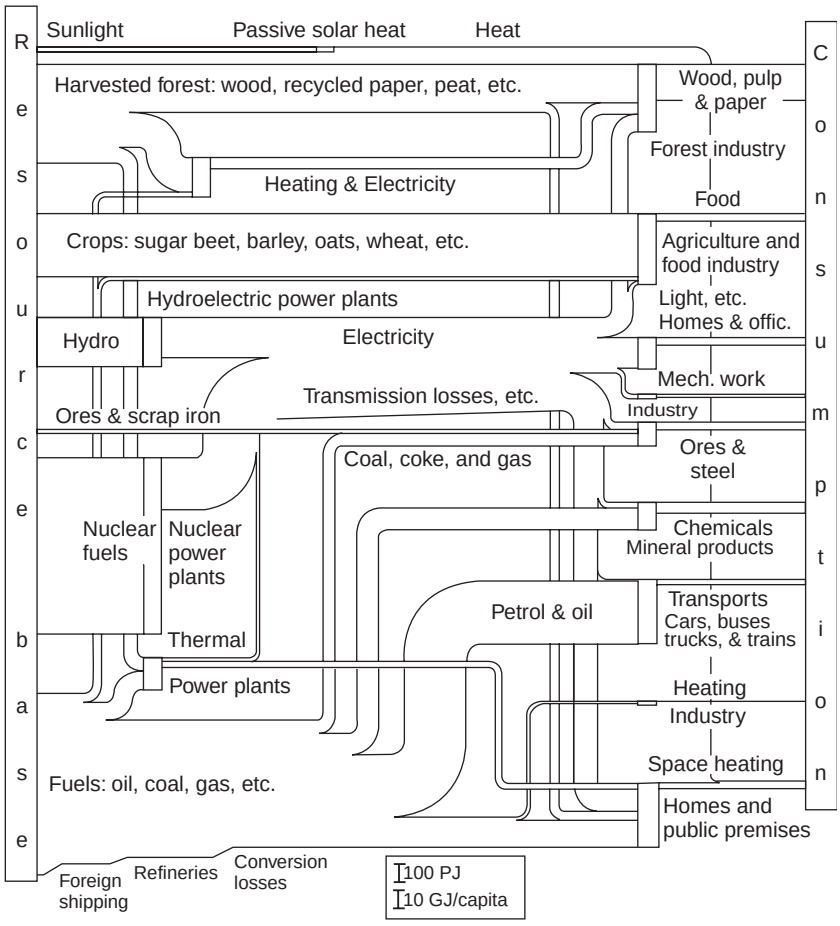

FIGURE 8 The exergy conversion system in the Swedish society in 1994. Total input was approximately 2720 PJ or 310 GJ per capita, and total output was approximately 380 PJ or 43 GJ per capita.

sectors related to agriculture and forestry it is not. In order to not make the diagram too complicated, only exergy flows exceeding 5 PJ are included. The inflows are ordered according to their origins. Sunlight is thus a renewable natural flow. Besides a minor use of wind power, far less than 5 PJ, this is the only direct use of a renewable natural flow. Harvested forests, agricultural crops, and hydropower are renewable exergy flows derived from funds, which of course are founded on the renewable natural flow of sunlight. Iron ore, nuclear fuels, and fossil fuels are non-renewable exergy flows from deposits, which are exhaustible and also carry toxic substances. The unfilled boxes represent exergy conversions, which in most cases represent a huge number of internal conversions and processes. The resources actually demanded by society appear as outflows on the right side of the diagram. The total inflow of resources during 1994 was approximately 2720 PJ or 310 GJ per capita, and the net output was 380 PJ or 40 GJ per capita. Thus, the overall efficiency of the supply sector can be estimated at less than 15%, which must be regarded as poor. As can be seen, some sectors are extremely inefficient. Some resource conversion systems have a ridiculously poor efficiency. For nuclear fuel to space heating through short-circuit heaters the utilization is less than 0.025% if the physically available nuclear exergy is considered.

Exergy is a concept to be used by society at large, e.g., in town and country planning. In addition to having an important pedagogical value, it bridges gaps between different areas of science (e.g., thermodynamics, information theory, economics, and ecology). Thus, exergy will play a central role in disciplines that are dedicated to sustainable development.

Glossary

chemical exergy The maximum work obtainable from a substance when it is brought from the environmental state to the dead state by means of processes involving interaction only with the environment.

dead state The state of a system when it is in thermal, mechanical, and chemical equilibrium with a conceptual reference environment, which is characterized by a fixed pressure, temperature, and chemical potential for each of the reference substances in their respective dead states.

environmental state The state of a system when it is in thermal and mechanical equilibrium with the reference environment—that is, at the pressure and temperature of the reference environment.

exergy (i) A general term for the maximum work potential of a system, stream of matter, or a heat interaction in relation to the reference environment as the datum state. Also known as available energy, availability, essergy, technical work capacity, usable energy, utilizable energy, work capability, work potential, and xergy. (ii) The unqualified term exergy or exergy flow is the maximum amount of shaft work obtainable when a steady stream of matter is brought from its initial state to the dead state by means of processes involving interactions only with the reference environment.

exergy analysis An analysis technique, based on the second law of thermodynamics, in which process performance is assessed by examining exergy balances, losses, and efficiencies.

exergy consumption The exergy consumed or destroyed during a process due to irreversibilities within the system boundaries. Also known as dissipation, irreversibility, and lost work.

physical exergy The maximum amount of shaft work obtainable from a substance when it is brought from its initial state to the environmental state by means of physical processes involving interaction only with the environment. Also known as thermomechanical exergy.

reference environment An idealization of the natural environment that is characterized by a perfect state of equilibrium—that is, the absence of any gradients or differences involving pressure, temperature, chemical potential, kinetic energy, and potential energy. The environment constitutes a natural reference medium with respect to which the exergy of different systems is evaluated.

reference state A state with respect to which values of exergy are evaluated. Several reference states are used, including the environmental state, dead state, standard environmental state, and standard dead state. Also known as ground state.

thermal exergy The exergy associated with a heat interaction—that is, the maximum amount of shaft work obtainable from a given heat interaction using the environment as a thermal energy reservoir.

Energy analysis is based on the first law of thermodynamics, which embodies the principle of the conservation of energy. Exergy analysis is a thermodynamic analysis technique for systems and processes that is based on the second law of thermodynamics and has several advantages over energy analysis.

First, more meaningful efficiencies are evaluated with exergy analysis since exergy efficiencies are always a measure of the approach to the ideal. Second, the inefficiencies in a process are better pinpointed with exergy analysis in that the types, causes, and locations of the losses are identified and quantified. For these reasons and others, exergy analysis has been increasingly applied during the past several decades. In this article, the role of exergy analysis in the assessment and improvement of energy systems is discussed. First, exergy and its use as a tool through exergy analysis are briefly described. Then, the range of energy systems that have in the past been assessed using exergy analysis are surveyed. Finally, several examples of applications of exergy analysis are presented, ranging from simple energy devices and systems to complex energy systems and large macrosystems.

1. EXERGY

Exergy is defined as the maximum amount of work that can be produced by a stream or system as it is brought into equilibrium with a reference environment, and it can be thought of as a measure of the usefulness or quality of energy. Exergy is consumed during real processes due to irreversibilities and conserved during ideal processes.

Exergy quantities are evaluated with respect to a reference environment. The intensive properties of the reference environment in part determine the exergy of a stream or system. The exergy of the reference environment is zero. The reference environment is in stable equilibrium, with all parts at rest relative to one another. No chemical reactions can occur between the environmental components. The reference environment acts as an infinite system and is a sink and source for heat and materials. It experiences only internally reversible processes in which its intensive state remains unaltered (i.e., its temperature T_o, pressure P_o, and the chemical potentials μ_{ioo} for each of the i components present remain constant).

Energy and exergy balances can be written for a general process or system. An energy balance for a system may be written as

$$\text{Energy input} - \text{energy output} = \text{energy accumulation}. \quad (1)$$

Energy input and output refer respectively to energy entering and exiting through system boundaries. Energy accumulation refers to buildup (either positive or negative) of the quantity within the system. Clearly, energy is subject to a conservation law.

By combining the conservation law for energy and nonconservation law for entropy (which states that entropy is created during a process due to irreversibilities), an exergy balance can be obtained:

$$\text{Exergy input} - \text{exergy output} - \text{exergy consumption} = \text{exergy accumulation}. \quad (2)$$

Exergy is consumed due to irreversibilities. Exergy consumption is proportional to entropy creation. Equations (1) and (2) demonstrate an important difference between energy and exergy: Energy is conserved, whereas exergy, a measure of energy quality or work potential, can be consumed.

2. EXERGY ANALYSIS

Exergy analysis involves the application of exergy concepts, balances, and efficiencies to evaluate and improve energy and other systems. Many engineers and scientists suggest that devices can be well evaluated and improved using exergy analysis in addition to or in place of energy analysis. Exergy analysis has been applied to a wide range of processes and systems. This article focuses on applications to energy systems.

2.1 Exergy Analysis and Limitations on Increased Efficiency

Increases in efficiency are subject to two constraints, which are often poorly understood: (i) theoretical limitations, which establish the maximum efficiency theoretically attainable for a process by virtue of the laws of thermodynamics, and (ii) practical limitations, which further limit increases in efficiency.

First, consider practical limitations on efficiency. In practice, when selecting energy sources and utilization processes the goal is not to achieve maximum efficiency but rather to achieve an optimal trade-off between efficiency and such factors as economics, sustainability, environmental impact, safety, and societal and political acceptability. This optimum is dependent on many factors controllable by society; furthermore, these factors can be altered to favor increased efficiency (e.g., governments can offer financial incentives that render high-efficiency technologies economically attractive and/or provide disincentives for low-efficiency alternatives through special taxes and regulations).

Now, consider theoretical limitations on efficiency. To assess the potential for increased efficiency, the theoretical limits must be clearly understood. In the past, lack of clarity on this issue has often led to confusion, in part because energy efficiencies generally are not measures of how close the performance of a process or device approaches the theoretical ideal. The consequences of such confusion can be very significant. For example, extensive resources have occasionally been directed toward increasing the energy efficiencies of devices that in reality were efficient and had little potential for improvement. Conversely, at other times devices have not been targeted for improved efficiency, even though the difference between the actual and maximum theoretical efficiencies, which represents the potential for improvement, has been large.

The difficulties inherent in energy analysis are also attributable to the fact that it considers only quantities of energy and ignores energy quality, which is continually degraded during real processes. Exergy analysis, as discussed earlier, overcomes many of the problems associated with energy analysis.

2.2 Applications of Exergy Analysis beyond Thermodynamics

Exergy concepts can be applied beyond thermodynamics. One area in which applications of exergy are increasing is that of environmental impact. Many suggest that the impact of energy resource utilization on the environment and the achievement of increased resource-utilization efficiency should be addressed by considering exergy, among other factors. Although the exergy of an energy form or a substance is a measure of its usefulness, exergy is also a measure of its potential to cause change. The latter point suggests that exergy may be, or provide the basis for, an effective measure of the potential of a substance or energy form to impact the environment.

Another area in which applications of exergy are increasing is that of economics. In the analysis and design of energy systems, techniques are often used that combine scientific disciplines (especially thermodynamics) with economics to achieve optimum designs. For energy systems, costs are conventionally based on energy. Many researchers, however, have recommended that costs are better distributed among outputs, based on exergy. Methods of performing exergy-based economic analyses have evolved and are referred to as thermoeconomics, second law costing, and exergoeconomics. These analysis techniques recognize that exergy, more than energy, is the commodity of value in a system, and they assign costs and/or prices to exergy-related variables. These techniques usually help determine the appropriate allocation of economic resources so as to optimize the design and operation of a system and/or the economic feasibility and profitability of a system (by obtaining actual costs of products and their appropriate prices).

2.3 Steps for Energy and Exergy Analyses

A simple procedure for performing energy and exergy analyses involves the following steps:

- Subdivide the process under consideration into as many sections as desired, depending on the depth of detail and understanding desired from the analysis.
- Perform conventional mass and energy balances on the process, and determine all basic quantities (e.g., work and heat) and properties (e.g., temperature and pressure).
- Based on the nature of the process, the acceptable degree of analysis complexity and accuracy, and the questions for which answers are sought, select a reference environment model.
- Evaluate energy and exergy values, relative to the selected reference environment model.
- Perform exergy balances, including the determination of exergy consumptions.
- Select efficiency definitions, depending on the measures of merit desired, and evaluate the efficiencies.
- Interpret the results, and draw appropriate conclusions and recommendations relating to such issues as design changes, retrofit plant modifications, etc.

3. SURVEY OF APPLICATIONS OF EXERGY ANALYSIS TO ENERGY SYSTEMS

Many applications of exergy analysis to energy systems have been reported in the literature, particularly during the past several decades. Some extensive bibliographies have been compiled, including one by Goran Wall (http://exergy.se). In addition, a journal devoted to exergy matters, *Exergy: An International Journal*, has been established.

The types of applications of exergy methods to energy systems that have been reported in the past are extremely varied and include the following:

- Electricity generation using both conventional devices, such as fossil and nuclear power plants, and alternative devices, such as fuel cells and solar energy systems
- Engines of various types
- Transportation systems for land, air, and water transport
- Heating and cooling systems for building systems and industrial applications
- Cogeneration systems for producing heating and electrical needs simultaneously
- Petrochemical processing and synthetic fuels production
- Chemical processes, such as sulfuric acid production, distillation, and water desalination
- Metallurgical processes, such as lead smelting
- Combustion technologies and systems
- Energy storage systems, such as batteries, pumped storages, and thermal energy storages

4. EXAMPLES OF APPLICATIONS OF EXERGY ANALYSIS TO ENERGY SYSTEMS

Examples of applications of exergy analysis are presented in the following four sections. Because the range of energy systems to which exergy has been applied is great, the four examples described here were selected to cover the breadth of complexity. Consequently, we start with a simple device (an electrical resistance space heater) and then consider a simple system (a thermal energy storage system), where simple is taken here to imply that the system has a very limited number of components. Next, we examine a more complex system (a coal-fired electrical generating station). Finally, we investigate the application of exergy analysis to a "macrosystem"—that is, a large conglomerate of energy systems that cover a region such as a city, province, or country.

5. SIMPLE DEVICE: ELECTRICAL RESISTANCE SPACE HEATER

An electrical resistance space heater converts electricity to heat at a temperature suitable for keeping a room at a comfortable temperature. It is illustrated in Fig. 1.

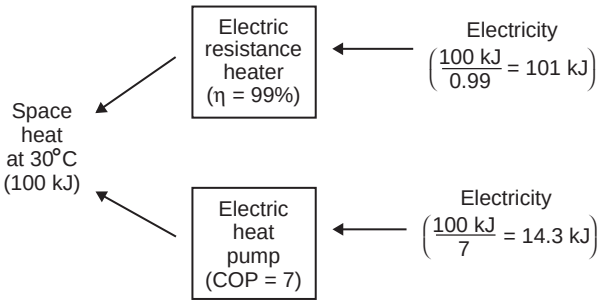

FIGURE 1 Comparison of the quantity of electricity required to provide a fixed amount of space heat (100 kJ) using two different heating devices: an electric resistance heater and an electric heat pump. η, energy efficiency; COP, coefficient of performance.

The energy efficiency of electric resistance space heating is often said to exceed 99%. The implication is that the maximum possible energy efficiency for electric resistance heating is 100%, corresponding to the most efficient device possible.

This understanding is erroneous, however, because energy analysis ignores the fact that in this process high-quality energy (electricity) is used to produce a relatively low-quality product (warm air). Exergy analysis recognizes this difference in energy qualities and indicates that the exergy of the heat delivered to the room is approximately 5% of the exergy entering the heater. Thus, based on exergy, the efficiency of electric resistance space heating is approximately 5%.

We therefore obtain useful information from the exergy results. Since thermodynamically ideal space heating has an exergy efficiency of 100%, the same space heating can theoretically be achieved using as little as 5% of the electricity used in conventional electric resistance space heating. In practical terms, one can achieve space heating with a greatly reduced electricity input using a high-efficiency electric heat pump (Fig. 1), using 15% of the electricity that electric resistance heating would require for a heat pump with a coefficient of performance of 7.

6. SIMPLE SYSTEM: THERMAL ENERGY STORAGE SYSTEM

A thermal energy storage (TES) system receives thermal energy and holds the energy until it is required. TESs can store energy at temperatures above or below the environment temperature, and there are many types of systems (e.g., tanks, aquifers, ponds, and caverns).

The evaluation of a TES system requires a measure of performance that is rational, meaningful, and practical. The conventional energy storage efficiency is an inadequate measure. A more perceptive basis for comparison is needed if the true usefulness of thermal storages is to be assessed and thus permit maximization of their economic benefit. Efficiencies based on ratios of exergy provide rational measures of performance since they can measure the approach of the performance of a system to the ideal.

That the energy efficiency is an inappropriate measure of thermal storage performance can best be appreciated by a simple example. Consider a perfectly insulated thermal storage containing 1000 kg of water, initially at 40°C. The ambient temperature is 20°C, and the specific heat of water is taken to be constant at 4.2 kJ/kg K. A quantity of 4200 kJ of heat is transferred to the storage through a heat exchanger from an external body of 100 kg of water cooling from 100 to 90°C. This heat addition raises the storage temperature 1.0°C to 41°C. After a period of storage, 4200 kJ of heat is recovered from the storage through a heat exchanger that delivers it to an external body of 100 kg of water, raising the temperature of that water from 20 to 30°C. The storage is returned to its initial state at 40°C.

For this storage cycle the energy efficiency, which is the ratio of the heat recovered from the storage to the heat injected, is 4200/4200 kJ = 1, or 100%. However, the recovered heat is at only 30°C and of little use, having been degraded even though the storage energy efficiency was 100%. The exergy recovered in this example is evaluated as 70 kJ and the exergy supplied as 856 kJ. Thus, the exergy efficiency, which is the ratio of the thermal exergy recovered from storage to that injected, is 70/856 = 0.082, or 8.2%—a much more meaningful expression of the achieved performance of the TES. Consequently, a device that appears to be ideal on an energy basis is correctly shown to be far from ideal on an exergy basis, clearly demonstrating the benefits of using exergy analysis for evaluating TESs.

7. COMPLEX SYSTEM: COAL-FIRED ELECTRICAL GENERATING STATION

Energy and exergy analyses are applied to a coal-fired electrical generating station. The coal-fired Nanticoke Generating Station is selected as the representative station for the analysis. The station has a net unit electrical output of approximately 500 MWe and is operated by the provincial electrical utility, Ontario Power Generation (formerly Ontario Hydro), in Ontario, Canada. This example clearly illustrates how exergy analysis allows process inefficiencies to be better determined than does an energy analysis and efficiencies to be more rationally evaluated. Consequently, the example identifies areas in which the potential for performance improvement is high and trends that may aid in the design of future stations.

7.1 Process Description

A detailed flow diagram for a single unit of the station is shown in Fig. 2. The symbols identifying the streams are described in Table I, in which data are provided for the streams. The diagram in Fig. 2 is divided into four main sections:

- *Steam generation*: Heat is produced and used to generate and reheat steam. In the station, eight pulverized coal-fired natural circulation steam generators each produce 453.6 kg/s steam at 16.89 MPa and 538°C and 411.3 kg/s of reheat steam at 4.00 MPa and 538°C. Air is supplied to the furnace by two 1080-kW, 600-rpm motor-driven forced-draft fans. Regenerative air preheaters are used. The flue gas passes through an electrostatic precipitator rated at 99.5% collection efficiency and exits the plant through two multiflued, 198-m-high chimneys.
- *Power production*: The steam produced in the steam generation section is passed through a series of turbine generators that are attached to a transformer. Extraction steam from several points on the turbines preheats feedwater in several low- and high-pressure heat exchangers and one spray-type open deaerating heat exchanger. The low-pressure turbines exhaust to the condenser at 5 kPa. Each station unit has a 3600-rpm, tandem-compound, impulse-reaction turbine generator containing one single-flow high-pressure cylinder, one double-flow intermediate-pressure cylinder, and two double-flow low-pressure cylinders. Steam exhausted from the high-pressure cylinder is reheated in the combustor.
- *Condensation*: Cooling water from Lake Erie condenses the steam exhausted from the turbines. The flow rate of cooling water is adjusted so that a specified temperature increase in the cooling water is achieved across the condenser.
- *Preheating*: The temperature and pressure of the feedwater are increased in a series of pumps and feedwater–heater heat exchangers.

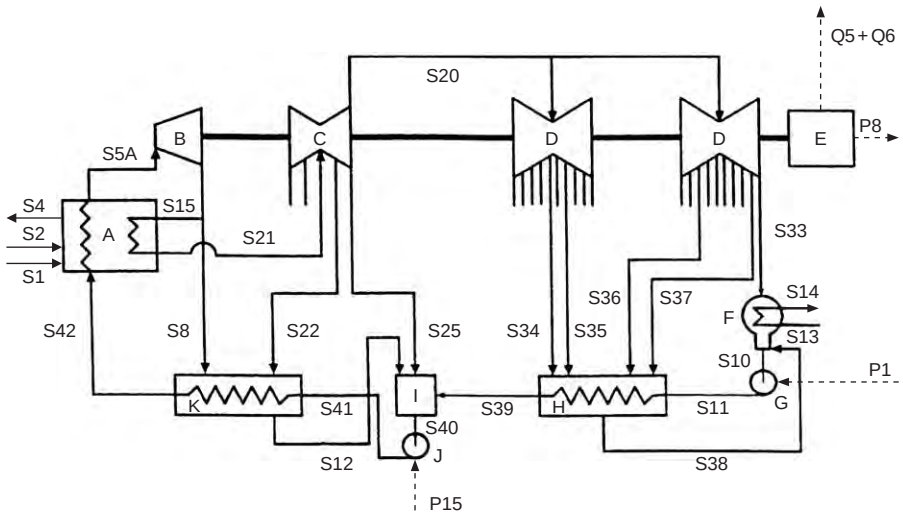

FIGURE 2 A unit of the coal-fired electrical generating station. Lines exiting the turbines represent extraction steam. The station has four main sections: Steam generation (A), power production (B–E), condensation (F), and preheating (G–K). The external inputs for device A are coal and air, and the output is stack gas and solid waste. The external outputs for device E are electricity and waste heat. Electricity is input to devices G and J, and cooling water enters and exits device F. A, steam generator and reheater; B, high-pressure turbine; C, intermediate-pressure turbine; D, low-pressure turbines; E, generator and transformer; F, condenser; G, hot well pump; H, low-pressure heat exchangers; I, open deaerating heat exchanger; J, boiler feed pump; K, high-pressure heat exchangers.

7.2 Analysis Assumptions and Simplifications

The reference environment model used here has a temperature of 15°C (the approximate mean temperature of the lake cooling water), a pressure of 1 atm, a chemical composition consisting of air saturated with water vapor, and the following condensed phases at 15°C and 1 atm: water (H_2O), gypsum ($CaSO_4 \cdot 2H_2O$), and limestone ($CaCO_3$). For simplicity, heat losses from external surfaces are assumed to occur at the reference environment temperature of 15°C.

7.3 Results and Discussion

Energy and exergy values for the streams identified in Fig. 2 are summarized in Table I. Exergy consumption values for the devices are listed, according to process diagram sections, in Table II. Figures 3 and 4 illustrate the net energy and exergy flows and exergy consumptions for the four main process diagram sections described in the legend to Fig. 2.

Overall energy and exergy efficiencies are evaluated as

$$\text{Energy efficiency} = \frac{(\text{net energy output with electricity})}{(\text{energy input})} \qquad (3)$$

and

$$\text{Exergy efficiency} = \frac{(\text{net exergy output with electricity})}{(\text{exergy input})}. \qquad (4)$$

Coal is the only input source of energy or exergy for the station, and the energy and exergy efficiencies are 37 and 36%, respectively. The small difference in the efficiencies is due to the fact that the specific chemical exergy of coal is slightly greater than its energy. Although the energy and exergy efficiencies for the station are similar, these efficiencies differ markedly for many station sections.

In the steam generation section, exergy consumptions are substantial, accounting for 659 MW (72%) of the 916 MW total exergy losses for the station. Of the 659 MW of exergy consumed in this section, 444 MW is due to combustion and 215 MW to heat transfer. The energy and exergy efficiencies for the steam generation section, considering the increase in energy or exergy of the water as the product, are 95 and 49%, respectively. The steam generation section thus appears significantly more efficient on an energy basis than on an exergy basis. Physically, this discrepancy implies that although 95% of the input energy is transferred to the preheated water, the energy is degraded as it is transferred. Exergy analysis highlights this degradation.

TABLE I

Flow Data for a Unit of the Coal-Fired Electrical Generating Station

Stream	Mass flow rate (kg/s)[a]	Temperature (°C)	Pressure (N/m^2)	Vapor fraction[b]	Energy flow rate (MW)	Exergy flow rate (MW)

[a] The composition of all streams is 100% H_2O, except that on a volume basis the composition of S1 is 100% carbon, that of S2 is 79% N_2 and 21% O_2, and that of both S3 and S4 is 79% N_2, 6% O_2, and 15% CO_2.

[b] Vapor fraction is listed as 0.0 for liquids and 1.0 for superheated vapors.

[c] Stream S3 (not shown in Fig. 2) represents the hot product gases for adiabatic combustion.

A large quantity of energy (775 MW for each unit) enters the condensers, of which nearly 100% is rejected, and a small quantity of exergy (54 MW for each unit) enters, of which approximately 25% is rejected and 75% is internally consumed. Thus, energy analysis results lead to the erroneous conclusion that almost all losses in electricity-generation potential for the station are associated with the heat rejected by the condensers, whereas exergy analysis demonstrates quantitatively and directly that the condensers are responsible for little of these losses (Fig. 4). This discrepancy arises because heat is rejected by the condensers at a temperature very near that of the environment.

In the power production and preheating sections, energy losses were found to be very small (< 10 MW total), and exergy losses were moderately small (118 MW in the power production section and 23 MW in the preheating section). The exergy losses

TABLE II

Breakdown by Section and Device of Exergy Consumption Rates for a Unit of the Coal-Fired Electrical Generating Station

Section/device	Exergy consumption rate (MW)
Steam generation section	
Steam generator (including combustor)	659.0
Power production section	
High-pressure turbine	26.4
Intermediate-pressure turbine	22.3
Low-pressure turbines	59.2

High-pressure heat exchangers	6.4
Hot well pumps	0.1
Boiler feed pumps	1.1
Total	23.4
Total consumption rate	844.0

are almost completely associated with internal consumptions.

In assessing the thermodynamic characteristics of a coal-fired electrical generating station, several insights into the performance of such stations have been obtained. First, although energy and exergy efficiencies are similar for the station, energy analyses do not systematically identify the location and cause of process inefficiencies, whereas exergy analyses do. Specifically, energy losses are associated with emissions (mainly heat rejected by condensers) and exergy losses primarily with consumptions (mainly in the combustors). Second, since devices with the largest thermodynamic losses have the largest margins for efficiency improvement, efforts to increase the efficiencies of coal-fired electrical generating stations should focus on the combustors. For instance, technologies capable of producing electricity without combustion (e.g., fuel cells) or utilizing heat at high temperatures could increase efficiencies significantly. This suggestion, of course, is overly simplistic because such decisions require consideration of other technical and economic factors in addition to thermodynamic efficiency.

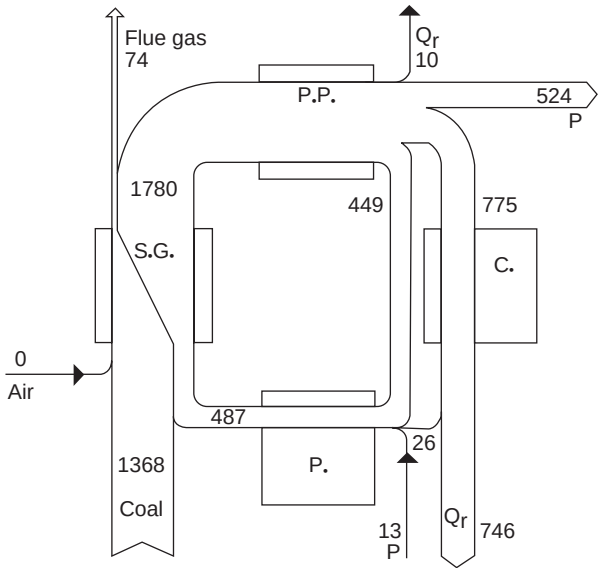

FIGURE 3 Simplified energy diagram for a unit of the coal-fired electrical generating station, indicating net energy flow rates (MW) for streams. Stream widths are proportional to energy flow rates. Station sections shown are steam generation (S.G.), power production (P.P.), condensation (C.), and preheating (P.). Streams shown are electrical power (P), heat input (Q), and heat rejected (Q_r).

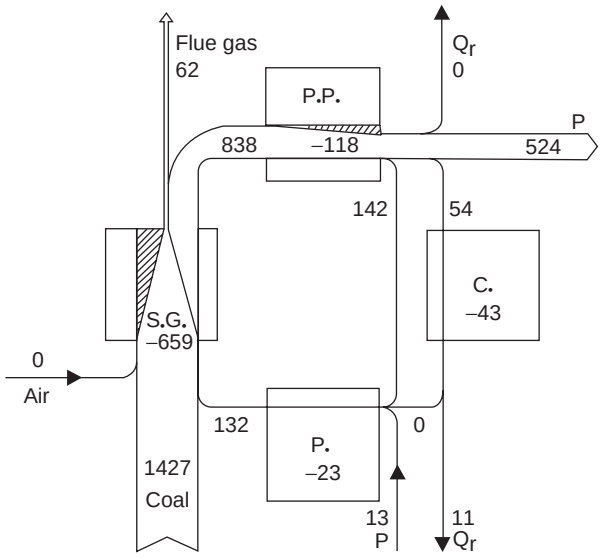

FIGURE 4 Simplified exergy diagram for a unit of the coal-fired electrical generating station, indicating net exergy flow rates for streams and consumption rates (negative values) for devices (MW). Stream widths are proportional to exergy flow rates, and shaded regions are proportional to exergy consumption rates. Other details are as in the legend to Fig. 3.

Third, the use of heat rejected by condensers only increases the exergy efficiencies by a few percent.

8. MACROSYSTEM: THE AGGREGATE ENERGY SYSTEMS OF A COUNTRY

The energy-utilization efficiency of a macrosystem, such as a region or country, can be assessed beneficially using exergy analysis. This section illustrates how the efficiency of energy utilization in a particular macrosystem, Canada, can be examined using both energy and exergy analyses. This example is based on a 1992 publication by the author titled "Evaluation of Energy Utilization Efficiency in Canada Using Energy and Exergy Analyses," which used Canadian energy data for 1986.

The relation between energy resources and sectors of a macrosystem can be modeled as in Fig. 5. The energy resources considered here are coal, petroleum, natural gas, nuclear energy, and hydraulic energy. Renewable energy resources (e.g., wind, solar, wave, and tidal) are neglected since the quantity used in Canada is minor relative to other resources. Four sectors are considered. The residential–commercial sector, which is driven mainly by fossil fuels and electricity, includes residential, public administration, commercial, and other institutional buildings and involves as principal devices space heaters, water heaters, cooking appliances, and clothes dryers. The transportation sector is primarily driven by fossil fuels and includes rail, marine, air, road and urban transport, pipelines, and retail pump sales. The industrial sector has as its main tasks work production and heating and includes mines, steam generation, pulp and paper mills, cement, iron and steel mills, petroleum refining, smelting and refining, other manufacturing, agriculture, chemicals, and nonenergy uses. The utility sector includes processes for electricity generation from coal, petroleum, natural gas, and nuclear and hydraulic energy sources. The same reference environment model as used in the previous section is used here but with a reference environment temperature of 25°C (except where noted).

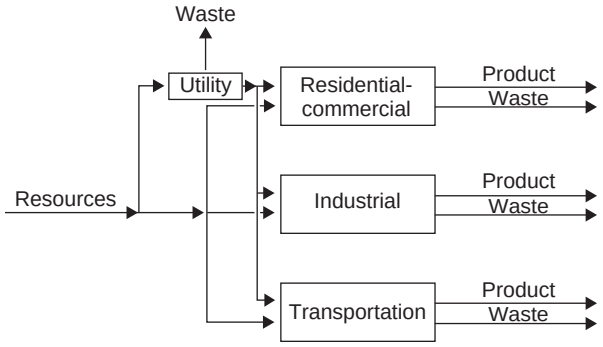

FIGURE 5 Illustration of the energy flows in a macrosystem.

8.1 Principal Types of Processes and Their Efficiencies

Energy and exergy efficiencies are based on the following general definitions:

$$\text{Energy efficiency} = \frac{(\text{energy in products})}{(\text{total energy input})} \quad (5)$$

and

$$\text{Exergy efficiency} = \frac{(\text{exergy in products})}{(\text{total exergy input})}. \quad (6)$$

The main types of processes encountered, for which energy and exergy efficiencies are evaluated, are as follows:

- Heating: Electric and fossil fuel heating processes are taken to generate product heat at a constant temperature.
- Work production: Electric and fossil fuel work production processes produce shaft work.
- Electricity generation: Electricity is generated from fossil fuel, nuclear, and hydraulic sources. The hydraulic source is taken to be the change in kinetic and potential energy of flowing water (even though coal equivalents are often used to represent hydraulic energy inputs). The nuclear source is taken to be nuclear-derived heat at a temperature so high that the energy and exergy of the nuclear-derived heat are equivalent. The efficiency definitions for nuclear plants used here follow nuclear industry conventions (although these efficiency definitions are inadequate because they are based on the heat released from the nuclear fuel rather than its energy or exergy content).
- Kinetic energy production: Fossil fuel-driven kinetic energy production processes occur in some transportation-sector devices (e.g., turbojet engines) and increase the kinetic energy of matter.

8.2 Sector Analyses

8.2.1 Transportation Sector

In the first four columns of Table III, a breakdown is presented by mode of transport of sector energy use, whereas the last two columns show corresponding energy efficiencies. Since vehicles generally are not operated at full load, a distinction is made between

TABLE III

Transportation Sector Data

Mode of transport	Main fuel types	Energy used in the sector, by mode of transport		Energy efficiences (%)	
		PJ	%	Rated load	Estimated operating
Rail	Diesel	75.39	4.6	35	28
Air	Jet fuel	131.2	8.1	35	28
Marine	Diesel, gasoline	74.82	4.6	—	15
Road and urban transit	Gasoline, diesel, propane, electricity	164.3	10.1	28	22
Retail pump sales	Gasoline, diesel, propane	1093	67.2	25	15
Pipelines	Natural gas	86.21	5.3	—	29

TABLE IV

Electricity-Generation Data for the Utility and Industrial Sectors

Mode of generation	Electrical energy generated (PJ)[a]	Energy input (PJ)	Energy efficiency (%)
Hydraulic[b]	1000	1176	85
Nuclear	230.1	767.0	30
Fossil	293.0	915.6	32

[a] Hydraulic and nuclear generation is entirely within the utility sector, whereas 262.3 PJ of fossil generation is within the utility sector and the remainder is within the industrial sector. The contribution by different fossil fuels is 91.2% coal, 6.7% petroleum, and 2.1% natural gas.

[b] The hydraulic source is taken to be the change in kinetic and potential energy of flowing water and not a fossil fuel equivalent.

TABLE V

Energy Consumption Data for the Residential–Commercial Sector

Devices	Energy used in the sector, by type (%)		
	Electrical	Fuel	Total
Space heaters	15.0	79.5	66.0
Water heaters	14.0	15.0	10.0
Cooking appliances	5.0	4.5	1.7
Clothes dryers	5.0	1.0	1.3
Others[a]	61.0	0.0	21.0

[a] This category includes fans, pumps, air conditioners, refrigerators, freezers, washers, lights, etc.

rated load (full load) and operating (part load) efficiencies. The energy efficiencies in Table III are equal to the corresponding exergy efficiencies. Weighted means are obtained for the transportation-mode energy efficiencies in Table III, where the weighting factor is the fraction of the total sector energy input that supplies each transportation mode (fourth column in Table III). Thus, the weighted mean overall efficiency for the transportation sector based on energy, which is equal to that based on exergy, is 18%.

8.2.2 Utility Sector

For the different types of electricity generation, Table IV lists energy efficiencies and the quantities of electricity generated and energy inputs. The energy efficiencies in Table IV are equal to the corresponding exergy efficiencies. Using data from this table, the mean overall energy and exergy efficiencies for the utility sector are found to be equal at 53%.

8.2.3 Residential–Commercial Sector

Energy end-use quantities for this sector are listed in Table V. Operating data for the principal devices in the sector are listed in Table VI and are used to determine the device exergy efficiencies. Weighted mean energy and exergy efficiencies are calculated for the overall residential–commercial sector using a three-step process. First, weighted means are obtained for the electrical energy and exergy efficiencies for the devices in Table VI, where the weighting factor in both cases is the ratio of the electrical energy input to the device to the total electrical energy input to all of the devices (as given in Table V). These energy and exergy efficiencies are 89 and 20%, respectively. Second, weighted mean efficien-

TABLE VI

Device Data for the Residential–Commercial Sector[a]

	Product-heat temperature (K)		Heating efficiency (%)			
			Electrical		Fuel	
Devices	Electrical	Fuel	Energy	Exergy	Energy	Exergy
Space heaters	328	328	100.0	17.1	65.0	11.1
Water heaters	350	374	93.0	25.4	62.0	14.0
Cooking appliances	394	—	80.0	22.5	—	—
Clothes dryers	350	350	50.0	9.6	50.0	10.3

[a] Corresponding reference environment temperatures are 272 K for space heating and 283 K for all other devices.

cies for the fossil fuel-driven devices in Table VI are similarly determined as 64 and 12%, respectively. Third, overall weighted means are obtained for the energy and exergy efficiencies for the electrical and fossil fuel processes together, where the weighting factor is the ratio of the total energy (either fossil fuel or electrical) input to the residential–commercial sector to the total energy input to the sector. Since 34% of the 2129 PJ input to the residential–commercial sector is electrical energy and the remaining 66% is fuel energy, the weighted mean overall energy and exergy efficiencies for the sector are 73 and 14%, respectively. These means are representative of the sector since the devices in Table VI account for more than half of the total sector energy consumption.

8.2.4 Industrial Sector

The industrial sector is composed of many industries, each of which encompasses a wide variety of complex plants. The five most significant industries were identified, and a single representative commercial process for each was examined. The identified industries with the selected commercial processes are as follows:

- Pulp and paper (integrated paper mill plant)
- Iron and steel (blast furnace and steel mill plant)
- Cement (hydraulic cement factory)
- Petroleum (petroleum refining plant)
- Chemical [NEC (salt) chemical preparation plant]

These five industries are taken to be representative of the sector since they account for approximately half of the sector energy use.

Only heating and mechanical processes are considered since these processes account for 81% of the industrial-sector energy consumption (66% for heating and 15% for mechanical drives). Following the temperature categories in Table VII, process heat data for the five selected commercial processes are listed in Table VIII, with the percentages of the heat in each range supplied by fossil fuels and electricity. Canadian energy consumption in the form of electricity and fossil fuels for each of the five main industries is listed in Table IX, with a breakdown of the total energy demand. The values are obtained by averaging the percentage of electrical and fuel energy demands for each of the industries shown. Subsequently, steam (from utilities) is treated as an industrial-sector product and thus passes through the sector unchanged, and electricity generation in the industrial sector is included in the utility sector.

TABLE VII

Process Heating Temperature Range Categories and Energy Efficiencies for the Industrial Sector

Product heat temperature category	Product heat temperature range (°C)[a]	Heating energy efficiency (%)	
		Electrical	Fuel
Low	<121	100	65
Medium	121–399	90	60
High	>399	70	50

[a] Temperature ranges were determined subjectively after examining many commercial processes.

Three steps are used in evaluating industry efficiencies. First, energy and exergy efficiencies are obtained for process heating for each of the temperature range categories in Table VIII using data from Tables VII and VIII. Second, mean heating energy and exergy efficiencies for each of the five industries (see the fifth and sixth columns of Table IX) are evaluated using a two-step procedure: (i)

TABLE VIII

Process Heating Data for All Categories of Product Heat Temperature for the Industrial Sector

Industry	Product heat temperature category	Mean product heat temperature (°C)	Energy used in each product heat temperature category, by type (%)	
			Electricity	Fuel
Pulp and paper	Low	67	100.0	0.0
	Medium	160	0.0	83.0
	High	732	0.0	17.0
Iron and steel	Low	45	4.2	0.0
	Medium	—	0.0	0.0
	High	983	95.8	100.0
Cement	Low	31	91.7	0.9
	Medium	163	0.0	9.0
	High	1482	8.3	90.1
Petroleum	Low	57	10.1	13.8
	Medium	227	9.4	22.6
	High	494	80.4	63.6
Chemical	Low	42	62.5	0.0
	Medium	141	37.5	100.0
	High	—	0.0	0.0

TABLE IX

Process Data for the Industrial Sector

Industry	Energy used in sector, by type			Energy and exergy efficiencies (%)			
				Heating		Total	
	Electrical (PJ)	Fuel (PJ)	Total (%)	Energy	Exergy	Energy	Exergy
Pulp and paper	181.4	169.6	16.8	80.0	20.4	82.0	33.0
Iron and steel[a]	155.7	284.5	17.2	58.0	43.4	64.0	52.0
Cement	5.38	52.29	1.4	56.0	37.5	62.3	47.0
Petroleum	16.45	87.81	2.9	65.0	29.4	70.0	41.0
Chemical	63.00	140.8	7.4	71.0	18.5	74.5	32.0

[a] This category includes smelting and refining industrial operations.

Weighted mean efficiencies for electrical heating and for fuel heating are evaluated for each industry in Table VIII using as weighting factors the values listed in the last two columns of Table VIII, and (ii) weighted mean efficiencies for all heating processes in each industry are evaluated with these values using as weighting factors the ratio of the industry energy consumption (electrical or fuel) to the total consumption of both electrical and fuel energy (Table IX). Third, weighted mean overall (i.e., heating and mechanical drive) efficiencies for each industry are evaluated using the values in Table IX, assuming mechanical drive energy efficiencies of 90% and using as weighting factors the fractions of the total sector energy input for both heating and mechanical drives (as noted earlier).

Weighted means for the weighted mean overall energy and exergy efficiencies (listed in the last two columns of Table IX) for the five principal industries in the industrial sector are obtained, using as weighting factors the fraction of the total industrial energy demand supplied to each industry (given in the fourth column of Table IX), as 73 and 41%, respectively.

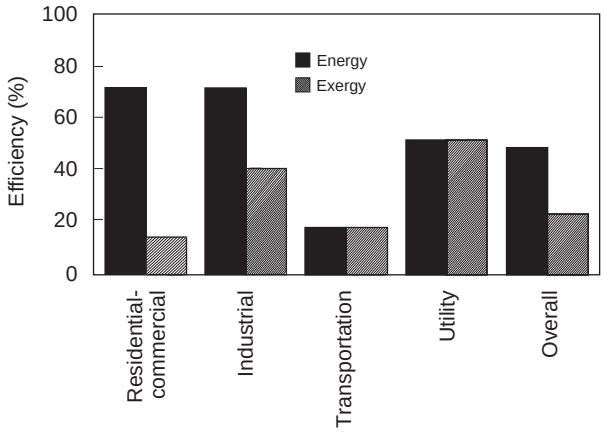

FIGURE 6 Energy and exergy efficiencies for the four main sectors of the Canadian economy and for the overall economy.

8.2.5 Sector Comparison

The efficiencies for the four sectors and for the overall Canadian economy are compared in Fig. 6. The energy efficiencies range from 18 to 73% and the exergy efficiencies from 14 to 53%. The most efficient sectors on energy and exergy bases are different. The residential–commercial sector exhibits the greatest differences for energy and exergy evaluations. The most significant differences between energy and exergy efficiencies are attributable to heating processes. For example, the overall exergy efficiency of the residential–commercial sector (14%) is much lower than the overall energy efficiency (73%) because high-quality energy (i.e., high exergy) sources are used for low-quality energy (i.e., low exergy) demands. The higher exergy efficiency of the industrial sector is mainly attributable to the high temperatures required for most industrial heating ($\approx$400°C) compared to residential–commercial heating ($\approx$25°C). The industrial sector thus utilizes relatively more of the quality or work potential of fuels.

8.3 Analyses for the Overall Macrosystem

Figures 7 and 8 illustrate, respectively, the flows of energy and exergy in Canada for the year considered. The left sides of the figures consist of the total energy or exergy inputs to all sectors by fuel type. These quantities are then branched according to sector demand. Fuels such as coal, gas, and petroleum are routed to "fuel for electricity" and include fuels used to produce electricity by utilities as well as by industry. Similarly, "fuel for end uses" represents the net fuel requirement for all sectors and is routed together with electricity and steam flows to the sectors. The final branching into useful and waste energy is achieved by multiplying the energy for end use (fuel, steam, and electricity) in each sector by the corresponding efficiency (see the values summarized in Fig. 6).

The energy flow diagram indicates that nearly 50% of the total energy consumed in Canada is

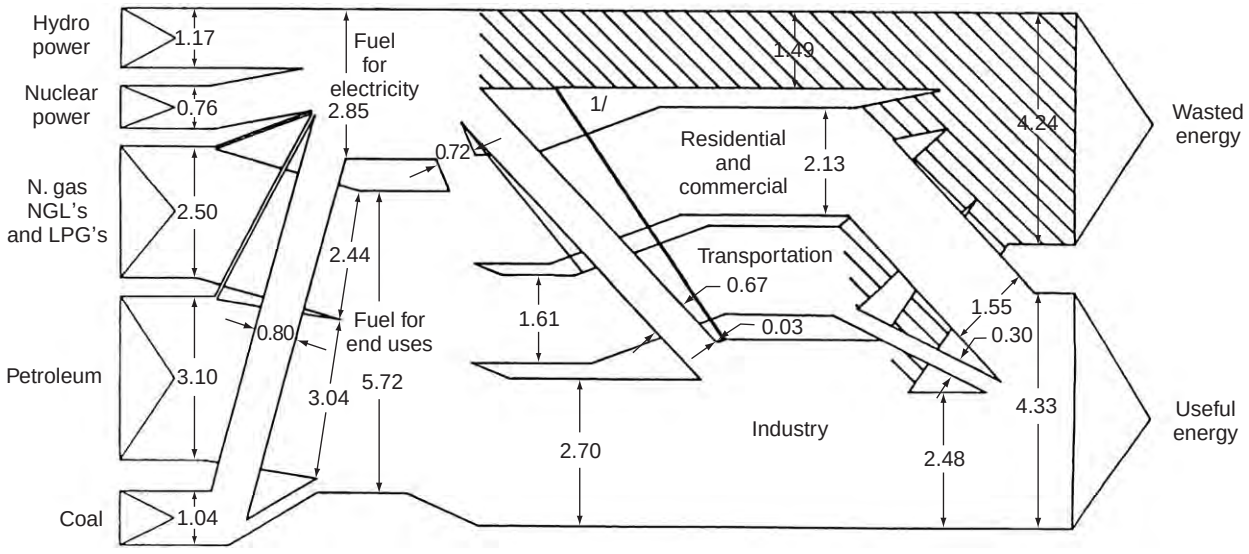

FIGURE 7 Flows of energy (EJ) in Canada. Widths of lines are proportional to the magnitude of the quantity represented. Hydraulic energy is reported in kinetic energy equivalent. The portions of coal, petroleum, and natural gas used for industrial-sector electricity generation are routed to the utility sector and then back to the industrial sector in the form of electricity. The flow associated with the symbol 1/represents steam produced in the utility sector for the end-use sectors.

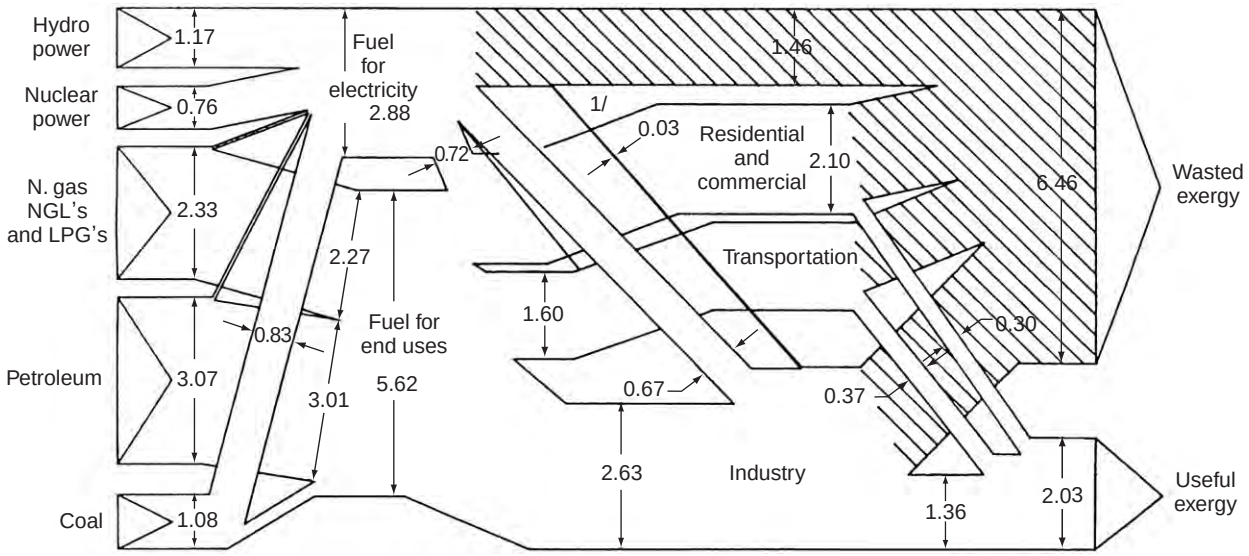

FIGURE 8 Flows of exergy (EJ) in Canada. Details are as given in the legend to Fig. 7.

converted to useful energy for end uses, and that the transportation and utility sectors produce the most waste. The exergy flow diagram differs markedly from the energy diagram in that only 24% of Canadian exergy consumption is converted to useful exergy for end uses, with the residential–commercial and industrial sectors producing the greatest waste. Thus, energy analysis indicates a more limited margin for efficiency improvement than exergy analysis. However, only exergy analysis indicates the margin for improvement that actually exists. Therefore, by using exergy rather than energy analysis, energy utilization efficiency in the macrosystem is more clearly illuminated, and more rational assessments are obtained for allocations of energy-related research and development (R&D).

9. CONCLUSIONS

Exergy analyses of energy systems provide useful information that can have direct implications on designs, improvements, and application decisions. Furthermore, exergy analyses, more than energy analyses, provide insights into better directions for R&D. Here, "better" is loosely taken to mean "more promising for significant efficiency gains." There are two main reasons for this statement:

- Exergy losses represent true losses of the potential that exists to generate the desired product from the given driving input. This is not true in general for energy losses. Thus, if the objective is to increase efficiency while accounting for energy degradation, focusing on exergy losses permits R&D to focus on reducing losses that will affect the objective.
- Exergy efficiencies always provide a measure of how closely the operation of a system approaches the ideal, or theoretical upper limit. This is not generally true for energy efficiencies. By focusing R&D on those plant sections or processes with the lowest exergy efficiencies, effort is directed to those areas that inherently have the largest margins for efficiency improvement. By focusing on energy efficiencies, on the other hand, one can inadvertently expend R&D effort on areas for which little margins for improvement, even theoretically, exist.

Exergy analysis results typically suggest improvement efforts should concentrate more on internal rather than external exergy losses, based on thermodynamic considerations, with a higher priority for the processes having larger exergy losses. Note that this statement does not indicate that effort should not be devoted to processes having low exergy losses because simple and cost-effective ways to increase efficiency by reducing small exergy losses should certainly be considered when identified.

In general, application and R&D decisions should not be based exclusively on the results of energy and exergy analyses, even though these results provide useful information to assist in such decision making. Other factors must also be considered, such as economics, environmental impact, safety, and social and political implications.

Glossary

chemical exergy The maximum work obtainable from a substance when it is brought from the environmental state to the dead state by means of processes involving interaction only with the environment.

dead state The state of a system when it is in thermal, mechanical, and chemical equilibrium with a conceptual reference environment (having intensive properties pressure P_o, temperature T_o, and chemical potential μ_{ko} for each of the reference substances in their respective dead states).

environmental pollution cost (EPC) The environmental cost of a pollutant, based on such factors as the cost to society for the correction or compensation of environmental damage and the cost incurred to prevent a harmful emission from escaping into the environment.

environomics A methodology for analyzing and improving energy-related systems by taking into account energy, exergy, economic, and environmental factors.

environmental state The state of a system when it is in thermal and mechanical equilibrium with the reference environment (i.e., at pressure P_o and temperature T_o of the reference environment).

exergy (i) A general term for the maximum work potential of a system, stream of matter, or a heat interaction in relation to the reference environment as the datum state. Also known as available energy, availability, essergy, technical work capacity, usable energy, utilizable energy, work capability, work potential, and xergy. (ii) The unqualified term exergy or exergy flow is the maximum amount of shaft work obtainable when a steady stream of matter is brought from its initial state to the dead state by means of processes involving interactions only with the reference environment.

exergy analysis An analysis technique, based on the second law of thermodynamics, in which process performance is assessed by examining exergy balances, losses, and efficiencies.

exergy consumption The exergy consumed or destroyed during a process due to irreversibilities within the system boundaries. Also known as dissipation, irreversibility, and lost work.

reference environment An idealization of the natural environment that is characterized by a perfect state of equilibrium—that is, the absence of any gradients or differences involving pressure, temperature, chemical potential, kinetic energy, and potential energy. The environment constitutes a natural reference medium with respect to which the exergy of different systems is evaluated.

reference state A state with respect to which values of exergy are evaluated. Several reference states are used, including environmental state, dead state, standard environmental state, and standard dead state. Also known as ground state.

removal pollution cost (RPC) The cost of removing a pollutant from a waste stream prior to discharge into the environment.

waste emission Release to the environment of a material that is not considered usable and is therefore being discarded.

Exergy analysis is a thermodynamic technique for assessing and improving systems and processes, which is similar but advantageous to energy analysis, in large part because it is based on the second law of thermodynamics. The exergy of an energy form or a substance is a measure of its usefulness. Exergy can be applied beyond thermodynamics to understanding waste emissions and reducing their environmental

 © 2004 Elsevier Inc. All rights reserved.

impact because exergy can also be viewed as a measure of the departure of a substance from equilibrium with a specified reference environment, which is often modeled as the actual environment. Furthermore, exergy is a measure of the potential of a substance to cause change. The exergy of an emission to the environment, therefore, is a type of measure of the potential of the substance to change or impact the environment. The greater the exergy of an emission, the greater its departure from equilibrium with the environment and the greater may be its potential to change or impact the environment. The exergy of an emission is zero only when it is in equilibrium with the environment and thus benign. These points suggest that exergy may be, or provide the basis for, one effective indicator of the potential of an emitted substance to impact the environment.

This article describes both the relation between exergy and the environment and the exergy of waste emissions. Such knowledge can permit the development of a better understanding of, and more rational approaches to mitigating, the environmental impact associated with waste emissions. First, exergy and its use as a tool through exergy analysis are briefly described. Then, energy and the environment and exergy and the environment, and some relations between them, are discussed. Finally, exergy is compared with other indicators for the environmental impact of waste emissions.

1. EXERGY AND EXERGY ANALYSIS

Exergy is defined as the maximum amount of work that can be produced by a flow of matter or energy as it comes to equilibrium with a reference environment. Exergy is a measure of the potential of a flow to cause change, as a consequence of being in disequilibrium with the reference environment. For evaluations of exergy, the state of the reference environment, or the reference state, must be specified completely, normally by specifying its temperature, pressure, and chemical composition. The reference environment used in exergy evaluations is discussed further in Section III.B. Exergy is not subject to a conservation law. Rather, exergy is consumed or destroyed due to the irreversibilities in any process.

Exergy analysis is a method that uses the conservation of mass and conservation of energy principles together with the second law of thermodynamics for the design and analysis of energy systems. The exergy method is useful for attaining more efficient energy-resource use because it enables the locations, types, and true magnitudes of wastes and losses to be determined. Therefore, exergy analysis can reveal whether, and by how much, it is possible to design more efficient energy systems by reducing the inefficiencies in existing systems. Applications of exergy analysis to many processes and systems are described elsewhere in this encyclopedia.

Exergy concepts can also be applied to disciplines outside of thermodynamics. One area in which applications of exergy are increasing is that of economics. Another area in which applications of exergy are increasing is that of environmental emissions and impact, and this is the topic of the current article.

2. ENERGY AND THE ENVIRONMENT

Energy production, transformation, transport, and end use have significant impacts on the earth's environment, and environmental costs are usually associated with the emissions—whether they are of a thermal, chemical, nuclear, or other nature—from processes and technologies. One means of reducing the environmental impact of emissions is to increase the efficiency of resource utilization. However, increasing efficiency generally entails greater use of materials and energy resources, and the environmental burdens associated with these can offset the environmental gains of improved efficiency.

Data on the current world distribution of per capita energy consumption suggest that a close correlation exists between a country's energy consumption and economic development. However, there does not appear to be a simple correlation between a country's energy consumption and the decay of its natural environment. As environmental concerns became major issues in the 1980s, increasing attention was paid to the relationship between energy use and the environment. However, there are limited works on the relationships between the exergy and environmental concepts even though to appropriately reduce energy consumption and the related environmental impact, engineers, scientists, and policymakers may benefit from such knowledge.

One of the major challenges of designing technologies so as to reduce their environmental impact involves determining an environmentally optimal configuration or selecting the most appropriate one from competing options. This determination or

selection is made difficult by the complex relationship between the technology being considered and the characteristics of the residuals produced. Process or technology changes generally affect the flow rate and composition of all resulting effluent streams. Therefore, evaluating alternatives often requires one to compare the relative environmental merits of distinctly different residual streams. Existing systems for performing such analyses have focused primarily on subjective ranking techniques.

3. EXERGY AND THE ENVIRONMENT

There is agreement among some researchers that a less subjective metric capable of providing greater insight may exist in the form of the thermodynamic quantity exergy. Exergy analysis provides information about energy and material quality that is both descriptive and physically significant. Because of its origins within the thermodynamic community, however, few applications and investigations of the potential of exergy methods for reducing environmental impact have been performed.

Some work is nevertheless being carried out. For instance, the Consortium on Green Design and Manufacturing at the University of California, Berkeley, is carrying out a project titled "Exergy as an Environmental Indicator" in an effort to increase the practical application of exergy analysis to rectifying the problems associated with material and energy flows in industry. This work has focused on developing a generalizable technique to calculate exergy in an industrial setting, exploring the significance of environmental ground states and how they might be utilized to leverage results, and establishing the requisite databases for performing a wide range of highly diverse analyses. In addition, several projects have been carried out at the Delft University of Technology and University of Twente to determine whether exergy analysis can be used as an instrument for environmental policy development, especially for the comparison of alternative production chains. These studies are investigating if the linkages of exergy with phenomena such as pollution and dispersion can be converted into a reliable tool on which policy decisions can be based, and they are exploring how the environmental effects of processes can be linked to or expressed in terms of exergy changes. Also, a methodology known as environomics has been developed for analyzing and improving energy-related systems by simultaneously taking into account energy, exergy, economic, and environmental factors.

The exergy contents of waste emissions are more meaningful than the corresponding energy contents as measures of potential for environmental impact. By definition, material and energy flows only possess exergy when in disequilibrium with a reference environment. The exergy associated with waste emission streams has the potential to cause environmental damage, particularly when it is released in an unconstrained manner into the environment. Some believe that by considering the exergy content of a waste emission, rational and meaningful assessments can be made of the environmental impact potential of the emission.

3.1 Reducing Environmental Impact with Exergy

Efforts to increase energy and exergy efficiency can reduce environmental impact by reducing energy and exergy losses. Increased efficiency frequently contributes to achieving energy security in an environmentally acceptable way, partly by reducing emissions. Increased efficiency also reduces the requirement for new facilities for the production, transportation, transformation, and distribution of the various energy forms; these additional facilities all cause some environmental impacts. To further reduce environmental pollution, efficiency-improvement actions often need to be supported by pollution-control technologies and/or fuel substitution. Regional and national actions to improve exergy efficiency, in particular, can have major impacts on environmental protection.

One study investigated thermodynamics and sustainable development and noted that one tool likely to be important for obtaining sustainable development is exergy analysis. That study stated that whereas energy can never be destroyed, exergy can be destroyed and this exergy destruction (irreversibility) should be appropriately minimized to make development more sustainable. This study also showed that environmental effects associated with emissions and resource depletion can be expressed in terms of one indicator, which is based on physical principles.

Several researchers have suggested that a potentially useful way to link the second law and environmental impact is through exergy because it is a measure of the departure of the state of a system from that of the environment. The magnitude of the

exergy of a system depends on the states of both the system and the environment. This departure is zero only when the system is in equilibrium with its environment. Eminent thermodynamicist Myron Tribus suggested in 1971 that performing exergy analyses of the natural processes occurring on the earth could form a foundation for ecologically sound planning because it would indicate the disturbance caused by large-scale changes.

An understanding of the relations between exergy and the environment may reveal some of the underlying fundamental patterns and forces affecting changes in the environment and help researchers to deal better with environmental damage. Before examining such relations, however, it is useful to discuss the reference environment used in exergy analysis.

3.2 Exergy and the Reference Environment

The exergy Ex contained in a system may be written as

$$Ex = S(T - T_o) - V(P - P_o) + N_k(\mu_k - \mu_{ko}), \qquad (1)$$

where the intensive properties are temperature T, pressure P, and chemical potential of substance k, μ_k, and the extensive properties are entropy S, volume V, and number of moles of substance k, N_k. The subscript o denotes conditions of the reference environment. It is evident from this equation that the exergy of a system is zero when it is in equilibrium with the reference environment (i.e., when $T = T_o$, $P = P_o$, and $\mu_k = \mu_{ko}$ for all k).

Exergy analysis requires a reference environment model. Exergy is evaluated with respect to the reference environment model, with the exergy of a flow and system being dependent on the intensive properties of the reference environment. The exergy of the reference environment is zero, and the exergy of a stream or system is zero when it is in equilibrium with the reference environment. There are several theoretical characteristics of the reference environment. The reference environment is in stable equilibrium and has all parts at rest relative to one another. No chemical reactions can occur between the reference environment components. Furthermore, the reference environment acts as an infinite system, is a sink and source for heat and materials, and experiences only internally reversible processes in which its intensive state remains unaltered (i.e., its temperature, pressure, and chemical potentials for each of the components present remain constant).

The natural environment does not possess the theoretical characteristics of a reference environment. The natural environment is not in equilibrium, and its intensive properties vary spatially and temporally. Many chemical reactions in the natural environment are blocked because the transport mechanisms necessary to reach equilibrium are too slow at ambient conditions. Thus, the exergy of the natural environment is not zero because work could be obtained if it were to come to equilibrium. In developing reference environment models for exergy analysis, a compromise is often made between the theoretical requirements of the reference environment and the actual behavior of the natural environment.

Several reference environment models have been proposed. The most significant classes of these are the following:

Natural environment subsystem models: These models attempt to realistically simulate subsystems of the natural environment. A model consisting of saturated moist air and liquid water in phase equilibrium was proposed in 1963. An extension of that model that allows sulfur-containing materials to be analyzed was proposed subsequently. The temperature and pressure of this reference environment (Table I) are normally taken to be 25°C and 1 atm, respectively, and the chemical composition is taken to consist of air saturated with water vapor, with the following condensed phases at 25°C and 1 atm: water (H_2O), gypsum ($CaSO_4 \cdot 2H_2O$), and

TABLE I

Reference Environment Model

Temperature, T_0	25°C	
Pressure, P_0	1 atm	
Composition	(i) Atmospheric air, saturated with H_2O at T_0 and P_0, having the following composition:	
	Air constituents	**Mole fraction**
	N_2	0.7567
	O_2	0.2035
	H_2O	0.0303
	Ar	0.0091
	CO_2	0.0003
	H_2	0.0001
	(ii) The following condensed phases at T_0 and P_0: Water (H_2O) Limestone ($CaCO_3$) Gypsum ($CaCO_4 \cdot 2H_2O$)	

limestone ($CaCO_3$). The stable configurations of C, O, and N, respectively, are taken to be those of CO_2, O_2, and N_2 as they exist in air saturated with liquid water at T_o and P_o (the temperature and pressure for the reference environment); that of hydrogen is taken to be in the liquid phase of water saturated with air at T_o and P_o; and those of S and Ca, respectively, are taken to be those of $CaSO_4 \cdot 2H_2O$ and $CaCO_3$ at T_o and P_o.

Reference substance models: With this model, a reference substance is selected for every chemical element and assigned zero exergy. A model in which the reference substances are selected as the most valueless substances found in abundance in the natural environment was proposed by Jan Szargut. The criterion for selecting such reference substances is consistent with the notion of simulating the natural environment but is primarily economic in nature, and it is vague and arbitrary with respect to the selection of reference substances. Part of this environment is the composition of moist air, including N_2, O_2, CO_2, H_2O, and the noble gases; gypsum (for sulfur); and limestone (for calcium). A related model, in which reference substances are selected arbitrarily, has also been proposed. This model is not similar to the natural environment. Consequently, absolute exergies evaluated with this model do not relate to the natural environment and cannot be used rationally to evaluate efficiencies or environmental impact.

Equilibrium and constrained equilibrium models: A model in which all the materials present in the atmosphere, oceans, and a layer of the crust of the earth are pooled together and an equilibrium composition is calculated for a given temperature was proposed by Joachim Ahrendts in 1980. The selection of the thickness of crust considered is subjective and is intended to include all materials accessible to technical processes. Thicknesses varying from 1 to 1000 m and a temperature of 25°C were considered. For all thicknesses, the model differed significantly from the natural environment. Exergy values obtained using these environments are significantly dependent on the thickness of crust considered and represent the absolute maximum amount of work obtainable from a material. Since there is no technical process that can obtain this work from materials, the equilibrium model does not give meaningful exergy values when applied to the analysis of real processes. Ahrendts also proposed a modified version of his equilibrium environment in which the calculation of an equilibrium composition excludes the possibility of the formation of nitric acid (HNO_3) and its compounds. That is, all chemical reactions in which these substances are formed are in constrained equilibrium, and all other reactions are in unconstrained equilibrium. When a thickness of crust of 1 m and temperature of 25°C are used, the model is similar to the natural environment.

Process-dependent models: A model that contains only components that participate in the process being examined in a stable equilibrium composition at the temperature and pressure of the natural environment was proposed by Bosnjakovic in 1963. This model is dependent on the process examined and is not general. Exergies evaluated for a specific process-dependent model are relevant only to the process. They cannot rationally be compared with exergies evaluated for other process-dependent models or used in environmental assessments.

4. RELATIONS BETWEEN EXERGY AND ENVIRONMENTAL IMPACT

Three relationships between exergy and environmental impact that may help explain some of the patterns that underlie changes in the environment are discussed in the following sections.

4.1 Order Destruction and Chaos Creation

The destruction of order, or the creation of chaos, is a form of environmental damage. Fundamentally, entropy is a measure of chaos. A system of high entropy is more chaotic or disordered than one of low entropy. For example, a field with papers scattered about has a higher entropy than the field with the papers neatly piled. Conversely, exergy is a measure of order. Relative to the same environment, the exergy of an ordered system is greater than that of a chaotic one.

The difference between the exergy values of the two systems containing papers described previously is a measure of the minimum work required to convert the chaotic system to the ordered one (i.e., in collecting the scattered papers). In reality, more than this minimum work, which only applies if a reversible cleanup process is employed, is required. The exergy destroyed when the wind scatters a stack of papers is a measure of the order destroyed during the process.

4.2 Resource Degradation

The degradation of resources found in nature is a form of environmental damage. A resource is a

material, found in nature or created artificially, that is in a state of disequilibrium with the environment. Resources have exergy as a consequence of this disequilibrium. For some resources (e.g., metal ores), it is their composition that is valued. Many processes exist to increase the value of such resources by purifying them (i.e., by increasing their exergy). This is done at the expense of consuming at least an equivalent amount of exergy elsewhere (e.g., burning coal to produce process heat for metal ore refining). For other resources (e.g., fuels), it is normally their reactivity that is valued (i.e., their potential to cause change or "drive" a task or process).

By preserving exergy through increased efficiency (i.e., degrading as little exergy as necessary for a process), environmental damage is reduced. Increased efficiency also has the effect of reducing exergy emissions, which, as discussed in the next section, also play a role in environmental damage.

The earth is an open system subject to a net influx of exergy from the sun. It is the exergy (or order states) delivered with solar radiation that is valued; all the energy received from the sun is ultimately radiated out to the universe. Environmental damage can be reduced by taking advantage of the openness of the earth and utilizing solar radiation instead of degrading resources found in nature to supply exergy demands. This would not be possible if the earth were a closed system because it would eventually become increasingly more degraded or entropic.

4.3 Waste Exergy Emissions

The exergy associated with process wastes emitted to the environment can be viewed as a potential for environmental damage. Typical process wastes have exergy, a potential to cause change, as a consequence of not being in stable equilibrium with the environment. When emitted to the environment, this exergy represents a potential to change the environment. In some cases, this exergy may cause a change perceived to be beneficial (e.g., the increased rate of growth of fish and plants near the cooling water outlets from thermal power plants). More often, however, emitted exergy causes a change that is damaging to the environment (e.g., the death of fish and plants in some lakes due to the release of specific substances in stack gases as they react and come to equilibrium with the environment).

Emissions of exergy to the environment can also interfere with the net input of exergy via solar radiation to the earth. The carbon dioxide emitted in stack gases from many processes changes the atmospheric CO_2 content, affecting the receiving and reradiating of solar radiation by the earth.

The relation between waste exergy emissions and environmental damage has been recognized by several researchers. By considering the economic value of exergy in fuels, in 1970 Gordon Reistad developed an air pollution rating in which the air pollution cost for a fuel was estimated as either the cost to remove the pollutant or the cost to society of the pollution (i.e., the tax that should be levied if pollutants are not removed from effluent streams). Reistad claimed the rating was preferable to the mainly empirical ratings then in use.

4.4 An Apparent Paradox

The reader may at this point detect a paradox. It was pointed out that exergy in the environment—in the form of resources—is of value, whereas exergy in the environment—in the form of emissions—has a "negative" value because it has a potential to cause environmental damage.

This apparent paradox can be resolved if the word constrained is included in the discussions (Fig. 1). Constrained sources of exergy in the environment are of value. Most resources found in nature are constrained. Unconstrained emissions of exergy to the environment have negative value. In fact, if emissions to the environment are constrained (e.g., separating out sulfur from stack gases), then there are two potential benefits: (i) The potential for environmental damage is blocked from entering the environment, and (ii) the now-constrained emission potentially becomes a valued commodity, a source of exergy.

4.5 Qualitative Illustration

The decrease in the environmental impact of a process, in terms of the three measures discussed in this section, as the exergy efficiency increases for the process is

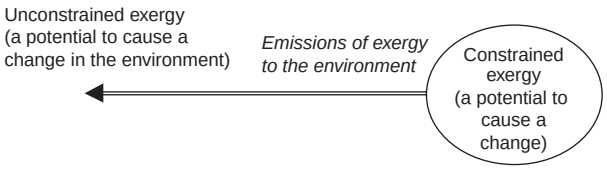

FIGURE 1 Comparison of constrained and unconstrained exergy illustrating that exergy constrained in a system represents a resource, whereas exergy emitted to the environment becomes unconstrained and represents a driving potential for environmental damage.

illustrated qualitatively and approximately in Fig. 2. Exergy methods also correlate with sustainability if, for simplicity, we consider sustainability to indicate the degree to which human activity can continue without facing a lack of resources or negatively changing the environment. To better illustrate the relation between exergy and sustainability and environmental impact, Fig. 2 can be expanded as shown in Fig. 3. In this figure, sustainability is seen to increase and environmental impact to decrease as the exergy efficiency of a process increases. The two limiting efficiency cases in Fig. 3 are significant:

- As exergy efficiency approaches 100%, environmental impact approaches zero since exergy is converted from one form to another without loss (either through internal consumptions or through waste emissions). Also, sustainability becomes increasingly great because the process approaches reversibility (i.e., no losses occur so the process can go forward and backward indefinitely).
- As exergy efficiency approaches 0%, sustainability approaches zero because exergy-containing resources are used but nothing is accomplished. Also, environmental impact becomes increasingly great because to provide a fixed service, an ever-increasing quantity of resources must be used and a correspondingly increasing amount of exergy-containing wastes are emitted.

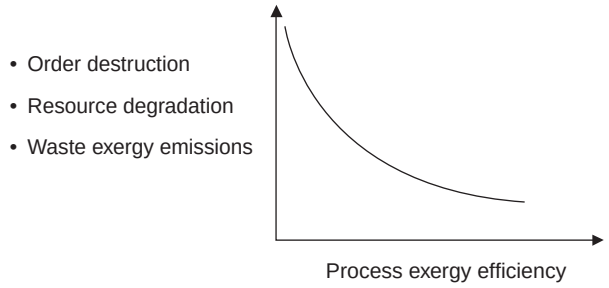

FIGURE 2 Qualitative illustration of the relation between the exergy efficiency of a process and the associated environmental impact in terms of order destruction, resource degradation, or waste exergy emissions.

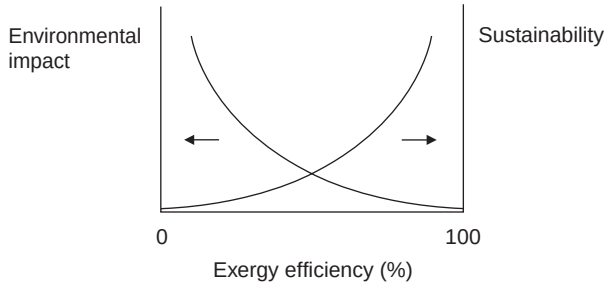

FIGURE 3 Qualitative illustration of the relation between the environmental impact and sustainability of a process and also its exergy efficiency.

4.6 Illustrative Example

The ideas discussed in this section are demonstrated for a unit of a typical 500-MWe coal-fired electrical generating station. Overall balances of exergy and energy for the station are illustrated in Fig. 4. This station was examined in the article titled "Exergy Analysis of Energy Systems." For this station, each of the three relationships between exergy and environmental impact described in the previous subsections are demonstrated:

- Waste exergy emissions from the plant occur with (i) the gaseous wastes exiting through the stack, (ii) the solid wastes exiting the combustor, and (iii) waste heat released both to the lake, which supplies condenser cooling water, and to the atmosphere. Contained within each of these emissions is a potential to impact on the environment. The societal

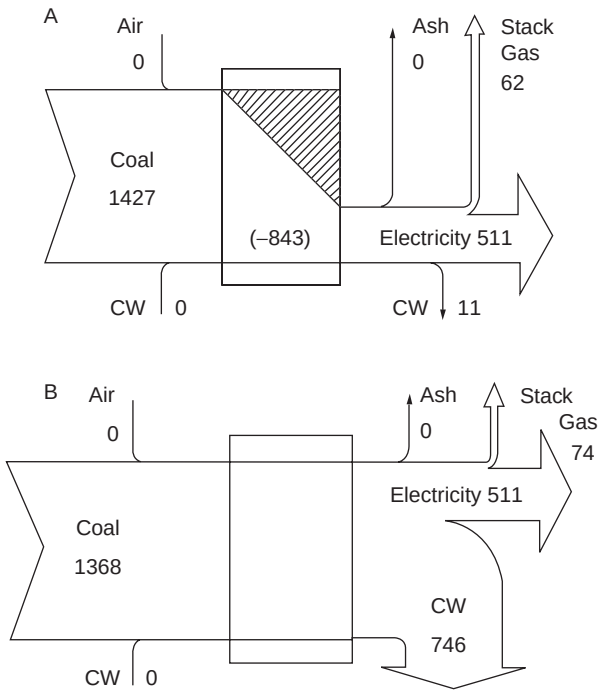

FIGURE 4 Overall energy and exergy balances for a unit of a typical 500-MWe coal-fired electrical generating station. The rectangle in the center of each diagram represents the station. Widths of flow lines are proportional to the relative magnitudes of the represented quantities. CW, cooling water. (A) Exergy balance showing flow rates (positive values) and consumption rate (negative value, denoted by hatched region) of exergy (in MW). (B) Energy balance showing flow rates of energy (in MW).

consensus regarding emissions of harmful chemical constituents in stack gases and "thermal pollution" in local bodies of water indicates that the potential for impact of these emissions is already recognized but not from an exergy perspective.

- During the electricity generation process, a finite resource (i.e., coal) is degraded as it is used to drive the process. Although a degree of degradation is necessary for any real process, increased process efficiency can reduce this degradation for the same services or products. In the extreme, if the process considered in the example were made ideal, the exergy efficiency would increase from 37 to 100%, and coal use as well as related emissions would decrease by more than 60%. These insights are provided by the exergy, but not energy, considerations.
- The more abstract concepts of order destruction and chaos creation are also illustrated. Certainly the degradation of coal to stack gases and solid wastes represents a destruction of order, especially since less exergy is present in the products of the process. The emissions of wastes to the environment increase the chaos of the world by allowing the constrained material and heat products of combustion to be released without constraint into the environment.

5. ENVIRONMENTAL IMPACT OF EXERGY LOSSES

As mentioned earlier, exergy losses, which are made up of exergy destruction and waste exergy emissions, have a significant effect on environmental impact. Exergy destruction, in particular, can be used as one of the most significant criteria for assessing the depletion of natural resources. Exergy analysis can assist efforts to minimize the use of natural resources because it can indicate where the work potential of natural resources in relation to the surrounding environment is lost (i.e., where irreversibility, or exergy destruction, occurs).

The exergy in a flow can only be entirely converted to products in a fully reversible process since there are no exergy destructions within the system and no waste exergy emissions to the environment. In real-world processes, which are irreversible, both destruction of the exergy of resources and waste exergy emissions occur. Much effort is being expended on reducing resource exergy destructions and eliminating waste exergy emissions—often by converting them into useful products. The reversible process noted earlier represents a theoretical ideal that we can strive toward but never actually achieve.

A waste emission possesses exergy as a result of its being in a state of mechanical, thermal, and/or chemical disequilibrium with the reference environment. It is useful here to follow the standard separation of exergy into two components—physical and chemical. In this article of exergy and the environment, the exergy of an emission attributable to mechanical and thermal disequilibrium is not considered significant because the potential impact on the environment of physical exergy is limited. That is, pressure differences between an emission and the environment normally dissipate soon after the emission reaches the environment, and temperature differences are normally localized near the emission source (e.g., thermal pollution in the region of a lake near the cooling water discharge of a thermal power plant) and can be controlled. The exergy of an emission due to chemical disequilibrium (i.e., the chemical exergy), on the other hand, is often significant and not localized. The chemical exergy of emissions is normally of more concern.

6. COMPARISON OF EXERGY AND OTHER INDICATORS FOR THE ENVIRONMENTAL IMPACT OF WASTE EMISSIONS

The exergy of waste emissions has been compared to some other measures to assess or control the potential environmental impact of emissions, including air emission limits established by the government of Ontario, and two proposed quantifications of "environmental costs" for emissions from fossil fuel combustion. These comparisons are carried out to detect trends and patterns that may permit the exergy of a substance to be used as a useful predictor of potential environmental impact and consequently as a tool in establishing emission limits that are rationally based rather than formulated by trial and error.

6.1 Background on Pollution Limits and Costs

Air pollution limits in Ontario, Canada, are covered by that province's principal legislation governing environmental quality, the Environmental Protection Act. The overall goal of the legislation is to ensure environmental conditions such that human health

and the ecosystem of the earth are not endangered. In Ontario, the Ministry of the Environment is the governing body that oversees the development and implementation of environmental legislation for industry. For the control of air pollution, allowable air emission limits (i.e., allowable mass of pollutant per volume of air averaged over a specified time period) that must be achieved prior to discharge (e.g., prestack) are provided for numerous substances. The potential of a substance to impact on the environment is evaluated by 10 parameters: transport, persistence, bioaccumulation, acute lethality, sublethal effects on mammals, sublethal effects on plants, sublethal effects on nonmammalian animals, teratogenicity, mutagenicity/genotoxictiy, and carcinogenicity. With this information, point of impingement (POI) air emission limits are determined through a method known as the best available pollution control technology.

6.2 Environmental Costs of Emissions to Air

Two methods for developing environmental costs for emissions to air are considered here:

- For air emissions resulting from the combustion of fossil fuels, consider the cost of removing the pollutants from the waste stream prior to discharge into the environment. This cost can be related to the exergy of the pollution and is referred to as the removal pollution cost (RPC). The removal costs for waste emissions are evaluated as the total fuel cost per unit fuel exergy multiplied by the chemical exergy per unit fuel exergy and divided by the exergy efficiency of the pollution removal process. The exergy efficiencies for the removal of pollutants from waste streams vary. Some sources indicate that exergy efficiencies are less than 5% when the removal process involves mechanical separation. For simplicity, exergy efficiencies of 1% for all pollutants are used here.
- Estimate environmental costs of pollutant, which are referred to here as environmental pollution costs (EPCs). Such work is most advanced for emissions released into the atmosphere resulting from the combustion of fossil fuels (e.g., carbon dioxide and sulfur dioxide). Environmental costs for some of these emissions have been estimated for Canada (Table II). Values for EPCs are based on quantitative and qualitative evaluations of the cost to society for the correction or compensation of environmental damage and/or the cost incurred to prevent a harmful emission from escaping into the environment.

TABLE II

Environmental Pollution Costs (EPCs) for Selected Pollutants

Pollutant	EPC (1998 Can. $/kg pollutant)[a]
Particulates[b]	4.11
CO	3.71
NO_x	2.91
SO_2	2.65
CH_4	0.97
Volatile organic compounds	0.45
CO_2	0.030

[a] The EPCs are based on values from 1990, with an adjustment applied to the dollar values to account for inflation in Canada between 1990 and 1998 (as measured by the Consumer Price Index for all products). Statistics Canada reports the adjustment factor as 1.164.

[b] Including heavy metals (e.g., lead, cadmium, nickel, chromium, copper, manganese, and vanadium).

6.3 Relations among the Measures

POI air emission limits, standard chemical exergies, RPCs, and EPCs for emissions have been studied and some preliminary relations discerned. For instance, evidence suggests that EPC increases with increasing standard chemical exergy. Also, EPCs generally appear to increase at a decreasing rate with increasing percentages of pollution emission exergy. These general trends are expected and logical.

Overall, the two measures considered here for the environmental cost of pollutants (RPCs, which are based on the cost to remove a pollutant from the environment, and EPCs, which are based on the costs attributable to the negative impact of the pollutant on the environment), although based on different principles and evaluated differently, are of the same order of magnitude for a given pollutant. The RPC methodology is based on a simple, theoretical concept, whereas the EPC methodology relies on subjective interpretations of environmental impact data. Thus, exergy-based measures for environmental impact may provide a foundation for rational environmental indicators and tools.

7. CONCLUSIONS

The relations between environmental impact and exergy, and between the chemical exergy values of

substances found in waste emissions and measures of environmental impact, could contribute to the development of simple, rational, and objective procedures for assessing the harmful effects on the environment and predicting the potential for environmental impact for a substance. This view is primarily based on the general premise that a substance has exergy due to its disequilibrium with respect to a reference environment, and therefore the exergy of unconstrained waste emissions has the potential to impact on the environment. The potential usefulness of exergy analysis in addressing and solving environmental problems is significant, but further work is needed if utilizable, objective exergy-based measures of the potential of a substance to impact on the environment are to be developed.

Glossary

exergy The maximum amount of useful work that can be extracted from a material as it approaches thermodynamic equilibrium with its surroundings by reversible processes. The second law of thermodynamics implies that it is never possible to utilize all available or potentially useful work for practical purposes. There is some waste or loss of exergy in every process. Lost exergy corresponds to increasing entropy.

Gibbs energy of formation The total amount of energy that is either used up or released during a chemical reaction. Gibbs free energy $(\Delta G) = (\Delta H) - t\ (\Delta S)$, where (ΔH) is the change in enthalpy; t is the temperature at which the reaction took place; and (ΔS) is the change in entropy, or amount of disorder, that occurs in the molecules involved during the reaction.

reference species One or more of the common chemical forms that characterize the final equilibrium state of a given "mix" of chemical elements, taking into account relative atomic abundance. The equilibrium state is what would finally result from free, spontaneous, and uninhibited interactions with all the other elements in the mix.

The standard chemical exergy, per mole, of any pure compound involving chemical elements can be computed by means of a simple formula. To calculate the chemical exergies of mixtures and composite materials, such as ores and alloys, it is only necessary to have detailed composition data and do the sums. To compile generic exergy tables, however, it is necessary to adopt a general convention on reference states.

1. STANDARD FORMALISM FOR CHEMICAL EXERGY CALCULATIONS

The standard chemical exergy, per mole, of any pure compound involving these elements can be computed by means of a simple formula, namely

$$B = G + \sum_j n_j b_j, \qquad (1)$$

where G is the standard Gibbs free energy of formation of the compound, the n_j are molar fractions of the jth chemical element, and the index j runs over the elements in the compound. The G values are tabulated in standard reference works, such as the *Handbook of Physics and Chemistry*. The b_j values have been calculated for all the important elements. To calculate the chemical exergies of mixtures and composite materials, such as ores and alloys, it is only necessary to have detailed composition data and do the sums.

To compile generic exergy tables, however, it is necessary to adopt a general convention on reference

states. This could be a daunting task if a very local definition were adopted for each case. However, noting that there are three major environmental media—or "sinks"—a reasonably general definition has been proposed. In the case of chemical elements found in the atmosphere as such (oxygen, nitrogen, inert gases) and carbon—because carbon reacts with atmospheric oxygen to yield a gaseous oxide (CO_2)—the composition of the atmosphere is taken to be the reference state. In the case of chemical elements whose oxides or chlorides are soluble in water, the composition of the ocean is taken to be the reference state. For all other elements, mainly metals whose oxides are insoluble solids, the average composition of the earth's crust down to some specified depth is taken to be the reference state. (The technical problem here is that the earth's crust is not in chemical equilibrium with either the atmosphere or the oceans. In particular, the earth's crust contains significant quantities of hydrocarbons and sulfides, of biological origin, that are potentially reactive with oxygen but that are not exposed to the atmosphere. Obviously in the very long run, in the absence of biological activity, these materials would be oxidized and all of the free oxygen in the atmosphere would ultimately be combined with nitrogen, carbon, or sulfur. Thus, the essence of the convention is to assume that the three media [air, oceans, and crust] are in chemical equilibrium in the short run—that is, in terms of the time scales of interest.) The latter definition is somewhat arbitrary, to be sure, but it turns out that calculated values in most cases are not extremely sensitive to the crustal depth assumption.

A procedure has been developed that results in a computed "standard" exergy for each material that is independent of the actual sink. This is done by assuming each element is obtained by successive reactions from a relatively stable chemical form that is chosen once and for all for each element and identified as its reference species. The reference species should be one of the more common chemical forms that would characterize the final equilibrium state of a given "mix" of chemical elements, taking into account relative atomic abundance. (The equilibrium state is what would finally result from free, spontaneous, and uninhibited interactions with all the other elements in the mix. This idealized situation is sometimes called a Gibbs reactor.) The reference state for most elements is taken to be either its most oxidized or chlorinated form, depending on volatility and solubility. To carry out this procedure the final compounds must be identified, along with their thermodynamic parameters, and specified at standard temperature (298.15°K) and atmospheric pressure (101.325 kPa).

It is normal practice in the thermodynamics of closed systems to assign a zero value for enthalpy of formation of pure elements. However, this convention makes calculation awkward for open systems. Instead, Szargut has proposed that the zero level should be assigned to the (unique) reference species. (Szargut *et al.* have identified 10 gaseous species for 10 chemical elements, 31 ions dissolved in seawater for 31 chemical elements and other reference species for the same number of elements.) Then the standard exergy for any chemical will be defined as the maximum work that can be extracted when that chemical is transformed by successive reactions into the reference species in the standard state of temperature and pressure.

There is also an adjustment for the reference species themselves, since their natural states are not the same as the standard state. For instance, the natural state is often one with a much lower vapor pressure due to low concentration. Thus, the standard exergy of the reference species in the natural state is the work that can be extracted in going from the standard state to the natural state. Thus, the standard chemical exergy of oxygen is bigger than the chemical exergy of atmospheric oxygen, because the latter is at lower (partial) pressure. Calculation of the chemical exergy for reference species depends on whether the species is found in the atmosphere, in seawater or in the earth's solid crust.

Implementation of the preceding scheme for a compound requires the following steps:

1. Calculation of the standard exergy of each of the elements $b^0_{ch,el}$ from the corresponding equation representing its formation (by a reversible reaction) from the reference species. (These equations are equations of formation of the reference species from elements, expressed in reverse.) Since there is just one reference species per element, the system of equations has a unique set of solutions. As noted already, reference species should be common components of the environment. Szargut has selected 10 reference species found in the atmosphere, 31 in the ocean, and 13 species in the earth's crust. The equation is as follows:

$$b^0_{ch} = \Delta G^0_f + \sum_{el} n_{el} b^0_{chel}, \tag{2}$$

where G_f is the Gibbs energy of formation of the target compound, b^0_{ch} is the chemical exergy of the target compound per mole, b^0_{chel} is the chemical exergy

of the component element (previous tabulated), and n_{el} is the number of atoms of the element in the compound.

2. To correct for differences between standard conditions and actual conditions and abundance in the three main media, we use one of the following three equations. For atmospheric species,

$$b^0_{ch} = -RT_n ln \frac{p_n}{p_{0n}}, \tag{3}$$

where p_n is the normal pressure (101.325 kPa) and p_m is the partial pressure of the compound in the atmosphere.

For reference species in the earth's crust,

$$b^0_{ch} = RT_n ln x_{\text{in}}, \tag{4}$$

where x_{in} is the average concentration (mole fraction) of the ith substance in the earth's crust.

In the case of reference species dissolved in seawater, the approach is slightly different. The following formula allows the direct calculation of the standard chemical exergy of the pure element contained in the reference species:

$$\begin{aligned} b^0_{ch} = & -j\Delta_f G^0 + \tfrac{1}{2} jz b^0_{ch\ H_2} \\ & - j\sum n_k b^0_{ch\ k} - 2.303 RT_n jz(pH) \\ & - jRT_n \ln m_n \gamma, \end{aligned} \tag{5}$$

where $\Delta_f G^0$ is the standard normal free energy of formation of the reference ion, j is the number of reference ions derived from one molecule of the element under consideration, z is the number of elementary positive charges in the reference ion, n_k is the number of moles of additional elements in the reference ion, m_n is the conventional molarity of the reference species in seawater, and γ is the activity coefficient of the reference species in seawater.

2. SINK-SPECIFIC REFERENCE SPECIES

Szargut's simplified approach is convenient for many purposes. However, it may be inadequate for purposes of assessing potential environmental harm from pollutants, where localized sink-specific reactions are typically important. For instance, the standard chemical exergy of sulfur in Szargut's scheme is based on the assumption that the end product is the SO_4^- ion (in water), independent of whether the sulfur was originally emitted into air or water. It is important to recall that the atmosphere is not in equilibrium with the ocean (nor is the ocean in chemical equilibrium with the earth's crust). The potential harm due to atmospheric emissions must be related to the exergy of the pollutant with respect to atmospheric reference species only. Clearly, the real situation is somewhat more complex than Szargut's simplified scheme, at least for some of the major biologically active elements and compounds found in pollutants.

The starting point for a *gedanken* equilibration process is a homogeneous mixture of pure chemical elements in a reactor. The chemical composition of the final "soup" of compounds depends on the elementary composition of the original mixture. This is the primary difference between the atmosphere, hydrosphere, and lithosphere. Each chemical element in the starting mix must be used up in the final soup of compounds. For instance, hydrogen tends to combine with oxygen forming water (H_2O) whenever possible. Thus, most of the hydrogen in the earth's crust—including the oceans and atmosphere—is in the form of water (including its ionized forms H^+ and OH^-). Similarly, most of the carbon is also combined with oxygen. This is in the form of gaseous CO_2 in the air, carbonic acid H_2CO_3 (in water), or one of its metallic salts such as calcium or magnesium carbonate in the earth's crust. (The only hydrogen and carbon that are normally found on the surface of the earth [i.e. in the atmosphere, oceans, sedimentary, or metamorphic rocks] that are not on one of these forms are in carbohydrates, fats, or hydrocarbons resulting [directly or indirectly] from photosynthesis. Fossil hydrocarbons, including coal, are derived from previously living matter. Graphite is mostly of metamorphic origin, from coal or other sedimentary hydrocarbon deposits. Hydrogen and carbon are very rare in igneous rock, although some hydrogen sulfide and ammonia [presumably dissolved under pressure in magma] are emitted by volcanoes.)

To get a feel for the situation, suppose the elements were mixed together initially in a gaseous soup but at a low enough temperature to permit stable molecules to survive. Assume that various reactions occurred in sequence, rather than simultaneously. The first step in the sequence might be for the two most mutually attractive elements to combine preferentially with each other. This reaction would continue until the supply of one of the reactants is exhausted. Then, the two most reactive of the remaining elements would combine until one of them is used up, and so on. The procedure continues, in principle, until every possible

(exothermic) reaction has occurred. The final result is a chemical equilibrium in which at least one and possibly several of the most reactive elements are found with only one partner, although that partner may combine preferentially with several others. (Thus, both hydrogen and carbon are found almost exclusively with oxygen, except when they combine with each other. Oxygen—being more abundant—is also the preferred partner of many other elements.) In a true equilibrium it makes sense (in most cases) to choose the most abundant compound of each element as the reference species for that element.

However, this simplified mental model of a sequential reactor fails to allow for a number of real-world factors. In the first place, one of the major combinations resulting from the vapor-phase reactions is water, which condenses at a relatively high temperature, whereas quite a few other light molecules, including hydrogen, methane, ammonia, hydrogen sulfide, and carbon dioxide, as well as molecular nitrogen, oxygen, and the rare gases, remain in vapor phase at the same pressures and temperatures. Thus, all known planets have volatile atmospheres as well as solid cores. The presence of liquid water on earth is a result of the specific combination of temperatures and pressures that make it possible. It also depends on the peculiar fact that frozen water is slightly less dense than liquid water and therefore floats rather than sinking. Absent this unique characteristic of water, polar ice would sink and accumulate on the Arctic and Antarctic ocean floors, gradually cutting off ocean currents. This would eliminate the major mechanism for cooling the tropics and warming the polar regions. The result would be hotter tropics, colder polar regions, and much more violent storms resulting from the temperature gradient. The storms would carry water vapor from the tropics to the poles, where it would condense as ice. It would also make the remaining tropical oceans more and more saline (like the Dead Sea). The end result would be a stable world of glaciers and salt.

Water is an extraordinarily powerful ionic solvent for some alkali metals and halogens, as well as sulfates and nitrates. But many other molecular combinations, especially of metals, do not dissolve to a significant degree in water. Nor do some of the major families of hydrocarbons and lipids. In short, the liquid water on the earth's surface constitutes a kind of filter, which efficiently separates soluble from insoluble species. The latter, of course, build up into sedimentary layers.

The composition of earth's atmosphere is unlike that of the dead planets. Both molecular oxygen and molecular nitrogen exist in the earth's atmosphere only because of biological processes. The role of photosynthesis in maintaining the carbon cycle is very well known. The corresponding role of denitrification organisms is less well understood. But without them, the atmospheric nitrogen would gradually combine with oxygen (thanks to electrical storms) and would be dissolved in the ocean as nitric acid.

Evidently the three major sinks (the atmosphere, the oceans, and the sedimentary layers of the earth's crust) are self-organized systems in a stable state that is far from thermodynamic equilibrium. Such systems exist thanks to complex biological and geo logical processes driven by a continuous flux of solar exergy, via photosynthesis and denitrifying bacteria.

However, there are problems with the simple theory. An example will help to clarify some points. When another element or compound (say sulfur) is injected into the atmosphere, it reacts with oxygen until it is entirely consumed. The usual product is SO_2. However, the SO_2 either reacts with water vapor to form sulfurous acid H_2SO_3 or it oxidizes to SO_3 and subsequently reacts with water to form sulfuric acid H_2SO_4. These acids either wash out in rain or react with ammonia to form ammonium sulfite or sulfate, which also washes out in rain. The acid rain causes corrosion on metal surfaces and changes the pH of soil and freshwater lakes. Eventually most of the sulfur does indeed end up as SO_4^- ion in the seawater. (But seawater is not a permanent residence for sulfur: the sulfate ion gradually combines with calcium or magnesium ions and precipitates into sediments.) Yet much of the potential environmental harm occurs in intermediate environments where the sulfur *enters* as sulfate ion and the most likely final (reference) state is probably calcium sulfate.

Curiously enough, the most abundant sulfur compound in the atmosphere is not sulfur dioxide, as one might expect; it is an organic compound carbonyl sulfide (*COS*), probably of biological origin. Yet there is a possibility that this compound is produced in the atmosphere by a reaction with methane such as $SO_3 + CH_4 \rightarrow COS + 2H_2O$. Unfortunately one cannot easily perform the relevant exergy calculations, due to unavailability of data on Gibbs energy of formation of *COS*.

In the case of sulfur, one might propose not just one but three reference states, depending on the medium of interest. In the atmosphere itself the

reference state would be either SO_2 or possibly COS; in seawater it would be SO_4^{2-} ion, and in the (sedimentary) lithosphere it would be calcium sulfate, probably in the form of the mineral gypsum $CaSO_4 \cdot 2H_2O$. In the case of sulfur (and other elements) another complication arises, namely that the lithosphere is anything but homogeneous. In particular, there are vast differences between the sedimentary or metamorphic component of the earth's crust (the part that has resulted from weathering and has been exposed to the atmosphere at some stage) and the unweathered igneous rock left over from the earth's original solidification. Most sulfur in nonsedimentary igneous rocks, however, is combined with metals as sulfides (MS, MS_2, etc.). As these are exposed to water or air (e.g., by mining operations), the sulfides gradually oxidize to sulfurous acid or sulfur dioxide.

2.1 Standard Theory

The standard theory calculates standard chemical exergy of sulfur by adopting SO_4^- dissolved in water as the reference species. Calculations are based on Szargut's analysis and give the following result:

$$b^0_{ch}[\mathrm{S}] = 609.6\ \mathrm{kJ/mole}. \tag{6}$$

2.2 Sink-Specific Approach

Three independent measures may be computed for the atmosphere, the seawater, and the lithosphere as follows:

Atmosphere. Apart from COS (mentioned earlier), the most abundant compound containing sulfur in the atmosphere is sulfur dioxide, SO_2. Its mean volume concentration in the atmosphere has been estimated as about $2 \cdot 10^{-8}$. From Eq. (2) we obtain for the reference species

$$b^0_{ch}[\mathrm{SO_2}] = 40.25\ \mathrm{kJ/mole}. \tag{7}$$

The formation of sulfur from SO_2 (or vice versa) can be written as follows

$$\mathrm{S} + \mathrm{O_2} = \mathrm{SO_2}. \tag{8}$$

Exergy does not have to be recalculated for oxygen since the original reference species selected by Szargut was atmospheric O_2. Thus, applying an exergy balance one obtains

$$b^0_{ch}[\mathrm{S}] + b^0_{ch}[\mathrm{O_2}] + \Delta G^0_r = b^0_{ch}[\mathrm{SO_2}], \tag{9}$$

and

$$\begin{aligned} b^0_{ch}[\mathrm{S}] &= b^0_{ch}[\mathrm{SO_2}] - b^0_{ch}[\mathrm{O_2}] - \Delta G^0_r \\ &= 107.96\ \mathrm{kJ/mole}. \end{aligned} \tag{10}$$

Mean residence time of sulfur dioxide in the atmosphere is fairly low (about 10^{-2} years), thus choosing this substance as a reference species is quite inappropriate. It is reasonable to assume that sulfur-containing compounds easily evolve toward other chemical forms, which produce SO_4^- dissolved in seawater.

Seawater. The chosen reference species is the ion SO_4^- As noted previously, Szargut calculated $b^0_{ch}[\mathrm{S}] = 609.6$ kj/mole However, Szargut assumed that the standard chemical exergy for oxygen in seawater was equal to that of atmospheric oxygen. Taking into account the lower concentration of oxygen in seawater, standard chemical exergy of O_2 increases to 21.11 kJ/mole. In principle, the exergy of sulfur should be recalculated. However, for some compounds it seems reasonable to assume (as Szargut does) that reactions actually occur in the vapor phase, even when considering ions dissolved in seawater or solid compounds.

Lithosphere. Szargut's chosen reference species is gypsum ($CaSO_4 \cdot 2H_2O$). Unfortunately, no data on the mass fraction of this mineral are available for calculating its standard chemical exergy as a reference species. However, if an estimated average concentration of 10^{-4} is assumed, we obtain (from Eq. 3)

$$b^0_{ch}[\mathrm{CaSO_4 \cdot 2H_2O}] = 22.83\ \mathrm{kJ/mole}. \tag{11}$$

The following reaction can be identified for the formation of sulfur from gypsum:

$$\begin{aligned} &\mathrm{S} + \tfrac{3}{2}\mathrm{O_2} + \mathrm{CaCO_3} + 2\mathrm{H_2O} \\ &= \mathrm{CaSO_4 \cdot 2H_2O} + \mathrm{CO_2}. \end{aligned} \tag{12}$$

$CaCO_3$ is another reference species for the lithosphere and its chemical exergy is 1.0 kJ/mole. Assuming that oxygen and carbon dioxide participate in the reaction in gaseous form and that a liquid reference state may be assumed for water, one obtains

$$\begin{aligned} b^0_{ch}[\mathrm{S}] &= b^0_{ch}[\mathrm{CaSO_4 \cdot H_2O}] \\ &\quad + b^0_{ch}[\mathrm{CO_2}] - \tfrac{3}{2} b^0_{ch}[\mathrm{O_2}] \\ &\quad - b^0_{ch}[\mathrm{CaCO_3}] - \Delta G^0_r \\ &= 171.27\ \mathrm{kJ/mole}. \end{aligned} \tag{13}$$

Thus, Szargut calculates the standard exergy for sulfur as 609.6 kJ/mole (assuming sulfate SO_4^{2-} in sea

water as the reference state), but a sink-specific approach yields very different figures, namely 107.96 kJ/mole to atmospheric SO_2 (not a good choice, however, because of its short life) and 171.27 kJ/mole to gypsum in the lithosphere.

The preceding example can be extended to many other elements. For instance, most of the silicon in the sedimentary part of the earth's crust is also combined with oxygen as silica (SiO_2). This is the logical reference species for silicon. In nonsedimentary rock, it is usually in one of the reduced metallic silicate forms $MSiO_3$ or M_2SiO_3. These silicates spontaneously react with carbonic acid H_2CO_3 to form silica SiO_2 and corresponding hydroxide MOH or $M(OH)_2$. The latter reacts further with any acid in the environment to form a metallic carbonate, sulfate, or chloride. Carbonates obviously predominate. Aluminum is always combined with oxygen (as alumina, Al_2O_3), even in igneous rock, so this is the logical reference species. Alumina and silica are sometimes combined in a single mineral (kyanite, Al_2SiO_5).

Sodium, potassium, and calcium in the lithosphere are normally oxidized as Na_2O, K_2O, and CaO. These are often combines in more complex minerals, such as feldspars. These are major rock-forming minerals that constitute up to 60% of many igneous rocks metal. They include potassium feldspars ($KAlSi_3O_8$), sodium feldspars (albite, $NaAlSi_3O_8$), calcium feldspars (anorthite, $CaAl_2Si_2O_8$), and all combinations. The oxides are convenient reference species for all three metals.

Phosphorus in the lithosphere is only found in one mineral, apatite [$Ca_3(PO_4)_2$], of biological origin. Apatite is subject to weathering by carbonation, much the same way in which silicates weather. This process releases phosphoric acid $H_3PO_4^-$ or HPO_4^{2-}. These would be natural reference species in water. However, in soil much of this phosphoric acid is bound (occluded) into complexes with iron and aluminum, so the latter would be the logical reference species in the lithosphere. Iron is mostly mined from oxide deposits, also of biological origin, but iron is often partially oxidized (ferrous iron) even in igneous rock. The likely (most abundant) reference species is Fe_2O_3. Among the other major metals (chromium, copper, lead, manganese, nickel, zinc, etc.), the heavier metals are found mainly as sulfides in igneous rock; however, Szargut chose reference species in the lithosphere that are all oxides.

The halogens (F, Cl, Br, I) combine preferentially with the alkali metals, sodium, potassium, magnesium, or calcium. The halogenated sodium, potassium, and magnesium compounds are quite soluble in water and are mostly accumulated in the oceans, except for evaporite deposits. The logical reference species for the first three are simply the ionic forms; F^-, Cl^-, and Br^-. For iodine it is IO_3^-. In igneous rock, these salts are only found in trace percentages. However, for chlorofluorocarbons (CFCs), which are accumulating in the atmosphere, a specialized sequence of reactions—involving diffusion into the stratosphere and ionization by UV—may suggest a different exergy calculation.

Nitrogen is a special case. Molecular nitrogen in the atmosphere results only from biological processes, namely bacterial denitrification of organic nitrogen compounds. Nitrates are stored in sediments as organic material. They are found in igneous rock only in trace percentages. In principle, molecular nitrogen tends to combine with oxygen as nitrogen oxide (NO), nitrogen dioxide (NO_2), and eventually nitric acid (HNO_3), which reacts with ammonia in the atmosphere or dissolves in water and washes out as acid rain. The acid, in turn, reacts with most metallic hydroxides (in water) to form the corresponding nitrates. However, as mentioned already, the oxidation reactions in air are negligibly slow at normal temperatures and pressures. (They do occur more rapidly at high temperatures and pressures).

In the circumstances, it probably makes sense from an environmental standpoint to assume that one of the alkali metal nitrates [$Ca(NO_3)_2$, $NaNO_3$ or KNO_3] is also the reference species for nitrogen, contrary to Szargut's view, despite the fact that other compounds of these elements are much more abundant in the lithosphere. This may lead to some confusion, but as long as it is understood to apply only to the case of nitrogen compounds (and not to other compounds of the alkali metals, it should be possible to maintain reasonable consistency.

To summarize, it can be argued that a substance with a long—but not infinite—residence time in the atmosphere (or the ocean) might be a candidate for treatment *as if* it were a permanent resident. The argument is that when a compound remains within an environmental medium for a significant time, but subsequently disappears from that medium (whether by transformation, diffusion, precipitation, or washout), it may nevertheless be considered as a reference species within that medium. Candidates for atmospheric reference species might include nitrous oxide (150 years), methane (10 years), carbonyl sulfide (5 years), especially in comparison with carbon monoxide (60 days), sulfur dioxide (14 days), or hydrogen sulfide (4 days).

3. EXERGY BALANCE AS A TOOL FOR ANALYSIS

Unlike energy, exergy is not a conserved variable. It can be gained or lost in physical processes. However, exergy can be accumulated or depleted. It can also be stored in mineral ores or fossil fuels, for instance. Finally, as noted previously, exergy inflows and outflows to and from any subsystem are definable and measurable. (Computational aspects are discussed earlier.)

In the case of hydrocarbon fuels and carbohydrates such as cellulose and sugars, the exergy content of a fuel is very closely related to the usual measure (heat-of-combustion or enthalpy). However, as noted already, the term exergy is much more widely applicable. Given the previously stated conventions, it is definable for any material substance whatsoever, whether combustible or not. For instance, the exergy content of a metal ore (i.e., the work required to separate ore of that grade from the earth's crust) reflects the amount of natural "low entropy" that is stored in the ore. This would be lost if the ore were dissipated (mixed) uniformly into the earth's crust or into the ocean. The better the quality of the ore, the greater its exergy content.

Exergy, $\boldsymbol{B}$ as defined previously, is not only a natural measure of the resource inputs to an economic system. It is also a measure of the material outputs. Exergy is lost in all processes, mostly—but not entirely—as low temperature heat. But some exergy is lost in the form of chemically or physically reactive materials. These production or consumption wastes are dissipated into the environment, where the insertion of unfamiliar chemical species (i.e., chemical potentials) in delicately balanced biogeochemical cycles can cause trouble. At the microscale, even small trace amounts of some chemicals are enough to disrupt life processes. In fact, there is a general label for such disruptive chemicals: they are toxins.

To calculate the exergy content of waste materials, in practice, there are two approaches. Ideally they should be used together for mutual verification. The first approach requires a detailed knowledge of the chemical composition of the waste stream and the Gibbs free energies of formation of the components. Once these are known, the calculation of exergy proceeds component by component. The difficulty is obvious: for many chemical and metallurgical processes it is difficult to obtain reliable data on the chemical composition of the wastes. Nevertheless, the composition of the waste stream can be estimated approximately, in many cases, if the basic chemical reactions, temperatures, pressures, and yields are known. Indeed, commercially available software suitable for use in a desktop computer is capable of making such calculations at minimal cost.

The second, alternative approach involves using the exergy "balance" equation:

$$B_{in} = B_{product} + \Delta B_{process} + B_{waste}, \qquad (14)$$

which can be rewritten

$$B_{waste} = B_{in} - \Delta B_{process} - B_{product}$$

Here $\boldsymbol{B_{process}}$ is essentially a balancing term. It represents internal exergy lost in the process. Evidently, if $\boldsymbol{B_{process}}$ is known, the exergy content of wastes can be determined directly from the composition of the process inputs (including utilities) and that of the main products. The exergies of process inputs and product outputs are computed, as before, using Eq. (13), when Gibbs free energies of formation are known. However, as a practical matter, the exergy loss (or gain) in the process is typically much larger than the exergy content of the waste. Thus, to use Eq. (15) it is necessary to calculate process losses precisely. This is sometimes feasible on a case-by-case basis, but it is rarely easy.

4. EXERGY AS A MEASURE OF RESOURCE AVAILABILITY OR LOSSES

The use of exergy as a measure of resource stocks and flows for purposes of resource accounting was first proposed by Wall. The use of chemical exergy (or its equivalent, potential entropy) as a measure of potential harm from process wastes was a more recent idea. The latter notion also suggests the possibility that chemical exergy may be a useful indicator of sustainability.

However, while the research in this area so far is suggestive, there is more to be done before the application methodology can be regarded as complete and unambiguously successful. The problem is that the computational methodology (developed by Szargut) assumes that the exergy of a given chemical element is independent of the composition of the environmental sink into which it is injected. This implies that the exergy is independent of what specific reactions are induced in the actual sink. This implication seems reasonable enough if, for instance,

exergy is being used for purposes of resource accounting.

However, if exergy is to be used as a measure of potential environmental harm, it is unreasonable to assume that the chemical composition (and other characteristics) of the particular environmental sink are irrelevant. Hence, this simplifying assumption should be replaced by a methodology for calculating sink-specific measures. In particular, critics have emphasized that waste exergy, as calculated in terms of the three gross sinks—atmosphere, oceans, and lithosphere—is not a valid indicator of environmental toxicity. It is possible that a better measure could be developed if the internal chemical environment of living cells were considered as a fourth major sink. However, considerable research would have to be done to verify this conjecture.

However, although waste exergy is not (yet) a reliable measure of environmental toxicity, exergy analysis can be used to evaluate and compare waste flows and aggregate emissions from period to period or country to country. The exergy content of wastes is not necessarily proportional to the potential environmental harm the wastes may cause, but the exergy content of a waste stream is nevertheless a rough measure of its reactivity in air or water (i.e., its tendency to initiate spontaneous uncontrolled chemical reactions in environmental media). In this regard, one can say that although the exergy content of a particular waste stream is not a measure of human or animal toxicity, it is certainly a better indicator of its potential for causing harm than is its total mass, for instance.

Glossary

diffusion Increase in market share of a \ew technology after a successful innovation.
economies of scale Decrease in unit cost of production through increase in scale of production.
experience curves The relationship between unit cost and cumulative deployment as represented by an exponential decay function.
innovation First commercial application of a newly developed technology.
interindustry spillover Transfer of knowledge, technologies, materials, and the like from one industrial application to another (e.g., the concept of jet engines from aeronautics to gas turbines).
intraindustry spillover Transfer of formerly exclusive knowledge and experience from one competitor to another (e.g., by labor mobility).
learning by doing Increase in skill level of labor through increasing experience.
learning curves The relationship between falling unit cost of production and increasing skill level of labor caused by an increase in experience, represented by an exponential decay function.

Experience curves are used to assess the future cost of a technology as a function of cumulative installations. The underlying rationale is that it is very costly to invent, develop, and prototype a new technology, process, or product. After an innovation—the first commercial application—a successful technology or product will spread from niche applications to larger markets. In this process of diffusion, unit costs will constantly decrease. This reduction of unit costs over time is described by experience curves.

1. DEFINITION OF EXPERIENCE CURVES FOR ENERGY TECHNOLOGIES

The concept of experience curves was derived from empirically observed learning curves in manufacturing. Learning curves describe the cost reduction effects by learning by doing. Through individual, organizational, and inter- and intraindustrial learning, the input of labor necessary to produce a certain product decreases as experience is gained. On the other hand, experience curves describe the cost reduction of a product or technology in general, disregarding the reasons for total cost reduction. Possible reasons for the reduction of unit costs during technology diffusion are economies of scale in all input factors (e.g., intermediates, transaction costs, other overhead), higher rates of production, changes in the production processes, and (particularly in the case of energy technologies) efficiency gains and changes in the product itself.

In the last years, experience curves have drawn considerable attention in the energy field due to a variety of technological challenges. Energy systems in many developing countries are in a phase of expansion and growth. Energy systems in most developed countries go through some restructuring, inducing a change in investor behavior. Both phenomena increase interest in present and future investment costs. Legislators, electricity generators,

 © 2004 Elsevier Inc. All rights reserved.

and other energy producers are also confronted with environmental demands (e.g., climate change, pollution, nuclear disposal and safety) that require the increased use of new cleanup technologies and new clean energy conversion technologies. Most of these new technologies are in early stages of their diffusion and considerable future cost reduction is expected.

Experience curves also play an important role in energy policy analysis. They are used to assess the "buy-down" cost of a new technology (Fig. 1). To optimize the size of a support program for a specific new technology, experience curves are used to determine how much additional investment is necessary to bring the cost of the technology down to levels at which it is economically competitive with other technologies. To that end, the incremental cost of the new technology and the speed of the cost reduction are determined from empirical data. The integral under the experience curve is equal to the investment required to buy down the cost of the technology between two arbitrary points on the curve.

Experience curves are also widely used in energy scenarios calculations. Investment costs and conversion efficiencies of energy technologies are important driving factors for future energy demand and supply. The most important energy system models, such as those of the U.S. Energy Information Administration and those used in the Intergovernmental Panel on Climate Change's (IPCC) Special Report on Emission Scenarios, use experience curves for the extrapolation of future energy costs because future investment costs for energy conversion and use are needed as inputs to these models. Because of their low data requirement and relatively robust nature, experience curves are very well suited to generate these inputs.

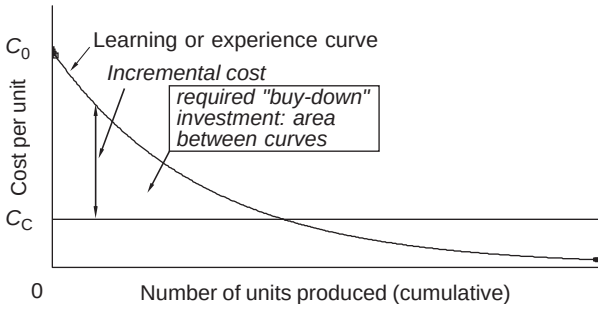

FIGURE 1 Experience curve for an equipment unit of a new energy technology. The unit cost for a piece of equipment falls with increasing cumulative deployment of the technology. C_0 is the cost of a technology at innovation. C_c is the cost of a conventional backstop technology. The integral over the incremental cost up to the point of intersection ("buy-down") indicates how much additional investment is necessary to make the new technology economically competitive with the established technology.

The more sophisticated energy system models can include dynamic specifications into the model code such that the prices used for optimization of the model are generated during the model runs and depend, in a dynamic way, on the respective deployment figures of the current simulation.

Management consulting firms (e.g., Boston Consulting Group) use experience curves for consulting clients on strategic price-setting behavior. Experience curves describe cost reduction as a "black box." The actual reasons for the cost reduction are completely ignored in the model. This makes experience curves seemingly simple to use but also imposes some caveats on the use of the concept. The data requirements for an estimation by linear regression are seemingly very low, and extrapolation into the future seems almost trivial. This article first gives more detail on the concept and then discusses the reasons why cost reduction for the whole product or technology might occur. It explains how these reasons should be incorporated into the model and what kind of data problems result. Several examples for cost reduction in various energy technologies and some extensions to the model are discussed.

2. EXPERIENCE CURVES

2.1 The Concept

Experience curves assume a logarithmic relationship between the experience from cumulative installation and cost. Typically, this is represented by the following functional form:

$$C_{\text{cum}} = C_0 * CUM^b, \tag{1}$$

where CUM is the cumulative output of the industry, C_{cum} is the cost of a unit product after output of CUM, b is the "learning index," and C_0 is the cost at the starting point of the data.

This functional form has some very convenient mathematical properties. For example, the parameter estimates are independent of the starting point of the data used for the estimation. The functional form is completely independent of the stage of development or diffusion of the technology. It implies that the cost reduction per additional unit of output decreases, so decreasing marginal reduction in costs is factored in. However, the functional form also prescribes that there is no limit to cost reduction. Some authors embrace this because they think that human ingenuity and competition will supply the opportunity for continually decreasing cost.

Other authors suggest including a minimum level of cost in the functional form by adding a simple linear term.

The functional form of the experience curve is estimated with linear regression after logarithmic transformation:

$$\log C_{\text{cum}} = \log C_0 + b \log CUM. \qquad (2)$$

Empirical studies usually estimate the coefficients of this equation using ordinary least squares and usually report highly significant correlations for the logarithmic form. However, highly significant correlations are to be expected in a logarithmically transformed linear regression of integrated variables and should not lead the investigator to conclusions that are not actually supported by the data. In fact, econometrically tested and statistically significant estimations of the experience curves are hard to find in the literature.

The data requirement for the estimation of Eq. (2) is very small. The data necessary for production cost forecasts (i.e., cumulative installations) are easily available from energy scenario calculations. The high level of aggregation of the data does not require any explicit knowledge about future changes in technological details that are particularly hard to predict. However, some researchers prefer to modify the parameters for time periods in the far future or distant past rather than assuming homogenous cost reduction over several decades.

2.2 The Progress Ratio

The "progress ratio" (PR) describes the relative cost after a doubling of cumulative installation. It is a very explicit and obvious benchmark for cost reduction effects. It is calculated from the learning index b estimated with the experience curve:

$$PR = 2^b. \qquad (3)$$

A progress ratio of 85% means that costs are reduced by 15% with each doubling of installed capacity. This ratio is constant. It is also independent of the rate at which the experience is accumulated, of the developmental stage of the technology, and of possible qualitative changes in the product or technology.

The progress ratio has been calculated for other, non-energy-related industries (e.g., products of the chemical industry or airplane manufacturing). Typically, progress ratios lie between 75 and 85%.

2.3 Scope

Experience curves have been estimated for single firms but are more common for a whole sector or whole industry (e.g., the wind turbine industry, all makers of combined cycle gas turbines) or for cumulative experience in all varieties of one technology (e.g., solar photovoltaics). In a globalized world, and specifically in energy technology markets, it is reasonable to assume that learning processes draw from a worldwide base of experience. Therefore, experience curves for energy technologies should reflect global experience, and global data should be used for their estimation.

3. REASONS FOR COST REDUCTION AND CONSEQUENCES FOR THE FORMULATION OF EXPERIENCE CURVES

Experience curves, as a typical black box model, do not make any assumptions about the reasons for cost reduction. However, for the applications of experience curves, these may not be ignored. This section explains the reasons for cost reduction and implications for the interpretation of progress ratios and cost reduction effects. In energy technologies, there are five reasons for cost reduction and improvements in the competitiveness of a technology: learning by doing, economies of scale in production of the equipment, improvements in the efficiency and quality of the equipment, standardization, and market conditions.

3.1 Learning by Doing

Learning by doing results in cost reductions whenever a firm or any other type of organization improves its productivity of labor through day-to-day operations. Wright studied the development in labor productivity in the U.S. airframe industry and showed that the number of hours required to produce an aircraft declines with the cumulative number of aircrafts produced. Arrow introduced the learning by doing hypothesis into economic mainstream and built a theory of macroeconomic growth on it.

Cost reduction through cumulative experience can be achieved within the firm, but firms can also profit from intra- and interindustry spillover effects. Mobility of "human capital" and copycat behavior are possible causes of intraindustry spillover and can be treated jointly with learning by doing even when looking at a

single firm. Argote and Epple showed that "organizational forgetting," which would reverse the cost reduction through learning by doing, occurs as well.

Cost reduction through learning by doing has been estimated in the past using the same functional form that later served as the blueprint for the experience curve. Learning by doing reduces the overall cost of a project to the degree that labor is used as a factor of input to production. The share of the total cost for this input factor is not likely to remain constant over time. Thus, if learning by doing is not the only factor contributing to cost reduction, theory does not fully support the use of the same functional form for both curves even if this is common practice.

3.2 Economies of Scale in Production and in Input Factors

The classic reason for cost reduction is economies of scale in the production process and in the procurement of input factors. When the output of an industry grows from a few hand-manufactured units per year to mass production, unit costs can go down by several orders of magnitude. Input materials for large-scale production can be purchased at better prices, and overhead can be reduced. Administrative effort and transaction cost per unit are reduced.

Upscaling a given production facility happens in an incremental way. Thus, even the cost of the aggregate production of a whole industry, particularly a small industry such as any national wind turbine industry, might not follow a smooth decay but rather have kinks. Just like in the case of learning by doing, there are natural limits to the size of factories, after which economies of scale might actually disappear and turn into diseconomies of scale in the form of increases in unit costs. The experience curve is a simplifying and generalizing representation of this growth process.

Economies of scale refer to the scale of current production, that is, to the current output per time. Because the classic experience curve concept does not control for time or the rate of production, estimating the equation can result in the same progress ratios for a given cumulative output at low and high rates of production. The experience curve concept assumes that the experience contribution of the xth unit depends only on how many units of experience have been gained before and not, for example on the cumulative sales in monetary terms. This points to the problem of defining the exact metrics to be used in the curve (e.g., whether the cumulative output should really be expressed in units produced or in a different metric), discussed in Section 4.

3.3 Improvements in Efficiency and Usefulness of the Product

Energy equipment can also exhibit qualitative changes over time that lead to higher efficiency of conversion without increasing unit cost in proportion. For example, bigger wind energy converters do not usually cost more in proportion as they grow larger, but their specific (marginal) cost per megawatt of capacity decreases. In addition, the efficiency of fuel use typically increases with changes in quality and size of the generator, so that the specific cost of the energy service goes down even more.

Efficiency changes can be taken into account in experience curves, but only if the delivered energy service (e.g., the kilowatt-hours of electricity) are the measure of experience as well as the unit for which costs are considered. Just like in the case of diseconomies of scale, equipment might evolve into an application suited for specific niche markets and, as a result of these qualitative changes, specific costs might be higher in later stages of technology diffusion.

3.4 Diffusion and Standardization

A fourth reason for the reduction of cost with increasing maturity of a technology is the standardization that a successful technology will undergo during its diffusion from niche markets into general markets. Standardization drives down overhead and compatibility costs. A logistic rather than exponential curve seems to be the appropriate representation of this phenomenon.

3.5 Market Conditions

All phenomena discussed so far might not have any effect on unit cost of production or on prices of the technology if the market structure is not sufficiently competitive. Not only might monopolists and oligopolists be able to charge prices that are far higher than the costs of developing, producing, and distributing a product or technology, but a noncompetitive market structure also relieves market participants from the pressure to improve products and production processes. Thus, learning and efficiency gains might be realized more slowly than in competitive situations. Other market conditions, such as the maturity of the market on the demand side and the opportunity of

spillover effects, might affect the speed of learning and improvements of the industry standard in economic or technological terms and, thereby, have indirect effects on the cost reduction over time.

In addition, the market situation in input factor markets (e.g., labor, materials) can play an important role in both improving and reducing cost reduction and experience effects. However, in an abstract and very general model of cost reduction with increased experience, it is very hard to account for these effects.

4. PROBLEMS OF DATA IDENTIFICATION AND STATISTICAL INFERENCE

Considering the reasons for a possible decrease in unit cost of energy technologies, it becomes clear that the variables representing experience as well as cost need to be chosen with care. Some of the changes (e.g., improved efficiency of conversion, improved reliability) only reduce the cost of the delivered output of the technology, whereas others (e.g., economies of scale in production, learning by doing) reduce the cost of equipment manufacturing and will have effects on both possible metrics: the cost of capacity and the cost of the energy service. Other identification problems and problems of statistical inference are discussed in this section.

4.1 The Dependent Variable

4.1.1 Cost per Capacity or per Energy Service

Most of the newer studies of energy technologies, particularly those in the field of renewable and intermittent energy sources, concentrate their analyses on the cost per unit capacity of the technology. These data are readily available for some technologies. Data on the cost of the energy itself (e.g., the power output for some technologies) are harder to obtain for several reasons. The actual energy output depends on local load factors and the supply with fuel inputs. Fluctuations in fuel prices and operation and maintenance (O&M) costs introduce additional uncertainties. Long-term trends in fuel prices or O&M costs might even offset any cost reductions through cumulative experience if measured in prices per energy service. Still, when experience curves are used for a comparison between different energy technologies, the assessment should always refer to the cost per unit of energy (e.g., kilowatt-hour) because this metric accounts for internal changes in the energy technology as well as in the other conditions that influence the relative costs of different technologies. Only this metric, if any, allows for the assessment of buy-down costs (as defined earlier as the amount of investment needed until the costs reach the level of any backstop technology). To do so, it is recommended to define standard (e.g., average) conditions for load factors and fuel input prices and quantities. To extrapolate cost reduction into the future, the standard situations (e.g., load factors, efficiency, fuel prices) need to be extrapolated into the future as well. This apparent abstraction is a reminder of the character of experience curves as a highly abstract tool for long-term technology assessment rather than as a planning tool for the design of an energy system on short and intermediate time horizons.

Related to this problem is the question of how to include O&M costs. These might be subject to a long-term cost reduction of their own as experiences with use of the new technology are collected and as the design of new equipment is improved for ease of use and reliability.

4.2.2 Costs or Prices

Another problematic aspect of the dependent variable is the question of whether cost or price data are used. Experience curve theory relates to the production cost for equipment or the energy product. Most empirical applications of experience curves to energy technologies use prices because they are easier to obtain than are cost data. When using price data as a proxy for costs, researchers implicitly make very restrictive assumptions on the market structure. Because experience curves include observations from many years, structural changes in the markets for energy technologies should be excluded if price data are used. Another major reason for various trends in prices and costs is changing market transformation policies and subsidy schemes for new energy technologies.

4.2 The Independent Variable: The Measure of Experience

4.2.1 Cumulatively Installed Capacity versus Cumulative Production of Energy Service

The measure of the accumulation of experience should be chosen in close analogy to the measure of cost for which the experience curve is estimated. For the reasons mentioned previously—economies of scale, market fluctuations, and qualitative changes in

the technology—cumulative energy services delivered would be the relevant measure for experience when thinking about the competitiveness of an energy technology, but data access and international aggregation are easier for cumulative capacity in megawatts. Current research investigates the usability of other measures of experience (e.g., cumulative investments, cumulative units of installation).

4.2.2 The Specification of the Technology

Whenever spillover effects from other industries are present, the estimation of cost reduction is possibly flawed. This is often problematic when technological concepts originate in other industries (e.g., gas turbine having its roots in jet engines). Also, the design of a technology might change in the course of product diversification and the establishment of a technology in new (e.g., distributed) applications.

The attribution of learning and accumulating experience also depends on which technology one actually examines. For example, the outcome when the experience collected with solar photovoltaic power generation is aggregated over all semiconductor materials that have been used for the purpose is drastically different from that when just the currently prevalent material is included in the experience measure. This phenomenon is highly technology specific, and no general recommendation can be given.

4.2.3 Global or National Scale

Typically, in a globalized world, the cumulative experience worldwide should be used as the driver for cost reduction through increased experience. With the exception of nuclear power, the markets for energy technologies are typically global markets. However, if there are specific local dynamics in a technology, the time series could become inconsistent. Furthermore, global data can sometimes be very hard to access, particularly for new technologies that are developed in several countries in parallel.

4.3 The Functional Form: Expression of the Speed of Cost Reduction

The assumption of exponential decay of costs reflects the fact that marginal improvements in the production processes diminish with increased experience. For experience curves, this form has been inferred from the idea of the learning curve. Fast learning with the first batches of production leads to rapid cost reduction initially, which can slow down during later stages of higher industry or business maturity. The traditional logarithmic shape of assumed cost reduction has very pleasant mathematical properties that technically allow for the estimation by simple linear regression and ordinary least squares methods. However, there is no reason to assume that the reduction in production cost for any piece of energy technology can be indefinitely continued, as implied by this functional form. Common sense suggests that the material cost is a natural lower limit for the cost. This means that the function should at least contain a constant price floor. The smooth logarithmic function also does not account for radical changes, implying that the curve should not be used for monopolies or monopsonies.

Furthermore, as discussed previously, learning and the other cost-reducing phenomena strongly depend on the rates of production. Thus, not all influences are captured by the classic functional form, and a multivariate approach might be much more appropriate even at the expense of the simplicity of the approach. In addition, market conditions and the circumstances of development and production of the equipment are likely to change during the time in which experience is accumulated, so that even at constant rates of deployment or constant rates of growth of production, the velocity of learning and improvements in the technology will not remain constant. Although the simple functional form has its own merits, it might not be able to account for the full story. This once again underlines the black box character of the approach. Experience curves are a tool for generating smooth curves for future projections on a large scale and for the long term, and they are not necessarily suitable for the assessment of historic trends or detailed short-term predictions. Because of this limited ability to reflect the actual processes, experience curves might be suitable only for very coarse assessments.

4.4 Spurious Regression

The experience curve concept implies a statistical relationship between a cumulative variable (e.g., cumulative deployment) and a noncumulative variable (e.g., unit cost). A statistical analysis of such a pair of variables needs to account for the autocorrelation and integration characteristics of the data. Typically, the cost at time t_{x+1} after the deployment of CUM_{x+1} will not be independent of the cost in time t_x after the deployment of CUM_x but can be represented by $C_{x+1} = C_x - \Delta C + \varepsilon$ (i.e., it should resemble a random walk with a downward drift term). Cumulative deployment CUM_{x+1} can be represented by $CUM_{x+1} = CUM_x + \Delta CUM$, where

ΔCUM equals the amount deployed during the period of observation. If the period of observation is a regular interval and the technology exhibits a typical growth pattern of a diffusion phase, the amount deployed during each period ΔCUM itself can be represented by $\Delta CUM_{x+1} = \Delta CUM_x + \Delta(\Delta CUM_x) + \varepsilon$ (i.e., it a random walk process with a upward drift). Thus, CUM_{x+1} does not fulfill the requirements for a stochastic variable. Rather, the classic concept requires an ill-defined regression of a random walk with drift with the integration of a random walk with drift. This vulnerates the standard assumptions of ordinary least squares regression, and in most cases a logarithmic transformation does not change the inherent characteristics of the data, so that the regressions based on the classic concept are most likely to be spurious. Extensive testing of the data and the error term should be conducted to prevent conclusions that are not supported by the data. However, proper statistical treatment and testing is the exception rather than the rule.

5. SOME CASE STUDIES

Recently, the classic experience curve concept has been applied to the area of new energy technologies, mostly renewable energy technologies but also combined cycle gas turbines. In this section, several technology-specific applications are discussed. These case studies demonstrate possible problems with the concept and new energy technologies and offer interesting ideas for improvement. Several large-scale research efforts on experience curves were aggregated in the International Energy Agency (IEA)-led International Collaboration on Experience Curves for Energy Technology Policy (EXCETP). All case studies have in common that where more than one estimate has been made, the estimated progress ratios span wide ranges where, as described previously, the estimate should be robust with regard to the selection of data. This fact is a clear warning to pay close attention to selecting the metrics and the database for the estimation and to testing the estimates for statistical validity, as explained previously. Figure 2 contains a classic display of several examples of estimates of experience curves that have been partly included in the following literature survey.

5.1 Wind Energy Converters

Several studies have applied the concept to various data sets with varying success. Junginger reviewed 16 studies on cost reduction in wind turbine production and found that they used different cost units and different proxies for the cumulative experience—and got very different results. Most of these studies interpreted the results of the classic function with a very specific set of reasons. These studies hardly ever accounted for the data, identification, or statistical problems mentioned previously. Most studies indicated that progress ratios for wind energy converters have been much higher (the cost reduction has been slower) than the classic rule-of-thumb progress ratios of 75 to 85%. The range of results was 62 to 96%.

5.2 Solar Photovoltaics, Niche Markets, and the Influence of Market Transformation Programs and Policies

Solar photovoltaics has been studied extensively with experience curves. Progress ratios between 68 and 82% have been estimated. The technology was characterized by high initial investment cost and comparatively high maintenance cost due to changing micro-design. The countries with the highest installed capacity of solar panels are Japan and Germany, where the installation was subsidized. Other market transformation initiatives have been launched for developing countries. Using these examples, the effect of market introduction subsidies on the cost of the equipment has been estimated. The induced cost reduction effects have then been

factored into the benefit/cost ratio of the policies to justify the intervention. The experience curves were the basis for the assessment of the necessary amount of subsidy.

Even if the fuel is free and even in good locations, electricity from photovoltaics currently is more expensive than standard grid power. However, in certain niche markets, either sunny rural locations remote from the grid or sunny urban locations where no backup power supply is available, photovoltaics can be a cost-effective solution. From this starting point, the current costs of photovoltaic systems, the market size of the niche markets, and the progress ratio can be used to calculate the point in time at which solar photovoltaics will break even with grid-connected power technologies.

5.3 Gas Turbines and the Influence of the Diffusion Stage of the Technology

Nakicenovic and colleagues estimated a two-stage learning process for gas turbines. After a steep decay in cost with a progress ratio of approximately 80% in the airline industry, a lower rate of cost reduction follows with a progress ratio of approximately 90% (Fig. 2).

According to Colpier and Cornland, who analyzed the economics of the natural gas-fired combined cycle gas turbine (CCGT), the specific investment price for larger CCGTs has decreased by as much as 35% in real terms during the past decade. Compared with experiences in other industries, this is a very high decrease. CCGT is not a new technology in itself but rather a combination of the established technologies of gas and steam turbines that has been used since the 1970s. To find an explanation for the high rates of cost reduction, Colpier and Cornland expanded the classic theory by taking into account strategic pricing behavior. They hypothesized that a strategically pricing firm sells at prices lower than marginal cost during the development phase of a product. The firm develops into a market leader, reduces its own marginal cost with increased experience and can sell under a "price umbrella," that is, at prices higher than marginal cost and constant until competitors have caught up. In the subsequent "shake-out phase," prices will drop sharply and approach marginal cost. The authors claimed that this phenomenon has been observed for many different technologies. Their analysis indicated that the prices for CCGT technology have been dropping in a way that looks like a margin shake-out rather than the less drastic decrease of unit construction cost through experience and economies of scale. This could be supported by the fact that the CCGT market is dominated by only four manufacturers and their licensees. The authors concluded that the decline of the specific investment prices is likely to level off in the future.

More generally, pricing behavior is linked not only to the developmental stages of a technology but also to the rate of deployment and the rate of technological change, both of which affect the rate of learning and of cost reduction in different ways.

5.4 Gas Infrastructure

Zhao investigated historical cost development of gas pipelines. She ignored O&M costs and focused on the construction cost per cubic meter of pipeline capacity. In the United States, these costs increased and decreased twice between 1985 and 1998. Zhao observed no learning effects in onshore pipeline construction and found no significant cost reductions or progress ratios. For offshore pipeline installation, she measured cost in U.S. dollars per cubic meter of pipeline volume and days required to lay 1 km of pipeline. Her data, in fact, indicated that costs go down, although no statistical significance could be achieved. She concluded that because pipeline construction is not a replicative process, learning effects are probably small. Economies of scale can be achieved (e.g., through increased capacities, i.e., pipe diameter), although it is unclear how she derived these results. Experience curves seem to be an inappropriate tool for the analysis of the cost of gas infrastructure.

6. CONCEPTUAL MODIFICATIONS

Quantitative estimates for experience curves should be used with caution because the theoretical foundation, as well as the empirical support, is rather weak. Nevertheless, the occurrence of cost reduction with increasing diffusion and market penetration of a technology is undisputed. To get better estimates for the velocity of cost reduction, more research is under way.

One school of modifications amends the factors that are ignored by the traditional formulations by a simple addition of the logarithm of cumulative expenses for research and development (R&D) in Eq. (2). This formulation implies that cumulative R&D expenses are a perfect substitute for commercial investments in the technology after its innovation

in their effect on cost reduction. Attempts to estimate this specification have not resulted in satisfactory results, due mainly to the statistical and conceptual problems discussed previously.

Other studies have tried to decompose the cost reduction effect into its components, as explained in section II. Here, too, the statistical problems of serially correlated and integrated regression residuals and unit roots have not been solved. However, future research into such multivariate approaches is necessary and promising.

In this respect, it is also useful to work on temporal analyses of economic cost functions. Isoard and Soriat took a first step in this direction when they combined cost functions and learning curves to capture the simultaneous econometric estimation of learning by doing and returns to scale, endogenizing technical progress. A test for Granger causality establishes the causal relationship between deployment and cost reduction.

Other extensions are possible and should be explored. In theory, experience curves can be conceived for aspects other than energy unit costs. Other parameters that improve with cumulative deployment through continuous changes in the average technological design could be the efficiency of energy conversion or the emissions of pollutants from a conversion process. For these, too, the average improvement over time could be modeled with exponential decay functions. Linking these results back to the unit cost can give additional insights into the nature of cost reduction processes.

For future research, it is important to strengthen the foundation of the concept. One such avenue is linking the concept to the life cycle analysis of technologies. The life cycle of a technology starts with the invention of a new technological concept. The concept is simulated and prototyped before the actual innovation. The innovation itself consists of the first commercial application of the technology. For energy technologies, this often happens in niche markets (e.g., aeronautics). The innovation is followed by a diffusion phase, when the market penetration of the technology increases, often along a similar (logistic) path as followed by the sinking cost of the technology. The forces effecting such a diffusion pattern can theoretically be subdivided into supply–push and demand–pull forces. Therefore, market forces and the economic environment should be included in deriving a better founded concept for the cost reduction of new energy technologies.

Glossary

British thermal unit (btu) The average amount of energy per degree Fahrenheit needed to raise the temperature of 1 pint of water from freezing to boiling at sea level, which is equal to the energy needed to raise the temperature by 1°F, from 60° to 61°.

common property It has exclusions on use and allocation of a benefit stream determined collectively by community agreement or through government.

e-folding time This is for exponential decay what doubling time is for exponential growth. Suppose that a stock can be described over time by exponential decay to zero. At initial time, the amount is X_0 and over time the amount is given by $X_t = X_0 \exp(-rt)$. The time derivative is given by $dX/dt = -rX_t$. At $t = 1/r$, $X_t = X_0/e$, where e is the exponential number, approximately 2.71828. The ratio $1/e$ equals approximately 37%, so the e-folding time is the time at which the stock declines by 63% of the original value X_0. For an annual decay rate, for example, if $r = 2\%$, the e-folding time is 50 years.

NO_x Oxides of nitrogen, such as nitrogen dioxide (NO_2) or nitrogen monoxide (NO).

private property This has exclusions on use and enjoyment of a stream of benefits that are determined by a private owner or owner's agent.

public goods or bads These are not depletable by use and not excludable.

Vickery auction named after Noble Laureate William Vickery, this refers to an auction designed to avoid strategic bidding and to encourage small incremental bids that reveal the marginal cost curves of the bidders. The total amount is specified in advance. Each bidder may submit multiple bids for incremental amounts, and the lowest bids are accepted up to the point at which the total amount is reached. All winning bidders are paid the same price, not the amount they bid, equal to the lowest of all the losing bids.

willingness to accept (WTA) A schedule of prices and quantities that gives the minimum amount a consumer would accept in exchange for giving up an additional unit, as a function of the number of units the consumer holds.

willingness to pay (WTP) A schedule of prices and quantities that gives the maximum amount a consumer would pay in exchange for obtaining an additional unit, as a function of the number of units the consumer holds.

The external costs of energy are the costs not reflected in the market price, well over 100% for some energy sources. This large divergence between the social cost of energy and the price occurs because of environmental externalities associated with conventional energy sources and national security subsidies for imported oil and for nuclear power. As we shift to imported energy supplies, the remaining investment in domestic energy supply—extraction, transportation, and transformation—is 8% of all investment in the U.S. economy (measured by fixed assets in 2001). Whether domestic or international, many of these energy investments (power plants, pipelines, refineries, and oil and coal extraction) last for 50 years or more. Market prices that omit externalities are encouraging consumption of fossil fuels, investments in military preparedness, international investments in fossil fuel supply, and domestic investments in low-fuel-economy vehicles. At the same time, the same market prices discourage investment in alternative energy technologies, discourage investment in high-fuel-economy vehicles and vehicles that use alternative fuels, and discourage investment in energy efficiency. External costs of energy provide incentives for long-term investments resulting in gross and lasting economic inefficiency.

External costs occur at each stage, from exploration to production, transportation, conversion, consumption, and waste disposal. National security

external costs accrue to oil because of national defense expenditures to secure oil that are paid by general taxes rather than taxes on oil imports. National security risks from the use of nuclear power range from the risk of attacks on power plants to attacks on waste transport and storage and the spread of nuclear technology and material. External costs of fossil fuels result from pollution through environmental media—soil, oceans, freshwater, the troposphere, and the stratosphere. Damage occurs to human health, there is a reduction of ecosystem services to the economy, and there is loss of the intrinsic value of nature. Economic theory helps to focus on marginal (rather than total) external costs and to separate external costs from costs that have been internalized through the market or regulation. Economic theory faces formidable challenges due to joint pollutants, nondepletable catalytic pollutants, and nonconvex, subtle, cascading effects among physical, biological, and social systems. Overly narrow applications of economic theory, particularly marginal benefits and marginal costs of externality abatement, are harmful to the formulation of well-designed policy options. The limits of the economic theory of externalities justify policies, such as the Clean Air Act, that do not require a balancing of marginal benefits and cost to set ambient air quality standards. The challenge is to design, implement, and improve policies that address unintended, harmful effects of energy development, production, and consumption.

1. ECONOMIC THEORY OF EXTERNALITIES

Economic efficiency is defined as occurring when it is not possible to make someone better off without making others worse off, which occurs when the marginal social benefit of consumption equals the marginal social cost of production. In theory, with a specific definition of "perfect competition," markets achieve economic efficiency. Some of the assumptions are the absence of market power, markets that provide costless and accurate information, rational behavior narrowly defined, the absence of public goods (or public bads), and the absence of externalities. Externalities occur whenever decisions of economic agents cause incidental costs or benefits borne by others that are not reflected in market prices. In particular, external costs drive a wedge between social and private marginal benefits and costs (Fig. 1).

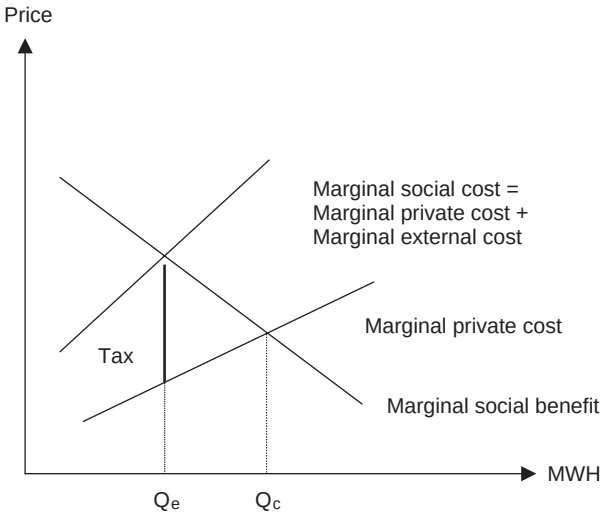

FIGURE 1 Marginal social benefit and cost.

If accurate information were costless, markets would be unnecessary. Markets provide imperfect information at a cost. All markets, whether for pollution credits, future prices of wholesale natural gas or electricity, or commodities sold to consumers, require government regulation to establish and enforce property rights. Property rights specify the right to pollute or, conversely, the right to a clean environment. Both markets and government enforcement of property rights that regulate markets are costly. Broadly, the idea of economic efficiency can inclusively consider the costs of markets and their regulation, including the costs of providing public goods and regulating externalities. In this sense, economic efficiency is the criterion most economists favor to evaluate policy changes. Although there is reason to be sympathetic toward the criterion of economic efficiency, the fundamental assumptions of economic efficiency are inconsistent with most applications to energy externalities. Finally, the criterion of economic efficiency is not adequate to assess strategies to reduce macroeconomic risks or technology forcing policies designed to alter the course of technological change.

1.1 Pigouvian Tax on Output versus Pollution Tax

The earliest analysis of externalities focused on external costs of production, for example, megawatt-hours (MWH) of electricity, where the marginal external costs are added to the marginal private costs to obtain the marginal social costs (Fig. 1). The amount consumed and produced by a competitive

market equals Q_c, and the economically efficient amount is Q_e. In order to achieve economic efficiency, government imposes a tax on output equal to the external cost at Q_e. This approach erroneously assumes that the externality is produced in fixed proportions so that, for example, a tax to account for NO_x emissions from a natural gas-fired power plant would also be applied—in error—to a solar thermal power plant.

Modern environmental economics poses the externality problem in terms of the marginal benefit and cost of externality reduction (Fig. 2). The marginal cost of reducing NO_x is given by listing all methods of pollution abatement in ascending order of incremental cost. The marginal cost is negative until the curve crosses the abscissa at N_f because investments in electricity conservation per megawatt-hour are cheaper than the incremental cost of building and operating new power plants. N_f is the level of air pollution abatement that is actually a free lunch. The marginal benefit of externality abatement depends on the property right—whether the polluter has the right or the public trust establishes a right to a level of a clean environment. The marginal benefit is given either by the damaged party's willingness to pay (WTP) for abatement or the damaged party's willingness to accept (WTA) payment in exchange for enduring the damage (Fig. 2).

The WTA is greater than the WTP due to an income effect and a substitution effect. If the polluter holds the right, the damaged party's budget constraint limits the WTP, but if the right is held by the public there is no budget constraint on the WTA; this is the income effect. The substitution effect can be understood using the example of air pollution; there are no close substitutes for cleaner air, so the WTA is much larger than the WTP. If the correct marginal benefit curve is WTP, then the optimal amount of abatement equals N_P and the optimal pollution tax equals T_P. If the correct marginal benefit curve is WTA, then the optimal amount is larger, equal to N_A, and the tax equals T_A. There is no unique solution.

Both the WTA and the WTP curves emanate from the point N_c in Fig. 2. The maximum possible reduction in NO_x emissions is equal to the total emitted so that N_c corresponds to zero emissions to the environment. Consequently, whatever the property right, the social demand for externality abatement reaches the abscissa at the point of abatement where the negative externality is zero. In order to simplify the figures and discussion that follow, a single marginal benefit curve (MB) replaces the WTA and WTP curves.

1.2 Demand for Externality Abatement over Time

Demand for externality abatement shifts from MB_1 to MB_2 to MB_3 in Fig. 3 for two reasons—public goods and concentration of the externality. Public goods, such as increased national security or air pollution abatement, have one key property: They are nondepletable in consumption. The social demand for nondepletable goods is found by vertically adding individual demand, in contrast to

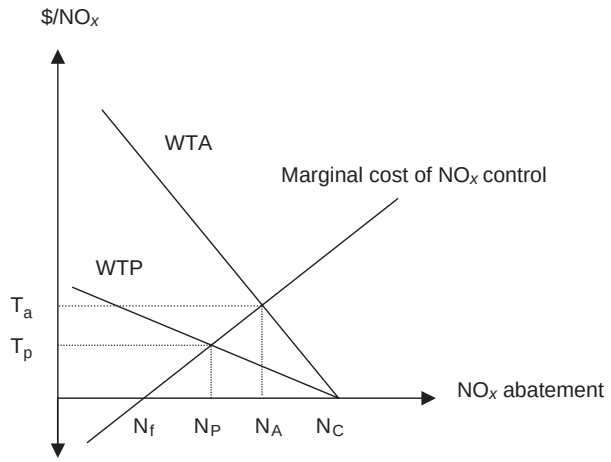

FIGURE 2 Marginal benefit and cost of externality reduction.

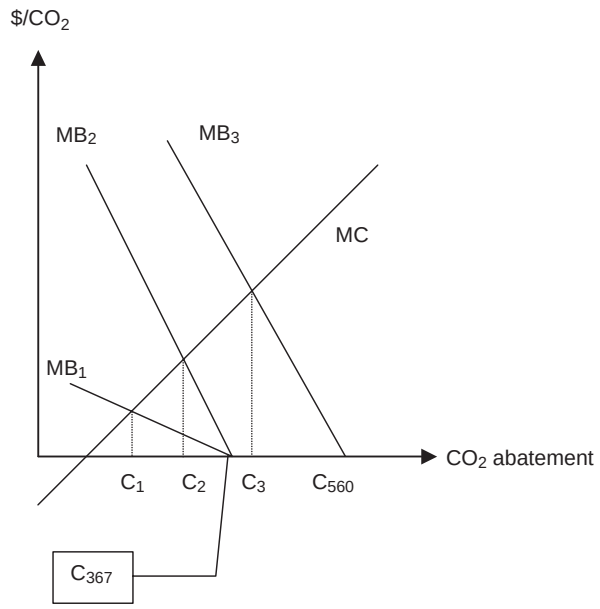

FIGURE 3 Optimal abatement over time.

the horizontal addition for private goods. Consequently, as population grows over time, the demand for externality abatement shifts from MB_1 to MB_2, holding pollution concentration constant.

An important air pollutant from fossil fuels is CO_2. CO_2 emissions have increased the ambient concentration of CO_2 since the industrial revolution. The ambient concentration was approximately 280 parts per million (ppm) in the late 1800s, and increased to 367 ppm by 1999. In the next 50 to 60 years, CO_2 concentration is forecast to reach 560 ppm, doubling the concentration since the preindustrial revolution. Within 200 to 400 years the concentration will increase 4 to 10 times unless we significantly abate emissions and sequester carbon from the atmosphere. In Fig. 3, let C_{367} represent the abatement necessary to return to 280 ppm in year 1999. Over time, the intersection of the demand for abatement and the abscissa will shift to the right, from C_{367} to C_{560} by the year 2055, resulting in the marginal benefit curve MB_3.

Over time, due to the public good nature of CO_2 abatement and population growth, and the growing concentration of the externality, the optimal externality abatement will increase from C_1 to C_2 to C_3.

1.3 Regulation, Internalization, and Incremental Change

Regulation internalizes the negative externality from pollution. For example, the local air pollution regulatory authority in the Los Angeles area established a set of stationary-source air pollution regulations requiring controls for power plants and oil refineries, among other pollution sources, to reduce particulates and precursors to ozone. The pollution control cost of electricity and refined petroleum products in southern California is reflected in the prices of these products. In 1990, the air basin was significantly out of compliance with the federal ambient air pollution standards—a point such as O_{1990} in Fig. 4. The federal standards for ozone, 0.12 ppm, exceed the state standards, 0.08 ppm, shown as $O_{0.12}$ and $O_{0.08}$, respectively. If the situation is correctly depicted in Fig. 4, the marginal benefit of abatement, B_{1990}, is greater than the marginal cost of abatement, C_{1990}, and additional abatement is efficient.

It is not possible, however, to estimate the marginal benefit curve for reasons discussed later. In the peer-reviewed literature, a team of economists, chemists, airshed modelers, and health experts estimated the incremental benefit to the Los Angeles region of attaining the federal standards for both ozone and particulate simultaneously. The estimate of incremental benefit equals approximately \$10 billion for federal attainment and \$12 billion (1990 \$) for state attainment, so the incremental benefit of moving from the federal to state standards was \$2 billion. If ozone and particulate were a single, homogeneous pollutant, and pollution abatement benefits were convex and met other technical assumptions in economic analysis, the incremental benefit of \$2 billion could be shown as the area under the marginal benefit curve in Fig. 4. Unfortunately, the standard economic theory of externalities shown in Fig. 4 is incorrect.

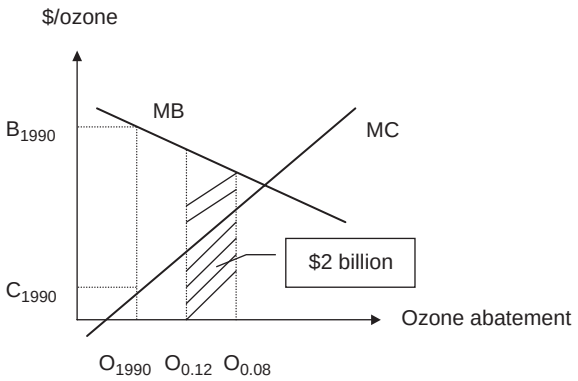

FIGURE 4 Partially internalized by regulation.

1.4 Joint Pollutants, Nonconvexities, and Nondepletable Catalytic Pollutants

Chemical reactions do not follow the assumptions of economic models. Ozone (smog) is created by the reaction of hydrocarbons and NO_x. Unburned hydrocarbons are released when we produce, process, and consume petroleum to get energy. Nitrogen, approximately 78% of the atmosphere, is stable at low temperatures, but fossil fuel consumption releases heat that creates NO_x. The ozone isopleths in Fig. 5A, similar to isoquants, give the combinations of reactive organic gases (ROGs) and NO_x that create a given amount of ozone. Because the isopleths include regions with positive slopes, in these regions decreases in NO_x actually increase the amount of ozone, holding ROGs constant, as shown by the arrow in Fig. 5A. The marginal benefit of NO_x abatement first rises and then falls, as shown in Fig. 5B, which is an example of nonconvexity.

Optimal abatement does not occur where the curves cross in Fig. 5B. First, if area A is less than B, it is better to do nothing (*ceteris paribus*). Second, emission control options typically reduce both NO_x and ROGs (*mutatis mutandis*), shifting the marginal

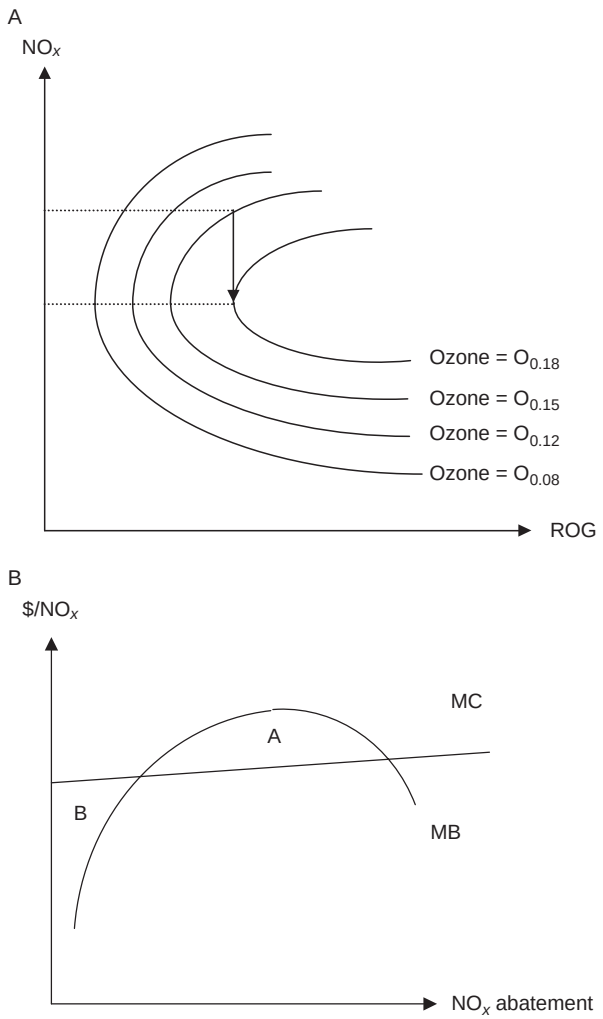

FIGURE 5 (A) Ozone isopleths. (B) Marginal benefit curve (MB) derived from isopleths.

benefit curve. Third, nitrate compounds from the nitrogen oxides are particulates with an aerodynamic diameter $<10\,\mu m$, small enough to slip through the nasal barriers and lodge into the lungs. The human body's immune system reacts in ways that cause irritation and exacerbate respiratory disease. Consequently, NO_x causes damage directly as well as indirectly through ozone. Since NO_x acts as a catalyst in the formation of ozone, the same molecule can later contribute to particulate. The analogy in economic theory is a public "bad", which is nondepletable in use. Hence, the marginal benefit of abatement is found by adding the demand for particulate abatement vertically to the demand for NO_x abatement derived from the demand for ozone abatement. These complexities render obsolete the economic theory of externalities for application to energy from fossil fuel.

1.5 Nonconvex, Subtle, Cascading Effects among Physical, Biological, and Social Systems

Consider the policy of planting shade trees and painting surfaces white to lower the urban heat island effect, reducing the demand for air-conditioning to conserve electricity. Electric utilities change the dispatch order, altering the amount of electricity generated from power plants within and outside the urban airshed. The location of power plants and the emission control equipment determine the change in emissions of ROGs and nitrogen oxides, each of which separately causes damage to human health and the environment, that together form ozone in the presence of sunlight and an inversion layer. Surface roughness, affected by planting trees, alters mixing and transport within the airshed. Different types of trees have different emissions of ROGs, further adding to the complexity of impacts. Financial impacts include the dollar values of fuel, pollution credits, electric system reliability and associated timing of power plant investments, tree maintenance, and painting, in addition to the external costs of changes in emissions of greenhouse gases and carbon sequestration. This level of complexity further renders useless the modern economic analysis of externalities depicted in marginal benefit and marginal cost curves for abatement.

1.6 Measuring Policy Options: Partial vs General Equilibrium

The portrayal of economic efficiency in Figs. 2–4 is based on partial equilibrium analysis. General equilibrium analysis models the interrelationships among markets, for example, accounting for impacts of changes in the price of oil that shift the demand for natural gas, shift the demand for vehicles, and shift the supply of transportation services, all of which in turn have effects that ripple throughout the economy.

Petroleum is a minor energy source in the residential and commercial sectors in the United States. Petroleum supplies 24% of the industrial sector, with ample room for substitutes, but petroleum supplies 97% of the transportation sector. Fuel cell technology is close to commercial viability and could be developed as a substitute for petroleum for transportation. Fuel cells would also substantially reduce urban air pollution. A policy to require that a fraction of sales be ultra-low-emission vehicles would speed the development of the infrastructure needed to commercialize fuel cells. A partial equilibrium analysis would deem a successful policy as a failure.

Whether based on hydrogen or natural gas-derived methanol, suppose a successful fuel cell program in 2002 results in transportation costs comparable to the price at that time—$30 per barrel of oil. Falling oil consumption would likely result in the collapse, or at least the diminishment, of the OPEC cartel market power. The resulting decline in oil prices could easily reach less than $10 per barrel, placing the fuel cells program politically at risk. Oil interests could commission partial equilibrium studies that show the fuel cells program to be an economic disaster at $30 per barrel, when in fact oil is at $10. Of course, the correct counterfactual for evaluating the fuel cells program would hypothesize oil prices in the context of a transportation sector without a substitute, requiring a computable general equilibrium (CGE) model with a cartel sector.

CGE models are routinely applied to environmental regulations to gauge the economic cost of policies to abate pollution. However, CGE models have not been modified to measure lost productivity from mortality, and ill-health effects of pollution causing worker absences or impairing human development, nor have they been modified so that increased medical expenses are measured as counterproductive rather than as adding to economic activity. Of course, the correct counterfactual for evaluating pollution abatement policy would correct CGE models to account for harm to human health, damage to agriculture and fisheries and forests, damage to vehicles and structures such as buildings and bridges, recreational losses, public good losses measured by contingent valuation studies, and so on.

2. CATEGORIES OF EXTERNALITIES: NATIONAL SECURITY AND POLLUTION

Although national security and pollution are the two most important negative externalities from energy production and consumption, neither should be estimated in isolation from the other. Most energy policies affect both national security and pollution.

2.1 Oil and National Security

Of the 68 million barrels of oil produced per day (mbd) in 2000, 30% were from the three top producers: Saudi Arabia (8.4 mbd), Russia (6.5 mbd), and the United States (5.8 mbd). This is changing because Iran, Iraq, Kuwait, Qatar, Saudi Arabia, and the United Arab Emirates hold 65% of the world's proven reserves, whereas the United States holds 2%. The United States consumes 19.7 mbd while producing 5.8 mbd, on net importing 70%. Of the total petroleum used in the United States, transportation use equals 68%. The transportation sector has virtually no substitutes for petroleum, which supplies 97% of all energy in that sector.

If externality abatement is subsidized through general taxes, the marginal cost of abatement is not necessarily equal to the optimal tax on the externality. As shown in Fig. 4, optimal policy design requires knowledge of both the demand for externality abatement and the cost of abatement. At the federal standard for ozone of 0.12 ppm, Fig. 4 depicts a marginal cost of abatement less than the marginal benefit. Another example is the national security costs of importing oil.

Broadman and Hogan identify three parts of an optimal oil import tariff: high oil prices that reflect monopsony power, adverse macroeconomic effects of higher oil prices on terms of trade, and the adverse impact of oil price shocks. Because the United States consumes 25% of world oil, the price depends on the amount consumed (monopsony power). The U.S. macroeconomy does not perform as well when oil prices are high, changing the terms of trade and requiring greater exports for the same amount of imports. The adverse impacts of oil price shocks are the basis of a 'security tariff' that can be calculated as the expected loss, equal to the product of the probability of an oil price shock from disruption of supplies multiplied by the negative impact of an oil price shock. The negative impact of an oil price shock can be estimated from the magnitudes experienced since 1970. The security tariff is interpreted as the willingness to pay for military protection of oil supplies, estimated in 1985 dollars to be equal to $7.00 per barrel (conditioned on the price of oil at $15/bbl). The axes in Fig. 2 could be relabeled so that the ordinate is in dollars per barrel and the abscissa is reduction in national security; thus, point N_C is complete security. Then the optimal tax, T_P, is $7.00 per barrel in 1985 dollars. The marginal cost curve in Fig. 2 would be the cost of additional security, including the cost of additional military preparedness and the cost of the strategic petroleum reserve.

Prior to the invasion of Kuwait by Iraq, the defense expenditures per barrel of imported oil plus the cost of the strategic petroleum reserve (SPR) were approximately $8.50 to $9.00 (in 1985 dollars) per barrel. I calculated the lost interest from storing oil, equal to the interest that would have accrued by investing the

amount of money paid for the oil that was stored in the SPR; in 1985 $ the lost interest equals $1.15 per barrel of imported oil, and there is an additional $0.60 per barrel for the increase in the size of the optimal reserve from its inception to the mid-1980s. I also performed a time series analysis of defense spending and oil imports during the period from 1968 to 1989. After removing time trends and random walks, the data reveal a correlation between defense spending in each year to oil imports lagged two years, where one year of the lag accounts for the time delay between publication of oil import data and Congressional appropriations, and the second year of the lag accounts for the delay between appropriations and actual budget years. The result is an econometric estimate equal to $7.30 of defense spending per barrel of imported oil in 1985 dollars. Consequently, the marginal benefit calculated by Broadman and Hogan is close to the marginal cost I calculated, and one may conclude that in the 1980s the United States provisioned close to the optimal amount of national security related to importing oil. The price of oil did and does not include the national security cost, as it was and still is paid through general taxes rather than a tax on oil imports, and this national security subsidy for oil has the unfortunate consequence of economic inefficiency.

Certainly, the national security cost of oil imports is higher today. Macroeconomic effects of oil price shocks include less productivity, greater unemployment, and an increase in general inflation. Some oil revenue flows to terrorists and states acquiring weapons of mass destruction. Recessions have reverberating impacts on presidential elections. Presidents Carter and George H. W. Bush and Vice President Gore lost reelection following oil price spikes. In all three cases, the Federal Reserve Board responded to general inflation caused by oil price spikes by increasing the discount rate. Whether the recessions were caused directly by the oil price spikes or indirectly by the misdirected response of the Federal Reserve Board, the effect is the same: a recession during a presidential election.

2.2 Nuclear Power and National Security

Three types of terrorism are plausible. First, nuclear power plants and research reactors in the United States are potential targets for terrorists determined to release radioactivity. Second, increased trade in nuclear fuel and waste products provides more opportunities for sophisticated or government-sponsored terrorists to obtain the materials for a nuclear device. Third, dispersion of radioactive material throughout a city requires little sophistication and may not cause a large amount of much human and physical damage but would have a substantial psychological impact.

2.2.1 Attacks on Nuclear Power Plants

Attacks from the inside and outside are technically feasible, and the risk is growing. For example, Iran threatened on Tehran radio, "U.S. centers and nuclear reactors can be more vulnerable than the missile bases of the Islamic Republic of Iran." Approximately one-half of terrorism incidents occur in the Middle East, followed by Europe and Latin America, particularly Colombia (drug related) and Peru (the Marxist Sendero Luminoso). A substantial portion of international terrorist attacks are on U.S. interests. More than 300 metric tons of plutonium is generated annually, 45 of which is separated and suitable for weapons. In comparison, 6 kg of plutonium was used in the bomb dropped on Nagasaki. Plutonium separated from spent fuel is shipped to waste disposal sites. Some of this transport occurs on commercial airlines and by truck, train, and ship.

2.2.2 Diverting Nuclear Material: Nuclear and Dirty Bombs

Nuclear material is a threat if used to make a nuclear bomb or if spread by a conventional bomb. Nuclear bombs can be made from plutonium or highly enriched uranium. Plutonium is produced in plants that reprocess waste from conventional reactors. Natural uranium contains approximately 0.7% of the fissile isotope U-235. Conventional reactors use uranium slightly enriched to approximately 5% U-235. Low-enriched (to 20%) U-235 is used in research reactors. Highly enriched U-235 is a category higher than 20%, and weapons-grade U-235 is enriched to 90%.

India and Pakistan both produce enriched uranium; India also produces plutonium. These countries and others publicly embarked on programs to produce nuclear power, transferred the technology, and developed parallel programs to develop nuclear weapons. North Korea and Iran are openly pursuing this path.

2.2.3 Diverting Nuclear Waste: Poisoning Cities

Nuclear waste from breeder reactors includes plutonium-239, which is extremely toxic in minute quantities and has a half-life of 24,400 years. Low-level nuclear waste from conventional nuclear power plants includes cesium-137 and strontium-190, which

are less toxic and have half-lives of approximately 30 years. Twenty half-lives is equivalent to 600 years, the time during which the waste poses a risk.

Unsophisticated terrorists, willing to accept exposure and death, could use nuclear waste to poison a city. The level of health risk from low-level waste may not be as great as that from an attack on a nuclear plant or from a bomb. However, the terror of exposure to nuclear radiation, no matter how low the dose, would still be considerable.

2.3 Pollution

Pollution occurs at every link in the chain from production to consumption: exploration, extraction, transportation, conversion, processing, consumption, and disposal. Pollution travels through environmental media, including tropospheric and stratospheric air pollution, surface and ground freshwater pollution, ocean pollution, and soil pollution. Damages vary across energy sources and uses, including human mortality and morbidity, reduction of ecosystem services to the economy, immiserization of the human spirit, and diminution of the intrinsic value of nature.

The objective of estimating the benefits of lower emissions is to determine, in economic terms, what damage society avoids by selecting one set of policy options over others. To determine this, the potential damages of emissions must be calculated. This involves the following:

1. Estimate the changes in emissions for all pollutants affected by policy changes.
2. Estimate the changes in ambient pollutant concentrations in all relevant environmental media predicted to result from changes in emissions.
3. Estimate the pollution transformation and transport to target.
4. Establish the exposure–dose/response relationships between ambient changes and health effects and impacts on horticulture, visibility, buildings/structures, etc. For human mortality and morbidity, this requires the additional intervening step of estimating changes in exposure and dose in the damaged population that would result from changes in ambient concentrations, where dose depends on body size, age, activity, and location affecting intake and internal concentration.
5. Calculate the level of effects projected.
6. Attach dollar values to the estimated effects.
7. Attribute dollar values to the pollutants that caused the damages or to the policy changes that reduced the damages.

There are various methods for accomplishing each of these steps, but each must be completed to calculate the economic value of a policy change. Each step represents a complex calculation that often violates economic assumptions, such as differentiability and convexity. All of the links in this chain present challenges and pose obstacles to consensus, as the following examples of urban air pollution and global warming illustrate.

2.3.1 Estimating Reductions in Emissions from Policies

Step 1 requires an inventory of all the types of pollutants affected by the policy options and the appropriate counterfactual with which to compare the policy. An example is regional air pollution caused by electricity generation. A seemingly straightforward policy is to hold a Vickery auction for renewable electricity generation of a certain number of megawatts, such as the auction held by the California Public Utilities Commission in 1994 (and rescinded the following year on the grounds that deregulation was impending and markets would best decide how much and what type of additional capacity to build). An electricity dispatch model is needed to calculate the change in emissions.

Power plants are typically dispatched in increasing order of short-run marginal cost until the system demand is met. As demand changes from off-peak to peak periods, the least expensive of the remaining plants is dispatched to meet load, subject to technical constraints, spinning reserve requirements to meet fluctuations in load, and a reserve margin to cover maintenance outage and unscheduled outages. Some plants cannot be shut down during the weekend and some have a minimum operating level. Some are slow-start plants and others are quick-start plants. Technical constraints determine the type of load each can serve.

The addition of power plants to a system alters all of the previous calculations. By accounting for the location of the units, one can calculate emissions for each airshed. The calculation of emissions is a direct function of the calculated dispatch order. Consequently, the emission estimates depend on the reordering of dispatch due to a change in the combination of power plants.

2.3.2 *Estimating Changes in Pollution Concentration*

Step 2 requires the application of a model to project how emission changes will alter ambient pollution concentration. This really has two parts; the baseline pollution concentration is forecast in the absence of the policy, and the altered pollution concentration is forecast conditional on the change in emissions. Fig. 6 provides an example of a baseline forecast of ambient CO_2, showing historical levels during the past 600 million years and projecting what could happen during the next 400 years based on consumption of economically available fossil fuels.

The Intergovernmental Panel on Climate Change uses 120 years as the e-folding time atmospheric residence for a pulse increase of CO_2 sufficient for $RCO_2 = 2$. RCO_2 is the ratio of CO_2 to the ambient concentration prior to the industrial revolution in the late 1800s. The e-folding time is the number of years at which the biosphere and ocean removes 63% of the increase from pre-industrial levels; so that if CO_2 were to instantaneously double and no additional emissions occurred, after 120 years ambient CO_2 concentrations would still be 37% higher. For increases greater than $RCO_2 = 2$, the e-folding time increases dramatically. Carbon uptake by plants is limited because biological material decays, releasing carbon. For example, at the Triassic–Jurassic boundary approximately 200 million years ago, CO_2 was so high that climate effects led to the disappearance of most species. Almost all models used by economists make the assumption of linearity, seriously underestimating ambient concentrations for a tripling ($RCO_2 = 3$) or more. At three times preindustrial concentrations, the e-folding time would be between 380 and 700 years. To model the atmosphere beyond a doubling of CO_2, the models used by economists are misspecified. For a tripling ($RCO_2 = 3$) or larger, the natural science literature assumes that 50% of the emissions remain in the atmosphere, as presented in three alternative baseline forecasts in Fig. 6B.

Three economic models, combined with the previously discussed assumption, predict baseline RCO_2 increasing to 9, 11, and 16. To get a sense of the scale involved, Fig. 6A shows atmospheric concentrations measured in RCO_2 during the past 600 million years. The macro models forecast that economic forces will cause, within the next 325–350 years, the atmosphere to revert to an era never experienced by most plants and animals living today—levels not experienced by Earth at any time during the past 375 million years.

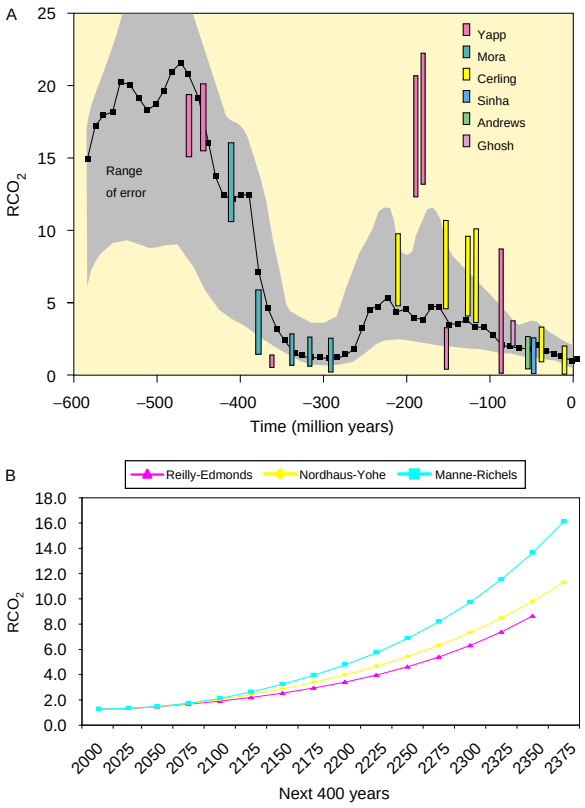

FIGURE 6 (A) Past atmospheric CO_2. Atmospheric CO_2 versus time for the Phanerozoic (past 550 million years). The parameter RCO_2 is defined as the ratio of the mass of CO_2 in the atmosphere at some time in the past to that at present (with a preindustrial value of 300 parts per million). The heavier line joining small squares represents the best estimate from GEOCARB II modeling, updated to have the effect of land plants on weathering introduced 380–350 million years ago. The shaded area represents the approximate range of error of the modeling based on sensitivity analysis. Vertical bars represent independent estimates of CO_2 levels based on the study of paleosols. Reprinted with permission from Berner, R. A. (1997). The rise of plants and their effect on weathering and atmospheric CO_2. *Science* **276**(25), 544–546. Copyright American Association for the Advancement of Science. (B) Baseline forecasts of RCO_2. The rate of emissions over time is based on three macroeconomic models that link forecasts of future economic activity with the potential use of fossil fuels. In descending order of the growth rate for CO_2 emissions, the macro models are labeled MR, NY, and RE. MR refers to Manne, A., and Richels, R. (1990). *Energy J.* **11**(2), 51–74. NY refers to Nordhaus, W., and Yohe, G. (1983). *In* "Changing Climate," pp. 87–153. National Research Council, National Academy Press, Washington, DC. RE refers to Reilly, J., Edmonds, J., Gardner, R., and Brenkert, A. (1987). *Energy J.* **8**(3), 1–29. Accounting for all fossil fuels, the economically available fossil fuels vary between 8 and 17 metric teratons. The MR forecast assumes 17 metric teratons, NY assumes 12, and RE assumes 8. Reproduced with permission from Hall, D. C. (2001). *In* "The Long-Term Economics of Climate Change: Beyond a Doubling of Greenhouse Gas Concentrations" (D. C. Hall and R. B. Howarth, Eds.). Elsevier, Amsterdam.

2.3.3 Estimating Pollution Transformation and Transport

To continue the example of global warming, ultraviolet sunlight passes through CO_2, warming the earth's surface. Infrared heat radiates back into the atmosphere, warming greenhouse gases (GHGs) such as CO_2 and radiating back to the earth (the greenhouse effect). As the concentration of GHGs rises, so does the mean global temperature. Coupled general circulation models of the atmosphere and oceans project increases in temperature and changes in rainfall frequency and intensity as GHGs rise.

Natural scientists expect the ambient concentration of GHGs to double within the next 100 years (most likely by 2060). Natural scientists use a doubling as a convenience in the thought experiment: If concentrations double, what will be the impact on global average temperature? The answer, from coupled general circulation models (GCMs), is 1.5–4.5°C. For easier cross-discipline comparison, economists use the same benchmark, $RCO_2 = 2$.

If we confine the baseline forecast to a doubling of concentration, it may be reasonable to assume that Earth's systems return to equilibrium, as is done in one famous model (DICE, RICE, and derivatives). Most economists assume that the ocean captures a significant amount of heat, with an e-folding time of 500 years, so increases in deep ocean temperature decay back toward the preindustrial revolution level outside the time frame of any model. This specification is inconsistent with findings of ocean surface water temperatures. More problematic for analysis of $RCO_2 > 2$, the Atlantic Ocean thermohaline circulation may end, resulting in a new stable equilibrium for ocean and atmospheric circulation.

Figure 7 presents baseline forecasts of mean global temperature from a model that specifies an ocean thermal lag, where one-half of the radiative forcing is stored in the ocean for 50 years and then released. The three baseline forecasts show how global temperature forecasts depend on key assumptions regarding the sensitivity of the climate to increases in CO_2 and the amount of economically available fossil fuels. The ocean thermal lag is consistent with findings that from 1948 to 1998, the heat content of the top 3000 m of the oceans increased by 2×10^{23} J, corresponding to a warming rate of 0.3 w/m^2 or approximately one-half of the warming predicted by GCMs for the past century.

Based on a comparison among three GCMs, for a doubling of CO_2 equivalent gases, the models predict 12% greater warming for the United States than the global mean because the United States is at a high latitude. As the earth warms, the largest temperature changes will occur near the poles.

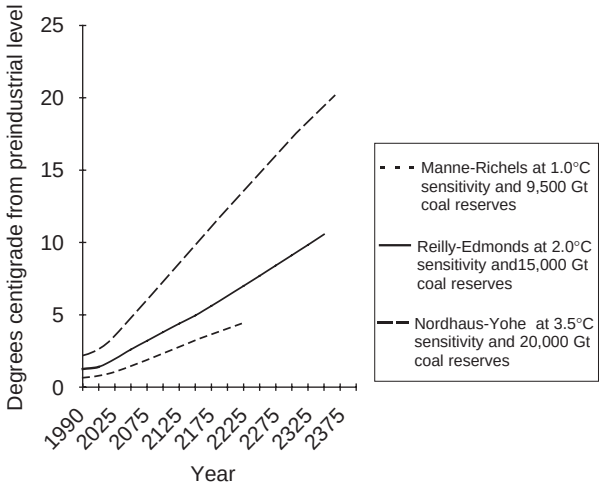

FIGURE 7 Mean global temperature increase.

2.3.4 Establishing Exposure–Dose/Response Relationships

Models of exposure–dose/effect relationships for air pollution are increasingly complex. Much of the past economics literature simply correlates air pollution concentrations with morbidity and mortality. One recent model calculates dose taking into account indoor, outdoor, and in-transit exposure; activity level that increases respiration; and body mass that changes with age. Exposure is measured in the REHEX model by time-weighted and location-specific ambient concentrations relative to indoor, in-transit, and outdoor activity for each age group and work status. Doses are integrated measures of pollutant intake. REHEX translates exposure into dose by accounting for activity and age. Dose is dependent on activity (e.g., work type) and age (children have higher metabolism and elderly people have lower metabolism).

Individual ill effects are identified in the health effects literature, with dose–response estimates that vary by age and health status. Effects range from eye irritation to hospitalization and death.

2.3.5 Calculating the Level of Effects

For some examples, such as climate change, the level of effects depends on the time frame for the analysis. Moderate climate change, based on a doubling of GHG concentrations, benefits midlatitude and upper latitude countries with milder weather; milder weather benefits agriculture, forestry, shipping, and transport; milder weather lowers heating bills and makes surroundings more conducive to human activity.

Damage to midlatitude countries includes more frequent and severe droughts and storms, hurricanes, cyclones, rapid snowmelt, and flooding; increased costs for water transport, storage, and flood control; migration of pests and increases in agricultural pest damage and control costs; migration, spread, and ill effects of disease and increases in health care costs; higher cooling bills; damage to coastal cities; reduced aquaculture yields; damage to coastal ecosystems and wetlands; and beach erosion. Damages to equatorial countries will be severe, including immersion of island nations and coastal properties, river delta flooding and damage to wetlands, damage to agriculture, loss of life, the destruction of coral reefs worldwide and the fisheries and tourism dependent on them, and severe droughts and floods.

Tripling or quadrupling of GHG concentrations would have severe consequences for the global economy, human health, and just about every aspect of human endeavor. Frozen deposits of methane in ocean sediments could thaw, instantaneously releasing massive amounts of GHGs into the atmosphere. There may be several global equilibria of GHG concentrations in the atmosphere and oceans. Tripling or quadrupling GHG concentrations could cause Earth's climate to shift to a new equilibrium and to never return to the climate of today. A tripling of GHG concentrations within 150 years is consistent with several models of economic activity and concomitant fossil fuel consumption. The range of uncertainty for a doubling of GHG concentration is between 1.5 and 4.5 degrees warming of mean global temperature, but we are ignorant of the range of temperature increase if GHG concentrations were to triple, quadruple or quintuple. We have modeled the range of temperature increase that would result would result in a shut-down of the Atlantic Ocean currents that keep the climate mild in northern Europe, but we are ignorant of the GHG concentration necessary to warm intermediate ocean water and release catastrophic quantities of methane to the atmosphere.

2.3.6 Attaching Dollar Values

Valuing the adverse effects associated with energy involves estimation of the value people place on avoiding the identified effects. Many of the effects are nonmarket goods, such as damage to human health and loss of life. Dollar values for nonmarket goods can be derived indirectly from hedonic studies or directly through surveys using contingent valuation methods or their derivatives. Hedonic studies use market data to obtain values such as differences in wages to measure wage premiums paid in exchange for higher risk jobs. From these studies, economists calculate the value of statistical life (VSL). Contingent valuation surveys ask respondents how much they are willing to pay to reduce risks or avoid ill effects.

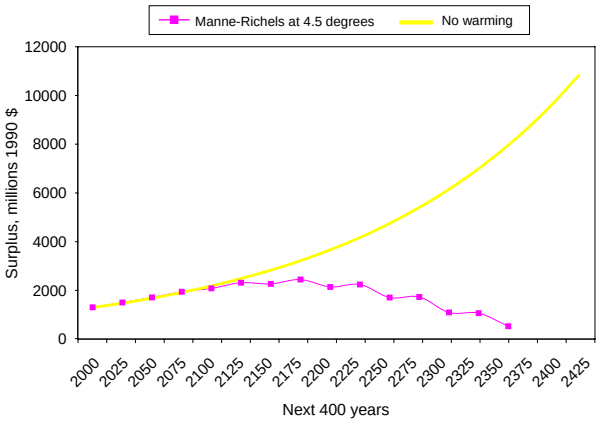

FIGURE 8 Agricultural surplus for wet climate.

VSL studies have recently been used to estimate the value of one life year. Assuming that the elderly are primarily at risk means that premature death from particulate matter (PM) is heavily discounted. When these biased estimates are corrected by including the risk of death to children, the estimated value of reducing particulates will increase, unless of course we use income stream over a lifetime and discount it. Then, the value of a child's life is much smaller than that of an adult at a prime earning age.

Valuation also requires the specification of a discount rate. With a rate greater than 3% (which is the minimum that many economists use), costs and benefits 100 years or more into the future are discounted to virtually zero in today's dollars and thus have virtually no impact on a benefit–cost calculation. For example, Fig. 8 shows an estimate of the time path of U.S. agricultural producer and consumer surplus in a scenario of climate change in which initially there are minor benefits from warming but ultimately agriculture in the United States collapses. With a discount rate of 5%, the present value of warming is greater than that of avoiding warming because the early minor benefits count more than the eventual collapse. If the discount rate is set to 1%, however, then economic valuation of the future years has significant weight to conclude in favor of avoiding collapse.

2.3.7 External Costs of Pollutants and Benefits of Policies

Step 6 requires knowledge of the precise relationships between ambient levels of all pollutants that

derive from the initial emissions and the ability to separate the contribution of each pollutant to ambient changes.

A study estimated the value of meeting federal ozone and PM10 standards in the South Coast Air Basin of California. For this purpose, steps 2–6 were completed. Step 1 was omitted because the question was what the benefits would be of meeting the standards, so the assumption was that emissions would be reduced enough to meet that objective. Step 7 was also omitted because there is no scientific or economic foundation for allocating inputs among joint products or for attributing products to nondepletable inputs. Another study based on the same methodology followed steps 2–5 for the purpose of projecting the pattern of exposure as emissions are reduced. These studies recognized the fundamental difficulties of evaluating a change in emissions relative to eventual damages, including the difficulties presented by the need to estimate air quality changes from emissions changes and to allocate damages back to emissions, and by the vast gap between what is known about the health effects of ozone and other pollutants and what can be quantified and valued in economic terms.

3. ESTIMATES OF EXTERNAL ENERGY COSTS

To understand the magnitude of negative external costs of energy, it is useful to aggregate and average over energy sources, comparing fossil fuels (coal, crude oil, and natural gas) with nuclear power, with solar power separately, and with solar power combined with natural gas to be operated as a baseload power plant. Aggregation in this sense can be easily misinterpreted as a set of estimated pollution taxes that would result in economic efficiency. This is not the case, as explained previously.

In Table I, the estimated externality values are in Year 2000 dollars, updated from previous studies using the implicit price deflator. The national security costs and carbon emissions can be directly attributable to specific energy sources. The national security costs of oil are the addition of national defense expenditures attributable to importing oil and the cost of the strategic petroleum reserve. Note that the national security cost of oil has not been updated to reflect events since 1990, so this estimate is low. The estimates for coal and nuclear power are specific to those energy sources. Numerous externalities have been omitted, particularly for coal, including water pollution, waste disposal, and wholesale destruction of ecosystems at mining sites. The air pollution damages from natural gas and oil, however, represent a sum total that has been attributed to the energy sources linearly, based on the proportions of specific air pollutants from each source.

Table I does not provide optimal taxes that will internalize the externalities. The economic theory of externalities, depicted in Fig. 1, shows a tax on output that coincides with the units of measurement in Table I, whereas Fig. 2 shows a tax on externalities that would have units of measurement in dollars per pollutant. Even if the values were reported in dollars per pollutant, such calculations are illustrative only because of nonconvexities (e.g., NO_x is a nondepletable catalytic pollutant that converts into both ozone and particulate) and the inability of models to capture subtle effects that cascade between natural and social systems.

TABLE I

External Costs from Pollution and National Security[a]

Energy source	Private cost market price 2000 $	External marginal cost					Social marginal cost
		Subsidies	Carbon emissions	Air pollution	Other externalities	National security	
Natural gas ($/mmbtu)	5.80	—	0.24	0.39	—	0	6.46
Crude oil ($/bbl)	29.50	—	1.92	14.88	—	12.70	59.20
Coal ($/ton)	31.70	—	9.05	17.98	—	0	58.73
Nuclear($/MWh)	6.75	1.80	0	0	1.80	0.12	8.68
Solar thermal ($/MWh)	9.51	0	0	0	—	0	9.51
Baseload solar and gas ($MWh)	5.80	0	0.14	0.22	—	0	6.16

[a] Source: Calculated from Hall (1990, 1992a,b) using the implicit price deflator for the Year 2000 relative to previous estimates.

Table I demonstrates that external costs of coal and oil are at least double the price; natural gas and nuclear power have much lower external costs than coal and oil; and the major problem with nuclear power is the private cost of building, maintaining, upgrading, and operating power plants and waste disposal. It is also clear from Table I that in the southwest United States thermal solar power with natural gas backup as a baseload unit has a lower social cost than nuclear power.

4. POLICY CHOICES

There are five aspects to good economic policy analysis. One is to consider all aspects of economic efficiency that policies affect. The second is to recognize when static economic efficiency arguments are not applicable due to misspecification of the alternatives, nonconvexities, nondepletable pollutants, uncertainty, timescale, and ignorance. The third is to incorporate the dynamic efficiency criterion in the context of state dependency of technology. The fourth is to consider policy strategies that increase flexibility and diversity to reduce macroeconomic risk. Finally, the fifth is to analyze wealth distribution effects of policies that determine political viability.

4.1 Evaluating All Market Failures That Policy Choices Affect

Externalities include benefits and damage from climate change. Many policies that would reduce emissions of GHGs would also reduce other forms of pollution caused by energy production and consumption, and some policies would also alter national security risks. Similarly, many policies that reduce regional air pollution also reduce water pollution, national security risks, and externalities from global warming. Policies to encourage investment in energy efficiency also address other forms of market failure, such as asymmetric information. Policies with joint benefits require benefit estimation that is inclusive and not exclusive; this is obvious, but it is rarely done in the economics literature.

Standard incentive-based policies include pollution taxes; tradable permits; hybrid combinations of long-term tradable permits with repeated, short-term permit sales; and permits tied to direct regulation of emission limits. These policies are evaluated with the static economic efficiency criterion but do not address some of the market failures associated with underinvestment in energy-efficiency technologies.

Studies show internal rates of return $>20\%$ on commercial applications of energy-efficient lighting ballasts, whereas interest rates are much lower. These market imperfections—adverse selection, high transaction costs, principle agent problems, and intrafirm information flows—result in economic inefficiency. Specifically, asymmetric information exists between ballast sellers and potential buyers for improvement in quality, resulting in a lemons market and adversely selecting the lower quality (at the lower price). Because separate meters do not exist for each use of electricity, and a single meter is used to calculate electricity bills, businesses have a high cost of evaluating the efficiency of appliances. One principle agent problem occurs when commercial buildings are leased, the owner is the agent for the lessee (the principle) in the purchase of fluorescent lighting, and asymmetric information exists between the principle and the agent regarding the replacement costs. Another principle agent problem occurs when the renter is not separately metered, but rather the owner pays the electric bill and the renter and purchases the lower priced and inefficient appliance.

There are three additional sources of market failure for energy efficiency investments. First, electricity customers face higher borrowing rates for energy efficiency investments than the interest rates faced by electricity producers to invest in additional supply. Second, retail rate design for electricity and natural gas is based upon short-run marginal costs rather than long-run marginal cost rate, so that rates encourage investment in energy efficiency only up to the point that the capital and operating cost of the energy efficiency investment is cheaper than the operating cost of energy production. Third, there are negative externalities in energy production that are avoided by energy conservation. If the borrowing costs are lower for electricity producers than electricity efficiency investments by electricity consumers, or if the electricity is priced equal to short-run marginal cost of production, then at the margin electricity consumers will not invest in efficiency even when it is less expensive than the marginal cost of building and operating additional power plants.

4.2 Policy Options and the Static Efficiency Criterion

Policy options include direct regulation (or pejoratively, command and control regulation) and incen-

tive-based approaches, including pollution taxes and tradable permits allocated to polluters. Direct regulation includes requirements for pollution permits that polluters install the best available control technology when rebuilding power plants. Pollution taxes have fallen out of political favor, and may have constitutional challenges because the optimal pollution tax may vary over time and each tax adjustment could legally require congressional approval. Tradable permits give the holder the right to pollute a certain amount, to buy permits if emissions increase, and to sell permits if emissions decrease. One version of tradable permits is to lease the permit at a market auction. The so-called property rights solution is to allocate tradable permits in accordance with past levels of pollution, in essence appropriating common property and giving the property right to the polluter, without a corresponding property tax or any recognition of the economic rent.

If the property right to cause the externality resides with the party causing the damage, then the WTP is the correct marginal benefit curve. If the property right resides with the damaged party, the WTA is the marginal benefit curve (see Fig. 2). Solutions proposed by economists imply different allocations of property rights. Pollution taxes retain the property right for the public. Tradable permits, whose allocation is based on past levels of pollution, allocate the property right to the polluter. If tradable permits are leased at auctioned prices, the public retains the property right. When the U.S. Environmental Protection Agency changed direct regulations so that dirty power plants no longer had to be retrofitted to reduce pollution, the property right shifted from the pollutee to the polluter, and the marginal benefit curve was reduced by fiat, from the WTA to the WTP in Fig. 2. There is no unique optimal level of externality abatement without assuming who should own the property right, a normative issue.

Modern economic analysis favors the property rights solution to negative externalities. This selection is based on the criterion of static economic efficiency applied to Fig. 2. The solution requires setting the permitted amount of externalities equal to $N_C - N_P$, and polluters will trade permits if they can reduce pollution at a marginal cost less than the price of the permit. The result will be N_P abatement and the equilibrium price of the permit equal to the optimal pollution tax, T_P. This solution avoids the cost of direct regulation inherent in having regulators determine the cost of technology—a job best left to the market.

The property rights solution is an obvious misnomer since the other solutions—taxes, direct regulation, and auctioned leases of tradable permits—all have property rights retained by the public. Because the tradable permits are not subject to property taxes, it is also a misnomer to refer to the right to pollute as private property. An alternative is to lease tradable permits, retaining the property right for the public; this is referred to as the common property solution, favored by a small but growing group of influential economists. The common property solution—leasing tradable permits to pollute $N_C - N_A$—results in N_A abatement and an equilibrium price equal to T_A in Fig. 2.

Both the property rights tradable permits and the common property tradable permits options do not result in efficiency unless the amount of permitted pollution depreciates over time so that abatement increases in accordance with the analysis in Fig. 3, with the marginal benefit of abatement increasing over time due to the public good nature of abatement and population growth, and the increase in the pollution concentration shifting the intercept of the marginal benefit.

More problematic for the tradable permit approaches is that they do not acknowledge the joint pollutants, nonconvexities, and subtle cascading effects among natural and economic systems that render marginal benefit and marginal cost curves irrelevant.

4.3 Dynamic Efficiency and State Dependence of Technology

Some new technologies show promise for reducing externalities from energy. If CO_2 can be economically captured, it could be stored in several ways. One idea is to release CO_2 at the bottom of the oceans, but ocean currents could recirculate it. A second approach is to inject CO_2 into depleted oil and gas wells, raising pressure to capture remaining oil and natural gas and leaving the CO_2 in an impermeable reservoir; Ontario Power Generation has purchased the rights to GHG emission credits of 9 million tons of carbon and plans to inject the gas into old oil fields in the United States. Another idea is to inject CO_2 into coal mines, displacing and capturing methane gas. A Norwegian oil firm is injecting CO_2 into a saline aquifer under the North Sea, where the carbon is sequestered by reacting with the salt.

The integrated gasifier combined cycle (IGCC) is a technology that might lead to economically capturing CO_2 by burning pulverized coal in the presence of steam, generating CO and hydrogen gas. The hydrogen can be used to operate fuel cells or burned

to generate steam for electricity, and the CO can be catalytically converted to CO_2 and captured.

Fuel cells can chemically generate electricity from either hydrogen gas or methane gas. Some buses, trucks, and smaller vehicles are powered by fuel cells. Fuel cells can also be strategically placed to stabilize a transmission and distribution grid, avoiding urban air pollution emissions.

Infrastructure investments for energy supply and transportation—dams, power plants, pipelines, roads, and transportation networks—all have lifetimes in decades, even centuries. We can identify irreversible environmental damage of staggering magnitude lasting centuries, but natural science is unable to pinpoint how much pollution the earth's systems can sustain prior to triggering cataclysmic events. What is certain is that eventually we need to redirect the path of technological change.

In the 1960s, economists argued correctly that as rising market prices reflected scarcity of fossil fuels, the result would be substitution, new discoveries of fossil fuels, and technological change that reduced the cost of discovering, extracting, transporting, and converting fossil fuels to useful purposes. It is the success of these arguments that makes it clear that policies that encourage technologies such as the fuel cell, IGCC, solar thermal power, solar electric power, biomass, geothermal energy, ocean thermal energy conversion, wind power, and other substitutes for polluting fossil fuels will also lead to further improvements in fossil fuel technology because owners of fossil fuels have extraordinary wealth that can only be protected by research and development that furthers fossil fuel supply and use. Economic forces and institutional and political infrastructure lead to technological path dependency.

Direct regulation has an advantage over tradable pollution permits when evaluated by the dynamic efficiency criterion for selecting among policy options. Direct regulation can force technological change and can do so quite flexibly. An example is to require a fraction of sales to be zero- or ultra-low-emission vehicles, allowing vehicle manufacturers to trade the requirement among each other. Another example is to require a fraction of the power purchased by a utility to be generated by zero or lower polluting technologies, called a "set-aside" for renewable energy; this can be efficiently accomplished with a Vickery auction —such as the 1994 auction held by the California Public Utilities Commission and discussed above. Energy efficiency standards for building design, electric motors, appliances, heating, ventilation, refrigeration, and air-conditioning are also examples. Technology-forcing policies include pricing and tax subsidies of renewable electricity technologies, and renewable energy tax credits; rebates, low-interest loans, and subsidized electricity rates for efficient appliance purchases; and mileage standards for vehicles (CAFE standards).

4.4 Flexibility and Diversity to Reduce Risk

Policies that reduce macroeconomic risk can be designed by applying the concepts of flexibility and diversity to hedge against adverse outcomes. Consider that an electric utility sets spinning reserve requirements at least as large as the amount supplied by the largest power plant in operation. Grid operation derates transmission capacity to account for loop-flow feedbacks that would cause the entire grid to fail if the largest transmission line were to short. Backup capacity is always on call in the amount equal to the largest single link on which the system relies. Our macroeconomic performance has hinged on a single supplier of oil, Saudi Arabia, with no backup capacity except the strategic petroleum reserve.

Solar thermal with natural gas backup, wind power, and other renewable technologies provide both flexibility and diversity. The small size of renewable electricity generators, coupled with the speed with which they can be built, permits a close matching of supply and demand, reducing the need for substantial reserve margins for electricity supply. Technology-forcing policies for energy efficiency and alternative energy sources result in more available substitutes in the event that fossil fuel prices increase.

4.5 Political Viability and Wealth Redistribution

The argument against pollution taxes is that the size of wealth redistribution makes taxes politically unfeasible. This argument is simply wrong and has been proven so. The argument against marginal cost water rates was that it is politically unfeasible—witness the Tucson, Arizona, city council voted out en mass 1 year after implementing such rates in the 1970s. However, a two-part increasing block tariff for water rates, based on long-term marginal cost, is politically feasible for the city of Los Angeles. Similarly, a two-part pollution tax could be levied with a low or zero tax up to some amount, and a higher tax thereafter, providing three policy tools: the initial tax, the breakpoint, and the higher tax. Furthermore, pollu-

tion taxes could be designed to be revenue neutral, potentially leading to greater efficiency in energy use and in other sectors of the economy. It is easy to imagine pollution taxes offsetting tax credits for technology development, for example.

Other pollution-reducing policies meet similar resistance. Auctioning pollution permits would be more efficient than allocating them to existing polluters, the latter model being the most often followed in the United States. Any effort to implement such an auction scheme is met with effective political resistance. Ironically, allocation with no auction is a large-scale wealth-distribution scheme that favors polluters.

Wealth redistribution clearly affects the political feasibility of policy options. Dating back at least to "The Logic of Collective Action," economists have recognized that the interests of small, well-organized groups regularly outweigh the larger public interest. The argument against pollution taxes is often couched in terms of the regressive effect on the average family. This is a disingenuous means of diverting attention from the very substantial economic rents that fossil fuel producers and marketers currently collect while placing health and other environmental risks on the families.

5. CONCLUSIONS

Economic analysis is useful for informing policy choices but not capable of proving that any single policy choice is more efficient than another. To do so would require the analyst to have all the information about costs and benefits that precludes central planners from replacing markets in the allocation of resources. The laws of chemistry and physics result in violations of assumptions in the theory of externalities. Furthermore, economic efficiency as measured in benefit–cost analysis is a narrow measure of net human welfare that indicates nothing about the equity of one option compared to another. It is the most inclusive method economists have developed to date, but it still is not appropriate as the primary means of choosing among policies that have far-reaching implications for this and future generations.

This should not be taken as an argument to abandon economic analysis but rather to work closely with other social and natural scientists to improve our ability to more accurately, transparently, and fully represent and compare alternative energy futures.

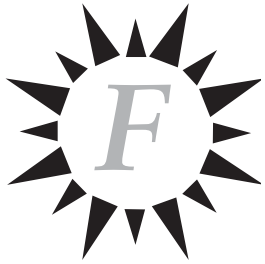
Fire: A Socioecological and Historical Survey



JOHAN GOUDSBLOM
University of Amsterdam
Amsterdam, The Netherlands

1. The Original Domestication of Fire
2. Agrarianization
3. Industrialization
4. Symbolic and Religious Aspects
5. Conclusion: The Eclipse of Fire?

Glossary

agrarianization The formation and spread of a socio-ecological regime structured around the domestication of plants and animals.

anthroposphere That part of the biosphere that has been affected by humans.

domestication The "taming" and incorporation into human society of originally "wild" nonhuman sources of energy.

industrialization The formation and spread of a socio-ecological regime structured around the exploitation of fossil fuels.

The ability to handle fire is, along with language and the use of tools, a universal human attainment: no human society in historical times is known to have lived without it. The ability to handle fire is also exclusively human: whereas other animals use rudimentary signals and tools only humans have learned to handle fire. From the outset, mastery of fire has strengthened the position of humans in the biosphere. At the same time, it has deeply affected the relations among humans themselves. Appreciation of the control over fire is therefore essential for an understanding of both the external expansion and the concomitant long-term internal transformation of the anthroposphere. The control over fire has been essential in the emergence of agriculture and stock raising, as well as the rise of modern industry. Its implications, including both benefits and costs, are so far-reaching as to often remain unnoticed and taken for granted. This entry intends to convey the enormous importance of the fire regime for human history and its profound impact on the biosphere.

1. THE ORIGINAL DOMESTICATION OF FIRE

1.1 Origins

Human life, like all life, consists of matter and energy structured and directed by information. All life is part of an ecosystem, and all ecosystems together constitute the biosphere—the total configuration of living things interacting with each other and with nonliving things. Every form of life continuously affects, and is affected by, its ecosystem.

As participants in the biosphere, the early hominids and their only surviving species, *Homo sapiens,* have gradually strengthened their position—at first slowly and almost imperceptibly, later at an increasingly more rapid pace with ever more striking consequences. In the process, they engrossed increasingly more terrain and incorporated increasingly more nonhuman resources into their groups: first fire, then, much later, certain selected plants and animals, and, later again, fossil fuels. As they incorporated more energy and matter into their societies, those societies grew in size, strength, and productivity, while at the same time also becoming more complex, more vulnerable, and more destructive.

During the first stage in human history and "prehistory," known in archaeology as the Paleolithic or Old Stone Age, which lasted for thousands of millennia, the overall pace of social and cultural development was slow in comparison with later

stages. Yet some momentous changes took place, with great consequences for the relationships between humans and the natural environment. Humans began not only to use but also to make tools of their own, and they learned to control fire. The combination of tools and fire enabled groups of humans to leave their original habitat, the savannas of East Africa, and to migrate into other parts of the world, penetrating first into remote corners of Eurasia and then also into Australia and the Americas. The Paleolithic can thus be seen as a long run up, which was later followed by an enormously accelerating sprint of which our present age is the latest episode. It was the scene of the incipient expansion of the human realm, the anthroposphere.

A basic trend in all human history, and certainly during its earliest phases (often designated as prehistory), has been the increasing differentiation between humans and all closely related animals in terms of their behavior, power, and general orientation or attitude—their habitus. Thanks to the flexibility acquired in the course of evolution, humans were able to learn a large repertory of new forms of behavior. Especially successful were those innovations in behavior that added to human power vis-à-vis other large animals, both predators and competitors. Transmitted by learning from generation to generation, those innovations entered into the human habitus and became second nature.

The primary condition for the process of differentiation in behavior, power, and habitus has been, and continues to be, the inborn human capacity for culture as manifested in technology, organization, and civilization, each of which represents the results of social learning. Indeed social learning is the crux of culture: gathering information and passing it on to others—at first in direct interaction, at a later stage in history through written texts and today by other audio-visual means as well. The stores of cumulated information (or "cultural capital") have enabled people to tap increasingly larger and more varied flows of matter and energy and to integrate those flows into their societies.

The domestication of fire was the first great human interference with natural processes. It had numerous far-reaching implications, stretching from the first hesitant beginnings to our contemporary fuel-driven economy. It demands our attention because it reveals something of the socioecological infrastructure of the contemporary world.

In several ways, the original fire regime may be seen as a paradigm for the socioecological regimes that were developed later. It presents a paradigm in a double sense. First, in actual practice the regime by which humans learned to extend their care for and control over fire could serve as a model for subsequent forms of care for and control over other forces in nonhuman nature such as plants and animals. Second, we may regard the domestication of fire as a model case in a more theoretical fashion, since it brings out the strong link between such apparently contradictory tendencies as increases in control and dependency, in robustness and vulnerability, and in the potential for production and for destruction.

1.2 First Impact

Fire, like all natural forces, has a history. Chemically fire is a process of highly accelerated oxidation of matter (fuel) induced by heat (ignition). Three conditions are therefore necessary for it to occur: oxygen, fuel, and heat. During the first eons in the history of the earth, at least two of these, oxygen and fuel, were absent. Oxygen did not become available until, after at least a billion years, life emerged. And it was only less than half a billion years ago, during the Devonian geological age, that life assumed the form of plants, providing matter suitable for burning. From then on, most places on earth with seasonally dry vegetation were regularly visited by fire, ignited on rare occasions by falling rocks, volcanic discharges or extraterrestrial impacts, but mostly by lightning.

Its domestication by humans opened an entirely new episode in the history of fire. Humans thoroughly altered the frequency and intensity of fires. They brought fire to regions of the planet where it seldom or never burned spontaneously, and they tried to banish it from places where without human interference it would have burned repeatedly. Thus, increasingly, "natural" fire receded and made way to human or, more precisely, anthropogenic fire.

Wherever humans migrated, they took their fire along. The presence of humans with fire deeply altered the landscape, including flora and fauna. The human impact is amply documented (though still controversial) for Australia—a continent that was colonized by humans rather late. Everywhere on the planet, areas such as rain forests, deserts, and the polar regions, which were not receptive to fire proved to be hard to penetrate for humans too.

Humans are the only species that has learned to manipulate fire. Control over fire has become a species monopoly, with an enormous impact on other species, both animals and plants. It provides us with

an excellent example of how new forms of behavior could change power balances—in this case, between humans and all other animals, ranging from primates to insects—and how shifts in power balances could engender changes in habitus, both among the humans who gained greater self-confidence from the presence of fire in their groups and among animals that might be bigger and stronger than humans but learned to respect and fear their agility with fire.

Control over fire, in addition to having become exclusively human, has also become universally human. We know of no human society of the past 100,000 years that lacked the skills needed to control fire.

The original domestication of fire was a dramatic transition. Palaeoanthropologists are still debating when exactly it took place. The estimates range from as many as 1.5 million to a mere 150,000 years ago. It is still an open and fascinating question whether the first steps to control over fire coincided with other changes in early human development.

In retrospect, the initial domestication of fire was an event of momentous import. A wild force of nature—blind, capricious, and hazardous—was now tended, cared for, and supplied with fuel. Our early ancestors went to all this trouble, not altruistically, but because it served them well. They put the potentially destructive and essentially purposeless force of fire to work for their own productive purposes. They managed to make fire regularly available. They no longer had to hunt for it, hoping to find somewhere the smoldering remains of a natural blaze; they made it a part (and even the center) of their own group, and they revered it as a symbol of eternal life.

The domestication of fire made humans less directly dependent on natural forces that continued to be beyond their control such as the alternation of day and night or the cycle of the seasons. It made the contrast between dark and light, between warm and cold, or between wet and dry more amenable to manipulation, and thus gave humans a greater margin of freedom from the grip of nature. It increased their power, defined as the capacity to influence the outcome of an interaction. Armed with fire, humans were able to open up impenetrable tracts of bush and to drive away animals much fiercer and stronger than they were. The gain in power made their lives more comfortable and secure. The possibilities of heating, lighting, and cooking all contributed to what we would now call a higher standard of living.

1.3 Long-Term Consequences

"Wherever primitive man had the opportunity to turn fire loose on a land, he seems to have done so from time immemorial." This statement by the American geographer Carl Sauer may sound exaggerated; but it still fails to convey the full impact that the domestication of fire has had, both on the larger biosphere and, within the biosphere, on human society itself.

The most immediate effect of the domestication of fire on the biosphere in general was an increase in the frequency with which fires occurred. Prior to its human mastery, fire was ignited mostly by lightning. From now on another source was added: even before they learned to make fire themselves, humans were able to preserve it in their hearths and to apply it wherever they saw fit. Consequently, as the number of anthropogenic fires increased, the proportion of natural fires diminished. The geologist Peter Westbroek has suggested, in an admittedly speculative manner, that the earliest human fire use may have affected the planetary atmosphere and caused some of the major climate changes in the Pleistocene. Substantive evidence indicating modification of the landscape by human foragers equipped with fire has been brought forward for Australia, where most of the indigenous forests were burned down in the millennia following the arrival of the first Aborigines.

From the very beginning, humans used fire in two basic forms: the hearth and the torch. The hearth was the original site at which a fire was kept, usually at a cave entrance where it could be protected against the rain and still receive some air circulation. Since it had to be tended and since fuel had to be brought to it, it served almost naturally as a center for group life, providing heat, light, and a common focus. From the hearth developed in the course of time a variety of fire containers such as crucibles, stoves, kilns and furnaces, and, in our day, the mobile engines of cars and airplanes.

The hearthlike uses of fire have always had two kinds of environmental side effects. First of all, fuel had to be supplied. As long as human communities were small and living in areas with abundant wood, this did not cause much of a problem. When greater numbers of people started living in large urban concentrations, however, the need for fuel became a strong contributing factor to deforestation over big areas and, in our own age, to depletion of fossil resources. The second side effect of hearthlike fire consists of its waste products: ashes and smoke. Although smoke might be useful in driving away

insects and other insidious creatures, it has always been considered mostly as a nuisance to be got rid of. As long as people lived in isolated caves or huts, this was relatively easy. Urbanization and industrialization have seriously aggravated the problem.

While the functions of the hearth were originally primarily turned inward, the torch was a more outward directed implement. It was used not only to provide light at night, but also by day to set fire to shrubs and grasses—an effective way to destroy obstacles for foraging and to rout animals, both predators and prey, and thus to extend the human domain. Torches undoubtedly contributed to deforestation: wood was burned wholesale, regardless of its possible value as timber or fuel. In the age of agriculture, the torch was used for slash and burn and other techniques for clearing land, and it served as the model for a whole array of fire weapons culminating in our own time in rocket-propelled missiles.

Surveying the entire trajectory of the human use of fire from its earliest beginnings, we can distinguish three stages. During the first stage, there were no groups possessing fire; there were only groups without fire. Then, there must have been a second stage, when there were both groups with fire and groups without fire. We do not know how long that stage lasted, nor do we know how often it may have recurred. All we know is that it has come to an end. It was a transitional stage, leading up to the stage in which humankind has now been living for thousands of generations: the stage when there are no longer any groups without fire. All human groups are groups with fire.

Although we lack empirical evidence for the first two stages, that very lack leaves us no choice but to accept the conclusion that societies with fire were in the long run obviously more fit to survive than societies without fire. If we then ask why it was that societies without fire disappeared, there seems to be only one plausible answer: because they had to coexist with societies with fire, and apparently in the long run such coexistence proved impossible.

This may sound like a dismal conclusion suggesting fierce contests ending in the elimination of the losers. If such contests did indeed take place, they have left no trace of empirical evidence; we only have the highly imaginative evocations of what might have happened in books and films like *The Quest for Fire,* directed by Jean-Jacques Annaud. However, we can also view the fact that possession of fire has become a universal attribute of all human societies as an important example of the general rule that changes in one human group lead to changes in related other groups. If group A had fire, and the neighboring group B did not, group B had a problem. It could either try to minimize contact with group A and perhaps move away, or do as group A had done and adopt a fire regime, which should not pose insurmountable difficulties as long as the capacity to learn from the others was sufficient. In the latter case, instead of a zero-sum elimination struggle there would have been what American freelance author and scientist Robert Wright calls a "nonzero" situation, with an outcome from which both parties benefited.

The rule that changes in one human group lead to changes in other related groups may sound like a rather tautological explanation for social change, but it is not. It is a highly generalized empirical observation, similar to an observation we can make about fire: fire generates fire and, in a similar fashion and more generally, change generates change, and social change generates social change.

Such is the nature of the dynamics of human society and culture. After the original domestication of fire, it was never humans alone who interacted with other human groups and with nonhuman nature. It was always humans with fire, equipped with fire and with the products of pyrotechniques: cooked food, pointed spears and arrows, earthenware, metal tools and weapons. Their presence put an end to humans without fire.

Another general conclusion to be drawn from these observations is the following: changes in climate and precipitation have never ceased to be important causes for humans to change their way of life. Humans are no different from other species in that they will always have to accommodate the basic conditions of earthly nature, such as the alteration of day and night or of monsoons and seasons. In the course of human history, however, in addition to these overridingly powerful extra-human conditions, conditions brought about by humans themselves have become increasingly more important to the extent that, in our contemporary world, humanity has become a major agent of ecological change.

1.4 Regimes

The domestication of fire meant that people tamed a strong and potentially destructive natural force and made it into a regularly available source of energy. In so doing they initiated changes in the natural environment, in their social arrangements, and in their personal lives. These three aspects (ecological,

sociological, and psychological) are all part of the changing human relationship with fire.

In its ecological aspects, the domestication of fire affected the relations between humans and the nonhuman world so deeply that we may call it the first great ecological transformation brought about by humans, which was followed much later by the second and third of such transformations, generally known as the agricultural and industrial revolutions and better characterized by the long-term processes of agrarianization and industrialization.

Each of the three transformations spelled the formation of a new socioecological regime: the fire regime, the agrarian regime, and the industrial regime, marked by, respectively, the utilization of fire and elementary tools, the rise and spread of agriculture and animal husbandry, and the rise and spread of large-scale modern industry. The later regimes have not made the earlier regimes obsolete; rather, they have absorbed them and, in so doing, transformed them. Each new regime brought an expansion of the anthroposphere within the biosphere.

Defining the three regimes jointly in similar terms is helpful in order to better understand each of them separately as well as in their interrelations. A common conceptual model invites and facilitates comparison. The comparison allows us to explain the sequence in the emergence of the regimes and to perceive not only their similarities and differences but also their interlocking.

2. *AGRARIANIZATION*

2.1 Continuities

The history of the past ten thousands years may be read as a series of events accompanying the process of agrarianization of humankind, a process in the course of which humanity extended the domain of agriculture and animal husbandry all over the world and in so doing made itself increasingly more dependent on this very mode of production.

The initial transition from gathering and hunting to agriculture and animal husbandry was not necessarily abrupt. A group that started to cultivate a few crops would not have to give up its older ways altogether. There would have been only few, if any, agrarian societies from which gathering and hunting disappeared completely at once. However, the proportion of products acquired in the older way inevitably diminished as agriculture and animal husbandry advanced.

From the very beginning, the process of agrarianization was linked closely to the domestication of fire. It is hard to imagine how people could have begun to cultivate plants and to domesticate animals had the art of handling fire not already been thoroughly familiar to them. For one thing, they needed a hearth fire to cook on. The first crops cultivated on any large scale were cereal grains such as wheat, rice, and maize, which, owing to their high nutritional value and their capacity to withstand storage for long periods, formed very appropriate staple foods for a human community; to serve this purpose, however, they had to be made more easily digestible with the help of fire.

A second and very different reason why the control of fire formed a precondition for agrarianization was the human predominance over all other mammals, which was grounded partly in the use of fire. The human species' monopoly over fire was so solidly established by the time agriculture began, and is today so easily taken for granted, that it is seldom given separate attention in this context. Yet it deserves mention. Their hegemony in the animal kingdom enabled people not only to bring certain species, such as goats and sheep, under direct control, but also—at least as important—to keep most of the remaining "wild" animals at a distance from their crops and herds.

Third, experience in controlling fire may have furthered plant and animal domestication in another, even more intangible way, which our distance in time makes it difficult to assess precisely but which we are also, for that very reason, likely to underestimate. The time-honored practice of handling fire could not have failed to prepare humans for the many chores involved in agriculture and animal husbandry. It taught them that extending care upon something nonhuman could be well worth the trouble and thus made it more acceptable to them to accommodate the strains of an agrarian life, full of self-imposed renunciation for the sake of a possible future yield.

The most immediately visible link between early agriculture and ancient use of fire lay in the custom of burning off land with an eye to food production. Of old, foraging peoples were wont to apply their torches in order to keep the land open for gathering and hunting. Even in recent times, those firing practices were continued in some parts of the world, as in Australia where the Aborigines' judicious use of fire in keeping their land open for kangaroos and humans has become known as "firestick farming," a term suggesting a form of proto-agrarianization.

2.2 Sequences

The rise of agriculture was in many respects remarkably similar to the domestication of fire. Again, humans added new sources of energy to their own, this time by adopting certain plants and animals and integrating them into human societies. Plants that were formerly wild now began to be cultivated, wild animals were tamed and used for food or other purposes such as traction, and all these species were made part of the human domain, of the anthroposphere, which thus increased in size and complexity.

The transition from foraging to agriculture did not automatically make people happier and healthier. Agrarian life brought new hardships. Diets became more monotonous. Sedentary life in villages increased the susceptibility to disease. It allowed for a rise in fertility, but it also caused higher mortality. The result was large numbers of children, many of whom never reached adulthood. Not surprisingly, research on skeletons reveals that after agrarianization, human lives tended to become briefer, and bodies shorter. It is equally understandable that the texts of the great religions of Eurasia all exhibit a nostalgia for the lost paradise of a pre-agrarian era.

The very nature of agrarian life foreclosed a return to foraging, however. There are a few known cases of such a return, but those are exceptions. Almost everywhere, with so many people, and so little land, the only option for the survival of an agrarian population was cultivation. "Work" was writ large over the agrarian world.

If, at a very early stage, the domestication of fire had made human groups more productive but also more vulnerable (because from now on they had to rely on their fire), the rise of agriculture had the same twofold effect. Being able to grow more food, human groups grew more populous and became more dependent on their crops, and thus more vulnerable to failure or loss of their harvests. As the expansion of agriculture and pastoralism left increasingly less land available for foraging, the opportunities to escape from this vicious circle dwindled.

The first stage in the process of agrarianization necessarily involved clearing the land, removing any existing vegetation that would compete with the planted crops. In many cases, the most efficient procedure to accomplish this was by means of fire. As long as land remained plentiful, continued recourse was often taken to fire in a system practiced throughout the world and known under various regional names that are usually subsumed in the standard literature under the label "shifting cultivation." Shifting cultivation implies that a piece of primary forest is first cleared by the method of slash and burn and is then used for one or more harvests of crops. When, after a while, crop nutrients in the soil become exhausted and undesired plants (weeds) begin to dominate, the farmers temporarily abandon the land and turn to an adjacent lot, burn the vegetation down, and bring it under cultivation, again until they find harvesting unrewarding. Eventually they return to their first plot, which by then has become secondary forest or secondary bush, and resume their activities of burning, planting, and harvesting there. The duration of the entire cycle may vary as to time and place, but the principle remains the same.

In many parts of the world, in the course of time, burning the land and letting it lie fallow for a number of years or seasons ceased to be a regular practice and was replaced by more intensive methods of working the soil, requiring greater investments of labor but yielding a larger output per acre and thus making it possible to feed more mouths. The most common means of accomplishing higher yields by harder work were irrigation and ploughing.

2.3 Fire in Settled Agrarian Societies

In all agrarian societies with permanent settlements, new uses of fire and new attitudes toward fire developed. During the long first stage of human fire use, the main concern always was to keep the communal fire burning. From now on, however, the main concern became almost the opposite: to keep the fires that were lit for numerous purposes from spreading and from running out of control.

The uses of fire became increasingly more varied. Specialized pyrotechnic crafts emerged, such as blacksmiths and potters. Among the growing urban populations, fire was regarded with greater anxiety, for several reasons: with the proliferation of fires, the risks of conflagrations increased, and with the accumulation of property, people had more to loose.

Of course, it was fire as a natural force with its self-generating destructiveness that was feared. But more and more, this natural force manifested itself almost exclusively in the guise of anthropogenic fire. With all the fires burning in a city, one moment of carelessness might cause a conflagration. People had to rely on other people's caution. They had to oppress attempts at deliberate fire setting. And they had to reckon with the very worst danger: the organized form of murder and arson known as war.

A common problem in all advanced agrarian societies was the prevention of uncontrolled fire in

cities. This problem may have been less urgent where the major construction material was stone or brick; but throughout the agrarian era we find major cities in which most houses were built from timber. Rome, Constantinople, Moscow, London, and Delhi as well as the capitals of China, Korea and Japan all suffered conflagrations; all of them faced problems of fire prevention.

Today we may tend to conceive of problems of fire prevention primarily in terms of technology: of building materials and technical equipment. However, the problems were (and still are) at least as much civilizational, or social. The crucial issue was human behavior, care, consideration. According to a well-known story, a temple in ancient Greece burned down because the servant was careless; similar events must have occurred all over the world. Everywhere it was the human factor that counted most of all.

This was also reflected in the presence or absence of fire brigades. Today, it may seem self-evident that a city should have a fire brigade. However, the power relations in earlier societies could be such that the authorities would forbid the organization of fire brigades by citizens. A dramatic example of a ban put on urban fire brigades is provided by two letters that were exchanged in the second century CE between the governor of a province in the eastern part of the Roman empire, Pliny the Younger, and his emperor, Trajan. In the first letter, Pliny informed the emperor that the capital city Nicomedia was completely ruined by a fire; people had watched the blaze passively, unable to do anything. He therefore asked permission to establish a fire brigade of citizens in order to prevent such disasters in the future. The emperor denied the request bluntly, for—as Pliny should have known—such an organization of citizens could easily turn into a club with subversive political activities.

It is still unknown to what degree Trajan's reply was typical of rulers in agrarian empires. The scattered evidence provided by local histories suggests that the situation was very different in the towns of medieval Europe, where the members of various guilds were required to take a share in fighting fires. This issue is a promising subject for comparative historical research.

3. INDUSTRIALIZATION

3.1 The Industrial Regime

While the basic theme of human history over the past 10,000 years has been the agrarianization of the world, the history of the past 250 years has unfolded under the aegis of industrialization. In the process, the anthroposphere has become one global constellation, extending all over the planet, and its impact on the biosphere has become more and more intense.

In line with the approach to the domestication of fire and agrarianization, industrialization can be defined as the formation of a socioecological regime, structured around a new source of energy: fossil fuel—first in the form of coal, later also of oil and gas. The nature of this new energy source has made the industrial regime different in a basic way from the earlier socioecological regimes. Unlike plants and animals, and even wood, fossil fuel is not directly connected to the continuous flow of solar energy. It is a residue of solar energy from a remote past contained in geological formations. The energy stocks are not diffuse like sunlight but concentrated in particular locations from where they can be extracted through concerted human effort. They have two seemingly contradictory properties: they are abundant and finite.

The abundance is indeed great. Coal, oil, and gas represent the remains of the nonoxidized biomass—in other words, unburned fuel—of over 3 billion years. When people began exploiting those enormous reserves they entered as it were, in the words of the environmental historian Rolf Peter Sieferle, a "subterranean forest" of inconceivably large dimensions, which, moreover, in the course of 250 years of exploitation and exploration proved to contain far more riches than was originally expected.

Yet no matter how large, the hidden stocks are also finite. In contrast to plants, which are the direct autotrophic products of the photosynthetic conversion of solar energy, and to animals, which are the heterotrophic consumers of plant and animal food, geological stocks of fossil fuel do not partake in any living metabolism. They are incapable of growth or reproduction, irreplaceable, unrenewable and, as is becoming more and more evident, their use generates combustion products that enter the biosphere.

3.2 Origins and Preconditions

The genesis of industrialization raises a whole array of intriguing questions concerning its preconditions and its immediate causes as well as its functions and side effects. These are in principle the same questions that can be raised about the domestication of fire and the origins of agriculture. Because industrialization began only recently, we have the benefit of far more and far more precise empirical evidence; never-

theless, the problems remain puzzling. Any answer that comes to mind can only be tentative and subject to caveats.

One thing is certain: industrialization was not triggered by a major change in climate. At most, its beginnings more or less coincided with the end of the most recent secular dip in temperature in Europe, from 1550 to after 1700, known as the little Ice Age; but no relationship with this climatological event was evident. Industrialization was a completely anthropogenic transformation, brought about by humans in societies that were fully equipped with fire and agriculture.

The beginning of industrialization heralded a new era in human history. Yet it was clearly a continuation of the fire regime, for every industrial process rested on controlled use of fire. Industrialization also presupposed agrarianization: it could never have started without a strong agrarian basis that was able to feed numerous people who were not engaged in agriculture themselves and who could therefore be recruited for work in industry and trade. From the outset, the industrial world coexisted and coevolved with the agrarian world, in close interdependence and symbiosis, culminating in our time in forms of industrial farming or agroindustry that lean as heavily on fossil fuel as any other form of industrial production.

3.3 Further Parallels

Just as agrarianization must have begun in small farming enclaves, carved out in an environment that continued to be the domain of foragers, industrialization started with single steam-powered factories—often called mills as if they still were driven by wind or water—standing apart in the agrarian landscape. To sketch their initially semi-isolated position, Sieferle's image of industrial archipelagos is appropriate.

From the very start, however, even as islands in an agrarian landscape, the factories had an ecological impact stretching beyond the land on which they stood. To begin with, considerable amounts of matter and energy went into building them. The usual construction material was partly timber, but to a larger extent brick, the manufacturing of which involved huge quantities of fuel. The engines were made largely of metal, also in a highly fuel-intensive fashion. Then, brick and timber were needed for the houses to accommodate the workers. So even before the factories began to operate, their tentacles were already reaching into the environment.

Once in operation, the factories had to be supplied with a continuous input of material, such as iron and cotton to be processed and of fuel to keep the engines going. The need for fuel explains the location of the early industrial plants: close to coal mines and, in the case of heavy industry, sites of iron ore deposits. Of course, a nearby sea or river port facilitated transportation; failing that, canals were built, and later railways, connecting the islands of industrial production with the areas where the raw materials were found and with the markets where the products were sold. In 19th-century Britain, an ever more extensive and intricate network of canals and railways was formed through which the industrial regime spread its reach over the entire country.

3.4 Industrialization as Intensified Land Use

Our earliest human ancestors treated the land they lived in as essentially all of the same nature—a territory for both collecting and hunting, for foraging food as well as fuel. In agrarian societies, most of the land was parceled up into three distinct parts with distinct functions: fields or arable planted with crops; pastures or meadows where cattle and horses grazed; and heath and wood land providing fodder for pigs and sheep and, even more important, fuel and timber. All three areas were controlled by humans, who were able to make the land thus divided up more productive for their own specific purposes, but who also found themselves faced with a continuously decreasing wild acreage.

Industrialization offered an escape from this predicament. The exploitation of coal was a highly intensified form of land use, which relieved the pressure to use large areas extensively for growing wood for fuel. The virtual expansion of land attained through the use of coal helps to explain the unstoppable advance of industrialization, once it was underway. Like the agrarian regime, the industrial regime made offers that were disagreeable in many ways to a great many people, but in the long run for all of them impossible to ignore or to refuse. The huge gains in energy could be transformed into economic, political, and military advantages that proved to be irresistible. All over the world, societies without fossil energy industry made way for societies with fossil energy industry, a process which could not fail to have profound consequences for the biosphere.

In our own age, each year more than 100,000 square kilometers of remaining wild land in Africa, Asia, and South America are subjected to human

exploitation. One of the causes is the need for fuel in the Third World; in many densely populated areas, fuel for the fire to cook on has become as proverbially scarce as the food to be cooked. In addition, there is a rising demand for timber and pulp from the most highly industrialized countries. The greatest threat to the continued existence of natural forests does not lie in felling the trees, however, but in the indiscriminate burning down of entire tracts in order to clear the ground for raising crops and cattle for commerce. The world economy generates a rising demand for products of tropical agriculture. To meet this demand, garden plots are converted into plantations, and the small farmers have to leave. At the same time, population continues to grow, so that pressure on land becomes even greater. As a result, the contradictory situation arises that in a world suffering from severe shortage of wood, each year many tens of thousands of hectares of forest are set on fire.

In Australia, exceptionally, anthropogenic fire has diminished since the establishment of a European colonial regime. From the time of their first arrival, the British had a sensation of the Aborigines going about burning the land incessantly. The British took every measure they could to repress these burning practices, with such success that rainforest has been regaining ground again in Australia over the past 200 years. An unintended side effect has been the increasing incidence of large wildfires during dry seasons, for the many fires of limited scope lit by the Aborigines prevented the vast fires that now, when they are raging, constitute a serious threat to the metropolitan suburbs.

3.5 Current Uses and Manifestations of Fire

The 20th and 21st centuries have seen a common shift in preference for energy sources all over the world. Wherever electricity is now available, it is the favorite means of generating light, and combustion engines are, along with electricity, the favorite means of generating motion.

The shift from steam engines to electricity and internal combustion is reflected in the changed industrial landscape, which in the Western world is no longer dominated by endless rows of factory chimney stacks. Yet the methods of production in modern industry, and in agriculture as well, continue to be highly fuel-intensive. Most of the energy consumed, including most electricity, is derived from the fossil fuels coal, oil, and gas. Combustion processes thus still play a central role, but they are relegated to special containers so that most people are not directly confronted with them. Soot, smoke, and fire risks are reduced to a minimum. The furnaces and combustion chambers in which enormous heat is concentrated remain cool on the outside.

Typical products of modern fuel-intensive industry are cars, with engines designed to be propelled by finely tuned and minutely controllable combustion processes. Indeed, the car may almost serve as a symbol of the highly complex and differentiated ways in which, in our day, thermal energy is being used. Cars are set in motion by burning fossil fuel. They are made of steel, plastic, and glass—materials that are produced and processed at high temperatures. Yet no one who gets into his or her vehicle and turns on the electrical ignition to start the engine needs be consciously aware of using fire and products of fire. When driving, people do not perceive the processes of combustion that keep their car going: they do not see the petrol gas burning under the bonnet, nor have most of them even remotely sensed the fire in the factories and power plants without which their cars would never have been produced at all.

A very different example to the same effect is farming. In the early 19th century, when Britain was already beginning to industrialize, practically all the energy consumed on the farm was still produced within the confines of the farm and its fields in the form of human and animal labor; the open fire that was burning in the hearth was fuelled with wood from the immediate surroundings. By the turn of the 21st century, the situation has become very different, with practically all the energy used now brought in from outside the farm, in the form of fertilizer, oil and petrol, and electricity.

A major advantage of the new sources of energy is their flexibility. The fuels are easier to transport and to distribute than wood or coal, and the combustion can be regulated more precisely. Given the technical facilities, gas, oil, and electricity provide for very even and accurately controllable flows of energy. Electricity has the additional advantage of being totally "clean" at the place of destination. Domestically, a few simple actions and a negligible risk suffice to provide people with an immense array of services: some substituting for old chores such as cleaning the floor and washing dishes, others based on entirely new appliances such as television sets and computers. Industrially, the same advantages apply at a much larger scale, permitting a far more diversified use of power than was possible with steam power.

The impact of electricity and internal combustion engines makes itself felt in every sector of social life: in agriculture, industry, traffic and transportation, domestic work and leisure. Everywhere it is possible to mobilize large quantities of energy with very little physical effort. The result is to make life more comfortable in many respects, enhancing the sense that physical processes can be mastered and also, at times, fostering the illusion of independence.

An illusion it clearly is. Regardless of whether people can avail themselves of energy in the form of a petrol engine, a battery, or a connection to an electric circuit or a gas main, in each case they are able to do so only because they are part of a complex and far reaching network of social interdependencies, connecting them eventually to the energy stored in fossil fuels. As long as the supply lines are functioning, and as long as people are able to meet their financial obligations, they do not need to bother much about the entire constellation. They are immediately confronted with it, however, the moment something goes wrong with any of the conditions.

In this way the exploitation of the new sources of energy clearly continues a trend that has begun with the first domestication of fire. Dependence on the forces of nature has become more indirect (which is not to say less important!), and by the same token dependence on cultural and social resources has increased. A complicated technical and organizational apparatus is needed to continuously maintain the supply of energy. Most of this apparatus is located behind the scenes of industrial society, invisible to the ordinary consumer. Energy is made available in such a convenient fashion that it is easy to forget the social effort required to produce it.

That social effort is spent, first of all, at the drilling wells and in the mines where the energy is won and, next, during the operations of processing it into consumable gas, oil, or electricity, and of transporting and distributing it. While the many provisions needed for the undisturbed flow of energy are often taken for granted, they cannot fail to exert permanent pressures on those who benefit from it as customers. The bills have to be paid, financially and otherwise.

The permanent availability of electricity, at every hour, in many parts of the world, has led to a diminution of the contrast between day and night. By the middle of the 19th century, the large investments made in their factories impelled many owners, under the pressures of competition, to let the engines run day and night. Gaslight illuminated the workplace. In the 20th century, night life has steadily extended, especially in the cities. Water mains, sewage, gas, electricity, telephone, fax, internet, radio, police, fire brigade, hospitals are all generally expected to operate day and night. International interdependencies never come to a halt. This is one of the reasons why many people turn on the news as soon as they wake up in the morning; before resuming their daily activities they wish to learn what has happened while they were asleep—in their own country, where it was night, and elsewhere, where it was day time.

Once in a while there is a hitch. Sometimes the local supply of electricity breaks down, as happened for a number of hours in the blackout in New York on July 13, 1977, and for longer periods at a regional scale in California in 2001 and in the northeastern United States and southern Canada in 2003. In New York the failure was due to technical causes; in California its primary causes lay in disturbances in the financial sector. A combination of economic and political complications brought about the international oil crisis of 1973, when the majority of oil-producing countries jointly managed to enforce a drastic increase in the world price of crude oil.

Disturbances are remarkably rare, in view of the prodigious growth of energy consumption since 1950. The industrial economy is a fuel economy, revolving around the regular supply of fuel that can be easily converted into energy. Light, warmth, motion, and even coolness are produced with fuel. The rising supply of all these fuel-intensive amenities in turn constantly stimulates demand from customers, who are eager to enhance both their physical comfort and their social status.

In a large part of the world, access to the benefits of modern technology is still restricted to a small upper crust of society. Moreover, while in the western world and parts of Asia effective measures have been taken to reduce the polluting effects of industrial and domestic fuel use in densely populated areas, the quality of the air has only deteriorated in the rapidly growing megacities of Africa, Asia, and Latin America. As a consequence, according to an estimate of the World Health Organization in 1997, air pollution killed about 400,000 people worldwide annually.

Still, economic growth has continued in the poor parts of the world, and this is bound to affect the rich countries as well. Wealth attracts poverty; history abounds with examples of this general rule. When the opportunity offers itself, many people from poorer regions will try to migrate to regions with a higher standard of material comfort.

Meanwhile, global fuel consumption continues to rise. In rich countries, advanced technologies permit

customers to enjoy the use of their appliances and vehicles without any physical inconvenience caused by the combustion processes. Poorer people generally are prepared to put up with noise and smell to profit from fossil fuel energy.

3.6 Fire and War

With growing interdependence among people, dependence on natural forces has become more indirect: longer and more ramified social chains are formed between the production of things and their use. Even the threat of violent destruction of lives and property comes far less often from natural forces than from forces unleashed by one human group against another. The most powerful groups are those that command the organizational and technical means to mobilize huge amounts of energy and matter against their enemies.

In our day, the search for the most effective means of violence has led to the exploitation of a new source of energy: nuclear fission. For the first time in human history, a new source of energy was first applied at a large scale in war, with the sole intent of massive destruction. It was the result of an enormously concentrated accumulation of technical, scientific, and economic capital, invested in a single one-purpose enterprise: the production of an atomic bomb.

But no matter how single-focused the effort, the invention of the atomic bomb followed a general rule in the history of technology and produced unintended side effects. One of these was that the development of the bomb by the United States became the first step in a process of escalation and proliferation, which has become the greatly enlarged version of the paradigmatic case *par excellence* of an arms race. Another unintended consequence has been the rising level of risk of fatal consequences in case of a breakdown in any of the nuclear plants that were built in the second half of the 20th century.

War has always been an important factor in the relations between humans and their physical environment. In most cases, it was directed at destruction of a part of the anthroposphere: especially that part in which the organizational basis of the enemy was supposed to be most vulnerable. The more investments a group made in controlling its environment, the more susceptible it became to losses through violence. Advanced agrarian communities could suffer a severe setback in case their rice fields, vineyards, or terraces were destroyed. Many cities in agrarian societies underwent drastic reduction or were even totally annihilated after military surrender: the greater the concentration of physical wealth, the more irreparable the destruction.

In industrial society, enormous means of destruction were developed even before the invention of the atomic bomb. During World War II, air raids brought devastation to a great many cities. Global industrial society proved to be sufficiently resilient and affluent, however, so that after the war every bombed city was rebuilt at its original site. Such were the powers of recuperation of the industrialized parts of the anthroposphere.

4. SYMBOLIC AND RELIGIOUS ASPECTS

4.1 The Blessings of Fire

We may safely assume that fire, having played such a crucial role in the development of human group life, has always kindled the imagination and given rise to rites and beliefs. Unfortunately, for the earliest stages we have only material remains to go by, and it is very difficult to reconstruct the symbolic and religious meanings attached to fire solely on that basis. Since the invention of writing, however, many facts relating to these intangible aspects have been recorded. More recently, anthropological fieldwork has yielded a profusion of data and insights.

Thus, from all over the world myths have been collected relating how man first came to master fire. Typically these myths represent the initial conquest of fire not as a gradual long-term process but as a single adventurous event, often marked by cunning and deceit. According to most myths, fire was at first possessed by the gods until, at a given moment, they gave it to humans or, alternatively, it was stolen from them, either by some animal who then passed it on to humans or by a semidivine Promethean culture hero.

All these myths convey a sense of the preciousness of fire. Fire is regarded as a unique possession, which separates humans from the animal world. As a corollary of this conception, many peoples used to tell that other peoples did not have fire and, consequently, could not cook their food so that they had to live like animals. Needless to say, fire has been a universal element of culture ever since the emergence of *Homo sapiens*, and all these stories are spurious and slanderous.

Directly related to such beliefs is the idea that fire steered by human hands has purifying effects. The domain of human culture is seen as coinciding with the range of domesticated fire. Thus, cooked meat is

regarded as edible for humans, raw meat as only fit for beasts. Similarly, land cleared by burning is trusted as belonging to the human domain, whereas uncleared bush and forest are feared as wild and dangerous, a hideout for predators, serpents, insects, and evil spirits.

The sense of preciousness of fire also found expression in rites. The communal fire would be the center of group life, and people would treat it as sacred, surrounding it with ceremony and taking great care that it would never cease burning. The Roman cults of the hearth of Vesta, the fire goddess, show how such ancient rites could persist in an urban setting. In many societies the perpetual burning of the communal fire would be interrupted once a year; all fires were then ritually extinguished and replaced by new, pure fire that had to be solemnly ignited by the chief priest.

4.2 The Curses of Fire

When, after the rise of agriculture, people increasingly came to live in villages and cities, the number and variety of fires also increased, and so did the risk that any one of these fires would cause a conflagration. Fire continued to be a cherished necessity, but since it was so abundantly available, the sense of its preciousness was often superseded by anxiety and fear of the dangers it posed.

The transition was reflected in some of the great religions that emerged in Eurasia during the past 3000 years. The veneration of fire was most strongly preserved in Hinduism, with its cult of the fire god Agni, and in Zoroasterism, with its cult of Atar. Both religions kept alive the age-old worship of fire as a primeval force of vital importance to humans; but this was combined with awe and anxiety for its destructive powers.

Christianity and Islam stand much further away from the ancient worship of fire. Some old traditions persist, as in the burning of incense and candles, including the renewal at Easter in Roman Catholic churches. Fire no longer plays any part in beliefs about the origins of human society, however. Instead, it is strongly associated with evil. Sinners and unbelievers are threatened with a life after death in which they will be tormented by eternal burning. It seems as if the agonies of city conflagrations as described by several pagan authors from ancient Rome have found a religious symbolization in the vision of hell.

Fire festivals, such as those held over Europe at Saint John's day when things considered impure would be committed to the flames, were occasions of combined joy and horror. Modern literature and art abound with evocations of the terrors of fire. When novelists describe the nightmare of a conflagration, they attribute the disaster, quite realistically, not to natural forces such as lightning but to human action—either to individual negligence, to madness or malice, or to collective hostilities in war.

4.3 Fire as an Element

A more neutral way of regarding fire, not in terms of its good or bad effects on human beings but as a natural phenomenon in its own right, was first proposed by philosophers of ancient Greece. They developed, out of various antecedents, a generally accepted doctrine according to which the universe consisted of four elements: earth, water, air, and fire. In China and India, similar systems of thought were worked out. With only minor modifications the worldview in which fire constituted one of the major elements remained the dominant cosmology for natural scientists and physicians well into the modern era.

Alchimists and chemists, as the direct successors of the metallurgists and fire masters of a previous age, made the study of fire into their central concern. Just as modern mechanical industry in its initial stages owed a great deal to the steam engine, the rise of modern physical science would have been inconceivable without the numerous efforts of investigators experimenting with and theorizing about fire.

5. CONCLUSION: THE ECLIPSE OF FIRE?

The controlled use of fire has been a human species monopoly since time immemorial. It constitutes an integral part of the apparatus with which humans have established and continue to maintain their dominance over other species.

Ever since the earliest stages of its domestication, the same phenomenon has recurred again and again in the human relations with fire: deliberately sought advances in control lead to unintended increases in dependency, and as the dependency sinks deeper into the social and economic infrastructure, it tends to become increasingly less clearly perceptible. Like agrarianization, industrialization began with conspicuously huge applications of fire. As industrial production became more specialized and highly organized, so did the use of fire. In everyday life in highly industrialized contemporary societies, flames

are visibly present only in such highly domesticated guises as cigarette lighters, candles for ceremonial use, or wood fires intended to create an atmosphere of comfort and relaxation. When, on the other hand, a fire is shown on television or in the press, it almost always spells war and disaster. The regularly controlled combustion processes on which industrial production largely rests are now mostly relegated away from public view.

In accordance with this apparent eclipse, natural scientists and philosophers no longer regard fire as one of the four elements out of which the world is composed. The very concept of fire has disappeared from scientific literature, to be replaced by the more abstract concept of energy—something that cannot be directly seen, heard, smelled, or felt. Similarly, many a day may pass in the life of the average citizen of a modern industrial state during which he or she does not perceive any physically observable fire. Yet it continues to be an integral part of the anthroposphere.

Glossary

active fishing gear Equipment used for fishing in which the aquatic organisms being targeted encounter the gear primarily through movement of the gear itself. Examples include cast nets, dredges, harpoons, jigs, and all forms of seine and trawl fishing.

animate energy Energy dissipated through the application of human or animal muscles to do work.

artisanal fisheries Small-scale fisheries that are typically executed by members of fishing households (as opposed to commercial companies) in which relatively small amounts of capital and energy and relatively small, if any, fishing vessels are employed.

culturally mediated energy All forms of energy dissipated through the application of technologies in the process of human activities.

energy intensity The amount of culturally mediated energy required to provide a given quantity of a product or service of interest. In the current context, energy intensity is expressed either as the total joules of energy required to land a live weight or "round" tonne of fish or shellfish harvested, or in terms of fuel use intensity, the total liters of fuel burned directly on fishing vessels per tonne of fish or shellfish landed.

energy return on investment (EROI) ratio A dimensionless ratio calculated by dividing the amount of useful energy provided by a given activity by the culturally mediated energy dissipated in providing it. In the case of food production systems, a common energy output used to calculate the EROI is the edible protein energy yield from the system being evaluated.

fishing Any activity that results in the catching, collecting, or harvesting of fish, and or aquatic invertebrates for any purpose other than scientific research. In the current context, the harvesting of aquatic plants and mammals is not considered as fishing, nor is aquaculture.

industrial fisheries Those fisheries typically undertaken by commercial companies in which relatively large quantities of capital and energy are deployed.

net primary productivity (NPP) The difference between the total amount of carbon taken up by plants via photosynthesis and the amount of carbon lost by living plants via respiration.

passive fishing gear Equipment used for fishing in which the aquatic organisms being targeted encounter the gear primarily through their own movement or as a result of the movement of the surrounding waters. Examples include all forms of hook and line gears, drift nets, gillnets, traps, and weirs.

Fishing is one of the most ancient and widespread of human endeavors. Contemporary fisheries harvest an enormous variety of aquatic organisms from virtually every aquatic environment on the planet using a diverse array of technologies. Reflecting the diversity of global fisheries, culturally mediated energy inputs also vary widely in both form and magnitude. At one extreme, traditional artisanal fisheries typically rely on relatively small inputs of exogenous energy, mostly in the form of wind, and animate energy to propel vessels and haul nets. Indeed, among subsistence fisheries in which animate energy inputs predominate, the nutritional value of the catch must routinely exceed the energy expended by the human muscles engaged in the fishery if it is to remain viable. Although such traditional, low-input fisheries persist in many parts of the world, high-input, industrialized fisheries now account for the majority of global landings. Among these fisheries, particularly those targeting high-value species, it is now common for direct fossil fuel energy inputs alone to exceed the nutritional energy embodied in the catch by at least an order of magnitude.

1. INTRODUCTION

As with all human activities, fishing entails the dissipation of energy in support of its primary activity, the harvesting of aquatic organisms. While the energetic cost of fishing is less obvious, and consequently receives much less attention than the direct impact that fishing has on targeted stocks and associated marine ecosystems, it is precisely the availability of abundant energy, in particular fossil energy, that enables many contemporary fisheries to continue even when stocks are in decline. Consequently, analyses of the forms and quantities of energy dissipated in fisheries, and in particular changes in energy use over time, can provide a powerful measure of the biophysical scarcity of exploited populations.

2. OVERVIEW OF GLOBAL FISHERIES

2.1 Scope and Extent

Data compiled by the Food and Agriculture Organization (FAO) of the United Nations indicate that, globally, approximately 90 million tonnes of fish and shellfish, representing more than 130 genera and 750 species, are harvested from the wild each year (Fig. 1). Although in excess of 200 countries report landings of fish and shellfish, the top 10 fishing nations account for over half of the total (Fig. 2). Similarly, while fishing is conducted in virtually every aquatic environment on the planet, over 90% of global landings are derived from marine waters, with most of this coming from highly productive coastal shelf and upwelling ecosystems.

2.2 Importance of Fisheries

One of the oldest forms of food production, fishing currently provides two-thirds of the fish and shellfish consumed by people worldwide, with aquaculture accounting for the balance. As a result, fishing directly contributes approximately 10% of the total animal protein intake by humans. In addition, although wild-caught food fish tend to contain less fat than terrestrial animals, the chemical composition of marine-sourced lipids is of significant nutritional importance. In particular, many species of wild-caught fish are relatively rich sources of Omega-3, or n-3, fatty acids, compounds that are believed to

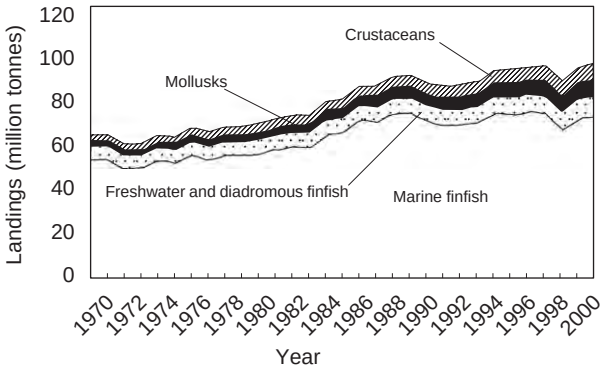

FIGURE 1 Global capture fisheries landings: 1970–2000. Data from FAO statistical database Fishstat+.

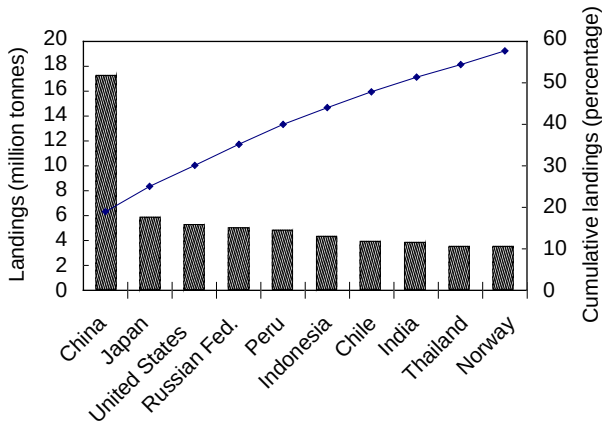

FIGURE 2 Absolute and cumulative fisheries landings by the top 10 fishing nations in 1998. Data from FAO (2000).

substantially decrease the risk of heart disease, inflammatory processes, and certain cancers.

It is important to note, however, the role of fish in human diets varies widely among countries and regions (Fig. 3). This variation not only reflects differences in resource availability and cultural preferences with respect to the seafood consumption but also, to a certain extent, development status. Of the 30 countries whose citizens are most dependent on fish as a source of protein, over 80% are less developed countries.

Of the approximately one-third of global landings not consumed directly as human food, the vast majority is destined for reduction to fish meal and oil. Currently, both of these reduction coproducts are directed overwhelmingly to livestock and aquaculture feeds, with smaller volumes of fish oil being consumed directly by people, either as edible oil products or nutritional supplements. Traditionally, however, fish oils have also been used in a wide

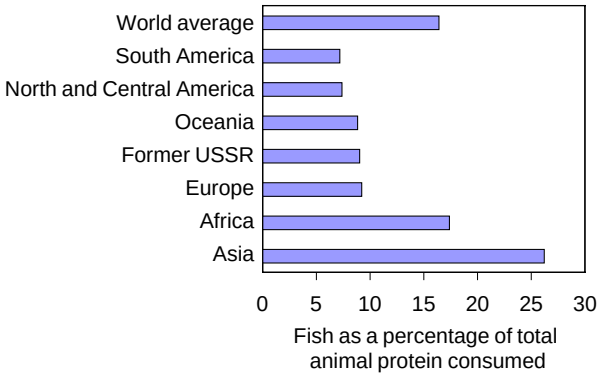

FIGURE 3 Importance of fish and shellfish from all sources to human diets.

range of industrial applications or burned as a source of fuel and illumination. While representing relatively small total landings, other nonfood fisheries are conducted to provide an array of high-value medicinal, decorative, and luxury products including shark cartilage, pearls, and live fish for the aquarium trade.

Reflecting their scale and diversity, it is not surprising that fisheries can play an important role in national and regional economies. Globally, the FAO estimates that as of the late 1990s, fisheries directly employed approximately 25 million people and yielded products whose first sale value exceeded $80US billion annually. The socioeconomic impact of fisheries is most pronounced, however, in many less industrialized countries and rural coastal communities throughout the world, where alternative employment opportunities are often limited.

2.3 Fishing Technologies

Based on archaeological evidence from central Africa, humans have been using dedicated fishing technologies, in this early instance a fishing spear, for at least 90,000 years. As the scope and range of fisheries has expanded over the intervening millennia, so too has the diversity of methods used to harvest fish and shellfish. While it is impractical here to explore the immense range of fishing techniques used around the world, a few broad generalizations are useful: fisheries in which some form of fishing vessel is used account for the vast majority of global landings, and most of the world's catch is taken using active fishing gears, particularly trawling and purse seining techniques in which large nets are respectively either towed behind fishing vessels or used to encircle schools of fish.

3. ENERGY INPUTS TO FISHERIES

Energy flows have been used to evaluate the performance of food production systems for over a hundred years. However, it was not until the first oil price shock of 1973 and the resulting concern regarding the dependency of industrialized food production systems on fossil fuels that systematic analyses were undertaken. One of the first major products of this period of research was Gerald Leach's handbook "Energy and Food Production" published in 1976. While it dealt primarily with agricultural systems, it included, for the first time, data on the major culturally mediated energy inputs to six fisheries from four continents. Since then, a small number of researchers in various parts of the world have continued to evaluate the energetics of fisheries from a variety of perspectives.

From an energetic perspective, fishing is a process in which a variety of culturally mediated forms of energy are dissipated in order to capture edible chemical energy embodied in the carcasses of fish and shellfish. The ultimate source of both the chemical energy embodied in the harvested organisms and most forms of culturally mediated energy is the sun. Consequently, the amount of solar energy required to sustain global landings and fishing activities is enormous. However, to date very few fishery-specific energy analyses have systematically attempted to account for solar energy inputs. As a result, other than a brief discussion of the ecosystem support associated with growing the biomass of animals harvested by global fisheries, solar energy inputs are not a focus of this review. Instead, this work deals primarily with the major forms and quantities of culturally mediated energy inputs to fishing.

3.1 Ecosystem Support of Fisheries

While not a direct measure of the solar energy flux underpinning fish and shellfish harvests, estimates have been made of the scale of ecosystem support appropriated by global fisheries. Typically, this is done by estimating the fraction of global aquatic net primary productivity (NPP)—or the amount of carbon fixed by plants via photosynthesis minus that lost through respiration—required to sustain the mass of fish and shellfish harvested. In 1995, Daniel Pauly and Villy Christensen, fisheries scientists currently based at the University of British Columbia, provided the most robust analysis of this measure to date. Their work indicates that as of the

mid-1990s, global fisheries landings and discards appropriated approximately 8% of the total NPP available in the world's aquatic ecosystems. More striking, however, were their findings regarding those highly productive freshwater and near-shore marine ecosystems that sustain nearly 85% of total fisheries landings yet spatially represent less than 10% of the planet's total aquatic environment. Within the context of these most productive aquatic ecosystems, fisheries alone appropriate between 24 and 35% of the NPP available.

3.2 Forms of Direct Energy Inputs

Culturally mediated energy inputs to fishing activities can be categorized into direct and indirect types. Common indirect inputs, often referred to as embodied energy inputs, are those associated with building and maintaining fishing vessels and providing fishing gear, bait, and ice. In contrast, in most fisheries, direct energy inputs are typically those required to propel fishing vessels and deploy fishing gears. The three dominant forms of energy dissipated to these ends include animate, wind, and fossil fuel energy, each of which are briefly described next.

3.2.1 Animate Energy

Animate energy is the one form of culturally mediated energy common to all of the world's fisheries regardless of their technological sophistication. In many traditional artisanal fisheries, human muscles still provide the bulk of the energy used to deploy gears, handle the catch, and, where they are employed, propel vessels. However, while animate energy inputs may represent the dominant form of energy applied in a fishery, in absolute terms, the quantities involved are typically small. For example, among subsistence fisheries in which animate energy inputs predominate, the nutritional value of the catch must routinely exceed the energy expended by the human muscles engaged in the fishery if it is to remain viable. In the case of most contemporary fisheries, however, while human animate energy inputs remain part of the production equation, they are generally dwarfed by the inputs of wind or fossil fuel energy.

Unlike preindustrial agriculture wherein a wide variety of animals were domesticated to provide important secondary sources of animate energy, relatively few fisheries have systematically employed animals. Examples, however, include the traditional use of trained fishing cormorants in parts of China and Japan and the now largely outmoded European practice of using otters and diving ducks to drive fish into traps.

3.2.2 Wind

For as long as people have sailed, it is likely that wind energy has been used to support fishing activities. The integration of wind energy into fisheries not only allowed fishing vessels to be propelled farther and faster than would otherwise be possible, it facilitated the development of fishing techniques that would otherwise have been impractical, if not impossible, to conduct from a rowed boat. Specifically, various trawl or dragger fisheries in which nets or dredges are towed either through the water or along the seafloor were almost all first developed within the context of sail fisheries.

Although little if any research has been conducted to quantify the wind energy inputs to sail-assisted fisheries, prior to the introduction of fossil fuels, it likely accounted for a large proportion of the culturally mediated energy inputs to global fisheries.

3.2.3 Fossil Fuels

As with most other food production sectors, fossil fuels have become the dominant form of energy used in fishing in a relatively short period of time. The process began in England in the late 1800s, when coal-fired steam engines were first installed on trawl fishing vessels to provide power for both propulsion and net hauling. With the advantages of increased speed and power, together with the ability to operate regardless of the wind, steam trawling expanded rapidly. Although coal- and oil-fired steam engines remained in use on fishing vessels throughout much of the 20th century, their significance was ultimately eclipsed by internal combustion engines.

Gasoline- and diesel-fueled internal combustion engines were first adapted for use on fishing boats in the early 1900s. Technological advances made during and after the Second World War, however, greatly accelerated their integration into fisheries. Consequently, over the past 50 years not only has the size of the global fishing fleet increased but so has its power. The trend to larger, more powerful fishing vessels is exemplified by the emergence of so-called supertrawlers, vessels that can exceed 100 m in length with propulsive engines well in excess of 10,000 horsepower. At the same time, more and more relatively small engines are introduced annually into small-scale fisheries around the world. Given these twin trends of increasing prevalence and size of engines, it is not surprising that the bulk of the

world's catch is now harvested using vessels propelled by fossil fuels.

3.3 The Relative Importance of Direct and Indirect Energy Inputs

Among modern industrial fisheries in which the major direct and indirect culturally mediated energy inputs have been systematically analyzed using either process analysis or input-output techniques, a consistent pattern has emerged. Direct fuel energy inputs typically account for between 75 and 90% of the total culturally mediated energy inputs, regardless of the fishing gear used or the species targeted (Fig. 4). Depending on the character of the fishery and the scope of the analysis conducted, the remaining 10 to 25% is generally composed of energy inputs associated with vessel construction and maintenance, and the provision of labor, fishing gear, bait, and ice if used.

On most fishing vessels, direct fuel inputs are used primarily for vessel propulsion. In some fisheries, however, secondary energy-consuming activities, including onboard processing, refrigeration, and freezing, can account for a nontrivial portion of the fuel burned. Squid jig fisheries are interesting and fairly extreme examples of fisheries in which a relatively large proportion of fuel inputs are used for activities other than vessel propulsion. In these fisheries, vessels typically employ batteries of high-intensity lamps, automated jigging machines, and freezers, all powered by diesel-fuelled generators to attract, hook, and preserve the catch while at sea. As a result, these nonpropulsion energy demands can, in combination, account for a much as 40% of the total fuel burned (Fig. 5).

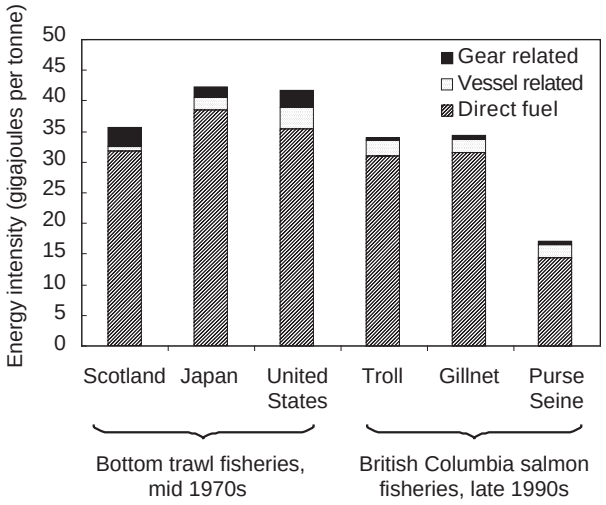

FIGURE 4 Relative contribution of direct and indirect energy to various fisheries. Data sources: Scotland: Edwardson, W. (1976). The energy cost of fishing. *Fishing News Intl.* **15**(2), p. 36–39. Japan: Watanabe and Uchida (1984); United States: Rawitscher (1978); British Columbia salmon fisheries: Tyedmers (2000).

Among indirect energy inputs, those associated with building and maintaining the fishing vessels themselves regularly account for the largest fraction (Fig. 4). This is particularly the case when a vessel's major components (i.e., its hull, superstructure, decks, and holds) are fabricated primarily from relatively energy-intensive materials such as aluminum and steel as opposed to wood or fiberglass. For example, an analysis of the direct fabrication and major embodied energy inputs to build and equip two equivalent 10 m long salmon gillnet fishing vessels, one constructed largely of fiberglass and wood and the other of aluminum, found that the embodied energy inputs were over 50% higher in the case of the aluminum-hulled vessel (Table I). Moreover, when the electricity required to fabricate the aluminum-hulled vessel is included in the analysis, the total embodied energy costs of this vessel rise to 2.5 times that of its fiberglass counterpart.

3.4 Comparing the Energy Performance of Fisheries

Most energy analyses of fisheries have focused largely, if not exclusively, on evaluating the direct fuel inputs to fishing. This relatively narrow focus

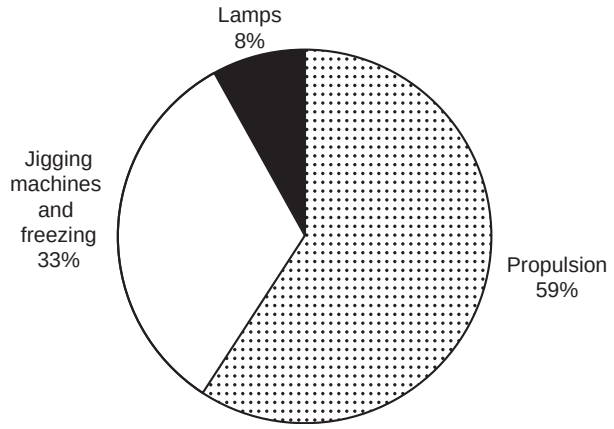

FIGURE 5 Functional fuel utilization on a Japanese long-distance squid fishing vessel. Data from Ishikawa, *et al.* (1987). A case study of energy analysis of long distance squid angling. *Bull. Jap. Soc. Sci. Fish.* **53**(9), 1525–1531.

TABLE I

Direct and Indirect Energy Inputs to Build a 10-Meter-Long Salmon Gillnet Fishing Vessel Fabricated from Either Fiberglass or Aluminum

	Material and embodied energy inputs			
	Fiberglass hull		Aluminum hull	
Inputs	kg	GJ	kg	GJ
Glass

Total embodied energy		329		506
Electricity to weld hull, etc.				324
Total		329		830

not only reflects the fact that these inputs dominate the energy profile of fishing, but detailed analyses of indirect inputs tend to be labor intensive and time consuming. Therefore, in order to facilitate the comparison of as wide a range of fisheries as possible, throughout the balance of this review only the direct fuel energy inputs to various fisheries is considered. Consequently, the energy intensities of various fisheries is expressed in terms of the liters of fuel burned per "round" or live weight tonne of fish or shellfish landed.

However, as food fisheries can also be thought of as food energy "producing" systems, it is also useful to calculate their energy efficiency. Traditionally within analyses of agriculture, aquaculture, and fisheries systems, this has been done by calculating either their industrial energy input to edible food energy output ratio or its inverse, the edible energy return on investment (EROI) ratio. As the nutritional importance of fish and shellfish is primarily a function of their protein content, edible protein energy output is the most meaningful basis of comparison. Therefore, edible protein energy return on investment (protein EROI) ratios for various fisheries are also presented.

4. ENERGY PERFORMANCE OF FISHERIES FOR HUMAN CONSUMPTION

To date, most energy analyses of fisheries for human consumption have concentrated on relatively large-scale industrial fisheries that are conducted for commercial gain. Moreover, few analyses have been undertaken on fisheries based in the Southern Hemisphere. As a result, much of the discussion that follows reflects these biases.

Given the diversity of fisheries for human consumption, both in terms of species harvested and fishing gears used, it is helpful to focus on broad subsets when considering their energy performance. Consequently, the following discussion is organized into four major divisions: fisheries for demersal species, or those fish that spend much of their life on or near the ocean floor; fisheries for pelagic species, or those fish that spend most of their life swimming in the water column; fisheries for invertebrates; and subsistence fisheries.

4.1 Fisheries for Demersal Species

Fisheries for demersal finfish species are some of the largest, most economically important fisheries in the world. Each year, upwards of a hundred species of demersal finfish may be harvested in fisheries globally. Of these, the most important include the various gadoid, or codlike species, and flatfish species. Given that, by definition, demersal species live on or near the ocean floor, fisheries for these species are undertaken in waters ranging from under 10 m to many hundreds of meters deep. As a result, many different types of fishing gears are used in their capture. By far the largest tonnages, however, are

harvested each year using trawl and to a lesser extent, long-line fishing gear.

As a result of their importance, fisheries for demersal species have been the subject of numerous energy analyses over the last three decades (Table II). Some of the most recent work to systematically evaluate the fuel consumption of a wide variety of demersal finfish fisheries examined 29 fisheries involving more than 3000 vessels based in Atlantic Canada, Iceland, Norway, and Germany. As of the late 1990s, these fisheries together harvested approximately 1.2 million tonnes of fish annually from ecosystems around the North Atlantic. While fuel use intensities varied by an order of magnitude among these 29 fisheries, from lows of just under 300 l/t to more than 2000 l/t, on average they consumed just over 500 liters of diesel per tonne of fish landed.

TABLE II

Energy Performance of Industrial Fisheries for Direct Human Consumption

Main fishery targets	Gear	Time frame	Location of fishery	Fuel use intensity (liters/tonne)	Edible protein EROI
Demersal fisheries					
Redfish spp.	Trawl	Late 1990s	North Atlantic	420[a]	0.11

Notes to sources: [a]Tyedmers (2001); [b]Watanabe and Okubo (1989); [c]Tyedmers (2000); [d]unpublished data.

Much of the variability in fuel use intensity among the 29 North Atlantic fisheries appears to be a function of two factors. Not surprisingly, the relative abundance and catchability of various targeted species has a major influence on resulting energy performance. Evidence of this is can be seen by comparing average fuel use intensities of various trawl fisheries targeting very different species assemblages in different parts of the North Atlantic (Table II). Specifically, Canadian and Icelandic trawl fisheries targeting redfish species experienced average fuel use intensities of just over 400 l/t while trawl fisheries for cod and related species from across the North Atlantic averaged 530 l/t. At the other extreme, German trawl fisheries targeting high value flatfish species in the North Sea consumed approximately 2300 liters of diesel per tonne of fish landed.

A second factor that affects the energy performance of fisheries is the type of fishing gear employed. This can be illustrated by focussing on those North Atlantic fisheries that targeted Atlantic cod and related species (Table II). On average, cod fisheries in which Danish seine nets were used burned approximately 440 liters per tonne of fish landed. In contrast, long-line fisheries averaged 490 l/t, while trawl fisheries for cod averaged 530 l/t.

Looking beyond the North Atlantic, a comprehensive analysis of the fuel use intensity of all Japanese fisheries as of the early 1980s suggests that North Pacific fisheries for demersal species may be more energy intensive than many of their North Atlantic counterparts (Table II). Specifically, Japanese trawl fisheries targeting either Alaskan pollock, various flatfish species or yellow croaker burned, respectively 600, 750, and 1500 liters of diesel per tonne of fish landed. It is important to keep in mind, however, when comparing the performance of these Japanese fisheries with those described previously from the North Atlantic, that almost 20 years has elapsed between when the two data sets were acquired. Over that period of time much can have changed that might influence the energy performance of any specific fishery. As we shall see, however, evidence from a variety of fisheries suggests that there has been a general tendency for the energy performance of industrial fisheries to decline over time.

From an energy efficiency perspective, the performance of fisheries targeting demersal species also ranges widely. As measured in terms of their edible protein EROI, the 29 North Atlantic fisheries discussed previously together averaged 0.095. This means that the edible protein energy content of all the fish that they landed amounted to just under 10% of the fuel energy that they burned. More generally, edible protein EROI values for individual fisheries targeting demersal species can range from approximately 0.02 to over 0.1 (Table II). While efficiencies in this range may seem low, they are broadly in keeping with the energy performance of other industrial fisheries and, in fact, compare favorably with other animal protein production systems (Table III).

4.2 Fisheries for Pelagic Species

Pelagic fish species harvested for human consumption encompass a diverse variety of animals. They range from the small, densely schooling, largely planktivorous herrings, to large, top-level carnivores including various tuna and billfish species. What they generally have in common, however, is that all are typically harvested using fishing gears deployed at or near the ocean's surface.

TABLE III

Edible Protein EROI values from Livestock and Aquaculture Production Systems

Production system (locale)	Edible protein EROI
Carp—unspecified culture system (Indonesia)	0.70

For sources, see Tyedmers (2001).

Reflecting the diversity of their quarry, fisheries for pelagic species display the widest range of energy intensities of fisheries for human consumption (Table II). At one extreme are those that target herring and associated species using purse seine or Danish seine nets. For example, recent analyses of herring fisheries from both the Atlantic and Pacific oceans indicate that they typically consume between 100 and 150 liters of diesel per tonne of fish landed. It is interesting to note, however, that an analysis of a herring fishery based in Japan, conducted in the early 1980s, reported a fuel use intensity of 1000 l/t. It is unclear from the data available why such a large difference should exist between this fishery and comparable fisheries in other parts of the world.

In sharp contrast, analyses of fisheries for relatively high value, large pelagic species like tuna and billfish report fuel use intensities ranging from 1400 to 3400 l/t (Table II). Among these fisheries, those that use long-line fishing gear are often the most energy intensive.

Between these two energy performance extremes, lie fisheries for Pacific salmon. Reported fuel use intensities of salmon fisheries range from just under 400 l/t to 1800 l/t (Table II). In a comparative analysis of the three fishing gears used to harvest salmon in British Columbia, Canada, it was found that purse seiners burned, on average, just under half the amount of fuel, per tonne of salmon landed, than did either gillnet or troll fishing boats.

Largely as a result of the major differences in the amount of fuel that they burn, the energy efficiency of fisheries for pelagic species, measured in terms of their edible protein EROI ratios, range from as low as 0.02 (or 2%) to over 0.5 (or 50%).

4.3 Invertebrate Fisheries

While fisheries for invertebrates account for a relatively small proportion of global landings (Fig. 1), they are some of the most lucrative fisheries in the world. It is not surprising therefore that in many instances they can be highly energy intensive. For example, fisheries targeting various species of shrimp and lobster often burn upwards of 1000 liters of fuel per tonne of landings (Table II). Interestingly, however, not all relatively high value invertebrate fisheries are this energy intensive. Some, including the valuable North Atlantic scallop and crab fisheries, consume between 300 and 350 liters of fuel per tonne of shellfish landed.

As measured in terms of their edible protein EROI ratios, many invertebrate fisheries are relatively energy inefficient. This not only reflects rather high fuel use intensities, but the fact that many species of invertebrates yield relatively small quantities of edible meat. For example, the adductor muscle in scallops generally only represents 10 to 12% of the live weight of the animal. Similarly, the edible portion of many crab and lobster species normally does not exceed 30% of their live weight. In contrast, edible muscle usually constitutes between 50 and 60% of most finfish species.

4.4 Subsistence Fisheries

To date, little attention has been paid to the energy performance of small-scale fisheries. However, an analysis of a northern Canadian aboriginal subsistence fishery targeting primarily pike and pickerel in rivers and lakes provides some intriguing and potentially worrying insights into their performance. From data collected through the late-1970s, human ecologist Fikret Berkes estimated that Cree fishermen, based in the community of Fort George, Quebec, burned, on average, approximately 1400 liters of gasoline per tonne of fish landed in the course of tending their fishing nets. Remarkably, this level of fuel use intensity is on the same scale as some of the most energy intensive industrial fisheries for human consumption in the world. It also highlights the extraordinary vulnerability of fossil fuel-dependent artisanal fisheries, and ultimately the communities that depend on them, to disruptions in the supply or increases in the price of fuel.

4.5 Temporal Trends in Energy Performance

Numerous analyses have been undertaken to evaluate how the energy performance of fisheries for human consumption has changed through time. Although the time periods and types of fisheries analyzed differ, when their results are expressed in a consistent format, say in terms of their edible protein EROI ratios, a regular and troubling pattern emerges (Fig. 6). Over time, the energy performance of virtually every fishery analyzed has declined, and in some cases quite dramatically. For example, the edible protein EROI ratio of the entire New Bedford, Massachusetts-based fishing fleet experienced a five-fold declined from just over 0.15 (or 15%) to under 0.03 (or 3%) over the period from 1968 to 1988 (Fig. 6A). Similarly, over the course of a decade, beginning in the late 1960s, the edible protein EROI

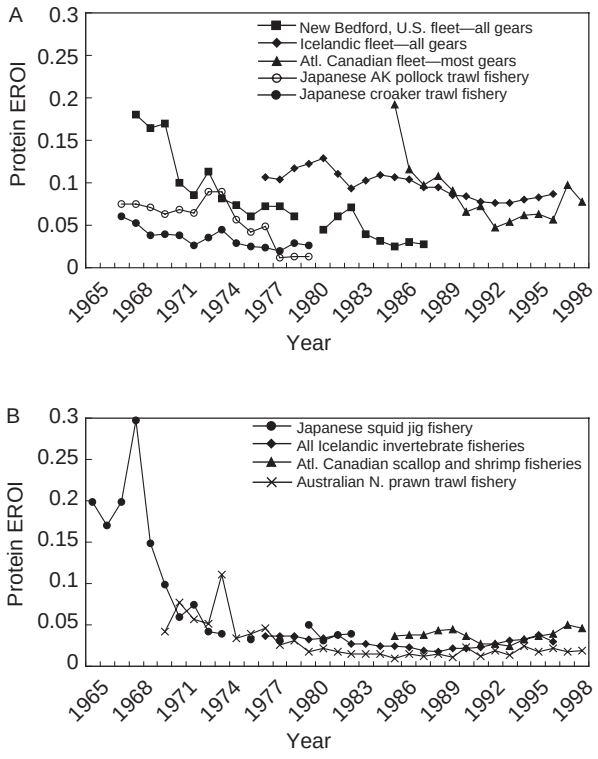

FIGURE 6 Changes in edible protein EROI ratios of fisheries for human consumption: 1965–1999. (A) Demersal finfish fisheries. (B) Shellfish fisheries. Data compiled from Watanabe and Uchida. (1984); Sato, K. *et al.* (1989). Chronological change of energy input for squid angling in Japan 1956–1983. *Bull. Jap. Soc. Sci. Fish* **55**(**11**), 1941–1945; Mitchell and Cleveland (1993). Resource scarcity, energy use and environmental impact: A case study of the New Bedford, Massachusetts, USA Fisheries. *Environ. Management* **17**(**3**), 305–317; Tyedmers (2001); and unpublished data.

ratio of the entire Japanese-based squid fishing fleet declined from over 0.20 (or 20%) to consistently below 0.04 (or 4%) (Fig. 6B).

While their relative importance may vary between fisheries, the two factors that likely contribute most to the general trend to poorer energy performance over time include decreases in relative abundance or proximity of targeted fisheries resources, and increases in the size, power, and technical sophistication of both fishing vessels and fleets.

5. ENERGY PERFORMANCE OF FISHERIES FOR REDUCTION

As many as 50 countries routinely report some production of fish meal and oil. However, less than a dozen account for the lion's share of total annual global output. The most significant of these include Peru, Chile, Iceland, Norway, Denmark, Japan, the United Kingdom, the United States, and the countries of the former Soviet Union.

TABLE IV

Fuel Energy Intensities of Reduction Fisheries as of the Late 1990s

Main fishery targets	Gear	Location of fishery	Fuel use intensity (liters/tonne)
Capelin/herring	Purse seine	NE Atlantic	20
Menhaden	Purse seine	NW Atlantic	32
Capelin/herring	Trawl	NE Atlantic	80
Blue Whiting	Purse seine	NE Atlantic	85
Sand Eels/herring	Trawl	NE Atlantic	95
Herring/sand Eels	Purse seine	NE Atlantic	100
Herring/mackerel	Trawl	NE Atlantic	110

Data source: Tyedmers (2001).

Although they account for 30% of global landings, most of the world's fish meal and oil production is derived from large tonnage landings of a relatively small number of species. In the waters off Peru and Chile the major species harvested for reduction include the Peruvian anchoveta, Inca scad, and the South American pilchard. In the northeast Atlantic, the main species destined for reduction include capelin, blue whiting, Norway pout, European sprat, various species of sand eel together with smaller quantities of Atlantic herring and Atlantic mackerel. In U.S. waters, Atlantic and Gulf menhaden account for virtually 100% of landings destined entirely to reduction.

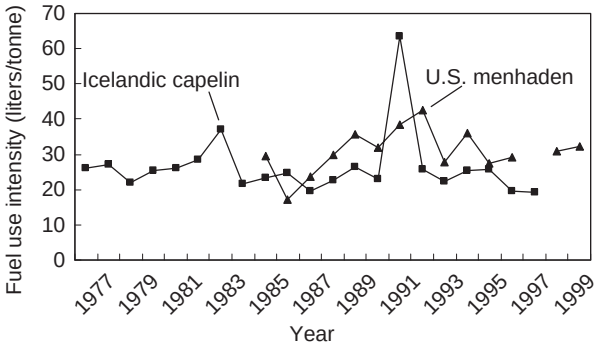

FIGURE 7 Changes in fuel use intensity of fisheries for reduction, 1977 to 1999. Data from Tyedmers, 2001, and unpublished data.

Recent analyses of various North Atlantic fisheries for reduction indicate that in most instances, they consume less than 100 liters of diesel per tonne of fish landed (Table IV). Remarkably, it is not unusual for some of the largest of these fisheries to routinely burn well below this mark. For example, time series data from both the Icelandic and American purse seine fisheries, targeting capelin and menhaden respectively, indicate that in recent decades, they have seldom consumed more than 40 liters of fuel per tonne of fish landed (Fig. 7). Such low and seemingly stable fuel use intensities would seem to suggest that in both instances, fish stocks and fleet effort are being carefully managed.

While the data available do not support direct head-to-head comparisons, from the spectrum of fuel use intensities associated with various North Atlantic fisheries for reduction, it would appear as if those employing purse seine nets are routinely less energy intense than those using trawl fishing gear (Table IV).

6. CONCLUSIONS

Global fisheries are highly varied. They harvest an enormous diversity of aquatic animals using a variety of mostly vessel-based fishing gears. Not surprisingly, therefore, the major forms and absolute quantities of culturally mediated energy inputs dissipated in their execution also vary widely. However, in the case of most fisheries, particularly large-scale industrial fisheries over the past half-century, fossil fuel inputs have come to dominate their energy profile.

Of concern, though, is evidence from a number of fisheries from around the world of a general tendency to poorer energetic performance over time. This pattern of ever-increasing apparent biophysical scarcity reinforces the oft expressed concerns regarding both the declining status of many of the world's fish stocks and the growing size and power of the global fishing fleet. In spite of the ongoing declines in their energy performance, however, many industrial fisheries for human consumption remain energetically competitive with other animal protein–producing systems.

Glossary

flywheel Rotating object, such as a wheel, often used for opposing and moderating by its inertia any fluctuation in speed in the machinery with which it revolves; also capable of storing mechanical energy.

high-temperature superconductor (HTS) A superconductor with a critical temperature above the boiling point of nitrogen.

motor/generator (M/G) Combined motor and generator used to convert between the mechanical energy of the flywheel and electrical energy.

rotational kinetic energy Energy in the form of rotational motion given by the quantity $KE = 1/2\ I\omega^2$, where KE is the kinetic energy (units of joules), I is the moment of inertia (units of kgm^2, and ω is the rotational speed (units of rad/s).

specific energy Energy stored divided by mass of object (units of m^2/s^2).

The flywheel, often in the form of a spinning disk or cylinder, stores rotational kinetic energy. As an integral part of the spindle whorl and the potter's wheel, the flywheel is among the most ancient mechanical devices known to humans. The use of the wheel for storing energy seems to be older than its use as a means of supporting vehicles. The flywheel is a fundamental element of many machines, opposing and moderating by its inertia any fluctuation of speed in the machinery with which it revolves. The flywheel principle is also used in several toys such as the top and the yo-yo. More recently, flywheels have been used as mechanical batteries to store energy for electrical applications. If a motor/generator (M/G) is attached to a flywheel, rotational kinetic energy may be transformed easily and efficiently into electrical energy and vice versa.

1. INTRODUCTION

The essential components of the flywheel are the rotor, bearings, power conversion, and containment. The rotor is the rotating mass in which the energy is stored. The bearings connect the rotating part of the flywheel to a nonrotating platform. Conversion of the stored energy to mechanical power may be accomplished with a mechanical linkage such as a transmission gear. When the flywheel is used as a mechanical battery, a motor/generator (M/G) converts energy between rotating kinetic and electrical. Flywheels are capable of attaining high specific energy, and tip speeds of high-performance flywheels are several times the speed of sound in air. Such flywheels are contained in a vacuum vessel, and an additional safety-related structure often surrounds the flywheel to contain possible debris in case of failure.

The kinetic energy E of a rotating rigid body is

$$E = 1/2\ I\omega^2,$$

where I is the moment of inertia of the body about the axis of rotation and ω is the angular frequency of rotation. The flywheel increases its rotational speed as energy is accumulated. The flywheel slows when it discharges energy for use.

A distinctive feature of all flywheel energy storage (FES) systems is their very high power density. They can be charged at very high rates and deliver very high powers, with the only limit being the rating of the transmission system and the torque the flywheel itself can withstand. Power densities greater than 500 W/kg are commonplace. The specific energy of a

 © 2004 Elsevier Inc. All rights reserved.

flywheel is comparable to electrochemical batteries in the range of 10 to 50 Wh/kg.

The discussion in this article is limited to the flywheel used for energy storage. Flywheels have several advantages over chemical batteries. First, flywheel life is nearly independent of the depth of discharge. The power is limited by the power electronics and the size of the M/G rather than by electrochemistry. Second, the state of the charge of a flywheel battery is readily determined from its rotational velocity, whereas determination of the state of charge for an electrochemical battery is more difficult. The flywheel generates no emissions, makes little noise, and is made of materials with negligible disposal problems.

2. ROTOR

The rotor is the rotating part of the flywheel. It consists of components of the bearing, the M/G, and material whose only purpose is to provide the moment of inertia.

The maximum amount of kinetic energy that can be stored in a rotating solid is determined by its geometry and the strength of the materials that compose the solid. For a rotor composed of a single isotropic material, which is the case for most metals, the maximum specific energy e is given by

$$e = K\sigma_u/\rho,$$

where σ_u is the ultimate burst strength, ρ is the density, and K is a geometric factor of unity or less. The geometric factor K depends only on the shape of the rotor, so the specific energy is independent of size. Because specific energy is proportional to the square of the velocity, a consequence of this equation is that, for a fixed geometric proportion, the rim speed at which a rotor will burst is independent of size. Thus, rim speed is a better figure of merit for comparing rotor materials than is rotational speed because the rotational speed at which the rotor bursts is inversely proportional to size; that is, smaller rotors can attain higher rotational speeds.

In general, when calculating the burst speed, one must take into account tangential hoop stress and radial stress independently. For most geometries with isotropic materials, hoop stress dominates. For operating flywheels, a factor of safety is introduced so that none of the components ever approaches burst speed. Moderate-strength steel, such as 4130, is often used for metallic rotors because of low cost and manufacturing experience. Maraging steel and titanium alloys are used for metallic rotors with higher specific energy. Circumferential stress must also be taken into account when the flywheel is accelerating or decelerating. However, in nearly all cases, the stress induced by acceleration is negligible when compared with the stress induced by centrifugal force.

The specific energy of flywheels can increase dramatically if anisotropic materials such as fiber composites are used to create the rotor. Although many combinations and designs of composites are possible, the most common designs contain long strands of high-strength filaments embedded in an epoxy matrix. The strands are wound predominantly in the circumferential direction. An example of such a rotor is shown in Fig. 1. E-glass, S-glass, graphite, and Kevlar are typically used fibers. Graphite fibers are the strongest and may be 3 to 10 times stronger than, and approximately one-fifth as dense as, steel. Graphite is a crystalline form of carbon. The diameter of an individual graphite fiber ranges from approximately 25 to 800 μm, and the strength of a fiber can range from approximately 2 to 8 Gpa. Usually, the smaller the diameter, the stronger the fiber.

In addition to providing higher specific energy, fiber composites provide an advantage over metals in the area of confinement. When a metallic rotor breaks, its debris usually includes several large pieces moving at high speed. A fiber composite rotor tends to fail with small shard-like pieces or even small grains.

Fiber-based composites exhibit low shear stress, which is related to delamination or separation of the epoxy from the fiber. Thus, hoop-wound designs that contain fiber composites are very strong in the hoop

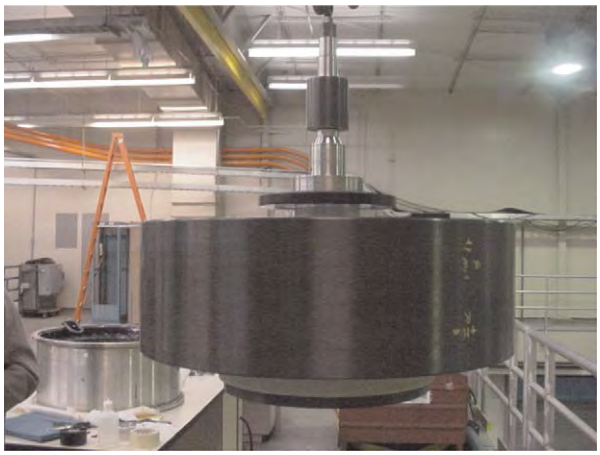

FIGURE 1 Photo of a 1-kWh flywheel with graphite fiber rotor. (Courtesy of Boeing.)

direction but relatively weak in the radial direction. Radial stress is the result of the tendency of the faster moving outer layers to expand more under centrifugal force than the slower moving inner layers. Radial strength can be increased by introducing fibers oriented in the radial direction in a small fraction of the rotor volume.

The radial growth problem also manifests itself in designs that position bearings and power conversion equipment on shafts or hubs at relatively small radii. Connection to a rim with a much larger radius must be made in a manner that takes into account the difference in radial expansion. This is often accomplished by using spokes, flexibly shaped hubs, or connectors that accommodate the radial expansion with a contraction along the axial direction of rotation.

With composite rotors, the kinetic energy in a (large) frisbee-sized flywheel would be approximately 1 kWh, and a person-sized flywheel could store 20 to 40 kWh. Metallic rotors are typically limited to rim velocities of 300 to 500 m/s, whereas composite rotors can easily achieve speeds above 1000 m/s. The highest reported rim velocity at the time of this writing was 2087 m/s. A commonly used rotor design calls for lower strength, lower cost glass fibers for the inner section of a wheel and higher strength, higher cost graphite fibers for the outer section.

It is desirable that the rotor remain rigid over all of its operating speed. Bending modes of the rotor may become resonant vibrations if the rotational speed is at the same frequency as the bending mode. Fibers may be strategically placed along the axial direction of the rotor or in some other direction to change the frequency of a bending mode.

Flywheel design must also take into account the influence of rotor dynamics. A prominent example of this influence is the use of flywheels as mechanical batteries on vehicles. A spinning flywheel has a gyroscopic moment that is proportional to the rotational velocity and acts to keep the axis of rotation always in the same direction. If the vehicle changes direction in a way that changes the axis of rotation, a large torque can be exerted on the vehicle. To overcome this tendency, the flywheel can be suspended in a special gimbaled mounting, or two counter-rotating flywheels can be paired so that the net gyroscopic moment is zero.

3. BEARINGS

The bearings connect the rotating part of the flywheel with a stationary housing and must support the weight of the rotor, keep it in position, and allow it to rotate freely. These functions must accommodate any motion associated with both the normal rotation of the flywheel and any change in balance of the rotating components. The bearings must resist any external influence that exerts a torque on the wheel that is resisted by the wheel's gyroscopic moment. Bearings may also be divided into thrust bearings and journal bearings. A thrust bearing provides most of its force along the axis of rotation, whereas a journal bearing provides most of its force perpendicular to the axis of rotation.

The bearings of a flywheel must provide stability against motion in any of the 5 degrees of freedom associated with a rotating rigid body. From a mechanical viewpoint, the bearings must provide levitation force, stiffness, and damping. The bearings provide stiffness, which may be thought of in terms of a set of springs that connect the rotor to a massive foundation. A suspended system of this sort will exhibit resonant frequencies at which oscillation amplitudes can be large if an exciting force exists at this frequency. If the rotor is rotating at a speed close to one of these resonant frequencies, it can excite this oscillation. Such rotational speeds are called critical speeds or criticals. The three fundamental modes of oscillation for a rotor with an axis of rotation in the vertical direction are shown in Fig. 2. The oscillation along the axis of rotation (vertical mode in Fig. 2) is generally not harmful. However, a mode transverse to this axis (radial mode) can lead to large imbalance forces as the center of mass rotates at some radius about the system's geometrical center, defined by the bearings. This imbalance force increases with oscillation amplitude and with the square of the rotational frequency. If the criticals are insufficiently damped, the imbalance forces may be large enough

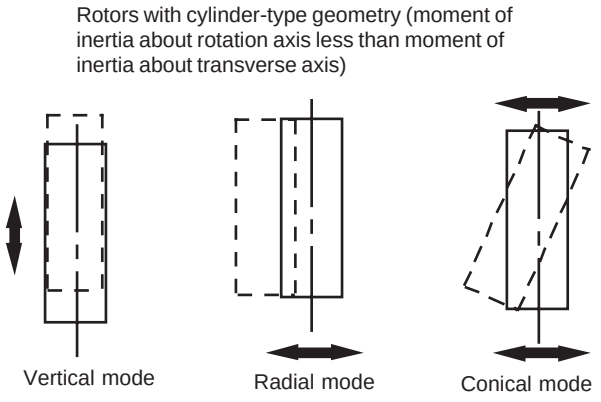

FIGURE 2 Schematic of rigid body critical modes for rotor with vertical rotational axis.

TABLE I

Influence of Bearing Type on the Design and Performance of Flywheels with Stored Energy in the 1- to 10-kWh Range

Bearing type	Levitation pressure (MPa)	Intrinsic loss fraction of KE_{max}/h	Parasitic loss fraction of KE_{max}/h	Total loss fraction of KE_{max}/h	Criticals	Sensitive to rotor imbalance
Mechanical	>10	0.1	0.02	0.12	Design out of operating range	Most
Magnetic	0.6	<0.001	0.01	0.01	Tunable	Some
Superconducting	0.3	<0.0001	0.001	0.001	Far below operating range	Least

to overcome the restoring force of the bearings and destroy the flywheel.

If the rotor runs in vacuum, some of the bearing components must run in vacuum. Typically, an auxiliary water cooling system is used for mechanical bearings and active magnetic bearings (AMBs). Superconducting bearings require a cryogen. The energy that is needed to operate the refrigerator of the pumps for the coolant is a parasitic loss.

Three general types of bearings are used in flywheels: mechanical, magnetic, and superconducting. Table I provides information for an approximate comparison of the influence of bearing type on flywheel design and performance of flywheels with stored energy in the 1- to 10-kWh range.

Table I shows that the losses of mechanical bearings render these bearings suitable for FES for storage times on the order of minutes to perhaps an hour. Losses of magnetic bearings render these bearings suitable for storage times up to perhaps a day. Superconducting bearings are suitable for FES with storage times up to many days.

FES systems with mechanical bearings have been sold commercially. Prototypes of FES devices that contain magnetic bearings and superconducting bearings are being field-tested. Development continues in all of these bearing technologies.

3.1 Mechanical Bearings

Mechanical bearings can be divided into several subcategories: rolling-element bearings, hydrodynamic journal bearings, gas bearings, squeeze-film bearings, and hydrostatic bearings.

Rolling-element bearings are probably the most common type of bearing used in machinery. They are relatively compact, can transmit heavy loads of various forms, and can be installed and serviced easily. Several specific design types with a range of stiffness are available. Damping in rolling-element bearings is very small but may be enhanced by squeeze-films.

Journal bearings consist of a circular section of shaft (the journal) rotating inside a bearing "bush," which is nominally circular. The clearance space between the two is partially filled by the lubricating fluid, which is pressurized by the motion. In addition to reducing the friction in rotational motion, this hydrodynamic film behaves like a complicated arrangement of springs and dampers and so influences the critical speeds and imbalance response. If designed improperly, the film can contribute to rotor instability, which is the result of self-excited vibration. Hydrostatic bearings differ from hydrodynamic bearings in that the lubricant pressure required to separate the bearing surfaces is supplied from some external pressure source and is not a result of journal rotation.

Gas bearings are similar to oil-lubricated bearings, but because the gas is compressible, the behavior differs. Compared with hydrodynamic bearings of similar surface area, gas bearings carry much smaller loads and generally operate with smaller film clearances. The advantage of gas bearings is that they tend to have much smaller rotational losses because the viscosity of a gas is much smaller than that of a liquid. Several types of gas bearings are available: self-acting, externally pressurized, porous wall, and flexible vane.

Squeeze-film bearings are a special case of hydrodynamic bearings. This type of bearing consists of a conventional rolling-element bearing and an external structure for damping radial motion. The outer race of the rolling-element bearing is surrounded by a damper casing. A small radial clearance between the outer race and the inner bore of the casing accommodates a thin lubricating film. The fit is so close that the outer race of the conventional bearing does not rotate. However, the squeezed film is pushed from one region to another by the radial force of the

outer race. The lubrication pressure is built up purely by the action of squeezing the film in this clearance. Friction between the lubricant and the races, and inertia in the lubricant itself, produces a radial stiffness.

If the rotor of the flywheel is rotating in air, any of the preceding bearings can be used. If the rotor operates in vacuum, the number of bearing choices is limited and the vapor pressure of the lubricant must be low. Solid-lubricated ceramic bearings (e.g., those made of silicon nitride [SiN] and lubricated with molybdenum disulfide or other proprietary solid films) are often used in this situation.

3.2 Active Magnetic Bearings

In AMBs, levitation is achieved by the attractive force between an energized magnet and a ferromagnetic body. Typically, the magnet is a stationary electromagnet and the rotor is a ferromagnet. Such a system is inherently unstable, so active feedback is used to modulate the field of the electromagnet depending on the position of the rotor. Such bearings have been used for decades in industrial applications and have been used recently in flywheel prototypes.

In the basic setup of an AMB, position signals from gap sensors are used by a controller power amplifier to set the appropriate currents and voltages of the electromagnets in such a way that stable levitation takes place. In the example of an iron rotor below a ferromagnet, if the rotor starts to fall so that the gap becomes too large, the current in the magnet is increased to increase the attractive force. Similarly, if the gap becomes too small, the current is decreased. Control is effective on bearing activation and continues for all rotational speeds.

A distinctive advantage of the AMB is that it can adapt itself to operating conditions and can communicate with its environment. Within certain limits, the AMB can be set to operate with arbitrary stiffness and damping, independent of the rotor position. The air gap (i.e., the position of the rotor) can be controlled in real time, independently of the stiffness. As a consequence, it is possible to maintain a fixed rotor equilibrium position for various loads. A rigid rotor can be made to rotate about its principal axis without transmitting vibrations to the foundation. By changing the stiffness and damping, the rotor is capable of easily crossing the critical speeds of the bearings. In addition, bending vibrations of an elastic rotor can be significantly reduced through an appropriately designed active control loop. Damping and stiffness are usually mutually dependent.

Early AMBs were powered by analogue controllers; however, the tendency now is toward digital controllers. The design of early AMB systems was based on proportional–integral–differential control algorithms. In general, the feedback law is chosen to be linear and is developed on the basis of the system linearized about the static equilibrium position. Recent investigations have shown that there is performance merit in the use of certain nonlinear feedback laws.

Typically, switching amplifiers are used to power the coils. These amplifiers use transistor switches that connect the coils to a DC voltage. The transistors are either on or off and produce on the coil a square wave voltage, which yields a sawtooth current. By controlling the on and off times, most current waveforms can be produced in the coils. The disadvantage of the switching amplifiers is that the oscillations in the current cause remagnetization loss in the magnetic bearing. However, the shorter the switching period, the weaker are these oscillations.

One of the fundamental limitations of an AMB is that the bearing force slew rate is limited because the magnet coils are inductive and the power supply to the driving amplifier is subject to a maximum voltage. The slew rate limitation causes the bearing force to change more slowly than the control signal demands and, thus, introduces a phase lag. Another way in which to state this effect is that the inductance of the coils and the maximum voltage provide an upper limit to the stiffness of the system.

The position sensor typically uses a high-frequency carrier and provides a linear signal versus the rotor location. Optical sensors, inductive displacement sensors, capacitance sensors, Hall effect sensors, and eddy current sensors are commonly used. The sensors must be contact free and able to measure a rotating surface. The surface quality of the rotor and the homogeneity of the material at the sensor will influence the measurements. A bad surface will produce noise disturbances, and geometry errors may cause disturbances with the rotational frequency or with multiples thereof. “Training” of the sensors in place may alleviate some of these noise problems. In this technique, the rotor is rotated at some fixed speed, the surface is measured over many revolutions, and the average of the measurements for a given set of angles is stored in a computer memory so that the sensor “remembers” the surface. The data set serves as a background that is subtracted from the measurement during regular operation.

A new type of AMB, which is under development, does not use sensors. In place of the usual current

amplifier, a voltage amplifier is used. The current is measured in the amplifier, and a control algorithm can be developed so that the rotor can be stabilized from this measurement.

In principle, the current requirements in the coils of an AMB can be made arbitrarily small if resolution of the sensors is high enough and the sensor and power electronics are fast enough to respond. That is, it takes less force (and therefore less current) to return a rotor from a 1-micron deviation from equilibrium than it does to return it from a 1-mm excursion. As sensors become faster and their resolution becomes higher, and as power electronics becomes faster, one may expect that the losses in AMBs will decrease. At some point, the homogeneity of the rotor and the magnet system will provide the determining limit of these losses.

3.3 Superconducting Bearings

In its simplest form, a superconducting levitation system includes a permanent magnet (PM) levitated in a stable position over a superconductor. Because the superconductor is not a magnet and exhibits special properties, its presence enables the system to bypass Earnshaw's theorem, a general theorem in magnetics that states that any magnetic system will be statically unstable. One of the fundamental properties of superconductors is their tendency to exclude magnetic flux from their interiors. This exclusion of magnetic flux, called the Meissner effect, makes them behave like a strong diamagnet. Accordingly, a superconductor with a PM positioned close above it develops a shielding current, which excludes flux in such a way that the actual magnet "sees" its mirror image.

More specifically, if the magnetization of the PM is in the vertical direction with its north pole down, the image will also be vertically magnetized but with its north pole up, exerting a repulsive force on the real magnet. The closer the magnet gets to the superconductor, the stronger the repulsive force; the farther away the magnet, the weaker the force. This setup can yield a levitation that is stable in the vertical direction.

The levitation phenomenon that is the result of the diamagnetic response is greatly enhanced by additional phenomena that are a result of flux pinning. A flux pinning center is a nonsuperconducting region such as an inclusion, a crack, or some other crystalline defect. Because the superconducting region that surrounds the nonsuperconducting center is strongly inclined to exclude magnetic flux, a magnetic flux line through the center tends to become trapped (pinned) there. With a sufficient number of flux lines trapped in the superconductor, the PM will remain stably levitated in position, even over a flat surface. The flux lines between the PM and the superconductor act in an imperfect analogy to mechanical springs with attachments on the PM and in the superconductor. If the magnet is moved vertically or horizontally, the "springs" will tend to pull the magnet back to its equilibrium position. If the flux pinning is sufficiently strong, the magnet may be stably suspended below the superconductor or even along its side.

The potential for superconductor levitation in various applications received greatly increased attention with the discovery of high-temperature superconductors (HTSs) that exhibited critical temperatures exceeding the boiling point of nitrogen. The current material of choice for superconducting bearings is Y–Ba–Cu–O (YBCO). This choice is due to its large superconducting current density at liquid nitrogen temperatures and the ability to grow large grains. In bulk YBCO, the grains can grow to diameters of several centimeters when made by a process called melt texturing. In the current state-of-the-art, the upper limit to this process appears to be a diameter of approximately 10 cm.

If the suspended PM is pulled hard enough to the side or vertically, it is possible to move one or more of the trapped flux lines into new pinning centers and so change the equilibrium position. Such a change leads to hysteresis in the levitation force and an associated energy loss if it occurs in a cyclic pattern.

So long as the magnetic flux distribution in the superconductor does not change, rotation of the PM encounters no resistance. In reality, hysteresis loss in the superconductor will act to decrease the rotation rate. If one picks a radius on the surface of the PM and travels in a circle (azimuthally) on the surface at that radius, one sees a large DC magnetic field with a small AC component. The AC component produces a changing magnetic field at the surface of the superconductor and produces a hysteresis loss. The ideal PM would exhibit a magnetization that is perfectly symmetric about its axis of rotation; that is, it would exhibit a high degree of azimuthal homogeneity. Real PMs contain defects that are a result of the manufacturing process. These defects are mainly a misorientation in individual grains of the easy magnetization from the intended direction. Typically, in PMs with the best homogeneities, at a fixed radius above the rotating surface, the amplitude of the AC component of the magnetic field is of the order of 1%

of the average field at that radius. This inhomogeneity, although small, is sufficient to cause a detectable decay in rotation rate when the magnet spins in vacuum.

Even if the PM were perfectly homogenous, hysteresis loss would still occur due to horizontal and vertical vibrations that are transmitted to the system from the outside world. However, in practical superconducting bearings, the loss due to PM inhomogeneity is much larger than that due to vibration transmission.

As discussed in section II, the bearing gives rise to oscillation modes with corresponding critical frequencies associated with these resonances, with the most important being radial resonance. (If the rotor is a long cylinder, conical resonance is also important, but the discussion is essentially identical to that for radial resonance.) Accordingly, one may divide the loss behavior into three regions: below the resonance, at the radial resonance, and above the resonance. Below the resonance, the losses are due to the inhomogeneity of the magnetic field of the PM. The resonance region typically occurs at low frequency, that is, much lower than the operating range of FES systems. Above the resonance, the losses are influenced by an additional factor, caused by the rotation of the magnet about its center of mass rather than about its center of geometry or center of magnetism. Above and below the resonance, the losses are velocity independent.

Because of the size limitation imposed during production of high-performance bulk superconductors, a large bearing system will need an array of superconductors. In the case of a single magnet levitated over an array of superconductors, an additional loss term arises due to the magnetization of the individual superconductors on levitation. The magnetization of the array leads to an AC magnetic field that is seen by the rotating PM and results in eddy current losses that occur in the PM and depend on the electrical conductivity of the PM.

The low stiffness of the HTS bearing has profound consequences in rotor dynamic behavior of flywheels that is not exhibited with other types of bearings. Rigid rotor bearing resonances, due to the magneto-mechanical interactions in the PM/HTS system, occur at very low frequencies that are on the order of several hertz. Thus, the operating speed regime of disk or ring-type rotors is in the supercritical range, that is, well above the bearing resonant frequencies. Therefore, the operating speed range between the bearing resonances and the frequencies at which bending modes start to appear in the rotor structure is usually large. Furthermore, the low-stiffness bearing allows the rotor to self-center at low speeds, with relatively low out-of-balance forces at these resonances, so that rotor balancing is less critical than with other bearing designs. The HTS bearings often contain large gaps between rotating and stationary surfaces and can tolerate radial oscillations of several millimeters in amplitude.

3.4 Magnetic Bias

In any of the bearing systems discussed in the preceding sections, considerable advantage in terms of reduced losses can be achieved by using a magnetic bias to take up most of the bearing load. For example, augmentation may take the form of an Evershed-type design, in which a PM pair, one on the stator and one on the rotor, are in attractive levitation (Fig. 3). The spacing of this magnet pair is adjusted so that, at the equilibrium position, the attractive force is between

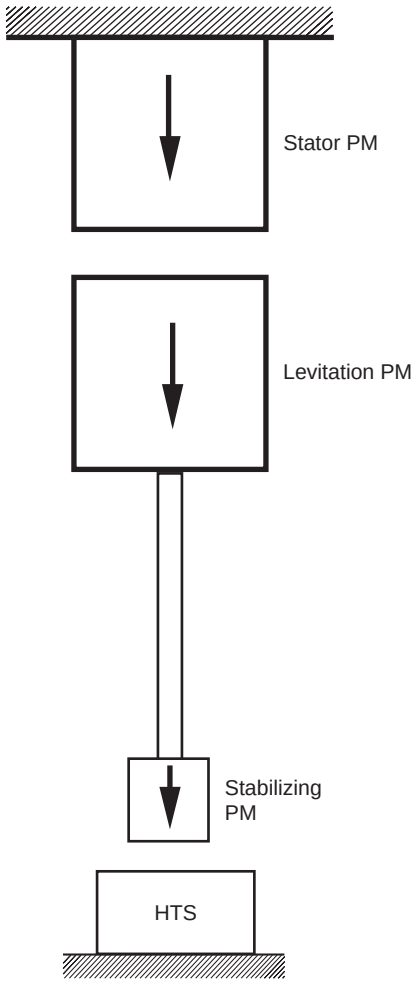

FIGURE 3 Evershed-type magnetic bearing with HTS bearing providing stability.

99 and 100% of the rotor weight. With this magnet pair, the system is stable radially but unstable vertically. An auxiliary bearing system (mechanical, active magnetic, or superconducting) is used to provide the remaining less than 1% of the rotor weight plus the required stiffness. The rotational losses of a PM pair generally consist of eddy currents induced in one PM by the azimuthal field inhomogeneity of the other PM. These losses are typically smaller than those associated with the auxiliary bearing that makes up the stabilizing part of the system. Low-loss magnetic biasing can also be accomplished with a PM and ferromagnet combination.

Because superconducting bearings provide a stabilizing stiffness in all directions, the magnetic bias can be designed with low stiffness. Because an AMB typically provides stable stiffness in only one direction, it may be appropriate to design the magnetic bias with a rather large stiffness that provides stability in all directions but one. Then, only one AMB controller is required to stabilize against movement in the unstable direction.

4. POWER INPUT AND OUTPUT

When the flywheel is used as a mechanical battery, energy must be converted from rotational kinetic energy to usable electrical power and vice versa. This conversion usually involves two major components: an M/G and power electronics. The M/G converts energy between mechanical and variable-frequency electrical. Power electronics then converts between variable-frequency AC and DC electricity. In some cases, the DC is the output of the flywheel. More commonly, additional power electronics converts between the DC and either the external AC electrical grid or a critical load.

Many types of M/Gs are possible. In one commercial flywheel design, the flywheel is on a coaxial shaft that is separate from, and spins faster than, the main generator. When power is required, a clutch is engaged to transfer torque to the constant-speed generator. The motor and generator could be separate components, but typically the M/G is one unit, with the function of operating as motor or generator determined by the power electronics.

A common design for the motor is the brushless synchronous type. In this design, one or more PMs, attached to the rotating part of the flywheel, move in close proximity to stator coils. The power electronics equipment supplies a voltage to the stator coils that is timed synchronously with the rotational angle of the rotor. When operated as a generator, the rotating PMs induce a voltage on the stator coils, and the power electronics regulate how much current flows. Both the output frequency and the output voltage of the generator depend on the angular velocity of the flywheel; both increase as velocity increases.

The primary function of the M/G is to provide torque to the flywheel. An undesirable side effect in most M/G designs is the production of radial and axial forces that tend to destabilize the flywheel. These forces must be accommodated by the bearings, and for magnetic or superconducting bearings, which are of inherently low electromechanical stiffness, the destabilizing tendency can be significant. Special M/G designs, with slightly lower specific power, have been used in flywheels with these bearings. In one method, a toothless back iron is used in the stator coils. A second method uses a special PM geometry called a Halbach array, which produces an internal dipole magnetic field and very little radial or axial force, even when the rotor part of the M/G is not perfectly centered relative to the ironless stator coils.

Progress in power electronics, particularly in high-power insulated gate bipolar transistors and field effect transistors, underlies higher power flywheel operation. Variable-speed motor drives can be used for the power input section. Several motor operating modes are possible, with a common one providing fixed-voltage pulses to the stator coils at various pulse widths. As the flywheel speed increases and the back electromotive force (EMF) on the stator coils builds, the pulse lengths become longer. Because the generator output voltage decreases with decreasing speed, there is a lower limit on the speed at which power can be withdrawn at the rated value. As speed and voltage decrease, if power stays the same, the current must increase. This means the power electronics must be designed for the lowest operating speed of the flywheel, leading to larger equipment than would otherwise be required for the higher speeds. As an example, a flywheel might be designed to provide full power anywhere from maximum to half-maximum speed. Because stored energy is proportional to the square of the velocity, the available stored energy would be only 75% of the maximum rotational kinetic energy.

5. CONTAINMENT

Flywheels are often contained in some type of housing to maintain the flywheel in a vacuum and to provide personal safety from contact or, in the case

of failure, from debris. Early flywheels were not enclosed, and this is true today of some modern low-performance flywheels such as those used in presses.

Housing flywheels in evacuated containers reduce aerodynamic drag, with the level of vacuum being determined by whatever value of windage loss is tolerable in a particular application. Today's systems typically operate somewhere between atmospheric pressure (100 kPa) and 1 mPa, with the highest speed devices operating at the lowest pressure. Lower speed flywheels are larger but can be operated in air with acceptable losses. Reduction of aerodynamic drag is important for high-performance flywheels not only to reduce the loss rate of stored energy but also to prevent the flywheels from overheating.

A potential parasitic loss is the power required to run the vacuum pumps. It is believed that the rotor containment chambers of commercial versions of high-performance flywheel systems will be exhausted and then hermetically sealed. Vacuum will be maintained over time by a getter system such as barium or activated charcoal. Considerable experience in this technology has been gained from the fabrication of vacuum-insulated containers such as thermos bottles and superconducting magnet dewars. If the rotor is metal, few problems should be encountered in accomplishing this. A properly cured composite should exhibit little outgassing at ambient temperature, but this remains a technical issue for high-performance rotors.

Good design makes the probability of a flywheel failure extremely small. However, for high-performance flywheels, where operating experience is still limited, a safety containment structure is often part of the vacuum housing. For systems that use magnetic bearings, the containment often includes a set of mechanical touchdown bearings. The safety containment of a flywheel is otherwise similar to that of aircraft gas turbines. It must avoid any fragment penetrations and avoid excess deformation; limit the forces, moments, and vibrations transferred to the outside; and avoid the emission of dangerous or pollutant substances.

When a flywheel breaks up, the total angular momentum of the debris cloud remains the same as before the breakup, and this moment must be accommodated by the containment structure. The motion of individual debris fragments is translational and rotational. For very small particles, the energy is nearly entirely translational. Composite material rims usually produce many tiny fragments. Depending on the type of failure, they may take the form of long needle-like shards or small grains. Any PM or metallic component usually forms larger fragments in the debris cloud. These fragments may provide strong local loading when they hit the containment shell.

Containment structures typically employ a suite of strategies. The energy of the particle pieces is often absorbed in plastic deformation of a collapsible structure inside the containment wall. Turnaround rings and deflection shields are often used to redirect particle momentum. Rotatable liners are sometimes employed to accommodate the angular momentum of the debris cloud.

6. APPLICATIONS

Flywheels have been used in numerous applications. They have provided the prime energy for turning the propellers of torpedoes and for numerous transportation applications in electric buses and railways, both onboard and as wayside power providers. They have been used in mine locomotives where explosion risk is present, and they have been used to power city buses. Flywheels are under consideration to replace chemical batteries in the International Space Station and for use as combined energy storage and momentum wheels in earth-orbiting satellites. Tiny flywheels are used as the universal prime movers in some toys. Flywheels with very high discharge rates, called compulsators, have been used to power electromagnetic rail guns.

Flywheels continue to be used in all reciprocating engines and in all machines that require very high power for a small part of their working cycles. All mechanical presses use flywheels, usually of the disk or rim type; these flywheels are quite massive for the quantity of energy they store. The ability of flywheels to deliver very high power for a short time has been used in inertial friction welding and in some machines such as inertial starters. Other applications of flywheels can be found in devices that must maintain their angular velocity in case of a power failure or during the shutoff of a plant; typical examples include lubrication or cooling pumps and emergency systems.

Flywheels used as mechanical batteries are often integral parts of hybrid electric vehicles. Here, the flywheel is used for times when high power is required, thereby allowing the internal combustion engine to run at a fixed rate where efficiency can be optimized and exhaust pollutants can be minimized. The engine runs an alternator that continuously charges the flywheel. The vehicle uses both an

internal combustion engine and an electric motor for propulsion. The basic idea is that the average power needed to propel the vehicle should be supplied by the engine, which then can operate at a nearly constant optimal speed, thereby reducing fuel consumption, air and noise pollution, and engine maintenance requirements as well as extending engine life. Short bursts of power, for climbing hills and acceleration, are taken from an energy store (a battery of one sort or another) that is replenished directly by the engine or by regenerative braking when the vehicle is slowed down.

Electric utilities have a great need for inexpensive energy storage systems, such as flywheels, because their inexpensive baseload capacity is typically underused at night and they must use expensive generating sources to meet their peak loads during the day. The availability of a distributed network of diurnal storage could also make use of underused capacity in transmission lines at night as well as add robustness to the electric grid. Efficient energy storage would also be beneficial to renewable energy technologies such as photovoltaics and wind turbines.

The most practical FES option assumes arrays of many individual flywheel units. Although FES units with stored energy as low as 2 to 10 kWh may have some applicability, electric utilities are most likely to desire units with approximately 5 MWh of storage capacity. Units with such capacity, composed of modules of individual 10-kWh flywheels, are approximately the largest that can be factory assembled and truck mounted for delivery to substations or energy storage facilities. With a fleet of FES units that handle real-time automatic grid control, a utility could manage generation variability as well as load variability. Such units could also provide uninterruptible power for factories.

6. Summary

Glossary

abiotic Pertaining to nonliving environmental factors, including light, temperature, water, nutrients, soil, and atmospheric gases.
assimilation efficiency The fraction of ingested food that an organism is able to absorb.
bioenergetics The study of the flow and transformation of energy within and between living organisms and their environment.
biotic Of or having to do with life or living organisms.
ectotherm An organism that regulates its body temperature largely by exchanging heat with its surroundings.
endotherm An organism that generates heat from food energy to maintain its body temperature, typically above the temperature of its surroundings.
homeotherm An organism, such as a mammal or bird, that maintains a constant body temperature, largely independent of the temperature of its surroundings.
maximum power hypothesis A concept stating that there will be selection for rate of energy use that yields the most useful work per unit time.
poikilotherm An organism, such as a fish or reptile, having a body temperature that varies with the temperature of its surroundings.

The amount of energy expended by an organism to collect a unit of energy is referred to as the energy costs of food capture. The ability of a species to capture and utilize energy is key to its survival. Therefore, all organisms expend energy to maintain basic body functions and require additional energy to feed, grow, and reproduce. The energy costs for capturing food include energy expenditure for finding, handling, digesting, and assimilating the food. Both biotic and abiotic factors influence the profitability of a given method of feeding, and the energy gained from feeding minus the energy costs of capturing that energy is an organism's net gain of energy that can be used to increase the fitness of a population.

1. INTRODUCTION

The influence of the environment on the success of food capture can be mediated by behavioral and physiological adaptations. However, such adaptations are not made by the organism, but are products of natural selection. The theory of evolution through the process of natural selection states that traits in organisms that produce the most descendants have been selected for over time. For an organism to create descendants, an organism must have a surplus of energy to invest in reproduction and/or the rearing of offspring. In a sense, organisms are players in a game in which there are fees, in terms of energy and nutrients, to remain a player and additional fees that must be invested into activities that may win a player surplus energy. Surplus energy can then be used to perpetuate their genes. In this game, the rules are determined by physical, chemical, and biological processes. Successful organisms are those that, by making profitable investments, acquire surplus energy per unit time of playing the game and then use this energy to perpectuate their genes.

Why are there so many species on Earth? This is one of the most fascinating questions asked by ecologists. The main reason for the richness of species may be that a diverse set of organisms is more effective than a limited set is at capturing available food energies. This idea is illustrated in the following discussions by describing the current understanding, for both plants and animals, of the

 © 2004 Elsevier Inc. All rights reserved.

energy costs of maintaining life and capturing food. The focus is on net energy gain, although it is recognized that resources other than energy, such as nutrient availability, can influence the profitability of a foraging strategy. How the biota minimize the energy costs of food capture using physiological and behavioral adaptations is also described.

2. BIOENERGETICS

Understanding the costs related to food capture requires a basic knowledge of an organism's demand for energy and the profitability of captured energy in terms of growth and reproduction. Bioenergetics is the study of the flow and transformation of energies used within and by living systems. A thorough review of bioenergetics is not the purpose in this section; instead, the focus is on an organism's basic needs for energy and how these basic needs relate to the environment, followed by a discussion of how an organism can invest its energy into capturing food to yield a net profit.

2.1 Energy Flow in Organisms

The pathways of energy flow in biota are similar among species. Species vary primarily in terms of rate or efficiency of processes, method of food capture, and types of foods consumed. Once food has been collected, it is defined as consumed. A common misconception is that everything consumed enters an organism. Sometimes an organism loses pieces or fluids of the food being consumed before it is utilized. The portion of food consumed that passes into an organism is defined as ingested material. Ingested food then passes through the internal energy pathways of the organism.

Ingested food must be absorbed or assimilated into the organism for food to be useful to do work. For plants, light energy that has excited a photosynthetic pigment is converted into internal available energy. In animals, food in the digestive system is assimilated through absorption across the digestive tract. Saprophytic organisms such as fungi assimilate foods by absorbing it directly into cells through diffusion. The efficiency of assimilation varies among biota and within species (Table I). These differences in efficiencies are due to many factors, such as rate of food ingestion (related to temperature, incidentally), food quality, and organism physiology. Energy that is not assimilated is lost through egestion in animals, through light reflectance and heat loss in plants, and through leaching in saprophytes. In animals, there is another loss associated with moving ingested materials through the body, i.e., specific dynamic action. Other organisms have smaller costs for internal transport of foods and rely mainly on diffusion and chemical processes.

Assimilated food energy is the actual quantity of energy available to fuel various life processes. In most cases, assimilated energy is used first to fuel metabolism. Total metabolism refers to the sum of energy used to rebuild and fuel the basic functions of life (basal metabolism) and the energy used to perform activities (active metabolism) such as swimming, flying, or walking.

2.2 Energy Costs and Demands for Food Capture

2.2.1 Energy Cost of Metabolism

The energy and time costs of capturing and finding food include both basal and active metabolism. Basal metabolism increases exponentially as a function of environmental temperature until the temperature reaches the optimal temperature for the organism and then declines with increasing temperature. Optimal temperatures for basal metabolic rate can differ among species and among individuals of a given type of species; this is primarily due to enzyme reactivity. In addition, basal metabolism decreases per unit body weight as body weight increases, and varies depending on whether an organism regulates its internal body temperature (Fig. 1). Time spent searching or waiting for food requires energy for basal metabolism. The increased physical energy used in active metabolism can be one of the largest costs in food capture and is difficult to measure or predict because it depends largely on behavior and, like basal metabolic rate, can be controlled by environmental conditions. For example, a tuna fish can increase its metabolic rate when foraging and when the tuna seeks prey in warmer surface waters.

2.2.2 Energy Costs for Locomotion

Time spent searching for food can be costly in energy for an individual. These costs can be large due to energy-intensive activities such as walking or the time required locating prey. The energy costs of various activities are often difficult to quantify. Scientists have developed elaborate techniques to measure active metabolism, including assessing metabolic tracers (e.g., oxygen), using sensors that measure muscle contractions, and analyzing movement using video equipment or mechanical devices

TABLE I

Assimilation Efficiencies for Poikilothermic and Homeothermic Species[a]

Species	Diet	Assimilation efficiency (%)	Production efficiency (%)
Aquatic poikilotherms			
Megalops cyprinoidea (fish)	Fish	92	35
Nanavax sp. (predatory gastropod)	Invertebrates	62	45
Hyallela azteca (amphipod)	Algae	15	15
Ferrissia rivularis (stream limpet)	Algae	8	19
Tegula funebralis (herbivorous gastropod)	Algae	70	24
Hydropsyche occidentalis (filter-feeding caddis fly)	Algae	55	10
Littorina sp. (periwinkle)	Detritus	45	14
Terrestrial poikilotherms			
Saltmarsh grasshopper	*Spartina*	27	37
Melanoplus species (grasshopper)	Lespedeza	37	37
Mites (Oribatei)	Detritus	25	22
Sugarbeet leaf (plant)	Light	16	—
Terrestrial homeotherms			
Least weasel	Mice	96	2.3
Little brown bat (*Myotis lucifugus*)	Insects	88	—
Marsh wren	Insects	70	0.5
Grasshopper mouse	Insects	78	5.7
Kangaroo rat	Seeds	87	6
Vole	Vegetation	70	3
Jackrabbit sp. (*Lepus*)	Vegetation	52	5.5
Jackass penguin (*Spheniscus demersus*)	Anchovies	78	—
Cottontail rabbit (*Sylvilagus* sp.)	Vegetation	52	6
Cattle	Vegetation	38	11
African elephant	Vegetation	32	1.5

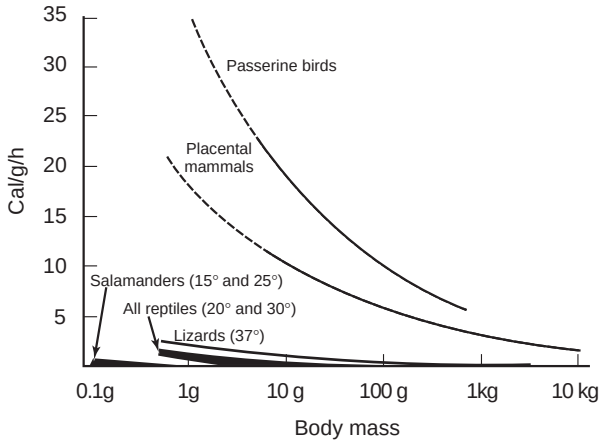

FIGURE 1 Resting metabolism as a function of body size and temperature (in °C). Ectothermic animals can be small because their energy consumption for maintenance is low. A bird weighing 1 g would use about 30 times the energy used by a reptile of the same weight. Not surprisingly, 1-g reptiles exist but 1-g birds do not. Reproduced with permission from Pough (1980), with permission from the University of Chicago Press.

(e.g., treadmills). For example, the field metabolic rate (FMR), the total metabolism for an organism in an environment, can be estimated for both terrestrial and amphibious animals by injecting "heavy" water into an animal's body. Heavy water has more neutrons than protons; the deuterium isotope, which replaces many of the hydrogen atoms in the water molecules, is detectable using laboratory techniques. Because the metabolic processes of most plants and animals depend on water, the rate of metabolic processes such as basal and active metabolism can be quantified by tracing the rate of uptake and release of the heavy deuterium isotope in the injected water. The field metabolic rate for many organisms has been estimated (Table II).

Movement is often the largest energy cost of food capture. Swimming, flying, and running are the basic types of movement. The energy efficiency of movement (distance traveled/unit weight/unit energy expended) differs with the medium that the

TABLE II

Measured Field Metabolic Rate and Energy Cost of Food Capture for Selected Ectotherms and Endotherms[a]

Species	Locomotion used	Feeding strategy	FMR[b] (kJ/g/day)	Cost of food capture (kJ captured:kJ cost)
Ectotherms				
Alder tree (*Alnus viridis*)	Nonmotile	Capture light energy	0.0005	10:1
Norway Spruce tree (*Picea abies*)	Nonmotile	Capture light energy	0.00275	9.1:1
Mussels	Nonmotile	Filter feeder		5:1

organism is traveling through (such as water or air) and the morphology, body weight, and speed of movement of the organism. The rate of movement that is most energy efficient is defined as the minimum cost of transport. Most organisms have a rate of movement that has the highest energy efficiency, but there are some exceptions (such as starlings), when energy efficiency increases with speed.

For each mode of locomotion, the energy cost of transport decreases per unit weight of organism with increasing body weight (Fig. 2). Large animals such as blue whales may expend much energy per unit time for movement, but the energy cost to move a gram of whale is relatively low compared to the energy cost of moving a gram of mouse the same distance. The relation between body weight and the cost of transport helps explain the profitability of movement in foraging energetics. The high cost of locomotion for small organisms is the reason why most migratory animals have body weights greater than 1 kg. It is simply too expensive for small animals to migrate long distances without additional forces such as wind and ocean currents. The present explanation for the increase in energy efficiency in locomotion with size is that, compared to smaller organisms, larger organisms have greater inertial forces that aid in locomotion, and frictional forces (such as gravity) are much less due to lower ratios of surface to body weight.

Swimming by fish is the most energy-efficient method of locomotion on Earth, followed by powered flight and then crawling and running (Fig. 2). Each species must have structures and physiologies suited to the type of environment in which they live. Swimming and flying are more

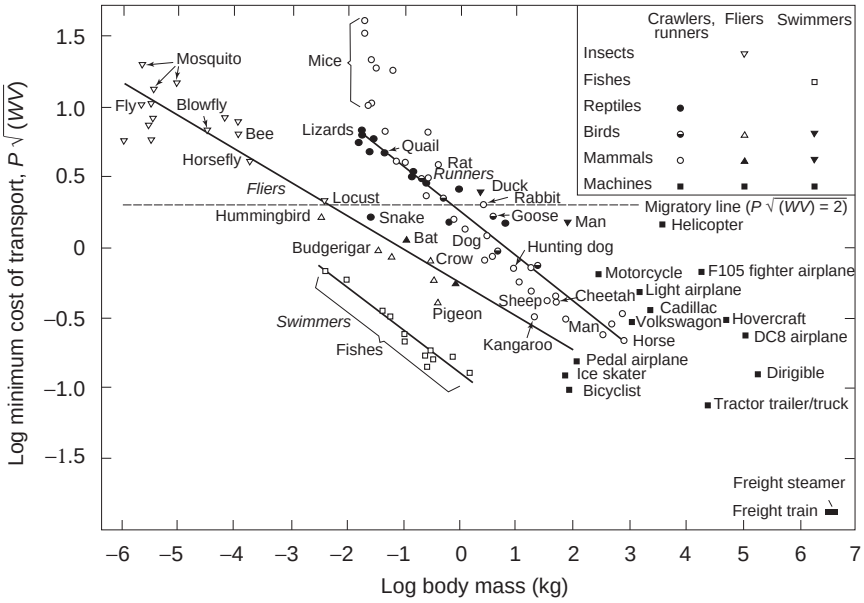

FIGURE 2 Energy costs of swimming, flying, and running, illustrating the energetic costs for searching for food. The data suggest that animals suited to swimming are more energy efficient at locomotion compared to flying and running species. Reproduced with permission from Tucker (1975).

efficient methods of movement than is running or walking because muscle efficiency is less in running or walking, compared other methods of transport. In running or walking, a muscle must contract and stretch to complete a cycle of movement such as swinging a leg. Contracting a muscle pulls on tendons that move parts of the body, and, in walking, muscles contract in the leg to push the body forward. Once the leg has contracted and performed work by pushing the body forward, the muscle must be stretched to maintain the body's center of gravity and to move the leg back into position for contraction. The energy expended to stretch a muscle is lost as heat in walking or running and performs negative work in that the stretch of the muscle must displace the appendage used in locomotion in a direction that is not the direction of travel. The main reason swimming and flying are a more energy-efficient means for locomotion compared to walking or running is that muscles are stretched less often. As a means for movement, however, swimming, not flying, is more energy efficient; until recently, scientists could explain only one-seventh of the difference in efficiency between these two methods of locomotion. Several aspects of swimming explain its efficiency: (1) muscles are typically stretched little in swimming; (2) most fish can regulate buoyancy using a swim bladder and/or their body density is similar to that of the surrounding medium, decreasing the energy used in maintaining a vertical position (flyers and runners must invest energy in maintaining their vertical position in the air); (3) vortices generated from the thrust of a foil, such as a tail, allow a swimmer to recover some of the energy lost in the movement of the tail; and (4) swimmers can utilize vortices produced by the environment, giving them the ability to achieve energy efficiencies greater than 100%. Machines such as submarines or boats have low energy efficiencies in movement compared to fish because their rigid hulls restrict the vessels' ability to utilize energy found in vortices in the environment. In addition, human mechanisms for converting mechanical energy into a jet or propulsive force do not generate vortices that are useful for recovering energy lost during thrust. Propeller-produced propulsion generates vortices that are perpendicular to the direction of movement and offer little potential for recovering energy. In this case, natural selection still seems to be a more efficient engineer than humans are.

Birds, bats, and insects are the only animals that have the ability for self-powered flight. Flying and swimming are similar in that lift and thrust are the two principal forces important to locomotion. Thrust is defined as the force applied by the organism to generate forward movement, whereas lift is the force exerted by an organism to change or maintain vertical position in a fluid. At a given body weight, flying is a less energy-efficient means of locomotion compared to swimming because more energy is

needed by flyers to generate lift. Both swimmers and flyers that use foils, such as wings and tails, generate vortices that can produce efficient jets of fluids. The jet produced by movement of a foil produces motion from thrust. Without a medium such as water or air, the movement of a tail or wing would not create a propulsive jet.

Walking and running organisms can recover some of the energy lost in stretching muscles by having elastic structures that store the energy used in stretching or by having many legs (e.g., centipedes), which reduces the energy expended in maintaining the center of gravity. The low energy efficiency of locomotion for small-bodied species has yet to be explained, but larger organisms are believed to have elastic tendons that can recover some of the energy lost in stretching muscles. As body size increases, animals have more tendon biomass to absorb energy used in stretching muscle. The recovery of energy used in stretching muscle is similar to the deformation of a bouncing ball. A ball bounces because the energy in the force of the ball hitting the floor is stored briefly in the deformed ball and then is released when the ball structure reforms, which pushes the ball away from the floor. Like a bouncing ball, biota can store in the animal's body some of the energy in the force of the animal's appendage hitting the ground, and then use this stored energy to maintain the center of gravity or for movement, by redirecting the energy into a force that can perform work.

The wheel has increased energy efficiency in locomotion from that of walking and running by reducing the number of muscles that are stretched. Imagine a person walking on a level surface and a person riding a bicycle next them; the walker's body dips during stride and then is pushed upward, but the bicyclist's body does not dip or bob during motion. A wheel maintains a person's center of gravity during stride and eliminates the bobbing action of a walker and the associated stretching of muscles. Each force applied to a pedal by bicyclist results in a perpendicular forward force using a gear. The ability of biota to perform certain types of locomotion has a large influence on the energy costs of finding and capturing food, but the environment sets the stage for the need for movement.

Once the energy cost of total metabolism has been paid, surplus energy and materials are used in foraging, growth, or reproduction. If surplus energy does not exist, life functions can be performed only by using the finite energy supply stored by the organism.

3. FOOD CAPTURE, MAXIMUM POWER, AND EVOLUTION

3.1 Optimal Foraging Theory and Maximum Power

Optimal foraging theory states that traits of an individual will be selected for that maximize the surplus energy gained per unit time from foraging. Optimal foraging theory is used to predict the most profitable feeding strategy for an organism given the energy costs for capturing food versus the energy gained from food capture. For example, as shown in Eq. (1), Holling's disk equation (so named because C. S. Holling used paper disks in his model of functional response) can be used to predict an optimal feeding strategy:

$$\frac{\text{Surplus energy}}{\Delta\text{Time}} = \frac{(\text{Energy gain} - \text{Cost of capture})}{(\text{Search time} + \text{Capture time})} \quad (1)$$

where surplus energy is food energy captured that is available for maintenance, activities, growth, or reproduction; energy gain is energy assimilated by capturing food; cost of capture is energy expended while searching for and capturing food; search time is time spent searching for food; and capture time is time spent capturing food. Equation (1) illustrates several components of a feeding strategy that can be altered to maximize the amount of surplus energy gained from feeding. An organism can reduce the time hence the energy costs to search for or capture food. In addition, the energy gained from consuming food can be maximized by selecting for the highest quality food items.

Optimal foraging theory fits neatly within a more universally applicable concept, Howard Odum's maximum power concept. The maximum power concept predicts that the optimal strategy would be to invest the amount of potential energy that yielded the largest quantity of useful work per unit time, which for organisms is surplus energy per unit time. An organism must invest an amount of potential energy into capturing food that yields the most work in terms of growth or reproduction per unit time, which may not be the most energy-efficient food capture strategy available to them.

3.2 Influence of Time and Space on Foraging Energetics

Factors that influence the cost of food capture can be spatially and temporally complex. Food supply may be patchy in distribution and these patches of food may move, shrink, or grow. In addition, physical conditions

may vary over space and time, influencing the cost of food capture. An organism can increase the profitability of a foraging strategy by investing energy and time into migration. For example, zooplankton production in the North Pacific Ocean changes over a season because the spatial and temporal variability of the environment affects the profitability of foraging strategy. Fish that remain in one location and consume the zooplankton may not maximize net energy gain because the food abundance shifts with the season. Even if animals find a good patch of food to feed on, it may be more profitable to move to a new location after a period of feeding than to remain in one place. Movement to new areas for foraging can be risky, in that it is uncertain whether an animal will find better foraging conditions, the animal may expose itself to predation risks, and there is an energy cost for locomotion.

Average-rate-maximizing foraging models use patch models to predict optimal feeding strategies by determining the most profitable investment of energy and time spent searching for food in a patch versus moving between patches. If the entire region available for foraging is thought of as a mosaic of patches of feeding conditions that vary in profitability, the mean profitability of patches can be used as the benchmark to determine the relative profitability of feeding in any given patch. Patch models predict the amount of time an organism should feed in a given patch by determining the profitability of foraging in a patch relative to the mean profitability of foraging in all patches and the amount of time required to move to a new patch. In conditions in which the relative profitability of a patch and the time required to move between patches are high, the model predicts that the forager will remain in the patch for a long period of time. Foragers are thought to move between patches often when foraging conditions are relatively poor when compared to other patches, and energy and time costs for travel are small. Foraging models aid in understanding the role of migration in foraging energetics, but these models are only formalizations of knowledge about these systems and hence are incomplete.

4. ENVIRONMENTAL IMPACT ON ENERGY COST OF FOOD CAPTURE

4.1 Environmental Factors Influencing the Energy Cost of Food Capture

Many factors in the environment can influence the energy cost of food capture, and understanding their individual effects is difficult because many factors interact. Abiotic and biotic conditions that influence foraging energetics include the quantity and quality of food, environmental temperature, light, fluid dynamics, nutrient availability, and risk of injury or mortality.

4.1.1 Quantity and Quality of Food

Quantity of food influences the amount of time and energy spent searching for food; food quality relates to the profitability of a food item for growth and reproduction. In many foraging systems, the amount of food available for foraging is not directly proportional to the energy cost of food capture. As food abundance increases, the amount of food captured per unit time reaches an asymptote (Fig. 3) and the energy costs of food capture decrease.

4.1.2 Environmental Temperature

Temperature is considered as the master regulator of metabolic rate. Knowing how a species responds to temperature is useful in understanding the ability of an organism to perform feeding activities and the associated energy costs. The response of an organism to environmental temperature is described as homeothermic, poikilothermic, ectothermic, or endothermic, based on the physiology of the organism. Homeotherms are species with internal body temperatures that vary little over time; poikilotherms have varying internal body temperatures. Humans are homeotherms that maintain internal body temperature at 98.6°F. Insects are examples of poikilotherms because their body temperatures may vary

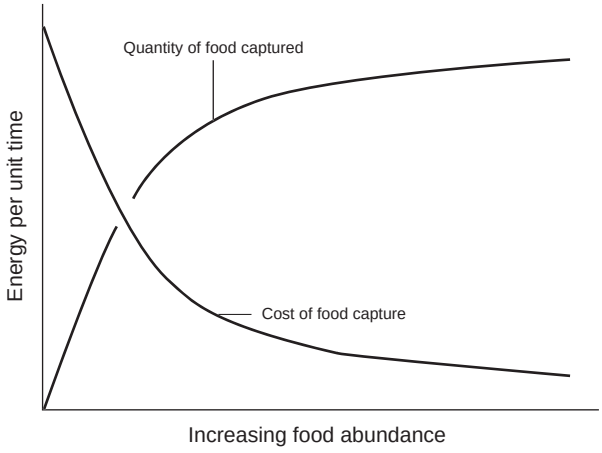

FIGURE 3 Energy cost of food capture as a function of food abundance, illustrating that in many feeding systems, the ability to capture food reaches an asymptote with increasing food supply.

greatly over time. Ectotherm body temperature is regulated by the external environment, whereas endotherms regulate their internal body temperature using internal energy. A homeotherm is a specialized endotherm that has a relatively constant internal body temperature, whereas endotherms do not necessarily need to have constant body temperatures. Each of these factors influences the efficacy and efficiency of energy capture.

Endotherms have a feeding advantage over ectotherms in cold climates, because the metabolism of ectotherms, and hence feeding, is restricted in a cold environment. Despite this restriction on feeding ability, ectotherms may not starve because the basal metabolic demand for energy is also less in cold weather. The endotherms have an advantage over ectotherms in these cold climates because they can generate internal body heat, increase their metabolism, and increase their foraging rate at an energy cost. Large size decreases heat loss through decreasing surface-to-volume ratios, thus polar bears in the Arctic reduce energy costs of maintaining elevated body temperature by being large and have higher metabolisms for foraging. A potential disadvantage to the homeothermic design is that, when compared to poikilotherms, it is a high-energy demand, low-energy efficiency system that requires more food for survival compared to a poikilotherm of similar body weight (Fig. 1; Tables I and II). If food is in low supply, the homeotherm may starve quickly because it must use its energy reserves to maintain an internal body temperature.

Robins (*Erithacus rubecula*) are a good example of the utility of increasing metabolism in a cold environment. The robin is homeothermic, but its prey (earthworms and insects) is both poikilothermic and ectothermic. The prey of the robin has a much lower total metabolism compared to a robin in a cold environment; the higher active metabolism of the robin enables it to catch prey easily because it can move much faster than the prey. The difference in active metabolism between prey and predator can decrease the predator's cost of food capture, as in the robin's case, or it can increase the cost of prey capture when the prey, compared to the predator, has much higher active metabolism.

The Komodo dragon (*Varanus komodoensis*) found in Indonesia is an example of a predator having difficulty running down and capturing its prey because it has a much lower active metabolism. The Komodo dragon preys on birds, rodents, and large mammals (such as deer). Deer, the primary prey item of dragons, are homeotherms, whereas the Komodo is a poikilotherm. It is difficult for the Komodo to run down a deer and physically overpower it because of the Komodo body structure and relatively low active metabolism compared to a deer. However, the dragon does have a good chance at injuring or subduing a deer through surprise attacks. Even if the prey escapes in a surprise attack, if the dragon has bitten the prey, the dragon often captures it eventually because the prey has been poisoned with a deadly bacteria (*Staphylococcus*) found in the Komodo's saliva.

4.1.3 Light

The quality and quantity of light affects the growth rates of plants and also the success of many foragers at capturing food. Light intensity influences prey detection, rate of photosynthesis, and indirectly several other factors that impact foraging systems. The amount of energy received from light per unit time is related to the frequency of photons that reach a surface. Frequency of light is inversely proportional to the wavelength traveled by photons. Wavelength also defines the type of light energy present in an environment. Wavelengths of visible light have certain colors. Light energy used for plant growth—photosynthetic active radiation (PAR)—ranges in wavelength from 400 to 700 nm. Red light, at a wavelength around 700 nm, has the lowest energy for photosynthesis. Blue light, at a wavelength of around 400 nm, is the highest energy PAR.

In aquatic communities, the amount of energy in various wavelengths determines how far light is transmitted through water and hence the availability of light to plants. If a photon of light is conceptualized as an arrow shot from a bow, the arrow that has the most initial energy, in momentum, will travel deepest into a body of water before frictional forces deplete the arrow's momentum. Thus green light is absorbed or reflected near the surface, whereas blue light, which has the most energy, will travel further than green light. The clarity of a gas volume or a body of water, which relates to the amount of materials in suspension, will influence how deeply light penetrates. As result of differences in the photons' ability to be transmitted through water, relative abundances of photons traveling across different wavelengths change with distance from the surface of a body of water.

Plants and fungi must invest energy to capture food energy by building structures and chemicals (e.g., chlorophyll). Adaptations in the structure of a forest canopy and in the composition of an ocean phytoplankton community appear to maximize surplus

energy captured from the sun. The structure of a forest canopy represents layer upon layer of vegetation in space whereby upper layers shade lower layers from sunlight. A fraction of the light intercepted by the overhanging canopy is reflected. Sunlight that penetrates into the forest canopy has a larger relative abundance of high-energy frequencies of light, but is lower in total energy compared to light at the top of the forest canopy, but still contains energy for photosynthesis. In a dense forest, the amount of leaves will increase per unit area the closer the canopy layer is to the forest floor, until the addition of leaf biomass does not yield a net gain from energy capture.

Natural selection has even used ultraviolet and infrared light for food capture. Rattlesnakes and blowflies are just two examples of the ways species sensing infrared or ultraviolet light can reduce the energy costs of finding food. Rattlesnakes are poikilotherms that have low active metabolisms in cold conditions (Table II). Thus, like the Komodo dragon, rattlesnakes have difficulty chasing and then subduing their prey and are more effective at capturing food as sit-and-wait predators that use poisons. The pit organs on the rattlesnake's head are receptors of infrared radiation that assist in locating food. Blowflies, in contrast, forage on carrion. Carrion is an ephemeral source of food and is patchy in distribution. Carrion is often a good source of energy and nutrients, creating a strong selection pressure for organisms that can find and utilize this resource quickly. Ultraviolet radiation is emitted at certain stages in carrion decay. If a light frequency matches that emitted from carrion decay, the fly investigates; otherwise, the fly conserves its energy for more likely sources of food. The blowfly's energy cost of food capture would be much larger without the ability to sense the presence of such an ephemeral food source.

The direct relation between light and the success of predator prey systems is apparent, but other indirect effects of light on these systems must not be overlooked. Most of life on Earth is fueled by solar energy. Temperature of the surrounding environment depends on energy in light, which in turn not only regulates the metabolism of organisms but determines other physical properties of the environment that affect the energy cost of food capture, such as fluid dynamics.

4.1.4 Fluid Dynamics

Fluid dynamics influence the cost of food capture and movement by controlling food availability. For example, caddis fly larvae and black flies feed on food transported in fluids. Species of caddis fly larvae live on stream bottoms and depend on food that has deposited in the stream bottom. Water flow may move food away.

On a larger scale, fluid dynamics generates hurricanes, tornadoes, and flooding that can greatly alter environments. Changes in foraging energetics for a species associated with a disturbance can be beneficial or nonbeneficial for growth and reproduction and the impacts on foraging may be long term or short term. Many foraging organisms have a high "energy returned on investment" (EROI) because they are exploiting the large energy flow of their environment.

Fluid dynamics also impacts the thermodynamics of biota. The movement of fluids increases the rate of thermal conductivity, causing phenomenon such as the wind-chill effect. The profitability to a homeotherm of foraging can be altered by changes in thermal conductivity because of changes in energy costs of maintaining body temperature. Similarly, by influencing thermal conductivity, fluid dynamics alters the ability of poikilotherms to perform foraging activities.

4.1.5 Nutrient Limitation

In plants, nutrient limitations increase the cost of capturing light energy by limiting the plant's ability to build the necessary structures and chemicals for photosynthesis. Nitrogen fixation is an energy cost for food capture that can compensate for nutrient limitation. Bacteria and blue-green algae are the only organisms capable of nitrogen fixation and are either free living or form symbiotic associations with plants or other organisms (e.g., termites, protozoa, and legumes). Nitrogen fixation is an energy-intensive method for fixing atmospheric nitrogen to compensate for nutrient limitation [Eq. (2)]. Nitrogen fixation is only profitable in nitrogen-depleted environments.

$$\begin{aligned} N_2\ (\text{atmospheric}) + 160\ \text{kcal} &\rightarrow 2N \\ 2N + 3H_2 &\rightarrow 2NH_3 + 12.8\ \text{kcal} \end{aligned} \qquad (2)$$

An interesting example of the energetic constraint that relative nutrient availability can have on energy cost of food capture is found in a trout pond ecosystem located below a pasture in western Manitoba, British Columbia. Several of the eutrophic Manitoba ponds studied by David Schindler (of the University of Alberta) had phytoplankton populations composed mainly of nitrogen-fixing, blue-green algae that were encouraged by the high concentration of phosphorus

in water from cow manure. Blue-green algae are a very poor source of food for upper trophic levels and in addition are poisonous, so trout died. Nitrogen was added to the trout ponds, which changed the algal assemblage to predominately green algae, because nitrogen fixing was no longer advantageous. Green algae are a high-quality food source for zooplankton and resulted in an increase in trout production.

4.1.6 Foraging Energetics in Relation to Risk of Mortality

The energy cost of food capture can be influenced by the risk of mortality by restricting the time and/or location that an organism spends foraging. For example, Barbara Peckarsky (of Cornell University) found that the presence of insectivorous fish (trout) gave a chemical signal for mayflies to forage mainly at night, rather than when trout could see them. The hiding of mayflies under stones during the day in response to the presence of trout increased the energy cost of food capture for both predator and prey.

Disease or injury can also increase the energy cost of food capture for plants. The tar spot fungi (*Rhytisma* sp.) infect the leaves of trees maple trees, creating large, black, tarlike spots on leaves. Sometimes the tar-spot infection is so profuse that the tree will drop all of its leaves and then grow new ones. Growing a new set of leaves costs the tree much energy and nutrients and the energy contained in leaf biomass is large enough that it is energetically profitable for a tree to reabsorb leaf energy and nutrients before shedding them. If the tar-spot disease affects the tree late enough in the growing season, the energy cost of developing new leaves is larger than the energy returned from photosynthesis in the remaining part of the growing season, and thus a tree will often not foliate until next spring.

5. FEEDING STRATEGIES AND THE COSTS OF FOOD CAPTURE

5.1 Individual Strategies

5.1.1 Net-Building Filter-Feeding Caddis Flies

In ecosystems that are made up of flowing water, organisms can minimize energy investment in capturing food by constructing nets. Filter feeding can yield low energy costs for food capture, but there are several physical and biological constraints. These constraints include hydraulic forces, variability in the physical conditions, abundance of drifting food, quality of drifting food, filter net design, general lack of net portability, and the ability and energy costs for an organism to maintain its position in a flow regime. Within these constraints are trade-offs when caddis flies exploit different habitats and types of food.

Often the most abundant and consistently available source of drifting food is in high flow-rate environments. The process of natural selection has produced several species of caddis flies that can utilize these environments. Adaptations include terminal hooks for securing the invertebrate to the substrate, silken safety cords to prevent drift when dislodged, and portable cases that act as ballasts in high water flow. Additional adaptations are found in net design because the fly must build a net that has a size, shape, and mesh size that functions most effectively at capturing the particle sizes available. As a result, filter feeding by caddis flies does not always yield high-energy returns. Net design is important in that hydraulics regulates the size of food that is transported in water column. As flow rate increases, the size of particles transported by water increases through increased kinetic energy. Larger food items are typically of higher quality (animal in origin) and are usually preferred by filterers, but the combination of large particles and high flow can destroy the net. Once energy has been invested in a net, the environmental conditions may leave a fly with a net that does not capture food effectively. This fly would then have to take an energetic loss and either abandon the habitat for better conditions, create a new net, or continue filtering with a net of marginal quality. Filter feeders have a large potential to minimize the cost of food capture, but the fly may not reach this potential in an environment that is temporally and spatially dynamic.

5.1.2 Filter-Feeding Mussels

Filter feeding using energy to pump water into and out of clams and mussels can also be a very profitable feeding strategy. To examine this, the basal metabolic rate of mussels can be estimated in the laboratory during a time when they are not feeding. Small plastic beads are then added to an aquarium container containing mussels; the mussels start to filter out the particles, increasing their oxygen consumption. Real food particles added to the chamber in place of plastic beads allow measurement of growth rate and food consumption. The quantity of food energy consumed per unit energy invested in feeding is then calculated by difference. The highest energy return in investment into feeding is estimated at about 500% (Table II).

5.1.3 Drift Feeding and Fishes

Some fish feed on suspended food in the water column. Alewives and other herrings have netlike or filter systems whereas other fish have an evolutionary modification in the buccal cavity that reduces energy cost in food capture. Energy costs for foraging by fish and by mussels and caddis flies are different in that fish have a much lower cost for powered locomotion compared to a mussel or caddis fly; this enables fish to adjust to environments with varying conditions.

Many fish have specialized buccal cavities that can literally suck up their food. This modification in the cavity increases capture success and reduces the amount of energy invested in movement of the fish to swallow prey. Sliding cartilaginous mouth structures underlie the mechanism that allows these fish to suck up their prey; the volume of the buccal cavity can be expanded when the mouth structures slide into position. When the cavity is expanded, the negative pressure created inside the mouth causes external water and food to flood inside the cavity.

A classic study by Kurt Fausch (of Colorado State University) on territoriality and foraging in salmonines shows how stream fishes use adaptations in the buccal cavity to minimize the cost of food capture. Fausch observed salmonines in a stream consume drifting food items. Stream hydraulics over space can be very complex. Rocks on the bottom generate shielding to water flow, creating pockets of slow-moving water that are in close proximity to water moving at a high rate of speed. A fish downstream of such a structure invests little energy to remain in position while having access to a nearby environment that has a good supply of drifting food. The mosaic of food availability and locations of such slow-water feeding habitats creates feeding locations of differing quality. Fausch found that fish defend these feeding zones, resulting in a hierarchy of fish occupying habitats of differing quality.

5.1.4 Territoriality Reduces Energy Cost of Food Capture

Territoriality within a species' population can maximize surplus energy yield from feeding according to what is called Allee's principal. At first, this principal appears to conflict with optimal foraging theory in that it would be seen that the increased cost for active metabolism in defending a territory would decrease surplus energy yielded from feeding. However, studies have shown that the energy cost in defending a territory is small in relation to the surplus energy gained by protecting the availability of resources. Additionally, Allee's principal says that the population would gain from an established "pecking" order, so that energy is not wasted in conflict. If populations grew beyond available space and resources, the mean individual fitness would decrease. A large population of trout may have such a high demand for energy that the available resources are used mainly for metabolism, leaving little or no surplus energy for growth and reproduction. An optimal number of fish relative to their food supply is one that creates a maximum amount of surplus energy.

5.1.5 Phytoplankton Migration and Nutrient Limitation

Some types of phytoplankton, such as dinoflagellates, decrease the energy cost of capturing light energy by investing energy into movement. A stationary phytoplankton can experience a decrease availability of local concentrations of nutrients needed for photosynthesis and growth. Phytoplankton that invest energy into movement are able to exploit water with higher nutrient concentrations.

5.1.6 Olfaction and Predation

Having the ability to detect prey through chemoreception or olfaction increases the probability of food capture by giving the predator the element of surprise over its prey or by preparing the predator for an encounter. Thus, this strategy reduces the energy costs for finding prey.

5.1.7 Cottrell's Analogy: Humans, Machines, Fossil Fuels, and Agriculture

Machines using fossil fuels have enabled humans to pay the energy costs of food capture. The use of machines to exploit resources is not exclusive to humans. Cottrell gives an analogy between the human invention of the steam engine and the evolution of the water pump in filter feeders. Both the steam engine and the filter-feeder's water pump have increased the power to perform food-collecting activities, the result being an increase in populations of humans and filter feeders. The fundamental difference between the humans and filter feeders is that humans gained the ability to subsidize the costs of food capture using an external source of energy, and the filter feeders costs are subsidized by individual active metabolism.

Subsidizing the costs of food capture using fuels can lead foragers to foraging strategies that deviate from what optimal foraging theory would predict, because the energy cost for food capture is no longer important. Modern ocean fishing techniques

illustrates how humans have increased their power for capturing food using fossil fuels. The quantity of ocean fish humans harvest in a year is increasing while the energy cost for capturing fish increases even as fish abundances decline. Humans continue to invest more energy into fishing, even though the energy profitability of catching fish is declining.

Cuban offshore fishing industry and agriculture are clear examples of the level of human dependence on paying the energy costs of food capture with fossil fuels. Cuban offshore fishing collapsed when cheap fossil fuel supplied by the former Soviet Union was no longer available (Fig. 4) to run large commercial fishing boats. In addition, the production of important crops such as sugar cane and tobacco decreased because the country could not support the energy cost of running farming equipment.

As human population has increased, so has food production. Some attribute this increase in food production to large technical leaps in food harvesting efficiency (Table II), but most of the increase is due to elevated rates of production made possible by fossil fuel subsides. In fact, data on the energy cost of food capture for various methods used in agriculture indicate that as farming practices evolved from shifting agriculture to traditional farming to modern agriculture, the rate of production increased but energy efficiency decreased (Table II). Earlier methods used for food capture, such as foraging and pastoralism, have much lower energy returned on investment compared to other methods and cannot be performed at high rates. Although shifting agriculture is one of the most profitable investments of energy into food capture for humans, it is insufficient to feed all of the human population worldwide because yield per hectare, when averaged over the entire area, is very low. Modern humans have subsidized the energy costs of food capture to the point where the EROI is far less important than yield per unit time or area.

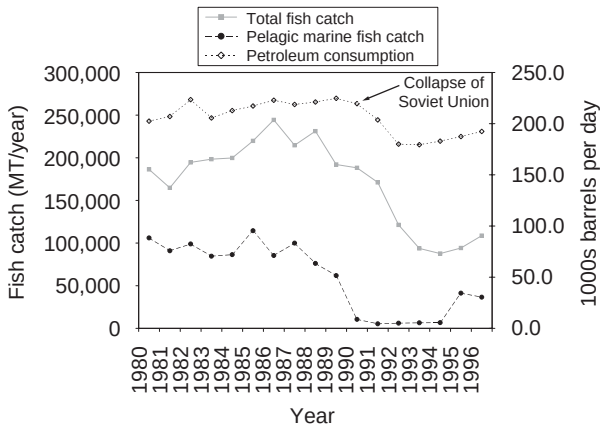

FIGURE 4 Fish catch in relation to quantity of oil consumption in Cuba. Cuban fisheries dependent on oil subsidies collapsed when the low-cost Soviet oil supply was no longer available. Compiled by J. Mead and P. Thompson (SUNY-ESF) using data from the Food and Agricultural Organization.

The foraging strategies described here are clearly a subset of the many others found in the world. For example, species have developed the use of sonar to find food (e.g., bats) to exploit food resources, and other species produce light to attract their prey (e.g., angler fish). The utility of studying energy costs in understanding feeding strategies is quite apparent.

5.2 Group Behaviors That Increase EROI in Food Capture

Foraging as a group of individuals can decrease the energy cost of food capture. Food may be located more effectively by groups than by individuals (e.g., dolphins, wolves), and food may be herded into locations or conditions that make capture much easier than otherwise, or the group can recover energies that are normally lost by an individual.

5.2.1 Dolphins and Whales: Herding Preys Using Bubbles

Herding of prey by a group of predators is not exclusive to humans. Whales and dolphins decrease the energy cost of food capture by herding their prey close to the water surface, where capture is easier. Small to medium-sized fish such as sardines school into tight groups of moving fish called "bait balls" when they detect a predator. Bait balls act as defense mechanism for many single-predator encounters because predators are typically much more effective at capturing individual fish. However, groups of cetaceans (whales, dolphins, etc.) take advantage of this defense mechanism by swimming under the bait ball, separating out individual fish from the outer perimeter of the ball and herding them up, toward the surface, where they are easy to capture.

5.2.2 Honeybees and the Waggle Dance

The time and energy needed to find food can be reduced if a population can focus its feeding on regions where food is abundant. Communication among members of a population allows an individual to instruct or lead other members of its population to a food source it has located. Honeybees have evolved communication skills to do just that. When a

foraging honeybee finds a good source of nectar, it collects a full load and then returns to the hive. On arrival at the hive, the bee performs an elaborate "dance" and emits a series of sounds using its wings, informing the other bees in the hive where the food is located. The movements and sounds the bee communicates with its wings are known as the waggle dance. Researchers have found that the communication of the foraging bee is very detailed, and includes direction, distance, and elevation of the food source.

6. SUMMARY

Thinking about foraging species in terms of energetics, environmental gradients, and foraging theory helps to comprehend and synthesize the performance of species in the world around us. Many factors influence the energy cost of food capture, but to understand the foraging strategy of an organism requires integration of these factors. The world has a fascinating array of different living systems, all of which depend on energy. There are low-energy, high-energy efficiency ectothermic organisms and high-energy, low-energy efficiency endothermic organisms. Organisms vary greatly in body size and physiological and behavioral adaptations; when considered collectively, these adaptations enable a strategy for capturing food that ultimately attempts to further the persistence of a species' traits. Based on the data in Table II, plants seem to be well adapted to capture a little more energy per unit energy invested in food capture compared to other nonhuman species. Also, humans have the ability to gain more energy from their energy investment in food capture compared to other species, but often sacrifice energy efficiency for rate of production, following Odum's maximum power concept.

Glossary

benefits transfer A process of taking environmental valuation estimates from existing studies and applying them outside of the site context in which they were originally undertaken.
discounting Adjusting a cost or benefit in the future so that it may be compared to costs and benefits in the present.
energy externality A cost or benefit that arises from an energy project but is not borne or appropriated by those involved in the energy project (e.g., pollution from energy generation).
environmental valuation The process of placing monetary values on environmental effects.
revealed preference methods Environmental valuation methods that use data from actual behavior to derive values for environmental assets.
sensitivity analysis A presentation of various possible outcomes of a future project or policy under conditions of uncertainty.
shadow pricing The process of adjusting a distorted market price to better reflect the true opportunity cost to society of using that resource.
stated preference methods Direct environmental valuation methods that ask people in a survey to place a value on an environmental asset.
total economic value A categorization of the various elements of value of a resource, project, or policy.
value of statistical life The translation of the value of a small reduction in the risk of death into a value for a project that would involve the equivalent of one life saved or lost.
welfare criterion The criterion in a cost–benefit analysis to assess whether a project or policy benefits society.
welfare measure A measurement tool to assess the strength of consumers' preferences for or against a project or policy in order to assess its costs and benefits.

Cost–benefit analysis applied to energy is the appraisal of all the costs and all the benefits of an energy project, policy, or activity, whether marketed or not, to whomsoever accruing, both present and future, insofar as possible in a common unit of account.

1. DEFINITION OF COST–BENEFIT ANALYSIS APPLIED TO ENERGY

Cost–benefit analysis (CBA), also known as benefit–cost analysis, is rooted in applied welfare economics. It is a way of organizing and analyzing data as an aid to thinking. It provides a set of procedures for comparing benefits and costs and is traditionally associated with government intervention and with the evaluation of government action and government projects. The underlying rationale for CBA is rational choice; that is, a rational agent will weigh the costs and benefits of any proposed activity and will only undertake the activity if the benefits exceed the costs.

A confusion that sometimes exists relates to the difference between social cost–benefit analysis and cost–benefit analysis. However, to an economist, social impacts and environmental impacts are economic impacts, so any analysis purporting to be a CBA must address social and environmental impacts.

 © 2004 Elsevier Inc. All rights reserved.

In this way, CBA differs from financial analysis in that it assesses the costs and benefits to the whole of society rather than to a portion of society. For example, a financial analysis of a proposed new power plant by a private energy supplier will not take into account the costs imposed on wider society (such as environmental impacts), whereas a CBA, by definition, will do so. In addition, there are various other subtle but important differences between financial analysis and CBA related to the fact that market prices do not always reflect the true value of goods and services to society. This provides the basis for a technique known as shadow pricing, which adjusts distorted market prices such that they may be used to value costs and benefits appropriately.

As the previous definition implies, a CBA must include all the costs and all the benefits to whomsoever accruing. Thus, the definition instructs that whether the costs or benefits are marketed or not makes no difference. In other words, even if some of the costs or benefits are not exchanged in markets at all and so do not have a price, they may still be of value. This provides the basis for the inclusion of environmental and wider social impacts in CBAs of energy projects and policies. The common unit of account in CBA is money. Therefore, insofar as is possible and reasonable, all impacts, including environmental and social, should be evaluated in monetary terms so that they can be compared with one another. This provides the basis for a technique known as nonmarket or environmental valuation—that is, placing monetary values on goods and services not exchanged in markets, such as environmental improvements and damages.

In many cases, the costs and benefits of a project or policy will arise at different times. This is the case in relation to most energy activities, where the consequences of actions may not be known until far into the future, particularly in the case of environmental impacts such as global warming. This provides the basis for a technique known as discounting, which allows future costs and benefits to be compared with those in the present.

CBA has been used *inter alia* to estimate the environmental costs of power generation, the net social benefit of different power supply options, the net benefit of the use of renewable energy sources (e.g., solar, wind, and hydroelectric power), the net benefits of alterative modes of transport, the benefits of energy efficiency programs in the commercial and domestic sectors, as well as for policy analysis of energy efficiency regulations such as energy rating and labeling.

2. HISTORY OF COST–BENEFIT ANALYSIS

Detailed histories of CBA can be found elsewhere, but the essence is as follows. In 1808, U.S. Secretary of the Treasury Albert Gallatin gave what is believed to be the first recommendation for the employment of CBA in public decision making when he suggested that the costs and benefits of water-related projects should be compared. In 1936, the U.S. Flood Control Act deemed flood control projects desirable if "the benefits to whomsoever they may accrue are in excess of the costs." In 1950, after a debate on the foundations of CBA in welfare economics, the U.S. Federal Inter-Agency River Basin Committee published a guide to CBA known as the "Green Book." From then on, there was considerable interest in CBA and the development of cost–benefit rules, with seminal contributions by a number of authors, particularly during the 1970 s. Although the distortions created by government intervention in the 1970 s provided much room for the application of CBA, the technique went through a lull in the early 1980s when structural reform replaced piecemeal intervention. However, CBA has made a comeback since then, mainly as a result of increased public awareness of environmental degradation and the associated demand that this cost be accounted for in analyses of projects and policies. However, for a number of years, the economist's view that environmental impacts could be assessed in monetary terms had little impact on policy, with many environmentalists having a particular problem with this concept. For example, in the U.S. Clean Air Act (1970), it was forbidden to use CBA, and the U.S. Clean Water Act (1972) set the objective of the elimination of all discharges into navigable waters. However, in the 1980 s, it became a requirement that the U.S. Environmental Protection Agency perform CBAs on all environmental directives to assess their economic efficiency and significant resources were devoted to researching cost–benefit techniques and methods of placing monetary values on the environment. Although it was not until the Single European Act was introduced in 1987 that a legal basis for European Union (EU) environmental policy was provided, the nature of environmental policy reflected the origins of the EU being an economic one. EU policy that "the potential benefits and costs of action or lack of action must be taken into account in the preparation of policy on the environment" provides an obvious platform for the use of CBA.

3. RATIONALE FOR COST–BENEFIT ANALYSIS APPLIED TO ENERGY

The need for CBA applied to energy results from the existence of market failure. If there were no market failure and all energy suppliers were privately owned, there would be no need for CBAs of energy projects and policies. If market signals were appropriate, those activities and projects that are in the best interests of society would be implemented automatically and financial analyses by firms would simply replace any need for CBAs. However, the market does not work perfectly. Market failure necessitates CBA of energy projects, policies, and activities as a result of the existence of externalities, the associated need for environmental policy instruments, state ownership of energy generation and supply, assessment of sustainability, and "green" national accounting.

3.1 Energy Externalities

One of the most significant areas of environmental concern today relates to the environmental impacts of energy generation from fossil fuels, particularly acidification precursors, greenhouse gases, and localized air quality impacts. Much of these emissions result from power generation and the transport sector. These environmental impacts occur at local, national, regional, and global levels.

The environment can be defined as those parts of our physical and psychological endowment that we somehow share, which are "open access." An economic analysis shows that it is precisely this shared nature of many environmental endowments that threatens their quality and character. In a market system, goods are allocated by the price mechanism. In a free market, the price of a good is determined by the demand for, and supply of, the good. Price is therefore a reflection of society's willingness to pay for, or the valuation it places on, the good in question. However, the shared nature of many environmental assets, such as air, the atmosphere, and water resources, means that they are not owned and so do not have a price. When goods are seen as free they are overused. Thus, the market fails to protect environmental assets adequately.

This failure of the market can be best demonstrated with a simple example: If a power plant produces SO_2 emissions resulting in acid rain, which causes forest damage and damage to buildings, in a free market these costs will not be reflected in the cost of power generation. Thus, the price of the energy will not reflect the true cost to society of generating it. In this case, more energy will be generated and more of the environmental asset depleted than is in the best interest of society. When a cost is imposed on those other than the person or business that produces the cost, this is known as an external cost. Of course, many energy projects will reduce such externalities, such as through renewable energy sources and improved heating and insulation systems.

When assessing the social efficiency of energy activities using CBA, it is necessary to include these externalities and other wider societal impacts. However, because by definition such costs and benefits are not traded in markets, there is no price to reflect their value. This provides the basis for the tools of environmental valuation.

3.2 Calibration of Environmental Policy Instruments

Unless some mechanism is found to internalize these externalities, they will cause a misuse of society's scarce resources. This provides the basis for government intervention in the market. The notion of externalities was addressed by economists as far back as the 1930s. Pollution was seen as the consequence of an absence of prices for scarce environmental resources and so the prescription for solving the problem was to introduce a set of surrogate prices using environmental (Pigouvian) taxes and charges. A large literature has developed on these so-called market-based instruments. One of the more controversial concepts in environmental economics is that there is an optimal level of pollution. Pollution is usually the by-product of a useful activity, such as the production of goods and services; in other words, it is an input into the production process. Reducing pollution usually involves a cost in terms of output forgone and/or the cost of the technical process of abatement. Therefore, there is a trade-off between the environmental improvement and the costs of pollution reduction. The optimal level of pollution occurs where the benefit of another unit of abatement (the marginal benefit) equals the (marginal) cost, with the (marginal) cost being higher after that point. In the case of an extremely hazardous pollutant, the optimal level of pollution will be zero or close to it, but in most cases the optimal level of pollution will be positive. CBA provides the tools to assess these trade-offs. In reality, few economic instruments are actually based on such valuations. Research on so-called target setting using

environmental valuation is still in a preliminary stage. However, it could be used to assess the optimal level of an energy tax.

3.3 State Ownership of Energy Generation and Supply/State Support of Energy Efficiency Initiatives

In some countries, energy supply companies are owned by the state. In some cases, the original rationale for such ownership was that no private company would bear the large fixed costs of developing an energy supply system. In addition, it is sometimes suggested that state companies can perform as natural monopolies and thereby exploit economies of scale while producing at minimum average cost and subsidizing energy for certain sections of society. CBA has a role to play in assessing the merits of such state initiatives and is particularly relevant when assessing the merits of government intervention to improve energy efficiency, for example, by subsidizing wind power or a domestic energy efficiency program.

3.4 Sustainability Assessment and Green National Accounting

CBA is useful in assessing sustainability; that is, what is the value of our resource stock, how is it being depleted, and is man-made capital that is replacing it of equal value? Green accounting adjusts traditional measures of economic performance such as gross national product to reflect environmental damage and the depletion of resources. In relation to energy, CBA may be used to assess the social costs and benefits of depleting energy resources such as fossil fuels.

4. COST–BENEFIT METHODOLOGY

4.1 Welfare Criterion

In using CBA to assess the costs and benefits of a project or policy to society, it is first necessary to define the social efficiency criterion. The most frequently used criterion in microeconomic theory is Pareto optimality. Using this criterion, a project would be deemed to pass a CBA if it made at least one person better off without making anybody else worse off. For an investment to pass the Pareto optimality test, compensation must be paid to those bearing the costs so as to leave them indifferent between their welfare *ex post* and *ex ante*. Most policies and investments leave somebody worse off and thus most would fail to meet the Pareto criterion. Frequently in CBA, the Kaldor–Hicks test is used. This test embodies the potential compensation principle. Kaldor categorized an action as efficient if those who gain from the action could compensate the losers and still be better off. Hicks framed the question slightly differently and labeled the action efficient if the potential losers from the action could compensate the potential beneficiaries of the action for not initiating the action. In both cases, the action is an improvement regardless of whether the compensation is actually paid. Thus, if the CBA shows the project to result in a welfare improvement under the Kaldor–Hicks test, this is essentially a potential Pareto improvement since there is the potential, in theory, to pay compensation to the losers such that nobody would be worse off. This will be the case as long as the benefits of the project outweigh the costs (i.e., the benefit:cost ratio is greater than 1).

Whether or not this potential payment is enough to show that a project is good for society has been the matter of much debate. Some authors have suggested that despite the shortcomings of the Kaldor–Hicks criterion, it is often useful to measure the effects of a change in the total value of output independently of the distribution of output; however, in judging the social efficiency of a project, equity aspects should also be considered. A two-part test may be used in which a project or policy is put to the Kaldor–Hicks test and then tested to determine if it improves (or at least does not disimprove) the distribution of income. Approaches that consider questions of equity therefore allow the possibility of acceptance of a project or policy that returns a negative figure for the sum of individual welfare changes if the gains from income distribution outweigh these losses. However, when considering equity the difficulty is in the assignment of weights to individual welfare changes. Consideration of equity issues and distributional consequences are particularly relevant in the case of projects that affect the price of energy and/or health. Energy price increases may be regressive unless poverty-proofing measures are put in place because energy is a necessity and therefore requires a larger proportion of the budget of less well-off people. On the other hand, improvements in domestic energy efficiency may bring significant health and comfort benefits to the elderly, who in some countries have been shown to be more likely to live in energy-inefficient homes and therefore more likely to be subject to winter morbidity and mortality.

4.2 Welfare Measures

In order to assess the costs and benefits of a project or policy, it is necessary to examine the strength of consumers' preferences for or against the project. The standard approach is to measure the benefit an individual obtains from a project or policy by the maximum willingness to pay on his or her part for such a benefit or the maximum willingness to accept compensation for not receiving such a benefit. Similarly, a cost can be measured by the maximum willingness to pay on the part of an individual to avoid such a cost or the maximum willingness to accept compensation for such a cost being imposed on the individual. Such welfare measures may be approximated using shadow pricing and/or direct valuation methods from surveys.

4.3 Temporal Considerations

Account must be taken of the fact that costs and benefits arise at different times. Thus, future costs and benefits must be discounted so that they can be compared with present costs and benefits. The rate of return for an investment can be strongly affected by the discount rate if there is a long time span involved. Therefore, the choice of discount rate is very important. In some estimates of damages from global warming resulting from the burning of fossil fuels, a small change in the assumed discount rate will have significant implications for climate change policy. However, despite the enormous literature on discounting, it is a difficult task to calculate the social rate of discounting. The discount rate is measured by some combination of a social rate of time preference and a measure of the opportunity cost of capital. Economists have been unable to provide a definitive figure for the social rate of discount, and so a rate tends to be chosen rather than measured.

In an application of CBA to any project or policy, a range of discount rates should be used. Often, for a government project, a published government test discount rate is used for making policy recommendations. These vary by jurisdiction. For example, UK treasury guidelines for the opportunity cost of public investment take the rate of return to marginal private sector investment as 6%. For pricing output sold commercially, public sector agencies are expected to achieve a required average rate of return of 8% to be consistent with the private sector. In the United States, recommended rates for investment projects vary. The Office of Management and Budget recommends a rate of 10%, whereas the General Accounting Office prefers a rate of 2.5% based on government bond yields. The World Bank has traditionally used an 8% rate in project analysis.

4.4 Uncertainty and Risk

In *ex ante* CBAs, investments with long time horizons are subject to uncertainty, particularly in relation to future prices. In addition, when evaluating costs and benefits *ex ante*, there may be considerable uncertainty regarding the magnitude of various parameters. This is particularly the case in relation to potential environmental impacts and their valuation. In cases in which there is a high degree of uncertainty in relation to the coefficients being used to give the monetary value of outputs of a project, lower bound estimates are sometimes used because, if the results are to be the basis for the recommendation of a change in policy, it is thought by some authors that it is better for the benefits to be underestimated rather than overestimated. It is important to note that lower bound results do not necessarily imply the lowest possible results. Rather, they denote the lower limits of a range of reasonable estimates.

Sensitivity analysis, whereby results are calculated for various scenarios, should be used in all CBAs. In addition, confidence intervals should be presented where possible. A general rule is that the more results the better while giving guidance and reasons for the particular estimates chosen by the author(s) for the purposes of recommendations based on the CBA results. Risk assessment may be incorporated by including probability estimates for various scenarios.

4.5 Shadow Prices and Wages and Community Stability

Shadow prices must be used when there are distortions within an economy that render certain prices invalid as measures of the social opportunity costs and benefits of using resources in the project in question. In the real world, market prices may not reflect the social value of goods or services because of distortions in the market, such as monopoly power (which inflates price), indirect taxes and subsidies (unless they are correcting some other distortion), and unemployment. Thus, when calculating each value of a project, it is necessary to assess the appropriateness of using the market value and, where necessary, these values should be adjusted for market distortions. This can be a problem in energy projects for which a particular piece of technology may be supplied by one

company and/or estimates must be made regarding how price would decline should such a piece of technology be widely adopted, for example, in a national domestic energy efficiency retrofit.

The approach to valuing labor is worth detailing. In reports purporting to be CBAs, labor or "employment" is sometimes treated as a benefit rather than a cost. Labor is an input into a project and, therefore, a cost even though it may have some additional benefits such as community stability, as discussed later. However, that cost may be less than the market wage would suggest. If labor markets clear, the shadow price of labor will equal the market wage. Any increase in employment in one sector of the economy will merely reduce the availability of labor to another sector. This is likely to be the case when the jobs are highly skilled and/or there is a shortage of such skills. However, for a country with a high unemployment rate, it could be argued that an increase in the demand for labor in one sector of the economy will not necessarily displace a job in another sector; that is, there may be employment additionality whereby if the new job is filled by a person who was previously unemployed, a very low cost (not zero, unless it is considered that the unemployed's spare time is totally unproductive) in terms of output forgone is imposed on society. In this case, the shadow price of labor would be close to zero. It has been the practice of some government CBAs to assume a shadow price of labor of zero. However, this is against the international practice of setting the shadow price of labor at most a fraction below the market wage. For example, in Canada, the shadow wage is usually 95% of the market wage, and in the United Kingdom they are usually considered equal. In many energy projects, specialized skills are required and so a shadow wage close to the market wage will usually be appropriate. However, in some household energy efficiency improvement schemes, long-term unemployed people have been trained how to fit various sorts of insulation, for example. In this example, a case could be made for using a lower shadow wage rate.

A related value that should be considered is whether an energy project may contribute to community stability. For example, would the provision of a new power plant in a rural area provide jobs such that depopulation of that area would halt? This value is not the value of the job per se. Rather, it is the added value of a job being in a particular place. These values are difficult to assess but are real. For example, it is often observed that employees will be willing to accept lower salaries to live in their hometown.

4.6 Valuing Changes in Energy Use

When calculating the benefits of reductions in energy use, the price of energy may be used to value such savings. However, it may be necessary to shadow price such savings. If the state supplies energy, an assessment must be made of whether there is any form of subsidy involved; if so, this should be removed. Where there is monopoly power in the energy market, either locally or, for example, through the monopolistic behavior of the Organization of Petroleum Exporting Countries, the price of energy is unlikely to reflect the true cost to society of its generation.

Energy supply is considered so essential that a premium may be placed on its supply from domestic sources if this reduces the risk of supply interruption. Most countries have assessed the importance of such supply, and this information may be used to assess any premium that should be applied. If the increase in supply that would be generated by the energy project under consideration is marginal to the total supply in a country, it is unlikely that such a premium would be significant.

In an *ex ante* analysis, a sensitivity analysis should be undertaken for alternative scenarios regarding the possible future changes in energy prices. These are difficult to predict because there are a number of offsetting effects. Possible deflationary pressures include the development of more energy-efficient machinery and technology, improved availability (and therefore reduced prices) of non-fossil fuel energy sources and systems, and any change in the regulation of the energy sector. Possible inflationary pressures include rapid economic growth and a consequent increased demand for energy, the exercising of market power in oil production, future scarcity of fossil fuels, and the introduction of carbon taxes and/or tradable permits in light of the Kyoto Protocol. However, if the price of energy is inflated by a carbon tax/emissions-trading system set to reflect the external costs of energy use, it is important to avoid summing external costs estimated by the techniques described later with the energy savings using this price because if the price already reflects the external effects, it would be inappropriate to include them a second time.

4.7 Externalities

Shadow prices adjust for one form of market failure. However, a CBA must also take into account the potential existence of externalities and public goods, as explained previously. The consideration of such

costs and benefits is extremely important in CBAs because all of the costs and all of the benefits to the whole of society are being considered. The difficulty is that these external costs and benefits are not exchanged within markets, so there is no price to reflect their value. For this reason, it is necessary to use nonmarket or environmental valuation approaches to place monetary values on these externalities.

5. VALUATION OF ENERGY EXTERNALITIES

Most energy projects have some impact on the environment that must be factored into a CBA. For example, a new coal-fired power plant will have implications for climate change, localized air pollution, and the production of acidification precursors. A cost–benefit analyst assessing the merits of a renewable energy project or an energy efficiency program will wish to factor in the value of reductions in such environmental effects.

5.1 Economic Value Concepts

A useful framework for assessing the effects of environmental impacts on humans is known as the total economic value approach. This expands the traditional concepts of economic value to include option value and existence value. In essence, an environmental asset is considered to have both use and nonuse value.

Use value can be broken down into actual use value and option value. Suppose we are estimating the value of damage caused to woodland from acid rain resulting from power generation. Actual use value is derived from the actual use of the asset and is composed of direct use value, such as timber from the woodland, and indirect use value, such as the value that would be yielded to inhabitants downstream should a forest reduce flooding.

Option value can be broken down into a number of components: the value individuals place on the preservation of an asset so that they may have the option of using it in the future (value of future options for the individual) for recreational purposes, for example; the value they attach to preserving the asset because it can be used by others (vicarious value); and the value they attach to preserving the asset so that future generations have the option of using it (bequest value). Thus, total use value is defined as

$$\begin{aligned}\text{Total use value} = {} & \text{direct use value} \\ & + \text{indirect use value} \\ & + \text{option value},\end{aligned}$$

where

$$\begin{aligned}\text{Option value} = {} & \text{value of future options for the} \\ & \quad \text{individual} \\ & + \text{vicarious value} \\ & + \text{bequest value}.\end{aligned}$$

Nonuse values are existence or passive-use values. Existence values reflect the benefit to individuals of the existence of an environmental asset, although the individuals do not actually use the asset. These values may exist due to sympathy for animals and plants and/or some human approximation of the intrinsic value of nature (i.e., this value reflects a sense of stewardship on the part of humans toward the environment). Existence value is classed as a nonuse value such that total economic value (TEV) is defined as

$$\begin{aligned}\text{TEV} = {} & \text{actual use value} + \text{option value} \\ & + \text{existence value}.\end{aligned}$$

It is important to note that the TEV approach attempts to encapsulate all aspects of a resource that enter into human's utility functions (i.e., it is anthropocentric). Thus, it does not attempt to find an intrinsic value for the environment, where intrinsic means the value that resides in something that is unrelated to humans. However, it does attempt to include the intrinsic value that humans bestow on nature. There is no agreement on the exact breakdown of the values in the TEV framework; however, the important point in CBA is to account for all these values as best as possible.

5.2 Environmental Valuation Methods

There are two broad categories of nonmarket valuation methods: revealed preference methods and stated preference methods.

5.2.1 Revealed Preference Methods

Revealed preference studies use data from actual behavior to derive values for environmental assets. Suppose the value of a marketed good depends in part on an environmental good. These methods try to isolate the value of the environmental good from the

overall value of the marketed good. Such techniques include the following:

Hedonic pricing method: The value of a house depends, in part, on its surrounding environment. This method examines the determinants of the house's value and then isolates the effect that the environmental feature (e.g., a nearby park) has on the house. This is used as an estimate of the value of the environmental asset in question.

Travel cost method: The value of the park can be estimated by the willingness to pay to attend the park in terms of costs of travel and entrance to the park.

Production function approaches: These value a decrease (increase) in environmental quality as a result of some activity by the loss of (addition to) the value of production due to that activity. For example, the cost of acid rain resulting from pollution from fossil fuel-based power plants might be measured by the lost output of timber from forests (dose–response functions), the cost of restoring the damage to buildings (replacement cost), or the cost of defensive expenditures.

The production function approaches may seem more applicable to estimating externalities of energy generation, but the hedonic pricing method and travel cost method may be used to estimate the value of an amenity such as a forest park. This value could then be used to calculate the cost of damage to the park from air pollution.

5.2.2 Stated Preference Methods

Direct valuation methods ask people in a survey to place a value on the environmental asset in question by rating (contingent valuation), ranking (contingent ranking), or choosing trade-offs between various policy alternatives (choice procedures). These direct methods via questionnaires are the only approaches that can estimate existence value. The best known and most controversial of these methods is contingent valuation.

The contingent valuation method (CVM) collects information on preferences by asking households how much they are willing to pay for some change in the provision of an environmental good or the minimum compensation they would require if the change were not carried out. Since the mid- to late 1980 s, this method has become the most widely used approach for valuing public goods and there has been an explosion in the number of CV studies.

The CVM approach is to choose a representative sample, choose an interview technique (face-to-face, telephone, or mail), and then construct a questionnaire containing:

- A detailed description of the good being valued and the hypothetical circumstance in which it is made available to the respondent.
- Questions that elicit the respondents' willingness to pay for the good being valued: open ended (How much would you pay?), bidding (Will you pay x, if not, will you pay $x-y$), payment card (Which of these amounts would you choose?), and binary choice (If it costs x, would you pay it? Yes/no).
- Questions about the respondents' characteristics (e.g., age, education, and income), their preferences relevant to the good being valued (e.g., how concerned or interested are they in the environment), and their use of the good.

The mean or median willingness to pay from the sample of households surveyed can be multiplied up to the population level to give a total valuation.

5.3 Valuing Environmental Damage and Improvements from Energy Projects

The most significant environmental effects of energy projects that are included in CBAs tend to be the contribution of such projects to global warming from changes in CO_2 emissions and acid rain resulting from the production of NO_x and SO_2. In addition, many energy projects have implications for the production of particulate matter that may have consequences for human health and visibility.

The impacts of climate change are as follows: storm and flood damage (increased in some regions, such as the Caribbean and Pacific, but not others), increased mortality and morbidity, effects on small islands (sea levels rise due to heating water and melting ice caps), increasing salinity of estuaries, damage to freshwater aquifers, and effects on agriculture and forestry. It is estimated that a substantial portion of the existing forested area of the world will undergo major changes.

There are three approaches to placing a monetary value on the benefits of greenhouse gas reductions. The damage-avoided approach values 1 ton of carbon not emitted by the cost of the damage that would have been done by global warming in the event that it had been emitted. The offset approach measures the value of not emitting 1 ton of carbon using one method compared to the next cheapest alternative method. The avoided cost of compliance

approach measures the 1 ton of saved carbon by the avoided cost of compliance with a global/regional CO_2 emissions reduction agreement. A variety of estimates have been produced regarding the benefits of reducing CO_2, including studies by the United Nations Intergovernmental Panel for Climate Change.

Several major research projects have endeavored to place monetary values on all the environmental effects related to energy. Two EU-funded projects, one on the external costs of power generation (ExternE) and the other on European environmental priorities, are very useful sources of information on such values.

The ExternE project used an "impact pathway" methodology. Under this methodology, the fuel cycle, or life cycle of the fossil fuel used for generation, is first divided into stages, such as extraction, transport, combustion, and waste disposal. The environmental burdens imposed at each stage and the likely impact of these burdens on the environment and the public are isolated. The impacts are then valued using a variety of economic valuation methods, such as contingent valuation, direct cost of damage, or cost of mitigation. These costs are then normalized to give a cost per unit energy output and a value per ton of a pollutant reduced.

The "priorities" project endeavors to derive values for various environmental externalities suitable for use in a European context. The impacts of SO_2 on acute mortality, morbidity, materials, and the fertilization effect are all included; however, some impacts are omitted, such as forest damage, adverse effects on ecosystems and cultural heritage, and the dampening effect that SO_2 has on global warming. The main areas of uncertainty relate to the value of mortality. NO_x emissions are dealt with under two headings, acidification and tropospheric ozone. The fertilization effect of NO_x is examined under acidification. For damage to health and crops, the effects of NO_x on tropospheric ozone are used. Again, the bias is toward underestimation because damage caused to forests, biodiversity, non-crop vegetation, and materials is excluded.

Care should be taken when using unit damage values such as those in the studies mentioned previously. First, the confidence intervals are large (and should always be quoted in a CBA). In addition, there is confusion about which emissions cause which adverse effects. For this reason, it is very easy to double count when using estimates derived from different studies. For example, in some studies negative health effects are included in SO_2 damage estimates, whereas in others the most significant health effects result from particulate matter emissions. Finally, the damage caused by 1 ton of most air pollutants (excluding CO_2) will vary depending on the geographical origin of the emission. However, most estimates are derived from an exercise known as benefits transfer.

5.4 Benefits Transfer

To reduce costs and where there is no alternative procedure, it is standard practice in CBAs to apply existing monetary valuation studies outside of the site context in which they were originally undertaken. This is known as benefits transfer. There are a number of rules when using this method, the most obvious being that the contexts of the studies should be very similar. In addition, appropriate statistical techniques should be used, including meta-analyses of best practice studies; the studies should have similar population characteristics; and property rights should be similarly distributed. The method is most accurate when the impacts are not affected by local characteristics (e.g., income and population size). The most comprehensive studies of energy externalities referred to previously involve significant benefits transfer.

5.5 Valuing Mortality and Morbidity

Placing monetary values on life and death is perhaps the most controversial area of economics. There are two major approaches for carrying out this task. The first values life directly through livelihood. This is known as the human capital method and is the oldest and most easily applied. It equates the value of life of an individual as the present value of future lost output of the individual, which is usually estimated using income. However, it is important to note the substantial drawbacks of this approach. Most obvious, it values livelihood rather than life per se. It is quite improbable that there would be a 1:1 relationship between individuals' earnings and their demand for risk reduction. In other words, the human capital approach makes no reference to how humans value risks to their own lives. One of the most glaring flaws of this approach, however, is the fact that it places a zero value on the retired population and those who do not "produce" marketed output (e.g., those who work in the home).

The appropriate way of valuing reductions in mortality is not to value a life per se but rather to value people's willingness to pay for a reduction in

the risk of mortality. These data derive primarily from one of three study formats: the wage risk model (also known as the hedonic wage model), the avertive behavior method, and the contingent valuation method. Although space does not permit a detailed explanation of these methods, the general approach is to value a small reduction in risk and then translate this into the equivalent of a life saved. This is the value of a statistical life (VSL).

There has been controversy regarding this approach in relation to the estimation of the costs of power generation. The VSL estimates would be expected to be considerably lower for a developing country because the willingness of people to pay to reduce risk of death is partially dependent on income. Thus, the VSL used for a developing country (e.g., for deaths from coal mining) would be expected to be lower than the VSL used for a developed area (e.g., for deaths from air emissions in Europe by the burning of such coal). It is notable that the ExternE project steered clear of controversy by using the same VSL for each area.

The value of morbidity may be assessed using a cost of illness approach. In the case of air pollution from energy generation, this would be the sum of the cost, both public and private, of hospital stays and drugs for the treatment of associated illnesses. More positively, the health benefits of improving domestic energy efficiency would be the associated avoided costs of illnesses. Other costs avoided by wider society include the loss of productivity from those who are ill and unable to work. The avoided cost to the individual beyond drugs and hospitalization direct costs (if any) is more difficult to calculate. One approach is to estimate individuals' willingness to pay to avoid "restricted-activity days." The priorities study referred to previously contains such estimates.

6. FURTHER ISSUES IN THE APPLICATION OF COST–BENEFIT ANALYSIS TO ENERGY

When undertaking or evaluating a CBA of an energy project, there are a number of additional issues that must be considered. The tool is not without its controversies. These arise because of its use of money as the common unit of measurement. First, assessing welfare changes using willingness to pay and/or willingness to accept is perfectly valid in theory if one believes that income is distributed optimally. However, care must be taken when the population(s) whose welfare is being assessed has a high income variance. Poor people will be willing to pay less, all else being equal, simply because of their budget constraint. In addition, because the values and market prices used in a CBA of an energy project or policy are in part a product of the existing income distribution, if that distribution changes, prices will change, and so will market and nonmarket values. Second, distributional effects tend to be ignored in CBAs and yet energy policies often have very different consequences for different socioeconomic groups. Because energy is a necessity, energy efficiency schemes may benefit those on lower incomes more than average. However, without poverty-proofing measures, energy taxes will comprise a much higher proportion of their income than average. Third, not all support attempts to place monetary values on environmental assets, and the value of the statistical life concept is particularly controversial. Some find it unpalatable to consider that the environment might be traded with other goods and services let alone "lives." In addition, as in all public policy or human actions, the environmental values used are by definition anthropocentric.

Finally, the environmental valuation methods are limited in their ability to assess values. Many environmental outcomes assessed by natural scientists are subject to large confidence intervals even before economists endeavor to value them. Also, the valuation methods vary in their ability to assess environmental values. Economists have identified a number of criteria by which environmental valuation methods should be evaluated: validity (the degree to which it measures the total economic value of a change in the environment), reliability (the extent to which the variability in nonmarket values is due to random sources), applicability (assesses where the techniques are best applied), and cost (the practicality and viability of carrying out the valuation study). In general, revealed preference methods (e.g., productivity loss and replacement cost) are widely accepted valuation methods that provide valid and often reliable estimates of use values. However, they are limited in that they only provide estimates of use values, and it is often difficult to find suitable and reliable links between market goods and environmental amenities. The estimated values are often sensitive with respect to modeling assumptions, reducing their reliability in such cases. In general, however, revealed preference methods are applicable for valuation of policies that primarily affect use values and can provide very reliable results. Stated

preference methods such as contingent valuation are capable of measuring both use and nonuse (existence/passive-use) values. They are applicable to a larger array of environmental issues than are revealed preference methods, and they are often the only applicable methods for benefit estimation. However, they do have a number of limitations and may be subject to a number of biases.

There are some simple rules for using cost–benefit techniques. Simpler environmental valuation methods should be used where possible (e.g., production function approaches) while recognizing these are primarily of interest when the policy changes will mainly influence use values. A high degree of reliability in stated preference methods may be achieved by adhering to sound principles for survey and questionnaire design and if the method is applied to suitable environmental goods. The methods work best for familiar environmental goods and for salient environmental issues. The methods are likely to be least reliable where the environmental good being valued is complex (e.g., in the case of biodiversity).

Finally, in CBAs of energy initiatives, it is important to note that the estimates of values are made at the margin. The plausibility of the techniques described depends in part on the fact that most things remain the same, with the implicit assumption that there is no paradigm shift in values, power, income, and the like during the time period of assessment.

Glossary

conversion efficiency The efficiency with which energy from one component (feed) is converted into another component (e.g., meat, milk) expressed as a $kg\,kg^{-1}$.

direct energy The energy requirement for a specific process, expressed as megajoules per kilogram ($MJ\,kg^{-1}$ or $10^6\,J\,kg^{-1}$).

embodied energy Sum of the energy requirements in all preceeding production steps required to generate a food product or intermediate.

energy requirement The energy input required in a certain step in the production of food.

indirect energy All energy requirements not considered as "direct"; for example, auto fuel is usually considered direct energy, whereas energy to build roads is considered indirect.

nutritional value A measure of the amount of energy that becomes available to the body after ingestion of a food product, expressed as kilojoules per kilogram ($kJ\,kg^{-1}$ or $10^3\,J\,kg^{-1}$); the nutritional value of a product is not related to the energy use in food production.

Energy use of food production systems starts with photosynthesis. Incoming sunlight is absorbed by chlorophyll in plant leaves. Water and carbon dioxide, which are required for the reaction, are taken up by the cell wall, and oxygen is emitted to the environment. The $(CH_2O)_n$ ("sugar") produced is the building block that plants use to make carbohydrates, proteins, and fats. This conversion process requires chemical energy.

1. DEFINITION AND BOUNDARY OF THE FOOD SYSTEM

Energy use of food production systems starts with photosynthesis, that is, at the interception of sunlight by plants and the subsequent transformation of $CO_2 + H_2O$ into $(CH_2O)_n$ and O_2. The incoming sunlight is absorbed by chlorophyll in plant leaves. Water and carbon dioxide, which are required for the reaction, are taken up by the cell wall, and oxygen is emitted to the environment. The $(CH_2O)_n$ ("sugar") produced is the building block that plants use to make carbohydrates, proteins, and fats. This conversion process requires chemical energy, which is obtained by the respiration of some of the products formed during photosynthesis: $CH_2O + O_2 \rightarrow CO_2 + H_2O +$ energy. For example, from 1 g glucose ($C_6H_{12}O_6$), a plant can produce 0.9 g other carbohydrates.

The transformation of sugars into other plant components is accompanied by more weight loss. For the production of amino acids, this loss depends on the source that supplies the nitrogen. For example, 1 g of glucose can be transformed into 0.7 g of amino acids when nitrogen is available as ammonia (NH_3). However, the usual source of nitrogen is NO_3^-, and in that case relatively much energy is needed for the reduction of nitrate into ammonia, according to the following pathway: $NO_3^- + 8\,H \rightarrow NH_3 + 2H_2O + OH^-$. This pathway results in the production of 0.5 g of amino acids from 1 g of glucose. The production of fat by plants is most energy demanding. For example, 1 g of glucose is required to

 © 2004 Elsevier Inc. All rights reserved.

generate 0.4 g of fat. The low conversion rate from sugars into fats on a weight basis is one of the reasons why the dry matter yield of oil-producing crops such as soybeans are significantly lower than the yields of starch-producing crops such as potatoes, rice, and grain, even though the lengths of their growing periods are not much different (Table I).

On average, plants use 1 g of glucose to produce 0.7 g of plant material that is made up of 25% protein, 55% cellulose, 6% fat, 6% sugars, and 8% minerals. Carbohydrates, proteins, and fats from plants can be used for human nutrition, but they may also be used as a feed for animals to produce eggs, dairy products, and meat.

Besides sunlight, various other sources and forms of energy are required during the subsequent stages of the food production system. That energy is directly needed to convert raw materials into new products or ingredients; therefore, it is called a direct energy requirement. Apart from energy input, there also is a loss of raw materials during each of the stages. Because raw material represents an amount of embedded energy, the materiel loss can also be described as an indirect energy requirement for the production stage. The total energy requirement for each stage is the sum of direct and indirect energy. For example, during the consumption stage at home, the direct energy is used to buy, store, and prepare the food. The indirect energy requirement at home is represented by the substantial amount of food (up to 15% of all food purchased) that is not consumed and ends up in the waste bin.

For a complete assessment of the embodied energy of food products, the entire life cycles of those products must be considered. These life cycles start at the farm, where the on-farm production takes place. Crops are sown, grown and harvested, whereas animals are bred, fed, and slaughtered. Food products end their life cycles at the moment of consumption. Some food products are consumed after a short and simple life cycle, for example, an apple that comes from a consumer's own backyard garden. On the other hand, shops offer a large variety of food products that are the result of sometimes long and complex life cycles. Such food products may contain exotic ingredients or ingredients that have undergone various processing steps, for example, a pizza with a topping of tropical fruits and processed meat.

Irrespective of the complexity of the life cycles of food products, several general handling steps can be discerned. The first step, already mentioned, is on-farm production. Following the harvest, agricultural products are transported either directly to a shop or to a factory for further processing (e.g., washing, cutting, cooking, mixing, packaging). Processed products are stored (either chilled or at ambient temperatures) and subsequently are transported to a retailer, where they are offered for sale. After purchasing the food, a consumer will carry the products home from the shop. At home, the products may be stored for a while, after which time they will be prepared for consumption. Alternatively the consumer can go to a restaurant to eat the food there. In that case, the restaurant owner/employees will have bought, stored, and prepared the food. Each of these steps, for which various alternatives exist, requires energy. In the end, the sum of all energy requirements in each step determines the total embodied energy of a certain food product. In what follows, this article looks in some detail at each step in the production chain and indicates potential differences in energy requirements between eating out and eating at home.

TABLE I

Yield per Hectare for Various Industrial Food Crops

	Yield (tonnes/ha)	Dry matter content (percentage)
Tomatoes	40–75[a]	5
Potatoes	30–70[a]	25
Vegetables	1–90[b]	5–20[b]
Grain	3–10[b]	95
Oil-producing crops(e.g., soybeans)	1–4	98

[a] Depending on agricultural conditions.
[b] Depending on the type of crop.

2. ON-FARM PRODUCTION

The embodied energy of food products (as distinct from nutritional or caloric value) differs among various food categories, and substantial differences also exist within a specific food category. Table II presents average embodied energy for some fresh ingredients from plant and animal origin under Dutch farm production circumstances. Crops grown in heated glasshouses, as is common in several northern countries, require substantial higher amounts of energy. That increase may be up to 40 MJ kg^{-1}. In some regions, glasshouses (or plastic equivalents) are used without heating just to make sure that heat from the sun is being collected

during the day and not lost too easily during the night. That practice saves energy and enhances the growth rate.

To raise the yield per hectare, fertilizers can be used. The production of fertilizers requires approximately 10 to 25 MJ kg^{-1}. The application of fertilizers may add up to 5 MJ kg^{-1} to the total energy requirement of the on-farm stage. However, in most cases, it is substantially lower than that. For crop protection, various chemical compounds are used (e.g., herbicides, pesticides, fungicides). The production of these chemicals requires between 100 and 1000 MJ kg^{-1}, and the applications vary substantially. The energy requirement for plant protection may rise up to the same level as for fertilizers. However, that figure can vary from year to year and from crop to crop because the application of crop protection aids depends very much on weather and local circumstances.

The embodied energy for products from animal origin is approximately a factor 10 higher than that for products from plant origin (Table II). Within the category of products from animal origin, fish–meat has a relatively low embodied content. The low energy requirement can be explained by the fact that fish are cold-blooded and, therefore, require less energy to produce body warmth (thermoregulation). There are two main sources of fish: sea fish and fish from aquaculture. The overall energy requirements for the production of these two do not differ much, but the buildups are rather different. For sea fish, a lot of energy is required for the ships at sea—between 2 and 50 MJ kg^{-1} depending on the type of fish. There are many variables that make an accurate calculation of the energy requirement for fishing very complex (e.g., the amount of by-catch, the efficiency of fish filleting, the use of by-products). In aquaculture, the fish are fed with fish meal, which originates from dry sea fish residues.

Feed-to-meat conversion ratios partly explain the differences in energy requirements between products from plant and animal origin. Table III shows the conversion efficiencies for chicken, pork, and beef based on long-term records of feeding efficiency ratios by the U.S. Department of Agriculture (USDA). Cumulative feed/gain ratios for chicken are between 1.8 and 2.0 for chickens in the most common 2.0- to 2.5-kg range. That ratio is raised by at least 10% to account for the feed requirements of breeder hens and cockerels that do not directly contribute to the meat production, as well as for the fact that some animals die prematurely. Ratios between 2.0 and 2.2 represent the standard of recent good performance. Typical rates from long-term statistics are somewhat lower (Table III).

TABLE II

Embodied Energy for Some Fresh Foods from Plant and Animal Origin Produced in The Netherlands

Product	Embodied energy (MJ kg^{-1})
Plant origin	
Potatoes	1
Vegetables	1–4
Fruit	2–5
Pulses	6–10
Animal origin	
Milk	10
Eggs	20
Fish (caught at sea)	20–40
Butter and cheese	50–60
Meat (chicken, pork, beef)	30–70

TABLE III

Typical Efficiencies for Meat Production

	Chicken	Pork	Beef
Feed (kg kg^{-1} live weight)	2.5	3.5	3–5[a]
Edible weight (percentage of live weight)	55	55	40
Feed (kg kg^{-1} edible weight)	4.5	6.4	7.5–12.5
Nutritional value (kcal kg^{-1})	1800	1700–3300	1200–3300[b]
Average energy conversion efficiency[c]	11.5	11.2	6.0–9.5

[a] Depending on the inclusion of milk production.

[b] Depending on fat content of the meat (average nutritional value 2500 kcal kg^{-1}).

[c] Percentage of the embodied energy in feed that is retained in the embodied energy of meat, assuming the average embodied energy for cattle feed of 3500 kcal kg^{-1}.

Pork is the least feed-intensive red meat due to pigs' inherently low basal metabolism. The overall feed/gain ratio for North American pigs from weaning to slaughter ranges between 2.5 and 3.5 with *ad libitum* intake of feed. In The Netherlands, on average 320 kg of feed is required for 115 kg of live weight pork. The addition of feeding costs of the breeding stock and adjustments (e.g., for premature mortality) can raise the overall feed/gain ratio significantly. From the early 1900s onward, the nationwide feed/gain ratio for pigs has declined only slightly, in spite of the substantially improved regimes, due to the selection of less lardy pigs. The efficiency of metabolizable energy conversion in pigs peaks at approximately 45%, whereas conversion to fat can be as efficient as 75%.

Cattle are the least efficient converters of feed to meat. Their basal metabolism is higher than that in pigs, and their large body mass and long gestation and lactation periods mean that feed requirements of breeding cattle claim at least 50% more energy than those of pigs and nearly three times as much as those of chickens. The USDA's historic feed/meat data for all of the nation's cattle and calves imply that as little as 3% of gross energy in feed is converted into energy in food.

From the energy makeup point of view, there is a rather poor energy conversion efficiency for meat products, although the situation is not as bad as the conversion efficiency factors in Table III may suggest. A large part of the cattle feed consists of materials that are left over from the human food chain, and cows can convert plant material that humans cannot digest (e.g., grass) into highly valuable food components such as milk and meat. However, we can certainly say that eating animal protein requires significantly more energy and requires more land than does eating vegetable food.

3. TRANSPORT

Crops that are not cultivated under controlled environmental conditions, such as those in heated glasshouses, can be grown only in a certain region during a limited period of the year. However, consumer demand for food is not restricted to these periods. This discrepancy can be overcome in two ways: conservation of the harvested produce and import of products from other regions. The latter option requires energy for transportation, which varies largely with the means and distances of transport (Table IV). As a consequence, major differences in the energy requirements will exist for products that are transported over a long distance: In general, the energy requirement for transport by airplanes is very high, whereas the energy requirement for transport by vessels is relatively low.

TABLE IV

Energy Requirement for Transportation

Means of transport	Energy requirement[a] ($MJ\,kg^{-1}\ 1000\,km^{-1}$)
Seagoing vessel	0.1–0.2
River vessel	0.4–0.7
Train	0.8–1.0
Truck	2–5
Airplane	10–25
Car	50–250[b]

[a] The energy requirement depends on size and load factor.
[b] Depending on petroleum use as well as the amount of products carried (20–40 kg).

TABLE V

Energy Requirements for Some Industrial Preservation Techniques

Preservation technique	Energy requirement ($MJ\,kg^{-1}$ end product)
Drying[a]	0–15
Freezing	5
Heat treatment[b]	5–10

Source. 1996 data from Unilever operations.
[a] The energy requirement ranges from nearly zero for sun drying to approximately 15 MJ kg^{-1} for hotair drying.
[b] Blanching, pasteurization, sterilization.

4. PROCESSING, PACKAGING, AND STORAGE

Many agricultural products undergo some industrial processing before they reach the consumer. Advantages of processed foods over fresh agricultural products include convenience and prolongation of shelf life. In general, industrial food production includes cleaning, mixing, preservation, and packaging operations. Preservation can be achieved by drying, freezing, or heat treatment (Table V). All processing steps require energy, but mechanical handling (interfactory transportation, mixing, and shaping) generally constitutes only 10 to 20% of the total energy requirement. The bulk of the energy

requirement in food processing is caused by heating and cooling required for food preservation.

Several options exist for the packaging of food products. Some food products may require specific packaging materials not only to safeguard food integrity and food safety but also for marketing purposes. Table VI presents data on the energy requirement for the production of the most commonly used packaging materials. When interpreting these data, one should take into account that the packaging for a particular product will require different amounts (weights) of the various packaging materials, thereby complicating a direct comparison of the data in the table. Moreover, the overall energy requirement related to the use of packaging depends on the waste treatment in a particular country due to the energy recovery potential during waste incineration. In case all waste is incinerated with energy recovery, the total energy requirement is reduced as shown in Table VI. Ranges for the overall embodied energy for the ready-to-eat meals, preserved and packed in different ways, are presented in Table VII.

Ready-to-eat meals are prepared in the factory. This preparation requires relatively little energy per portion because the production is large scale. The final product needs to be stored and transported at low temperatures; hence, it requires more energy. Preparation of food at home usually starts with fresh ingredients. In the chain from farm to home, there usually is a significant amount of product loss that does not occur with factory production. In restaurants, the energy requirement and product losses usually are higher than for the two other routes. But in general, the total energy requirements (including the embodied energy of losses in the chain) for food prepared at home and ready-to-eat meals do not differ a great deal.

Finished products are finally stored and distributed to a point of sale. This requires energy for transportation (Table IV). In addition, some food products have to be kept cool or frozen. Average energy requirements for cooling and freezing vary substantially (Table VIII). The most efficient is storage in a well-isolated warehouse, whereas storage in a small open freezing cabinet is very energy demanding. The latter option is often used in shops to stimulate consumers to buy such products. In those cases, priority is given to easy access and not to efficient energy use.

There seems to be a direct relationship between embodied energy and product cost, particularly for commodity food products, as indicated in Fig. 1. Only a few products are situated above the line, representing those products produced in greenhouses with subsidized energy. There are many products below the line, mainly branded and seasonal food products. In those cases, the price that is being paid in the market is higher than the energy equivalent because there also is an emotional value to the product.

TABLE VI

Energy Requirements for the Production of Some Packaging Materials

Material	Energy requirement (MJ kg^{-1})	Recovery potential (MJ kg^{-1})

[a] The wide ranges are due to the variety of cooling and freezing cabinets, ranging from well-isolated facilities to small open boxes.

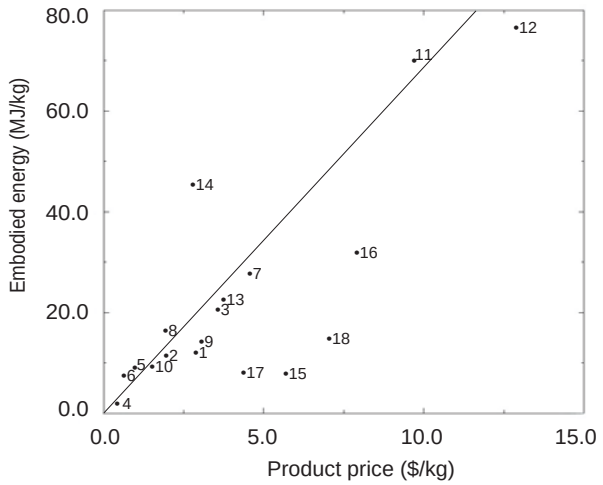

FIGURE 1 Relationship between embodied energy and product price for the following food products: (1) whole-meal bread, (2) wheat flour, (3) rice, (4) potatoes, (5) carrots, (6) onions, (7) jam, (8) sugar, (9) margarine, (10) milk, (11) butter, (12) cheese, (13) eggs, (14) greenhouse tomatoes, (15) beer, (16) wine, (17) fresh vegetables, (18) strawberries.

5. CONSUMPTION

After purchasing the food, a consumer will add to the overall embodied energy of the product by using a car to take the product home, by storing it in a refrigerator, by cooking it, by washing the dishes, and (ultimately) by disposing of the nonconsumed waste. In most countries in the Western world, on average, shopping adds 0.5 to 3.0 MJ kg^{-1} because a substantial part of all shopping is done by car. Nearly 50% of all Dutch consumers use a car to do their supermarket shopping at a distance of approximately 3 km from their homes, buying on average approximately 20 kg of products each time. Dutch consumer habits seem to be comparable to those in other countries, although the distances to the supermarkets are longer in some countries (e.g., France, the United States) and the proportion of motorized shopping differs to some extent.

In-house, some food products can be kept at ambient temperature, whereas others require energy for cooled or frozen storage (Table VIII). The amount of energy for storage depends on the energy efficiency of the refrigerator and/or freezer, its storage capacity, the temperature installed, the amount of product stored, and the frequency of opening. The storage capacity that is required for a household is related to the frequency of shopping. This relation is demonstrated in Table IX, where the energy requirement for four different situations has been calculated. In each case, the same amount of food is purchased per week and the shopping trips are done by car. Cars use petroleum (46 MJ/kg) at an average rate of 6.5 L (4.8 kg or 215 MJ) per 100 km.The distance to the shop has been varied (2 or 5 km), as has the shopping frequency (two or three times/week). Our calculations demonstrate that for small distances between house and shop, the total energy requirement for shopping and storage is not very much influenced by the shopping frequency. At longer distances, the energy requirement for transporting the goods is so high that it pays to have a large refrigerator to store the goods.

Ready-to-eat meals are prepared in a factory. This preparation requires relatively little energy per portion because the production is large scale. In many cases, the final product needs to be stored and transported at low temperatures; hence, it requires more energy. Preparation of food at home often starts with fresh ingredients. In the chain from farm to home, there usually is a significant amount of product loss due to material deterioration and processing inefficiencies. Those losses are usually substantially lower in the case of factory production

TABLE IX

Energy Requirements for Shopping and Storage of Food at Different Shopping Distances and Frequencies

Shopping distance (km)	Shopping frequency ($week^{-1}$)	Energy requirement for shopping (MJ $year^{-1}$)	Storage capacity (L)	Energy requirement for storage (MJ $year^{-1}$)	Total energy requirement for shopping + storage (MJ $year^{-1}$)
2	2	895	235[a]	1235	2130
2	3	1341	155[b]	1020	2361

5	3	3354	155[b]	1020	4374

[a] As 210 L for cooled storage and 25 L for frozen storage; energy requirement 0.4 kWh per day per 100 L.
[b] As 140 L for cooled storage and 15 L for frozen storage; energy requirement 0.5 kWh per day per 100 L.

TABLE X

Energy Requirements for Cooking

Situation	Energy requirement (MJ kg^{-1})
Home	
Homemade	5–7
Ready-to-eat	1–2
Restaurant	10–15

TABLE XI

Energy Requirements for Dishwashing in an Average Dutch Household (2–3 Persons)

Method	Energy requirement per event (MJ)	Daily energy requirement (MJ)
Manual dishwashing		
Water heated by gas	1.0	1.0
Water heated by electricity	2.5–3.0	2.5–3.0
Dishwasher	4.0–5.5	2.5–3.5

due to better controlled logistics. In some restaurants, the energy requirement and product losses are higher than those for eating at home, but that depends very much on the number of customers and the amount of food that has to be discarded. In general, the total embodied energies (including the embodied energy of losses in the chain) for food prepared at home and ready-to-eat meals do not differ a great deal (Table X).

The amount of energy for cooking depends on the method of preparation, the energy source (with gas being more efficient than electricity), the energy efficiency of the cooking device, and the type of recipe. A major additional factor is the number of portions being prepared at the time. In general, the amount of energy required per portion diminishes at higher numbers. For very small numbers, cooking by microwave is to be preferred; for larger numbers, cooking with gas turns out to be most energy efficient.

After a meal, the dishes have to be washed. The energy requirements for this activity depend on the energy needed to heat the water and on whether dishwashing is done manually or with a dishwasher. Dishwashers vary in their energy efficiency. Households that use electrically heated water may save on total energy requirements by using an energy-efficient dishwasher (Table XI). This is due to the fact that the production of electricity as an energy source has an efficiency of only 40%. The data in Table XI are based on 17 L as the average amount of water used for manual dishwashing. The energy used to produce the dishwasher itself is negligible in comparison with the amount of energy that is needed for the actual dishwashing during the life span of the machine (10–15 years).

Finally, at the end of the food chain, consumers dispose of inorganic waste such as packaging materials and organic waste (e.g., leftovers, parts of the foods that were removed during the cleaning and cutting of the ingredients of the meal). On average, some 10 to 15% of the total energy makeup of the foods that are purchased by consumers are not used for consumption but rather discarded. This loss equals an amount of approximately 1000 MJ/year/person.

6. CONCLUSIONS

For all food categories, there is a wide variety of energy requirements over the production chain that are due predominantly to the following:

- *Time and place of consumption in relation to the period and region of production.* Foods that need to be stored for a long period and/or transported over long distances inevitably have higher energy requirements than do foods that are consumed during the season of production close to the area where they originate. However, in some (warm) regions, food can be cultivated much more efficiently than in others, so production of food away from home does not necessarily always lead to increased energy requirements.
- *Production method.* Cultivation under controlled environmental conditions in glasshouses requires additional energy for heating.
- *Degree of processing.* All preservation steps inevitably add to the energy requirements.
- *Consumer food preference.* Consumers can opt for protein sources with high overall energy requirements, such as meat and meat products, or protein from plants with much lower energy requirements.
- *Consumer behavior.* Inadequate shopping, storage, and preparation of food products may add substantially to the energy use of the food system.

black liquor Spent pulping liquor.
charcoal A black porous solid wood fuel that consists mainly of elemental carbon; produced from heating wood in a vessel devoid of oxygen.
cogeneration A process that produces both thermal and electrical energy.
disembodied technological change Technological change that does not require substantial capital investments; influences only the input efficiency of already installed vintages.
embodied technological change Technological change that requires substantial capital investment; influences only the input efficiency of the most recent vintage of the capital stock.
hogged fuels Forest residues from extracting industries such as woodchips that are used to produce energy.
pulpwood Forest products that are used to produce pulp such as woodchips and logs.
wood fuels Forest products that are used for energy generation; include black liquor, fuelwood, charcoal, and residues.
wood pulp Pulp that is produced from virgin forest fibers.

Wood fuels, or energy derived from forest products, are an important contributor to renewable energy supply worldwide. In developing countries, the household sector is the largest consumer of wood fuels. In many developing countries, total consumption of wood fuels is increasing but with a declining fractional share of wood fuels in total national energy supply. Of course, substantial regional and subregional differences exist. In the developed world, industrial consumption of wood fuels has mostly replaced traditional household wood fuel use. The pulp and paper industry is largely responsible for this development through its use of chemical pulping processes. The pulp and paper industry is one of the most energy-intensive manufacturing industries. Over the past half-century, it has gone from primarily purchasing the process energy required to produce pulp and paper toward self-generation from wood fuels often more than half of its energy needs. Now in the beginning of the 21st century, some paper companies are even net energy exporters, primarily due to cogeneration capabilities. Continued transition to self-generation of energy contains important implications for material use in the industry and is influenced by economic, organizational, and technological issues. Consequently, an in-depth analysis of the pulp and paper industry is warranted to understand the prospects for a continued increase in the share of energy supplied from forest products in developed countries.

1. THE FOREST PRODUCTS INDUSTRY: ORGANIZATION AND MAIN PROCESSES

The forest products industry produces two major classes of products: (1) lumber and wood products and (2) paper and allied products. The lumber and wood products sector produces whole logs, lumber, woodchips, hardwood flooring, furniture parts, and the like. It operates primarily on purchased energy, and total energy consumption in this sector is relatively low. In the United States, it accounts for 16% of the total energy consumed by the forest products industry as a whole. Thus, this article

 © 2004 Elsevier Inc. All rights reserved.

focuses on the other half of the forest products industry—the paper and allied products industry.

The paper and allied products industry, or the pulp and paper industry, produces products such as pulp, newsprint, printing and writing papers, and paperboard. The United States currently produces 38% of all pulp produced in the world, followed by Canada, which produces 16%. Correspondingly, the United States produces 36% of all paper and paperboard produced in the world, followed by Japan, which produces 10%. The industry accounts for 0.7% of gross domestic product (GDP) in the United States, but in Finland and Sweden the industry contributes approximately 3.4 and 4.5%, respectively.

The organizational structure of the industry can be divided into three broad sectors: pulp mills, paper and paperboard mills, and finishing. The first two sectors account for more than 97% of all energy use and 100% of all self-generation of energy. In the United States, the industry is mostly competitive and is vertically integrated both upstream and downstream. For instance, it is common for paper companies to own the timber resources they use as a source of raw materials; for example, the three largest paper companies own more than 47% of all privately held timberland. In the United States, it is also common for paper and pulp mills to be located at the same site—what is called an "integrated mill." The capacity of the mills that are integrated tends to be much larger than that of the mills that are not. On average, an integrated mill has a capacity of 1000 tons/day, whereas a paper mill that is not integrated has a capacity of 200 tons/day.

Internationally, capacity utilization rates are extremely high and have been over 90% in the United States for the past quarter-century. Capacity utilization rates are defined as total annual production divided by total annual production capacity. The reasons for those historically high capacity utilization rates are the immense capital intensity of the industry and low profit margins. To remain profitable, the industry must run its machinery very close to full capacity. Because it is too expensive to shut down the equipment or let it lay idle, it is difficult to retrofit already installed machinery, for example, to improve energy efficiency. Consequently, most capital that is installed is used for a long time. This manifests itself in a slow rate of capital turnover and implies that technological improvements occur only incrementally. New improvements tend to be those that can be retrofitted without major fixed-capital expenditures and extensive downtime or those that are considered cobenefits to process or product improvements. This has significant implications for energy use and energy conservation in the industry. The production of paper and paperboard closely follows the organizational structure of the industry and is discussed next.

1.1 Pulp and Paper Manufacture

The two main processes in pulp and paper manufacturing are pulp and paper/paperboard production.

1.1.1 Pulping

Pulping is the process where fibers are separated and treated to produce pulp. The wet pulp is then converted into paper at an integrated pulp and paper mill or is dried and transported from the pulp mill to a paper mill. Different pulping processes are used depending on the fiber material and the desired end product. Fiber materials consist mostly of virgin or waste fibers. Virgin fibers are derived from pulpwood such as from woodchips or logs. Virgin fibers are used to produce a variety of pulps, with the main categories broadly characterized as chemical pulp (where the main process is called kraft pulping), semi-chemical pulp, and mechanical pulp. Pulp mills may also produce pulp from plant materials other than wood, collectively known as nonwoods. Nonwood fiber sources include agricultural residues and industrial fiber crops such as hemp. Wastepaper pulping took off during the past decade. For instance, in Denmark and the United States, waste fibers account for close to 100% and 38% of total fiber use, respectively (Fig. 1).

Pulp mills can use only virgin fibers, waste fibers, or a mix of both. When producing pulp from virgin

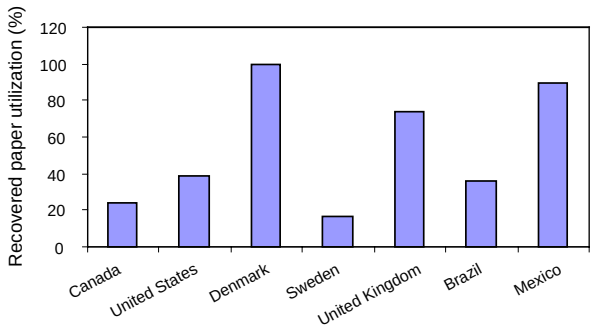

FIGURE 1 Use of wastepaper in selected countries in 2001. Recovered paper utilization rate is defined as the amount of wastepaper used in the production of paper and paperboard divided by the total amount of paper and paperboard produced. From the Food and Agricultural Organization, www.fao.org/forestry.

fibers, the raw materials are first prepared, for example, by debarking and chipping. The next step is the actual pulping process. The primary purpose of pulping is to free the fibers from the lignin that binds the fibers together and/or to separate the fibers in water. Pulp with longer fibers and less lignin is considered to be of highest quality and produces the strongest paper. Mechanical pulping is used for lower grade paper such as newsprint and is the process used for recycled fibers. The advantage of this process is that it gives much higher pulp yields (90–95%) than do other processes but at the same time produces weaker paper because the method yields shorter fibers. Also, if virgin fibers are mechanically pulped, the paper ages faster due to the presence of lignin. Mechanical pulping of virgin fibers is energy intensive and requires 15 million to 16 million BTUs per ton of pulp produced and does not provide the pulping liquors necessary for the self-generation of energy from black liquor. However, the pulping of waste fibers is much less energy intensive and requires approximately 4 million BTUs per ton of pulp.

Chemical pulping is by far the most common method for pulping wood both in Europe and in the United States. In the United States, it accounts for more than 80% of all pulp produced. Chemical pulps have a low yield (40–55%), but the pulp produced is of very high quality. The most common process, the kraft process, accounts for more than 95% of all chemical pulp produced both in the United States and in Europe. In this process, the virgin materials are mixed with a chemical solution, called white liquor, in a digester, where they are pressurized and heated to dissolve the lignin from the wood. After being dissolved, the virgin material is separated into individual fibers and the chemical mixture, now called black liquor, is concentrated in an evaporator. Then, it is burned in a recovery boiler, where the energy is recovered, often cogenerating both steam and electricity, which is then used as process energy. Kraft pulping requires 5 to 7 million BTUs per ton of pulp, but chemical recovery requires an additional 4 to 7 million BTUs per ton of pulp.

Semi-chemical pulping is a combination of chemical and mechanical pulping, where the fibers are chemically treated before they are mechanically pulped. Following any of the pulping processes, the fibers either move on to the bleaching phase to reach a certain level of brightness or move on directly to the papermaking phase. The bleaching phase requires 5.0 to 7.5 million BTUs per ton of pulp.

1.1.2 Papermaking

Different types of pulp are used for the production of various paper products. Given the different energy requirements and opportunities for energy self-generation, the output mix, and thus demand for paper, has major implications for energy use in the industry.

Mechanical pulp is most often used to produce newsprint. Sometimes, chemical pulps are added, for example, to improve strength. Bleached kraft pulp is used mainly in quality printing and writing papers, and unbleached kraft is used to produce linerboard and sack paper. Semi-chemical and chemimechanical pulps typically are used to produce boxboard and sanitary products.

The papermaking stage is made up of paper and paperboard mills and consists of three main processes: stock preparation, paper production, and finishing. First, the pulp is dispersed in water and combined with additives. Then, this slush of pulp, water, and various additives is fed to a paper machine, and eventually dry bulk rolls or sheets of paper or paperboard are produced. The drying process is the most energy-intensive part of papermaking, but the total specific energy use ranges from 3.5 to 10.0 million BTUs per ton of paper depending on the paper type being produced.

2. FOREST PRODUCTS AND ENERGY CONSUMPTION

2.1 Total Energy Use and End Use Efficiency

Internationally, the pulp and paper industry is a major energy consumer and one of the most energy-intensive manufacturing industries. In the United States, only petroleum and coal products production rival its energy intensity (Fig. 2).

The American Paper Institute (API) and later the American Forest and Paper Association (AF&PA) have gathered and analyzed energy consumption in the industry since 1972. According to their data, the industry consumes approximately 12% of total manufacturing energy use. As the industry has grown, total energy consumption has increased on average 1.2% per year. At the same time, the intensity of energy use has declined considerably, from 39.3 million BTUs per ton of paper and paperboard in 1972 to 29.32 million BTUs per ton in 1998. This decline amounts to on average 0.9% per year decline in energy intensity (Fig. 3).

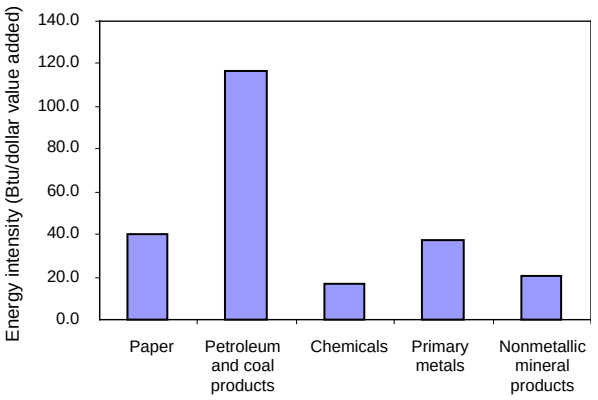

FIGURE 2 Total energy consumption (thousands of BTUs) per dollar of value added by industry. From the U.S. Energy Information Administration, 2002 Energy Consumption Survey, 1998 Annual Survey of Manufacturers.

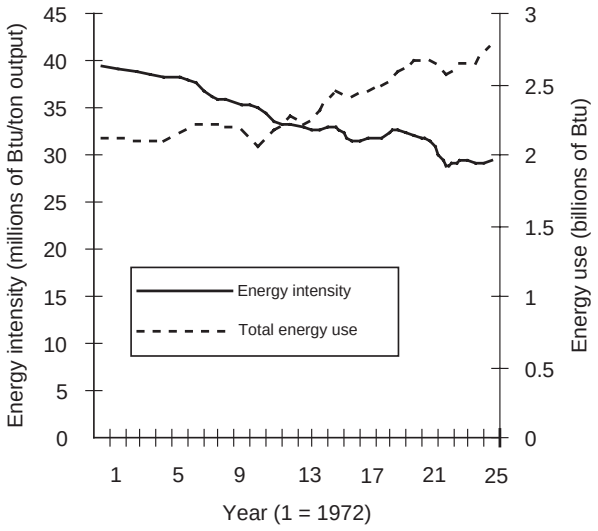

FIGURE 3 Total energy use (billions of BTUs) and energy use per output (millions of BTUs/ton output) in the U.S. paper and allied products industry. From the American Forest and Paper Association, various years.

Despite substantial improvements in energy intensity, total energy use has continued to increase because production growth on average has increased faster than have improvements in energy intensity. As depicted in Table I, which demonstrates the decline in energy intensity in selected countries, energy intensity has declined the most in the United Kingdom and the least in Sweden.

The data in Fig. 2 and Table I depict national annual averages. However, major geographical and temporal differences exist, both in terms of absolute quantities and in terms of changes in total fuel use and energy intensity. Geographical differences rest on

TABLE I

Relative Changes in Energy Intensity Expressed as Annual Changes from 1973 to 1991 (Percentages)

Country	Annual change

the variation in processes that are used and, thus, on the products produced. They also are influenced by regionally heterogeneous input prices, input availability, public policies, and the like. Studies have shown that the factors having the largest impact on changes in energy intensity and total energy use are changes in output levels, changes in output (and thus process) mix, and changes in production efficiency.

By definition, an increase in output levels, without a change in output mix, increases the use of energy. But based on the relative energy intensities of the processes in use, the total amount of energy used by the industry can either increase or decrease due to a change in the mix of output given that each output category can somewhat be associated with a particular pulping and papermaking process.

The difference in energy intensities of various products rests mainly on three factors: the pulping process that is used (and thus whether chemical recovery is required), the question of whether to bleach the paper or not, and the papermaking process (Table II).

Table II illustrates the relative energy intensities of various paper and pulp manufacturing processes that are in widespread use relative to the least intensive pulping process—wastepaper pulping. The data demonstrate that the energy intensity of different pulping processes can vary by more than 400%.

In addition to the varying energy requirements based on output and process mix, variations in total energy use and energy intensity originate in the amount of energy required to heat air and ground water that is used in the production process. For instance, according to the AF&PA, total energy requirements per ton of output decrease significantly

TABLE II

Relative Energy Intensities of Major Processes Using Current Technologies versus Wastepaper Pulping

Process	Process/wastepaper pulping

during the summer months in the northern United States by a difference of 15 to 20%.

2.2 Energy-Saving Technological Change

Energy efficiency also has changed due to embodied and disembodied technological change. Energy-saving disembodied technological change is defined as low- or no-cost operational changes in the energy efficiency of the existing capital stock. Embodied technological change requires substantial capital investments through which new technologies diffuse into the capital stock. Such diffusion requires either expansion or replacement investment. Expansion investment, by definition, expands the existing capital stock, enabling increased production levels and increased total energy use, albeit usually at a slightly lower level of energy intensity, assuming new capital is more efficient than existing capital. Replacement investment directly replaces retired capital and includes the investment spent on retrofitted capital. Consequently, replacement investment does not expand the capital stock. By definition, it does not increase total energy use; thus, it enables a faster decrease in energy intensity than does expansion investment, assuming new capital is more efficient than old capital.

Embodied technological change is considered a more permanent change in energy efficiency, even though disembodied change accounts for a substantial part of energy savings, as is the case in the pulp and paper industry. This is because embodied changes are directly imbedded into the capital stock, whereas disembodied gains are more easily reversible. Disembodied changes occur, for example, due to the accumulated experience of employees (learning by doing). Consequently, if the rate of employee turnover increases, the rate of disembodied change slows down.

Historically, energy-saving technological change in the pulp and paper industry has been incremental and a combination of embodied and disembodied changes, an expected feature of a mature industry. This incremental change in energy intensity has provided a continued counter to the increase in output levels and has resulted primarily from gradual process improvements, a shift to wastepaper pulping, and better housekeeping practices. Again, the historical low rate of capital turnover is one of the main culprits in keeping the rate of change incremental. Other reasons include, for instance, that research and development in the industry is very much geared toward improving existing production technologies, as is the case in most mature industries. In the United States, private research and development (R&D) expenditures in the pulp and paper industry are the lowest among all manufacturing industries—and are spent by companies that specialize in consumer products. This suggests that much of R&D expenditures are directed toward incremental product development rather than toward energy intensity improvements. What this indicates is that the incremental development of the industry's knowledge base over time favors already existing processes and that this acts as a barrier to the adoption of new technologies. This is called technology lock-in. Thus, as the industry becomes more mature, it becomes less inclined to update its technologies and, as a result, closely follows a specific predetermined technology trajectory. Second, the total cost of energy is on average lower than that of other inputs such as fibers, and fossil fuel prices in the United States are low and fluctuating. Thus, other investments besides energy-saving investments may seem more profitable and returns less uncertain. Third, the required rate of capital recovery for an investment in energy-saving

equipment—the payback period—is approximately 2 years. Consequently, if an energy conservation project does not offer benefits other than energy cost savings, the payback period must be less than 2 years.

Combining those factors, and taking into account the low profit margins and the necessity to maintain a high capacity utilization rate, makes it hard to justify and execute substantial investments in energy-saving equipment leading to embodied changes in energy efficiency. As a result, the norm in the pulp and paper industry is a gradual decline in energy intensity through efficiency improvements that generally result from improved housekeeping practices or that are side effects of other process- or capacity-related changes.

2.3 Energy Mix

The pulp and paper industry uses two types of end use energy: thermal and electrical. Electrical energy is used primarily to drive pumps and fans. Thermal energy, which is in the form of steam, is used, for example, in digesters, in evaporators, and in the drying of pulp. The industry is in the enviable position of being able to generate itself a large proportion of both the required thermal energy and the required electrical energy. For instance, in the United States, it generates more than 55% of the sum of required electrical and thermal energy, and more than 80% of that energy is generated directly as a by-product of chemical pulping. As depicted in Fig. 4, the remaining energy consumption (collectively called purchased energy) is divided mostly among purchased electricity, coal, natural gas, and residual fuel oil, with a small fraction being allocated to distillate fuel oil and liquid petroleum gas.

The fuel mix in the U.S. pulp and paper industry has changed substantially since 1972. The industry has slowly increased the use of self-generated energy, with an annual average increase of 3.27% for the past 30 years or so. At the same time, the fractional share of purchased fuels has declined. Of purchased fuels, residual fuel oil is slowly being phased out, and the fractional share of natural gas is increasing. The fractional share of coal has remained relatively constant since the early 1980s.

Between 1972 and 1983, the U.S. pulp and paper industry rapidly switched from purchased fuels to self-generated energy, as indicated by the decline in purchased energy intensity and the increase in the intensity of self-generated energy use (Fig. 5).

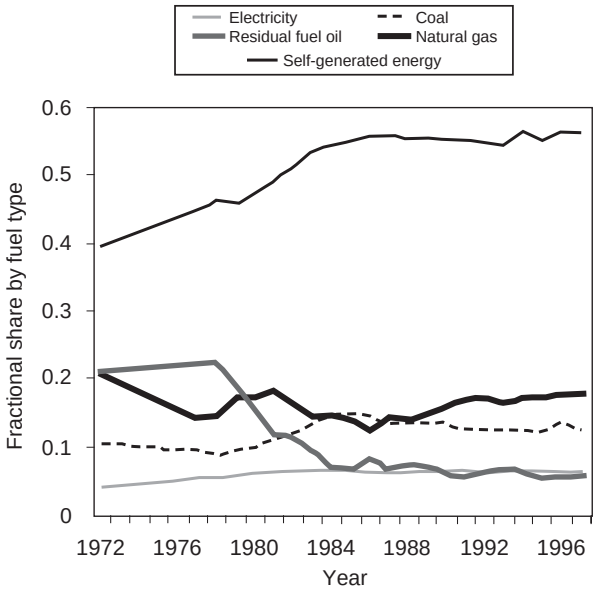

FIGURE 4 Fractional share of fuels by type in the United States pulp and paper industry. From the American Forest and Paper Association, various years.

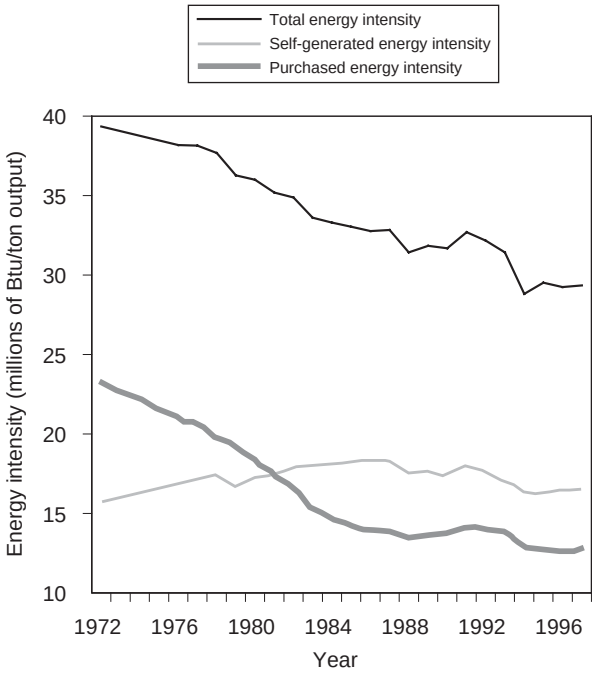

FIGURE 5 Total energy intensity, intensity of purchased energy, and intensity of self-generated energy in the U.S. pulp and paper industry. From the American Forest and Paper Association, various years.

This expansion occurred in part as a result of higher energy prices during the 1970s and a change in the Public Utility Regulatory and Policies Act of 1978 (PURPA). Those two events made cogeneration

of steam and electricity economically efficient. Lower energy prices and the close link between material and energy use reduced the rate of cogeneration after 1983. As previously discussed, more than 80% of the energy that is self-generated is a direct by-product of chemical pulping of virgin fibers. A continued increase in the fractional share of self-generated energy either requires an increase in the share of the chemical pulping of virgin fibers (which has important implications for the use of recycled fibers and the output mix) or requires technological change that will increase the energy and economic efficiency of cogeneration. The former requirement is a major obstacle to an increase in the share of self-generated energy and vividly illustrates the close interconnection between materials and energy cycles in the industry. The latter requirement is a smaller obstacle given that such technology already exists; however, the character of the industry presents a formidable challenge to the ability of this new technology to diffuse into the capital stock. This issue is discussed later in section IV, where the potential for energy conservation and continued expansion into self-generation is explored.

3. FOREST PRODUCTS AND ENERGY GENERATION

As illustrated in section II, and in Figs. 4 and 5, the pulp and paper industry enjoys substantial flexibility in its choice of energy inputs. This historical fuel flexibility of the industry results from its direct access to wood fuels and its heavy use of steam for process heat. Because steam systems can use a wide variety of fuels, the industry has been able to shift with relative ease from residual fuel oil to gas and to substitute bark and forest residues for fossil fuels. In addition, the industry contributes to energy supply indirectly by supplying some of the materials that contribute to methane generation in landfills that can be used for electric power generation and the like.

3.1 Direct Use of Forest Products as Energy

3.1.1 Wood Fuels: Categories and Importance

Wood fuels are a renewable and climate-friendly energy source because they are considered carbon neutral if used and produced in a sustainable and efficient manner. Wood fuels consist of four main commodities: fuelwood (also called firewood), charcoal, black liquor, and wood waste.

Fuelwood is used extensively in most developing countries and is collected from the forest, often as fallen branches or twigs. In domestic applications, it is converted into heat in simple ovens, often for cooking, baking, or drying, and/or is used for space and water heating. The fuel gases are also used for the smoking of food products. Contrary to popular belief, the gathering of fuelwood is not responsible for large-scale deforestation; however, it can contribute to localized forest and soil degradation. Larger issues associated with the traditional use of fuelwood are the health effects of using inefficient stoves in poorly ventilated areas. This leads to emissions of pollutants such as carbon monoxide, methane, and nitrogen oxides that carry serious health risks. For instance, those pollutants are known to cause respiratory infections, adverse pregnancy outcomes, and tuberculosis. In addition, the collection of fuelwood is hard physical labor. Because women are mostly responsible for collecting fuelwood and cooking, women and small children are most adversely affected. Commercial fuelwood is also used as an industrial source of energy in many developing countries. Typical industrial uses include curing and drying, food processing, and lime and brick burning. Although the total amount of wood consumed by the industrial sector is much smaller than that consumed by households, it is nonetheless significant. For example, in Kenya and Sri Lanka, 26 and 18% of fuelwood is used by industry, accounting for more than 70 and 65% of all industrial energy use, respectively.

Charcoal is produced from wood through carbonization or pyrolysis. The wood is heated in a closed container that is devoid of oxygen. The absence of oxygen prevents the wood from burning to ashes; thus, the wood decomposes to charcoal, among other residues. Charcoal plays an important but a much smaller role than does fuelwood in both industrial and household sectors of most developing countries. In households, it is used for tasks similar to those of fuelwood, but a switch from fuelwood to charcoal provides numerous benefits. Those include the fact that charcoal generally does not decompose in storage, it burns without smoke for the most part, it does not create dangerous flames while cooking, and it requires a simple stove whose heat output is relatively easy to control. As a result, a switch to charcoal often represents an increase in the quality of life. The disadvantages of charcoal use are related primarily to the inefficiencies inherent in its produc-

tion and use. Production efficiency in most developing countries ranges between 8 and 28% and is a function of moisture content and type of equipment. Charcoal is also inefficient in use. Although charcoal stoves are more efficient than fuelwood stoves (20–35% vs 10–25%), charcoal stoves are much less efficient than modern fuel stoves such as kerosene (35–50%) and electric stoves (75–85%). The combined production and use inefficiencies have important consequences for the abundance of local wood resources given that cooking with charcoal often uses three to four times more wood than does cooking with fuelwood. Charcoal is also used in industrial settings in both developing and developed countries, for instance, in the production of iron and steel, in metallurgy, and in the chemicals industry.

The other two categories of wood fuels are derived from secondary sources and consist of black liquors from pulp production and wood waste from forest products industries and other products from society such as wastepaper.

Wood fuels account for approximately 7% of the world's total energy supply and are an extremely important source of energy in many developing countries. According to the Food and Agricultural Organization (FAO), developing countries consume approximately 77% of the world's supply of wood fuels, and this in turn accounts for 15% of total energy consumption in the developing world. Consumption in developed countries accounts for the remaining 23%, but this share amounts to 2% of total energy consumption in the developed world. Of course, substantial regional and national differences exist. Developing countries rely mostly on fuelwood and charcoal, but in most developed countries the pulp and paper industry is instrumental in supplying and using such energy. For instance, in 1997 in New Zealand, black liquor accounted for nearly 100% of all energy derived from forest products, and in Japan, Portugal, Sweden, Norway, and Finland, it accounted for 95, 87, 81, 79, and 80%, respectively (Table III). Forest products provided approximately 17% of total national energy supply in Finland and Sweden.

In the United States, black liquor alone contributes 63% of all energy derived from forest products, accounting for slightly over 2% of total energy supply.

TABLE III

Wood Fuel Consumption in 1997 by Selected Countries and Types (Petajoules)

Country	Fuelwood	Charcoal	Black liquor	Total
Bangladesh	307.39	—	0.95	318.34

3.1.2 Wood Fuel Use in the Pulp and Paper Industry

The pulp and paper industry uses not only black liquors but also solid biomass residues such as woodchips, forest residues, wastepaper, and bark. When using solid biomass residues, the industry uses so-called "wood-fired" power boilers (which are similar to coal-fired boilers), where the forest residues are burned to generate steam and/or electricity. Also, it is common for boilers to have multifuel capabilities, enabling the aforementioned fuel flexibility in the industry. Wood has an advantage over natural gas, coal, and oil in that the industry has a cheap supply in the form of wood wastes, bark, and hogged fuels, giving a substantially higher thermal energy content per dollar spent when compared with both oil and coal. Furthermore, wood waste can be burned alongside coal. Disadvantages in use of solid biomass residues are the often high moisture content in the wood waste and low volumetric energy density. Despite those disadvantages, the use of hogged fuels, bark, and wood waste accounts for approximately 20% of self-generated energy in the U.S. industry.

The process of using black liquor to produce energy begins with a process called chemical pulping. In that process, sodium compounds called white liquor are used to cook the virgin wood to release wood fibers from the lignin in the wood. After the woodchips are cooked, they are separated from the lignin/sodium solution, washed, and screened after which they proceed on to the papermaking process. However, the lignin/sodium solution, which now is called black liquor, is transported to a condenser, where it is evaporated to create concentrated strong black liquor. Then, the strong black liquor is transported to a recovery boiler. The most

common model is the Tomlinson recovery boiler. In the recovery boiler, the black liquor is combusted to yield recoverable thermal energy and an inorganic solution of sodium compounds. The inorganic chemicals are extracted as smelt at the bottom of the boiler, giving green liquor. Then, the green liquor is converted to white liquor and reused. The thermal steam energy from the boiler is used directly as process energy, such as for the evaporation of black liquor, and also in driving steam turbines to produce electrical energy, which can be either used on site or sold. This double use of waste heat as steam in the production process and the simultaneous production of electricity is called cogeneration. The industry is the leading manufacturing industry in the United States in the cogeneration of steam and electricity, having produced in 1998 39.4% of all cogenerated electricity.

3.2 Indirect Use of Forest Products as Energy

Indirect generation of energy also occurs as a result of paper waste management practices. In 1995, the U.S. Environmental Protection Agency (EPA) estimated that 49.8 million tons of paper and paperboard were discarded as municipal solid waste in the United States, representing a tremendous amount of usable matter that is buried every year. There are at least two means by which this energy can be harnessed: through the direct incineration of wastepaper (preventing the wastepaper from entering the landfill) or through the capture of methane (which forms in landfills as a result of paper decomposition).

Decomposition of paper and wood products in landfills occurs in a series of stages. The first stage of decomposition is characterized by the removal of oxygen from the waste by aerobic bacteria. Then, the environment becomes oxygen limiting and the bacteria shift to fermentative metabolism. During the second stage, fermentative bacteria hydrolyze polymers into sugars, and those are then fermented further into short-chain carboxylic acids, carbon dioxide, and hydrogen. As acids are produced, the acidity of the refuse increases but then stabilizes due to the removal of acetate and the release of metallic cations that dilute the hydrogen ions. Eventually, this leads to the development of a pH level that is close to neutral. A neutral pH is a necessary prerequisite for the landfill to enter the third stage of decomposition. During this final stage, acetogens further oxidize the remaining short-chain carboxylic acids into acetate, carbon dioxide, and hydrogen. Because the acetogens cannot perform this final stage of decomposition unless the hydrogen ions are removed, this process must occur parallel to the growth of hydrogen-consuming bacteria such as those that produce methane, hence the production of methane.

TABLE IV

Methane Generation Potential of Various Paper Products (Gram Methane/Gram Refuse)

Material	Methane potential
Printing and writing	0.098
Newsprint	0.054
Tissue	0.131
"Other"	0.108

Source. Micales and Skog (1997). Adjusted with permission from Elsevier.

Because lignin inhibits decomposition, the methane generation capacity of paper products varies as a function of the amount of lignin that remains present (Table IV).

Newsprint is produced using mechanical pulp that retains most of the initial lignin; thus, the methane generation capacity is lower for newsprint than for other paper categories. Because tissue is produced using chemical processes, all of the lignin has been removed, hence the highest methane generation potential. Currently in the United States, approximately 10% of the methane generated in landfills is captured for energy purposes, indicating a substantial future potential.

4. THE FUTURE: ENERGY CONSERVATION AND SELF-GENERATION POTENTIALS

The question remains, will the pulp and paper industry be able to become even more self-sufficient in terms of energy generation and even become a net energy exporter and, thereby, increase the role of wood fuels as a source of energy? Will the industry simultaneously be able to reduce total and purchased energy intensity? This section addresses those issues by highlighting technological and economic potentials and the looming barriers to change. A short conclusion follows.

4.1 Technical Potentials

This subsection examines whether technical potentials exist to (1) increase the share of self-generation

of energy and (2) reduce energy intensity. The discussion is based on a study performed at the Lawrence Berkeley National Laboratory by Ernst Worrell, Nathan Martin, and colleagues on U.S. industry potential to increase its energy efficiency and energy self-generation.

4.1.1 Increase in Energy Self-Generation

Black liquor gasification is arguably the most promising new technology to increase self-generation capabilities in the industry. As discussed previously, the cogeneration of electricity and steam usually is performed by recovery boiler/steam-driven turbines. However, the new biomass cogeneration technologies use gas turbines rather than steam turbines. Compared with conventional steam turbines, gas turbine combined cycle cogeneration offers high power to steam ratios and high thermal cycle efficiencies. For instance, power output is three times higher than what is possible with the conventional Tomlinson recovery boiler. Thus, black liquor gasification can potentially have a revolutionary impact on the industry by allowing kraft mills to become self-sufficient in both thermal and electrical energy as well as to become net electricity exporters. Despite high initial capital costs, it is believed that in the long run black liquor gasification systems will prove to be economically efficient.

4.1.2 Improvements in Energy Efficiency

Improvements in efficiency are technologically feasible at every level of pulp and paper production. The discussion in this subsection is a nonexhaustive account of some of the potential improvements in energy efficiency and is intended to illustrate the potential for change. Keep in mind that the average energy intensity of the U.S. pulp and paper industry is close to 29 million BTUs per ton of output. When preparing raw materials, the already available energy-saving technologies, such as ring-style debarkers and cradle debarkers, would save approximately 0.03 million to 0.05 million BTUs per ton of output, and improved screening processes could save up to 0.5 million BTUs per ton of output. Those three investments have a payback period of less than 1 year given U.S. energy prices. In mechanical pulping, biopulping could reduce energy intensity by 3.4 million BTUs per ton of output and could reduce various refiner improvements by 1.6 million BTUs per ton of output. However, the payback period is estimated to be 30 years for biopulping, whereas it is only 3.4 years for refiner improvements. In thermomechanical pulping, potential improvements range from 1 million to 7.5 million BTUs per ton of output via improved heat recovery with a payback period of 4.7 years. Efficiency of chemical pulping can increase by 8.4 million BTUs per ton of output by using continuous digesters with a payback period of 7.7 years. The efficiency of papermaking can increase the most by improving drying technologies such as through the use of Condabelt drying. Energy savings are estimated to be up to 2.40 million BTUs per ton of output with a payback period of 3.8 years. Dry sheet forming, or production of paper without the addition of water, will save up to 5.5 million BTUs of energy per ton of output with a payback period of 88 years. Numerous general measures can also be applied, including installing energy efficient lighting, which will save up to 0.1 million BTUs per ton of paper with a payback period of 3.7 years, and pinch analysis, which optimizes thermal energy flows throughout the plant. This measure is likely to save up to 2.5 million BTUs per ton of paper with a payback period of 1 year. Substantial improvements can also be made to make the production and distribution of steam more efficient, including improved boiler maintenance, which will save approximately 1.7 million BTUs per ton of output with a payback period of 0 years. Other measures include leak repair and steam trap maintenance, with energy savings of up to 0.7 and 2.5 million BTUs and with payback periods of 0.1 and 0.3 years, respectively. Finally, the industry can reduce total primary energy consumption by increasing the use of recycled fibers. This switch might not reduce purchased energy requirements unless the waste pulp is replacing mechanical or thermomechanical pulp.

Clearly, significant economically efficient engineering potentials exist for the pulp and paper industry to increase process energy efficiency. An investment is deemed economically efficient if the payback period is 0 to 3 years. According to the aforementioned study from the Lawrence Berkeley National Laboratory, such cost-effective energy savings amounted to 16% of total primary energy use in the industry in the United States in 1994, and including the expansion of recycling increased that potential to 22%.

4.2 The Barriers to Energy-Saving Potentials

The first culprit, as normally is the case with very capital-intensive mature industries, is the low rate of capital turnover. Because it is extremely expensive to

replace old capital, not just due to capital costs but also due to the required downtime of equipment, capital is kept as part of the capital structure for up to 100 years. Second, energy-related investments compete with other investments for capital, and the relatively low fuel and electricity prices that have prevailed since the mid-1980s have reduced the profitability of energy-saving investments. Combining that with fluctuating energy prices, uncertain returns, and a very short payback time (less than 2 years) explains much of the unused potential for saving energy. Third, the close link among the input materials, output types, and amount and type of energy that the industry can use acts as a limit to the extent to which the industry can switch over to self-generated energy. Fourth, energy savings often seem far from the radar screen of decision makers, who focus more often on improving and extending existing product lines.

5. CONCLUSION

Wood fuels that are derived from forest products remain an important source of renewable, potentially carbon-neutral energy. As countries developed, the role of wood fuels declined and shifted from primarily household use to industrial use. In developed countries, the pulp and paper industry, through its use of chemical pulping, is the main user and provider of wood fuels, thereby keeping them on the horizon as a significant source of energy. The pulp and paper industry is one of the most energy-intensive manufacturing industries, but in the United States the industry self-generates from wood fuels (mostly black liquor) more than 55% of its energy needs. Further extension of energy self-generation partially depends on the rate of diffusion of new technologies, yet the character of the industry poses formidable challenges to technological change, as do economic factors such as low and fluctuating energy prices.

An increase in the share of self-generated energy is also closely tied to the use of specific input materials and output demand because black liquor is a by-product of chemical pulping of virgin fibers. If paper companies increase the use of pulping processes that rely on virgin fibers, they continue to be able to cogenerate steam and electricity from black liquor. An increase in the use of recycled fibers conserves forest resources. This may, on the one hand, be more energy intensive in terms of purchased energy if the waste pulp replaces chemically created pulp. On the other hand, the replacement of recycled pulp for mechanically produced pulp conserves a significant amount of purchased energy.

Because methane has 21 times the global warming potential of carbon dioxide, important trade-offs also exist regarding greenhouse gas emissions. Those trade-offs are linked directly to waste management. If wastepaper is put into landfills, it will generate methane and carbon dioxide. If it is recycled and the waste pulp replaces nonbleached chemical pulps, it may increase purchased energy consumption and, thus, increase carbon dioxide emissions. If it is incinerated, it will not contribute significantly to methane emissions but will not play a role in the conservation of forest resources. It seems that in this particular industrial system, it is challenging to conserve one resource without using more of another or to reduce emissions of one greenhouse gas without emitting more of another.

Despite formidable barriers to change, the future is not bleak for the pulp and paper industry. Major potentials exist for improving energy efficiency, and new cogeneration technology can transform a substantial part of the industry into a net energy exporter—completely reliant on renewable self-generated energy. In the future, the industry could derive large profits from selling energy or, alternatively, could let the utilities sector invest in and operate the new cogeneration technology. Either way, the potential exists for an increase in the energy efficiency of the pulp and paper industry as well as for an increase in the role of forest products, and thus wood fuels, in the total supply of energy in the developed world.

energy The capacity to do work.
heat The transfer of energy as a result of a temperature difference.
kinetic energy Energy by virtue of movement.
potential energy Energy by virtue of position.
radiant energy Energy due to electromagnetic vibrations.
work The transfer of energy into a useful form.

An understanding of the physical world requires the concept of energy, or the capacity to do work. Our modern society depends on energy for heating, cooling, transport of all kinds, lighting, and communications, to name but a few vital needs. Thousands of years ago, human energy requirements were limited to the body's own energy and that was fueled by food—the carbohydrates and fats of a hunter–gatherer's diet. Today, the total energy required to ensure the survival and well-being of a person in a modern society is many hundreds of times greater than that of a person in a primitive society.

1. INTRODUCTION

Energy is defined as "the capacity to do work." It can take many forms. We talk of kinetic energy (obtained from ocean waves and from wind), gravitational energy (obtained from falling water), electrical energy (obtained from batteries and turbines), chemical energy (obtained from exothermic reactions such as combustion of diesel and gasoline), thermal energy (obtained from burning coal or wood), radiant energy (from sunlight), and nuclear energy (obtained from fission or uranium atoms or fusion of hydrogen nuclei). Some of these energy forms are more useful than others and many can be transformed from one form to another. For example, the energy from a nuclear reaction can be used to heat water, which in turn can be used to do work by turning a turbine to make electrical energy to heat our houses.

A fundamental law of thermodynamics (the study of the transformations of energy) is that energy is conserved in any process. This implies that when energy transfer does take place, no energy is lost in the process. Usually in the transfer process, a significant fraction of the energy is lost to useless heating of the environment. The efficiencies of conversions can be as low as 10 or 20%. This law of conservation of energy was a major breakthrough in the understanding of energy and has never been violated. One of its implications is that energy cannot be created. In other words, perpetual motion is impossible. This, however, has not stopped hundreds of would-be millionaires from sending their plans to patent offices around the world.

2. THE HISTORY OF THE CONCEPT OF ENERGY

The concept of energy took a long time to develop and was hindered by incorrect and unsubstantiated

 © 2004 Elsevier Inc. All rights reserved.

ideas of Aristotle and many others. The turning point came when Galileo and then Newton, in the 17th century, properly defined the force, f, acting on a body of mass, m, moving with an acceleration, a, as

$$f = ma. \quad (1)$$

It took another two hundred years before energy was correctly formulated by William Thomson in 1851. It was the steam engine that catalyzed the concept. Energy was defined as the work done in moving a body a distance $\times$ against a force, f,:

$$E = w = fx. \quad (2)$$

But it was not until the middle of the 20th century that the separate units for heat (the calorie) and work (the erg) were dropped in favor of the joule and the link between energy, heat and work was finally made.

During the early part of the twentieth century, it was shown that energy can only occur in discrete packets or quanta, and the concept of the quantization of energy was born. For most forms of energy, these packets are so very close to each other that they effectively form a continuum and the sum of all the quantized energies approximates to the energy as defined by Newtonian physics. The quantization of energy becomes important when dealing with small energies related to small particles such as electrons and atoms. In particular, vibration, rotation, and electronic energies are affected and quantum effects must be considered.

3. KINETIC AND POTENTIAL ENERGY

We tend to think of energy in its many manifestations, some of which are given in the introduction. However, in reality, there are only three types of energy: kinetic, potential and radiant energy. The kinetic energy of the body of mass, m, moving with a velocity, v, is defined as

$$E_K = 1/2mv^2. \quad (3)$$

It is the energy a body has as a result of its movement.

The potential energy of a body, on the other hand, is the capacity of the body to do work by virtue of its position. A body of mass, m, dragged up a height, h, against gravity, has the potential energy

$$E_{PE} = mgh, \quad (4)$$

where g is the acceleration due to gravity, which on Earth is about $9.8\,m\,s^{-2}$. This body has potential energy as it rests in position. From that position it can be made to do useful work, such as if it is allowed to fall under gravity while linked to a pulley which lifts a weight.

The link between kinetic and potential energy and other forms of energy is not always clear. Electrical energy, for example, is really the potential energy of electrons in the presence of positive charges. Chemical energy is a sum of the potential energy of electrons in chemical bonds and the kinetic energy of the bonding electrons as they move around an atom or a molecule. Nuclear energy is due to the potential energy and kinetic energy of the subatomic particles within an atomic nuclei.

4. HEAT AND WORK

The terms heat and work are synonymous with energy, and both are simply ways of transferring energy. Heat refers to the transfers of energy as a result of a temperature difference (ΔT). The energy transferred from a hot body of mass, m (in contact with a cold body), as the body's temperature drops from T_1 to T_2 is given by

$$\Delta E_{HEAT} = mS\Delta T, \quad (5)$$

where $(T_1 - T_2) = \Delta T$ and S is the specific heat of the body. The specific heat is defined in terms of Eq. (5) and is the energy required to heat 1 g of the material of the body, through 1 K. For pure water it is $4.18\,J\,g^{-1}\,K^{-1}$. (This is equivalent 1 calorie per gram per Kelvin.)

Work, on the other hand, refers to the transfer of energy into a useful form (i.e. lifting a weight). For example, the work done, w, in lifting a mass, m. through a height, h, against gravity is

$$w = mgh. \quad (6)$$

Work is an agent of transfer and can take many forms. Types of work include expanding a surface, expanding a volume of a gas, pushing electrons along a wire (electricity) and lifting weights.

Heat and work are best understood in terms of the movement of molecules. The molecules of a stationary body at a temperature greater than 0 K (-273.15 K) move in a chaotic manner. If the molecules all moved in the same direction, the body would move! These molecules may rotate, vibrate, or translate. The latter refers to kinetic motion. These movements are collectively known as thermal motion. Molecules in a hot body have a greater thermal motion than the molecules in a cold body. The

transfer of energy from a hot body to a cold body is a result of the stimulation of molecules in the cold body to move more vigorously by the molecules in the hot body. Heat can thus be considered as the transfer of energy that makes use of the chaotic motion of the molecules (see Fig. 1A).

When work is done, the molecules or electrons all move in the same direction in an organized way. When a weight is lifted against gravity, all the molecules of the weight move in the same direction—upward against gravity. When electrical work is done, the working electrons all move in the same direction. Work must therefore be considered as the transfer of energy that makes use of organized motion (Fig. 1B).

Looking back at the historical use of energy, it was relatively easy for early humans to use heat to transfer some forms of energy to thermal motion. For many thousands of years, humans used burning logs of wood and presumably sunlight (radiant energy) on sun-facing caves to warm their caves. The transfer of energy so that work is done is a very much more difficult process and was not really done by machines until the advent of steam engines, which heralded the Industrial Revolution less than 200 years ago. Work, other than that done by human muscles in lifting, pushing, and pulling, is a recent phenomenon.

5. MEASUREMENT OF ENERGY IN TERMS OF THE SI SYSTEM OF UNITS

The measurement of energy involves no less than six of the seven fundamental quantities and units that make up the Système International d'Unités. The quantities and units together with their symbol are given in Table I. All other quantities can be derived from these fundamental ones. For example, acceleration can be written in terms of distance and time (L/T^2), force is the product of mass, and acceleration and energy can be written as the product of force and distance ($ML/^2T^2$); this combination is often called the dimensionality of the quantity. All energy forms have the same dimensionality, as do all units of pressure and all units of force and so on. The unit size of a quantity in the SI is the product of the fundamental units of which the quantity is composed (Table II).

The Newton meter^{-2} (Pascal) is a rather small unit of pressure for many everyday purposes and one more commonly uses the bar (100 000 Pa), which is very close to atmospheric pressure (1 standard atmosphere = 101 325 Pa).

The SI has a set of conventional multipliers, which are used for quantities larger and smaller than the basic units (Table III). The rate of energy flow is the Watt (W)

$$1\ \text{Watt} = 1\ \text{J s}^{-1}.$$

Electrical energy is often metered and measured in kilowatt hours (kWh):

$$1\ \text{kWh} = 3\,600\,000\ \text{J}.$$

The distinction between power (rate of flow of energy) and energy is often badly made especially in

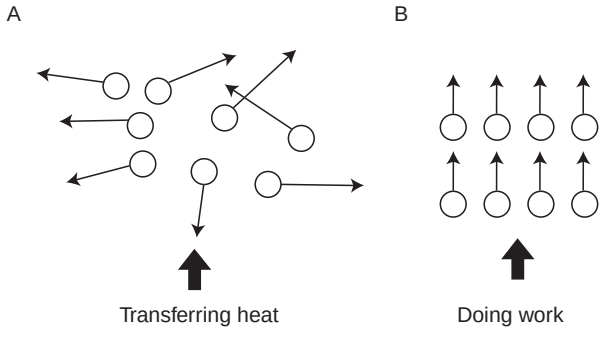

FIGURE 1 (A) Heat is the transfer of energy that makes use of the chaotic motion of molecules. (B) Work is the transfer of energy that makes use of the organized motion of molecules.

TABLE I

The Seven SI Units

Quantity	Name	Symbol
Length	Meter	m
Mass	Kilogram	kg
Time	Second	s
Temperature	Kelvin	K
Amount of substance	Mole	mol
Electric current	Ampere	A
Luminous Intensity	Candela	cd

TABLE II

Some Secondary SI Units

Quantity	Definition	Name	Symbol
Energy	$\text{kg m}^2\,\text{s}^{-2}$	Joule	J
Force	kg m s^{-2}	Newton	N
Pressure	$\text{kg m}^{-1}\,\text{s}^{-1}$		
	N m^{-2}	Pascal	Pa
Power	$\text{kg m}^2\,\text{s}^{-3}$	Watt	W

TABLE III

Prefixes Used in the SI System of Units

Multiplication	Multiple or submultiple	Symbol
10^{12}	tera	T
10^{9}	giga	G
10^{6}	mega	M
10^{3}	kilo	k
10^{2}	hecta	h
10^{1}	deca	da
Base unit		
10^{-1}	deci	d
10^{-2}	centi	c
10^{-3}	milli	m
10^{-6}	micro	μ
10^{-9}	nano	n
10^{-12}	pico	p
10^{-15}	femto	f
10^{-18}	atto	a

reporting electrical power/energy. This confusion frequently leads to the use of the term "kilowatts per hour," which is neither an energy unit nor a unit of power, and kilowatts when kilowatt hours is meant.

Extensive properties, those that are proportional to the amount of substance such as heat capacities are in SI units expressed in terms of energy per mole. Except in chemical practice the mole is little used and extensive properties are frequently expressed as specific properties—that is, properties per unit mass. For example, the molar heat capacity of copper is $24\,\mathrm{J\,mole^{-1}\,K^{-1}}$ or in specific terms $378\,\mathrm{J\,kg^{-1}\,K^{-1}}$.

It is to be noted that if all quantities in a calculation are expressed in SI units then the result will also be in SI units. This coherence is of considerable practical use in ensuring that the results of calculations do not come out in strange units.

6. FORMS OF ENERGY

6.1 Mechanical and Gravitational Energy

Mechanical forms of energy can be considered as those that relate to movement and position. The most important type is translation or kinetic energy and it can be calculated from Eq. (3). Kinetic energy can be found in the energy of the wind and ocean waves.

Wind energy and its transformation into electricity have the advantage of being environmentally friendly. There are no emission of toxic substances, and it is a renewable resource. It is however, not a steady source and furthermore, it is a secondary energy form as it depends on the radiant energy from the sun. All this means that wind energy is a dilute and weak form of energy. In spite of this, a large number of wind turbines are being erected in most continents, and wind energy could be an important renewable energy source in the future.

The amount of energy reaching a wind machine can be calculated from Eq. (3), given the wind speed, the wind collecting area of the vanes, and the density of the air. For example, if the wind velocity is $10\,\mathrm{m\,s^{-1}}$, the wind vane collecting area is $10\,\mathrm{m^2}$, and the density of air is $1.2\,\mathrm{kg\,m^{-3}}$, then the kinetic energy, E_K, per second is

$$E_K = 1/2\,mv^2 = (0.5 \times 10 \times 10 \times 1.3 \times 10^2)\mathrm{J}$$

$$\text{Power} = 6.5 \times 10^3\,\mathrm{J\,s^{-1}}.$$

The harnessing of ocean waves is severely hampered by the corrosive nature of the sea, and very few such projects remain in the world after much enthusiasm in the 1980s and 1990s. The ocean waves are dependent on the moon-earth gravitational attraction and also on wind direction. Wave energy is thus also a secondary energy source and hence is rather dilute compared to primary sources.

The gravitation potential energy between two bodies of mass m, and m_2, separated by a distance r, depends on the force between the bodies, f_G:

$$f_G = \frac{Gm_1m_2}{r^2}, \tag{7}$$

where G is the universal gravitational constant and has a value of 6.673×10^{-11} Newton meter $\mathrm{kg^{-1}}$. The potential energy E_G is thus equal to

$$E_G = \frac{Gm_1m_2}{r}. \tag{8}$$

The acceleration, g, due to gravity on any mass, due to m_2, is given by

$$g = \frac{Gm_2}{r^2}, \tag{9}$$

and on earth, g has a value of about $9.8\,\mathrm{m\,s^{-2}}$. (The radius of the earth is about $6.37 \times 10^6\,\mathrm{m}$ and the mass of the earth is about $6.0 \times 10^{24}\,\mathrm{kg}$.)

The gravitational potential energy of falling water can be considerable if the flow of water and the fall is large. There are many very large power stations

around the world that utilize hydroelectric power. It is a clean energy source, free of chemical pollutants. Unfortunately, there is a limit to the number of places on earth where large volumes of falling water can be found. Hydroelectric power contributes about 2% of the total amount of energy used in the world (a 1994 figure).

There are other types of mechanical energy forms that are scientifically interesting and important but are not on a scale large enough for exploitation as an energy source. These include vibrational, rotational, and electronic energies. The potential energy of a spring is given by

$$E_{VIB} = 1/2kx^2, \tag{10}$$

where x is the displacement of the spring from its rest position and k is the spring constant. Such energies are important in understanding the bonding that takes place between atoms. These vibrational energies are quantized and the available energies are small and given by

$$E_{VIB} = (v + 1/2)h\nu \; v = 0, 1, 2, 3\ldots, \tag{11}$$

where h is Planck's constant (6.626×10^{-34} J s) and ν is the frequency of the vibration This frequency can be calculated from the spring constant and the masses of the two atoms involved in the bond.

Rotational energy is found in molecules and in planets. The rotational energy of molecules is even smaller than the vibration energy of the bonds between atoms. Rotational energy is also quantized and the energies confined to

$$E_{ROT} = \frac{J(J+1)h}{4\Pi I} \; J = 0, 1, 2, \ldots, \tag{12}$$

where I is the moment of inertia about an axis.

Electronic energy is the extra energy an outer electron needs to move to a higher electronic orbit. It is also the energy given out when an excited outer electron moves back to its ground state. This energy is radiant energy and sometimes the emission is in the visible region of the electromagnetic spectrum, and we can see it as a color. When sodium atoms are excited (NaCl in a bunsen-burner flame or electrically excited sodium vapor in a street lamp), they emit an intense yellow flame. Electronic energy is quantized, and the energies are related to the frequency, ν, of the emitted electromagnetic energy by

$$E_{ELEC} = h\nu. \tag{13}$$

The energies of translating atoms and molecules are also quantized but the allowed energy levels are so close together that the energies can be considered as a continuum, and the equations of Newtonian physics apply to these particles. The allowed energy levels for a particle of mass, m, in a one-dimensional box of length L is given by

$$E_{TRANS} = \frac{n^2h^2}{8mL^2} \; n = 1, 2, 3, \ldots. \tag{14}$$

There is another type of mechanical energy that is related to steam engines and to expanding gases or vapors. The work done by a gas or vapor when it expands (with a volume change of ΔV), against a pressure p, is

$$w = p\Delta V. \tag{15}$$

As an example, let us consider the work done by a mole of water at its boiling point, as it turns into a vapor (with a volume change of $\Delta V = 30 \times 10^{-3}$ m^3), against atmospheric pressure (101325 Pa). The work done is

$$w = (101325 \times 30 \times 10^{-3})J = 3040 \text{ J}.$$

This is the energy that drives steam engines.

To put the other larger mechanical energies into perspective, let us consider the kinetic energy of a moving tennis ball and the potential energy of water about to fall.

The energy of a tennis ball (m = 60 g) hit by Serena Williams, traveling at a velocity of 100 km s^{-1}, has a kinetic energy of

$$E_{KE} = 1/2mv^2 = (1/2 \times 0.060 \times 100^2)J = 300 \text{ J}.$$

The potential energy of 1.0 kg of water, about to fall 100 m under gravity (g = 9.8 m s^{-2}) is

$$E_{PE} = mgh = (1 \times 9.8 \times 100)J = 980 \text{ J}.$$

Both energies are rather small.

6.2 Chemical Energy

Chemical energy is stored in molecules through the bonds that bind atoms, and some of this energy can be released when chemical reactions take place. In this process, some bonds are broken (involving an input of energy) and some bonds are made (involving a release of energy). The overall effect is either endothermic or exothermic. However, for most reactions, the process is exothermic and energy is released. This release is usually in the form of thermal energy.

The thermal energy associated with a chemical reaction is always measured at constant pressure and is known as the enthalpy of the reaction, $\Delta_r H^\theta$, and relates to conditions of 1 bar pressure (10^5 Pa)

and 298.15 K. As an example, let us consider the reaction between hydrogen and oxygen:

$$2H_2(g) + O_2(g) = 2H_2O(g). \quad (16)$$

This reaction involves breaking two moles (or molecules) of H–H bonds, one mole (or molecule) of O–O bonds and making four moles of O–H bonds. As the values of the bond energies are known ($\Delta H^{\theta}_{H-H} = 436\,kJ\,mol^{-1}$, $\Delta H^{\theta}_{O-O} = 497\,kJ\,mol^{-1}$ and $\Delta H^{\theta}_{O-H} = 463\,kJ\,mol^{-1}$), it is possible to determine the enthalpy of the reaction, $\Delta_r H^{\theta}$:

$$\begin{aligned}(\Delta_r H^{\theta}) &= (-4 \times 463 + 497 + 2 \times 436)kJ \\ &= -483\ kJ\ (\text{the negative sign implies an exothermic process}).\end{aligned}$$

The experimental enthalpy value for the formation of two moles of $H_2O(g)$ from two moles of $H_2(g)$ and a mole of $O_2(g)$ is indeed -483 kJ.

It is important to know that the sum of the bond energies in a molecule do not make up the total energy of the molecule. The bond energies relate only to chemical reactions. The total energy involves all types of energies, including the energy of binding protons to neutrons and inner electrons and so on. The total energy of a molecule is difficult, if not impossible, to determine.

Chemical energy is the most important type of energy on Earth. It accounts for 96% of all energy sources. These include oil (37%), coal (24%), natural gas (21%), and biomass (14%). These are 1994 figures. Chemical energy supplies the energy for all modes of transport, whether it be ships, cars, trucks, buses, or planes, through the combustion of hydrocarbons such as gasoline and diesel. Chemical energy also supplies energy to most of the electricity power stations in the world through the combustion of natural gas (CH_4), oil, or coal. Typical combustion reactions are

$$\underset{\text{(gasoline)}}{C_8H_{18}(l)} + O_2(g) \rightarrow CO_2(g) + H_2O(l)$$
$$\Delta_r H^{\theta} = -5461\,kJ\,mol^{-1} \quad (17)$$

and

$$\underset{\text{(methane)}}{CH_4(g)} + O_2(g) \rightarrow CO_2(g) + H_2O(l)$$
$$\Delta_r H^{\theta} = -890\,kJ\,mol^{-1}. \quad (18)$$

These reactions involve a relatively large amount of energy for a small mass of fuel. The gasoline reaction (Eq. 17) produces 47900 J per gram of n-octane and the natural gas reaction (Eq. 18) produces 55600 J per gram of methane. The steam engine, by comparison, produces 169 J per gram of H_2O.

Biomass energy refers to the use of plant material as an energy resource. It includes the growing of sugar cane and corn for alcohol production (a viable exercise in Brazil and also in the mid-west United States) and the burning of wood for heat and energy. Much of the energy used in third world countries is of the latter type. Another interesting and useful biomass process is the exploitation of methane gas from landfills. The decomposition of organic material, under anaerobic conditions, produces an equal volume of methane and carbon dioxide gases. The methane gas may be used for heating or to generate electricity. Energy from landfill projects are now commonplace in many countries of the world, notably in the United Kingdom and the United States. The energy is a renewable resource and exploitation does reduce the amount of methane gas (a greenhouse gas, which is 27 times more effective that carbon dioxide) that enters the atmosphere.

The energy used by humans for mechanical activities such as running, lifting weights, pulling, and so forth comes from the combustion of food (carbohydrates, fats, etc.) in much the same way as does the energy of an internal combustion engine. Not a very nice thought. The combustion process in the human body is done through a series of complex reactions, and the overall reaction looks similar to that of burning wood or diesel! Typical carbohydrate and fat reactions are

$$\underset{\text{(carbohydrate)}}{C_6H_{12}O_6(s)} + 6O_2(g) \rightarrow 6CO_2(g) + 6H_2O(l)$$
$$\Delta_r H^{\theta} = -2803\,kJ\,mol^{-1} \quad (19)$$

and

$$\underset{\text{(fat)}}{C_{45}H_{86}O_6(s)} + 63\tfrac{1}{2}O_2(g) \rightarrow 45CO_2(g) + 43H_2O(l),$$
$$\Delta_r H^{\theta} = -27820\,kJ\,mol^{-1}. \quad (20)$$

The carbohydrate (glucose) and the fat produce $15.6\,kJ\,g^{-1}$ and $38.5\,kJ\,g^{-1}$, respectively. The fat produces more than twice the energy per gram that does the carbohydrate. You might have seen these energy values in health food literature as 3.7 and 9.2 kcal per gram, respectively. The calorie is an old-fashioned unit for energy and 4.18 J = 1 calorie. You might also have seen these energy values written as 3.7 and 9.2 Calories per gram, respectively. The Calorie is a health food unit for a kilocalorie.

Chemical energy is measured in calorimeters and the simplest type is known as a "bomb" calorimeter. The bomb is made of thick steel, and is of the order of 100 mm high with an internal volume of about $300\,cm^3$. The only type of reactions that can be investigated in these calorimeters are combustion reactions. The inside of the bomb contains a sample holder and contacts to attach a high-resistance fuse wire. The contacts are connected to a cable through gas-tight seals, to a battery and a switch, outside the bomb. The bomb is also fitted with an oxygen inlet pipe and a pressure valve, rated at 30 atmosphere. The sample (e.g., a few grams of glucose) is weighed out (m_1) and placed in the sample holder, and the fuse wire is connected to the contacts and bent so that it passes through the sample. Oxygen is pumped into the bomb until the pressure is about 20 atmospheres. The bomb is then placed in a tank of water, which has been weighed (about 3 kg) (m_2) and a thermometer and stirrer placed in the tank. Once the bomb and water has reached equilibrium (30 minutes), the temperature of the water is noted (T_1), the fuse is fired through the external switch and battery, and the combustion reaction (Eq. 19) takes place. The heat of combustion heats the bomb, which in turn warms the water. When an equilibrium has been reached (another 30 minutes), the temperature of the water is noted (T_2). The bomb and the water should have the same change of temperature i.e., $(T_2–T_1) = \Delta T$.

The energy given out by the glucose sample is balanced by the energy absorbed by the water and the bomb. If the energy per mole of glucose combustion reaction is $\Delta_r U^{\theta}$, then

$$[(m_g/MM)\Delta_r U^{\theta}]_{glucose} = [m_2 s_2 \Delta T]_{water} + [m_1 s_1 \Delta T]_{bomb}, \quad (21)$$

where m_g is the mass of glucose, MM is the molar mass of glucose, s_2 is the specific heat of the water ($4.18\,J\,g^{-1}\,K^{-1}$), and m_1 and s_1 are the mass and specific heat of the calorimeter. The product ($m_1 s_1$) is unique for each calorimeter (it is called the bomb's heat capacity) and can be determined from calibration experiments using a standard substance such as benzoic acid. The value of $\Delta_r U^{\theta}$ is calculated from Eq. (21). This energy refers to a constant volume experiment. The value of $\Delta_r H^{\theta}$ is usually very close to $\Delta_r U^{\theta}$. The exact value can be calculated from

$$\Delta_r H^{\theta} = \Delta_r U^{\theta} + \Delta n RT, \quad (22)$$

where Δn is the change in the amount of gas in the reaction. For this reaction (see Eq. 19), there are six moles of $O_2(g)$ on the reactant side and six moles of $CO_2(g)$ on the products side. For this combustion reaction $\Delta n = 0$ and $\Delta_r H^{\theta} = \Delta_r U^{\theta}$.

There is another type of chemical energy that should be considered and that is the energy of a phase change. By phase change we mean a solid changing to a liquid or a liquid changing to a vapor. A common example is the change of liquid water to steam. This type of energy has been called the latent heat and is due to intermolecular interactions which bind molecules together as a result of the attractions of dipoles and fluctuating dipoles that are created by the electrons wizzing around molecules. The larger the molecule, the more electrons in the molecule and the greater will be this interaction and the greater will be its latent heat or its enthalpy of phase change. For water, the enthalpies of fusion (melting) at 273.15 K and vaporization at 373.15 K are 6.0 and $40.7\,kJ\,mol^{-1}$, respectively. It obviously takes a lot more energy to separate the liquid molecules to form a vapor than it does to separate the molecules in solid water to form a liquid. Much of the energy (coal) used to fire up a steam engine is used to overcome the enthalpy of vaporization of water and create steam from liquid water.

It is possible to store energy using the reversible property of phase equilibria. For example, solar energy can readily be used to melt Glauber salts ($Na_2SO_4.10H_2O$) because of its low melting temperature (306 K). This molten material will revert to a solid when the temperature drops below the melting point (at night) and will release the stored energy, which is the enthalpy of fusion.

6.3 Electrical Energy

Electrical energy is the most useful of energies as it can be readily transported along copper or aluminum cables for long distances. It can also be conveniently switched on and off. Electrical energy is not unlike the gravitational energy of falling water with the electrons moving under a potential difference replacing water falling under the influence of gravity.

The electrical energy of electrons moving under a potential difference of V with a current i for a time t is

$$E_E = Vit. \quad (23)$$

Electrical energy is readily converted from chemical energy, creating a flow of electrons. Such devices are batteries and one such battery is the Daniel cell. The natural reaction between zinc and a solution of copper sulfate to form zinc sulfate and metallic

copper can be demonstrated by placing a piece of metallic zinc in a solution of copper sulfate whereupon the zinc will begin to dissolve and red metallic copper will be precipitated. The overall reaction can be represented as the displacement of the copper ions from solution as metallic copper by the formation of zinc ions from the zinc in the process of which electrons are transferred from the zinc to the copper ions:

$$Zn(s) + Cu^{2+}(aq) \rightarrow Zn^{2+}(aq) + Cu(s). \quad (24)$$

This reaction can be made to take place in a more controlled way in an electrochemical cell (the Daniel cell), in which zinc and copper electrodes are each immersed in a solution of its sulfate and are separated by a membrane which allows the diffusion of ions. If an external metallic connection (a piece of wire) is made between copper and the zinc rods, an electric current (electrons) can flow between the two rods; zinc metal will dissolve to form zinc ions and the copper ions will deposit as metal on the copper rod. The completion of the flow of electric charge will be achieved by the movement of zinc ions through the membrane and the movement of copper ions toward the copper rod. This electrochemical cell is a prototype of the many different kinds of battery that are used to power various devices from hearing aids to video cameras and flashlights in daily use.

6.4 Radiation of Electromagnetic Energy

Radiation energy is a unique form of energy. It is characterized by a wave with a wavelength and a frequency:

$$c = \lambda \nu. \quad (25)$$

where c is the speed of light ($3 \times 10^8\,m\,s^{-1}$). The magnitude of radiant energy is given by

$$E_R = h\nu. \quad (26)$$

Radiation energy is emitted from an object in the form of electromagnetic waves, which consist of electric and magnetic fields whose amplitudes vary with time. These waves propagate out from the object at the speed of light. Familiar examples of electromagnetic radiation include gamma rays, X-rays, ultraviolet waves, visible waves, infrared waves, microwaves, TV waves, and radio waves. The full range of the electromagnetic spectrum spans cosmic rays at the short wavelength and radio waves at the long wavelength end (see Fig. 2). It is the wavelength that categorizes the different types of radiation. Only a small region of the spectrum is visible to the human eye. That part is called the visible spectrum. The radiant energy that causes sunburn and possible cancer is the ultraviolet rays. These are of shorter wavelength (hence greater energy) than the visible rays and the infrared rays. It is the latter that gives us the sensation of warmth. These rays have similar energies to the vibration energies of the molecules in our bodies and hence are readily absorbed.

The main source of electromagnetic radiation on Earth is the sun. This radiation involves only the UV, visible and IR parts of the electromagnetic spectrum. Sunlight is the mainstay and support for all plant and animal life on earth. The total amount of sunlight reaching the earth each day is 3.11×10^{23} J. This is an enormous amount of energy and 11 days of sunshine over the whole earth is equivalent to all the fossil fuel (gas, oil, coal) in the earth. However, the earth's surface is large and the amount of sunshine reaching the earth peaks at about $1.2\,kW\,m^{-2}$ on the equator at midday. This is really a small amount of energy. A solar energy collector of almost $8\,km \times 8\,km$ is needed to create a reasonably large electricity generating power station of 1.0 GW (assuming a conversion factor of 10%). Even this is unrealistic as it assumes all the solar collecting panels are dust free and clean and that the sun shines brightly 8 hours every day. Solar energy is a dilute form of energy, but it is a renewable and clean energy source and will certainly be an important source in the future as the earth's fossil fuel resources become exhausted.

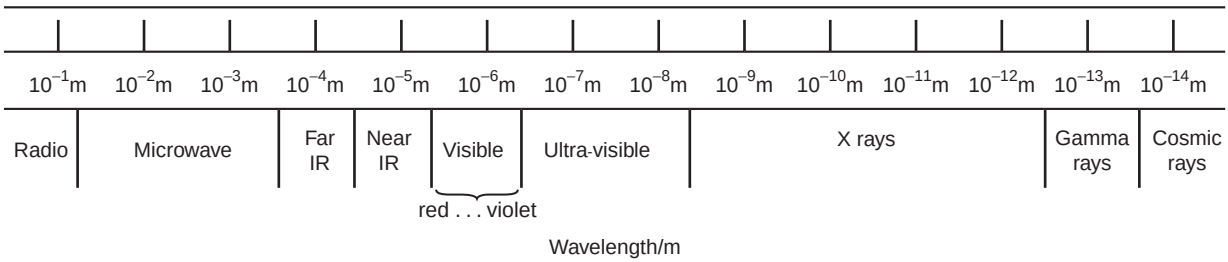

FIGURE 2 The electromagnetic spectrum.

6.5 Nuclear Energy

Nuclear energy comes from reactions involving the nuclei of atoms. In these reactions, the subatomic particles, neutrons and protons of the reacting species, find a more stable arrangement in the products. For nuclear reactions to take place, the reacting species must penetrate the negative electron shield surrounding the nucleus and then penetrate the positively charged nucleus. Thus, the reacting species must have large kinetic energies and preferably should have zero charge. That is why neutrons (zero charge) are often used. In chemical reactions, by contrast, the nucleus is never part of the process and the rearrangement that takes place relate only to the outer electrons of the atoms.

A simplified version of a typical nuclear reaction taking place in our sun is the reaction between two hydrogen isotopes (deuterium) to form an isotope of helium:

$$ {}^{2}_{1}H + {}^{2}_{1}H \rightarrow {}^{3}_{2}He + {}^{1}_{0}n. \qquad (27) $$

Reactions of this type produce large amounts of energy. This particular reaction produces 3×10^8 kJ per gram of deuterium. This is significantly greater (by about six orders of magnitude) than the magnitude of the chemical reactions we met earlier (Eqs. 16 through 20). The deuterium reaction in Eq. (27), involving a fusion of nuclei, is called a fusion reaction. The energy that is released in this reaction and in other fusion reactions comes in many forms: radiation energy (δ-radiation, U-V, IR, and visible light), kinetic energy, and thermal energy.

Another type of nuclear reaction involves the splitting of a nuclei by high-energy neutrons. Such reactions are referred to as fission reactions and the material that undergoes the splitting is called fissile material. Uranium-235, uranium-233, and plutonium-239 are examples of fissile material and all of these are used in nuclear power plants. To ensure fission, the kinetic energy of the neutrons must be high enough to enter the nucleus and split it. For many isotopes of many elements, the arrangement of neutrons and protons in their nuclei is sufficiently stable to ensure that the bombardment by high-energy neutrons has no effect.

A typical fission reaction is

$$ {}^{235}_{92}\mathrm{U} + \mathrm{n} \rightarrow {}^{141}_{56}\mathrm{Ba} + {}^{92}_{36}\mathrm{Kr} + 2{}^{1}_{0}\mathrm{n} $$
$$ \Delta \mathrm{E} = -8 \times 10^{10}\ \mathrm{J\,mol^{-1}}. \qquad (28) $$

The amount of energy is again more than six orders of magnitude greater that typical chemical reactions used in power generation.

If the number of neutrons and the concentration of uranium-235 nuclei is high enough, the nuclear reaction becomes self-sustaining. The minimum mass is known as the critical mass. If the reaction is too vigorous, an explosion will occur. This is what happened in Nagasaki and Hiroshima in 1945 and in Chernobyl in 1986. Nuclear reactors for power generation have strict mechanical control over the uranium-235 enriched rods and moderators to reduce the possibility of runaway nuclear reactions (chain reactions).

The release of energy in nuclear reactions always involves a loss of mass. The relationship between the energy output, ΔE, and the loss of mass, Δm, is given by Einstein's famous equation:

$$ \Delta \mathrm{E} = \Delta \mathrm{m} c^2, \qquad (29) $$

where c is the speed of light, $3.00 \times 10^8\ \mathrm{m\,s^{-1}}$.

In a nuclear reactor, the energy heats a heat exchanger (e.g., water or sodium), which transfers heat to water to make steam, which is then used to turn a turbine and create electricity. Nuclear energy makes up 2% of all the energy used in the world. France has taken the lead here, and 80% of its electricity is produced from nuclear energy. In 1995 there were 400 nuclear powerstations in more than 30 countries. This represented about 10% of the world's electricity.

There are two major problems with fission nuclear power: (1) the products are radioactive and need to be contained for hundred of years because of their long half-lives and (2) there is the possible danger of a runaway chain reaction resulting in an explosion and the subsequent contamination of the environment with radioactive fallout. Solutions to these problems will bring about a resurgence of nuclear power production worldwide, especially as the world's fossil fuel reserves are beginning to run down and the temptation to extract large amounts of nuclear energy from small masses of fuel becomes irresistible.

Fusion reactions would, in theory, be the saving grace of the nuclear industry because the products are essentially free of radioactivity and, moreover, the fuel (deuterium) is available from seawater. Unfortunately, the fusion process is difficult to achieve in practice because of the difficulty in supplying the deuterium molecules with enough energy for the nuclei to strike each other with enough force to allow them to interact and for the neutrons and protons to rearrange. Much work is currently being done in a number of laboratories

around the world, but the process is costly and technically challenging.

Geothermal energy (the energy that heats natural hot-water springs) is due to energy from radioactive sources deep inside the earth. This energy is being tapped in Iceland and in Italy.

The measurement of the energy from nuclear reactions can be determined from a special type of calorimeter, but it can also be calculated from a detailed analysis of the relative atomic masses of the products and reactants, followed by the application of Einstein's equation (Eq. 29).

7. CONCLUSION

A knowledge of the forms of energy available on our earth (and a knowledge of how to measure and calculate the magnitudes of each type of energy) gives us the necessary data to begin to make the important decisions as to which type of energy can be exploited in the future. This is particularly pertinent as the world's fossil fuel reserves begin to dwindle.

Glossary

anode The fuel electrode, where electrons are donated as the fuel is oxidised. The negative electrode in a fuel cell.
balance of plant All the components that make up a power system, other than the fuel cell stack, for example, the control system, reformer, power conditioner, or compressor.
bipolar plate A dense, electronic (but not ionic) conductor that electrically connects the anode of one cell to the cathode of another. It also distributes fuel or air to the electrodes.
cathode The air electrode, where electrons are accepted and oxygen is reduced. The positive electrode in a fuel cell.
electrocatalyst A catalyst incorporated into both the anode and the cathode to promote the electrode reactions.
electrolyte A dense ionic (but not electronic) conductor. Each fuel cell type is distinguished by the nature of the electrolyte used within it.
interconnect Another term for the bipolar plate (see above).
membrane electrode assembly (MEA) An assembled anode, cathode, and electrolyte.
open circuit voltage The voltage from the fuel cell when no current is being drawn from it.
overpotential The voltage loss within an operating fuel cell due to electrode kinetics, mass transport limitations, and component resistance.
positive electrolyte negative (PEN) The assembled cathode, electrolyte, and anode of a solid oxide fuel cell.
reformer The fuel processor that converts the fuel to a hydrogen-rich gas suitable for the fuel cell.
stack An assembly of many individual fuel cells, complete with gas manifolds and electrical outputs.

A fuel cell is a device for directly converting the chemical energy of a fuel into electrical energy in a constant temperature process. Fuel cells operate on a wide range of fuels, including hydrogen, and are seen as a clean, high-efficiency power source and an enabling technology for the hydrogen economy.

1. WHAT IS A FUEL CELL?

The fuel cell can trace its roots back to the 1800s when a Welsh-born, Oxford-educated barrister, Sir William Robert Grove, realized that if electrolysis, using electricity, could split water into hydrogen and oxygen, then the opposite would also be true. Grove subsequently built a device that would combine hydrogen and oxygen to produce electricity—the world's first gas battery, later renamed the fuel cell.

It was another British scientist, Francis Thomas Bacon, who was the first to develop a technologically useful fuel cell device. Bacon began experimenting with alkali electrolytes in the late 1930s, using potassium hydroxide instead of the acid electrolytes used by Grove. Bacon's cell also used porous "gas-diffusion electrodes" rather than Grove's solid electrodes. These increased the surface area over which the electrochemical reactions occurred, improving power output. In the early 1960s, Pratt and Whitney licensed the Bacon patents and won the National Aeronautics and Space Administration contract for the Apollo spacecraft utilizing onboard liquid hydrogen and oxygen to provide both power and water. Innovation and development has continued since that time with pioneering work by, for example, Westinghouse, Union Carbide, and General Electric, among others.

Today, potential applications for fuel cells range from battery replacement in consumer goods and portable computers, through residential scale combined heat and power (CHP), to distributed energy generation. However, the key problem limiting the

 © 2004 Elsevier Inc. All rights reserved.

significant commercial uptake of fuel cells is cost, and it is cost reduction, together with the need to demonstrate high levels of reliability and durability, that are the primary concerns of fuel cell developers today.

As demonstrated by Grove's gas battery, a fuel cell is analogous to a battery, but one that is constantly being recharged with fresh reactants. In a similar manner to a battery, each fuel cell comprises an electrolyte, which is an ionic conductor, and two electrodes (the negative anode and positive cathode), which are essentially electronic conductors.

The nature of the ion transfer varies between the different types of cell, but the principle shown in Fig. 1 for a polymer electrolyte membrane fuel cell (PEMFC) is representative. In this case, hydrogen is fed to the anode of the cell where it splits into a proton and electron, the former passing through the electrolyte and the latter forced around an external circuit where it drives a load. The proton and electron combine with oxygen from the air at the cathode, producing pure water and a small amount of heat. The overall reaction is thus

$$H_2 + 0.5O_2 \Leftrightarrow H_2O. \quad (1)$$

The anode is then the negative electrode of the device, and the cathode the positive.

The fuel cell differs from a conventional heat engine (such as the internal combustion engine or the gas turbine), in that it does not rely on raising the temperature of a working fluid such as air in a combustion process. The maximum efficiency of a heat engine is subject to the Carnot efficiency limitation, which defines the maximum efficiency that any heat engine can have if its temperature extremes are known:

$$\text{Carnot efficiency} = (T_H - T_L)/T_H, \quad (2)$$

where T_H is the absolute high temperature and T_L is the absolute low temperature. In contrast, the theoretical efficiency of a fuel cell is related to the ratio of two thermodynamic properties, namely the chemical energy or Gibbs free energy (ΔG^0) and the enthalpy (ΔH^0) of the fuel oxidation reaction:

$$\text{Maximum fuel cell efficiency} = \Delta G^0/\Delta H^0. \quad (3)$$

Figure 2 provides an illustration of the theoretical efficiency possible from a fuel cell running on hydrogen and air as a function of temperature and compares this to the Carnot efficiency of a heat engine at the same temperature, assuming a low temperature of 25°C. As the Gibbs free energy for reaction (1) falls with increasing temperature, while the enthalpy remains largely unchanged, the

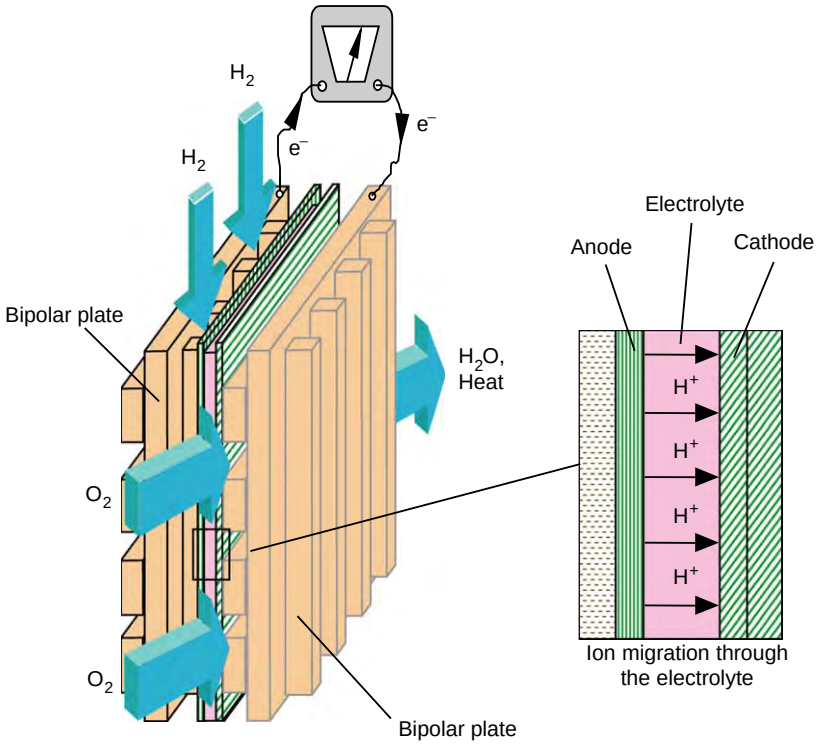

FIGURE 1 Schematic illustration of a polymer electrolyte fuel cell.

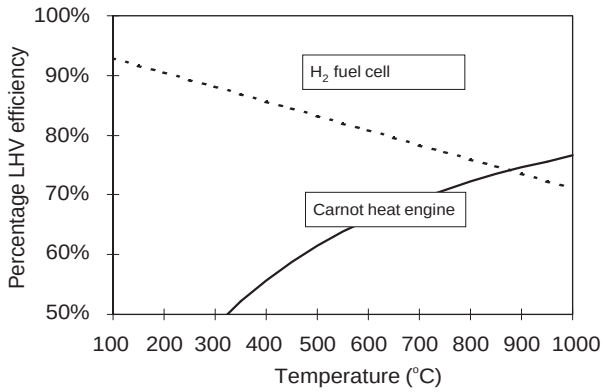

FIGURE 2 Maximum efficiency (on a lower heating value basis) of a hydrogen/air fuel cell, and a heat engine limited by the Carnot cycle, as a function of temperature.

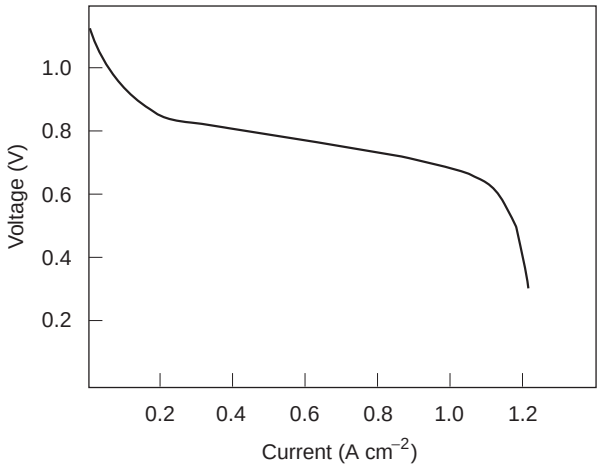

FIGURE 3 Schematic illustration of a typical fuel cell current-voltage curve.

theoretical efficiency of the fuel cell falls with increasing temperature. Indeed, at high temperatures the theoretical efficiency of a heat engine is higher than that of a hydrogen driven fuel cell. However, because of the need for motion in a heat engine, either rotary or linear, significant materials issues are associated with operating them at high temperatures, from the perspective of both durability and cost. Fuel cells do not have moving parts operating at high temperatures and thus are less susceptible to this problem.

However, other factors play a role in determining the actual efficiency of an operating fuel cell, in particular operating temperature, fuel type, and materials selection. For example, losses associated with the kinetics of the fuel cell reactions fall with increasing temperature, and it is often possible to use a wider range of fuels at higher temperatures. Equally, if a fuel cell is to be combined with a heat engine, for example, in a fuel cell/gas turbine combined cycle, then high fuel cell operating temperatures are required to maximize system efficiency. All these factors mean that there is considerable interest in both low-temperature and high-temperature fuel cells, depending on the application.

Figure 3 illustrates the shape of the current-voltage characteristics that would be expected from a typical fuel cell. When no current is being drawn from the fuel cell, the cell voltage is at a maximum, termed the open circuit voltage (E), which increases with the partial pressures of the fuel and air gases and decreases with increasing temperature, according to the Nernst equation:

$$E = E^0 - RT/nF \ln\left(pH_2O/pH_2\ pO_2^{0.5}\right). \quad (4)$$

where E^0 is related to the Gibbs energy for the reaction via:

$$\Delta G^0_{298} = -nE^0F, \quad (5)$$

where n is the number of electrons involved, 2 for reaction (1), and F is the Faraday constant ($96495\,C\,mol^{-1}$). As the value of ΔG^0_{298} for the reaction of hydrogen with oxygen to form water is $-229\,kJ\,mol^{-1}$, then an open circuit voltage of around 1.2 V would be expected from a hydrogen/air fuel cell operating at near ambient temperatures under standard conditions.

As current is drawn from the cell, additional irreversible losses result in a decrease in the cell voltage (E_{cell}), according to:

$$E_{cell} = E - iR - \eta a - \eta c, \quad (6)$$

where iR refers to ohmic losses within electrodes, interconnects, and current take-off's due to the finite resistance of the materials used, ηa refers to the overpotential at the anode, reflecting losses due to both electrode kinetics and mass transport limitations, and ηc refers to the equivalent overpotential at the cathode. Different loss terms are reflected in different regions of the current-voltage curve, with the initial fall in voltage reflecting electrode kinetics, the central linear region being dominated by iR losses, before mass transport limitations dominate at high current densities.

Hence, under load a single cell produces a reduced cell voltage due to the losses highlighted here. It is the task of the fuel cell designer to minimize these losses by judicious selection of materials and cell geometry. Electrodes, for example,

are required to be porous to enable gas transport to and from the active catalyst region adjacent to the electrolyte, yet also to be good electronic conductors. As such, there is considerable research into electrode structures and materials, so as to minimize overpotentials. Another choice facing the fuel cell system designer is the operating cell voltage.

At any point other than very close to the open circuit voltage (where parasitic loads become significant), then, the higher the cell voltage, the higher the cell efficiency—but the lower the power density. In general, a cell voltage of about 0.6 to 0.7 V is taken as the operating point. This is a compromise between efficiency (a high-efficiency reducing fuel consumption) and power density (a low-power density increasing stack size and weight, and hence capital cost). To achieve a useful output power, individual cells are connected together in a "stack". This is achieved using an interconnect or bipolar plate, which joins the anode of one cell to the cathode of the next cell. The interconnect also separates and often distributes the fuel and oxidant. An example of a PEMFC stack is shown in Fig. 4. In this case, the interconnect is known as a flow field plate, and the combination of electrolyte and electrodes as the membrane electrode assembly (MEA). Other fuel cell types use different terminology (positive electrolyte negative or PEN for an SOFC, for example) for these components, but their function remains the same.

The fuel cell stack is then incorporated into a system, which meets the demand of a specific application. Fuel cell systems can include a range of balance of plant (BoP), depending on the fuel used, the application, and the fuel cell type. BoP can include a fuel processor, compressor, power conditioner, and control system. Together, these can add significant cost to the overall system. As well as high efficiency and low emissions levels (discussed further in Section 6), a number of further advantages are cited for fuel cells:

1. They are quiet and involve few moving parts, other than some fans or a compressor to blow air into the device, and hence do not require much maintenance.
2. They are modular, such that several can be coupled together to increase the capacity of a system, but can be mass-manufactured to reduce cost.
3. They exhibit an increase in efficiency at low loads, unlike a heat engine, which normally only exhibits maximum efficiency around the design point for the device.

2. FUEL CELL TYPES

There are five main classes of fuel cell, each with differing characteristics, and differing advantages and disadvantages. The five types are summarized in Table I, with each taking the name of the electrolyte used in its fabrication. These five classes of fuel cell can essentially be further grouped into one of two classes, distinguished as either low-temperature fuel cells (AFC, PEMFC, PAFC), or high-temperature fuel

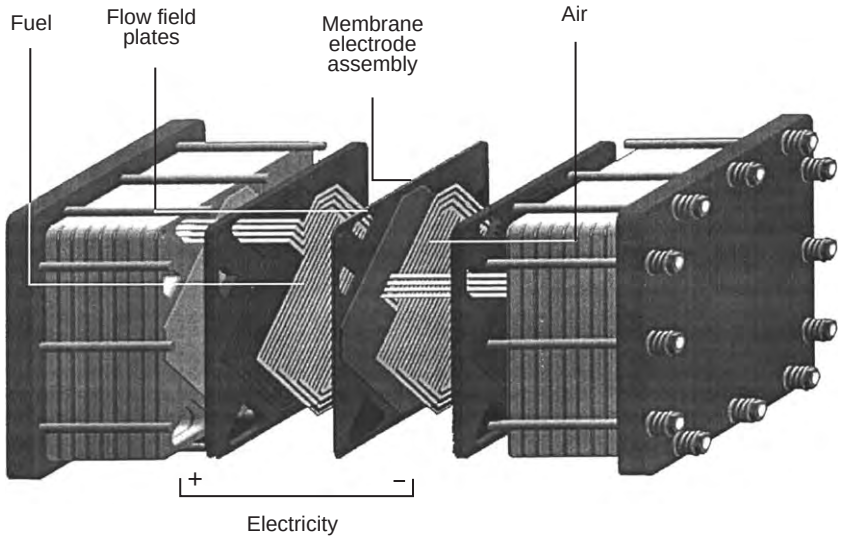

FIGURE 4 Example of a polymer electrolyte fuel cell (PEMFC) stack.

TABLE I

Summary of the Five Main Fuel Cell Types

Fuel cell type	Alkaline	Polymer	Phosphoric acid	Molten carbonate	Solid oxide
Acronym	AFC	PEMFC	PAFC	MCFC	SOFC
Operating temperature	60–250°C	80–120°C	150–220°C	600–700°C	600–1000°C

cells (MCFC, SOFC). The low-temperature fuel cells can be distinguished by the following common characteristics:

- They require a relatively pure supply of hydrogen as a fuel (e.g., AFCs are sensitive to carbon dioxide, PEMFCs to carbon monoxide). This usually means that a fuel processor and some form of gas cleanup is required, adding cost and reducing system efficiency.
- They incorporate precious metal electrocatalysts to improve performance.
- They exhibit fast startup times.
- They are available commercially (AFC, PAFC) or are approaching commercialization (PEMFC).

In contrast, high-temperature fuel cells can be classed as having the following general features:

- They have fuel flexibility; they can be operated on a range of hydrocarbon fuels at high efficiency.
- Their increased operating temperature reduces the need for expensive electrocatalysts.
- They can generate useful "waste" heat and are therefore well suited to cogeneration applications.
- They exhibit slow startup times.
- They can require expensive construction materials to withstand the operating temperature, particularly in the balance of plant.
- Reliability and durability are concerns, again due to the operating temperature.
- They are suitable for integration with a gas turbine, offering very high efficiency combined cycles.
- They are further from commercialization, though a significant number of demonstrators are in operation.

The previous summary is, of course, a generalization. For example, a significant amount of work is ongoing to develop intermediate temperature SOFCs (IT-SOFCs), which operate at temperatures toward 600°C and which aim to overcome a number of the disadvantages of high-temperature fuel cells cited here. Similarly, work also is being carried out to develop low-temperature fuel cells that operate directly on methanol rather than clean hydrogen, eliminating the need for a fuel processor. Nonetheless, it is reasonable to distinguish between the low-temperature and high-temperature variants as being broadly best suited to transportation and stationary power applications, respectively, applications that place differing requirements on the fuel cell stack and system. Each of the main fuel cell types is discussed in more detail in the following sections.

2.1 Alkaline Fuel Cells (AFCs)

The alkaline fuel cell has a long history in the space program. It is still used in the space shuttle in an expensive guise, producing power for the onboard systems by combining the pure hydrogen and oxygen stored in the rocket-fuelling system.

The electrolyte is concentrated (85 wt%) potassium hydroxide (KOH) in AFCs operated at 250°C, or less concentrated (35 to 50 wt%) KOH for operation below 120°C. The electrolyte is retained in a porous matrix (typically asbestos), and electrocatalysts include nickel and noble metals. The main difficulties with this fuel cell type are (1) carbon monoxide, always found in hydrogen produced by reforming hydrocarbon or alcohol fuels (see Section III), is a poison to the precious metal electrocatalysts, and (2) carbon dioxide (in either fuel or air) will react with the KOH electrolyte to form potassium carbonate. As such, applications are essentially limited to those where either pure oxygen and hydrogen can be used.

2.2 Polymer Electrolyte Fuel Cells (PEMFCs)

PEMFCs have high-power density, rapid startup, and low-temperature operation (around 80 to 120°C), and so are ideal for use in applications such as transport and battery replacement. The electrolyte used is a proton conducting polymer. This is typically a perfluorinated polymer, though other hydrocarbon-based membranes are under development in an attempt to reduce cost or to enable

operation at temperatures approaching 200°C. The catalytically active layer sits adjacent to the membrane, supported on a PTFE treated carbon paper, which acts as current collector and gas diffusion layer. For operation on pure hydrogen, platinum is the most active catalyst, but alloys of platinum and ruthenium are used when higher levels of carbon monoxide are present (CO is a poison in all low-temperature fuel cells). Water management in the membrane and electrodes is critical for efficient performance, because the membrane must be hydrated, while avoiding flooding of the electrode pores with water.

The present cost of PEMFC systems is high. While mass-manufacturing techniques will help bring down those costs, further technical innovation is also needed. The potential for replacing diesel standby generators that are often noisy, expensive, and unreliable is engendering great interest. As many countries move toward liberalization of their energy systems, the opportunities for decentralized generation are also growing. Demonstrator plants of 250 kWe are also being produced and operated. These run on natural gas using a reformer, for the main part, and offer very low emissions but high efficiency as their benefit.

2.3 Phosphoric Acid Fuel Cells (PAFCs)

Phosphoric acid fuel cells have been very successful in fuel cell terms over the past 5 years as stationary cogeneration plants, with more than 220 commercial power plants delivered. The PAFC fleet has demonstrated over 95% + availability, and several units have passed 40,000 hours operation. PAFCs operate at 150 to 220°C, using a 100% phosphoric acid electrolyte retained in a silicon carbide matrix. Generally platinum electrocatalysts are used in both anode and cathode.

Typical applications lie in hospitals, where the waste heat can be used in laundry and other areas and where consistent and reliable power is required; in computer equipment power provision, where the absence of power surges and spikes from the fuel cell enables systems to be kept running; and in army facilities and leisure centers that have a suitable heat and power requirement. While the PAFC is by far the most commercial of the fuel cells to date, it may well be superseded in the longer term by PEMFC plants that can potentially be produced more cheaply and by SOFC or MCFC plants that have more useful heat output and that operate at higher efficiencies on hydrocarbon fuels such as natural gas.

2.4 Molten Carbonate Fuel Cells (MCFCs)

The electrolyte in the MCFC is usually a combination of alkali carbonates, retained a ceramic $LiAlO_2$ matrix. The temperature of operation is 600 to 700°C, where the alkali carbonates form a highly conducting molten salt, with carbonate ions providing the means for ionic conduction. The increased temperature of operation means that precious metal electrocatalysts are not needed, and generally nickel anodes and nickel oxide cathodes are used. A design constraint with the MCFC is the need for CO_2 recirculation, meaning that it is difficult to operate below the 100 kWe's scale, removing the market in micro combined heat and power (micro-CHP).

2.5 Solid Oxide Fuel Cells (SOFCs)

Solid oxide fuel cells operate at elevated temperatures, generally above 800°C for the all ceramic high-temperature variant and in the range 600 to 800°C for metal-ceramic intermediate-temperature solid oxide fuel cells. The electrolyte is a dense ceramic, usually yttria stabilized zirconia (YSZ), which is an oxide ion conductor at elevated temperatures. The cathode is typically a perovskite material such as strontium doped lanthanum manganite, often mixed with the YSZ in the form of a composite. The anode is a cermet of nickel and YSZ. The main difference between the high temperature SOFC and the IT-SOFC lies in (1) the thickness of the electrolyte, which tends toward 20 μm thick films for IT-SOFCs to reduce ionic resistance, and (2) the interconnect material, with stainless steel being used at the lower temperatures of the IT-SOFC, whereas more expensive high chrome alloys, or oxides such as lanthanum chromite, are needed at higher temperatures.

SOFCs lend themselves to applications in which their high-temperature heat can be used. This heat can be used in two basic ways: for heating processes such as those in industry or in homes or for integration with turbines in hybrid cycles for very high efficiency electricity production. Recent advances in microturbines have led to the concept of a combined power plant of 250 kWe with an efficiency approaching 70%. Specific applications in which SOFCs may be used are in decentralized electricity generation of 250 kWe to 30 MWe, industrial cogeneration of 1–30 MWe, or domestic applications of 1–5 kWe. Intermediate temperature SOFCs are also of interest for vehicle auxiliary power unit (APU) applications, operating on diesel or gasoline. Carbon

monoxide is not a poison for SOFCs, meaning that a wide range of fuels can be used, together with a simpler, and therefore cheaper, fuel processor. It is also possible to recuperate heat from the fuel cell within the fuel reformer, improving system efficiency when compared to low temperature fuel cells when operating on hydrocarbon fuels.

3. FUEL SELECTION

All fuel cells can run on hydrogen as a fuel. This is combined with oxygen, normally fed into the fuel cell as air, to form water, as shown in reaction (1). However, high-temperature fuel cells can also run on other fuels, especially hydrogen-rich gases, and some low-temperature systems are able to run on specific liquid fuels. The application of the fuel cell system often determines on which fuel it will run. Although fuel cells require comparatively clean fuels, they are also flexible in which ones they will accept. High-temperature fuel cells will operate directly on hydrogen-rich gases such as methane and are being successfully tested on forms of biogas. They, and their lower temperature cousins, will also accept any form of gas produced from liquid or solid fuels, provided that it contains a high percentage of hydrogen. This allows for great flexibility according to location and enables the efficient conversion of many indigenous or waste resources. This is discussed in more detail in the following for two applications, stationary power generation and transportation.

3.1 Stationary Power Generation

The common fuel for those commercial stationary systems that exist (mainly PAFC based) is natural gas, which is reformed by a separate steam reformer before the hydrogen is fed into the fuel cell stack. Demonstration PEMFC systems also use this method. In contrast, high-temperature fuel cells are able to operate directly on some gas streams, though they may need to be cleaned up by the removal of sulfur and higher hydrocarbons. The advantage is that high-temperature cells are able to reform the fuel (methane, for example) directly on the anode of the fuel cell because they have sufficient thermal energy and catalyst present to do so. Both steam reforming and partial oxidation reforming can be used. The former is preferred on the grounds of efficiency, though partial oxidation may be needed in an external reformer or for startup:

Steam reforming:

$$C_nH_m + nH_2O \Leftrightarrow nCO + (n + m/2)H_2 \qquad (7)$$

Partial oxidation:

$$C_nH_m + (n/2)O_2 \Leftrightarrow nCO + (m/2)H_2. \qquad (8)$$

Good thermal integration by incorporating the reformer within a high-temperature fuel cell stack offers significant efficiency gains over an external reformer. However, the internal reforming process can cause severe temperature gradients across the stack, and many designers prefer to use a separate catalyst bed, distributed within the fuel cell stack. These processes are called direct and indirect internal reforming, respectively. As well as the reformer, low temperature fuel cells also require a high- and low temperature shift reactor to carry out the water gas shift reaction of CO to CO_2:

$$CO + H_2O \Leftrightarrow CO_2 + H_2, \qquad (9)$$

together with selective oxidation, to reduce the CO content to parts per million levels.

Fuel cells will also run on reformate from other fuel sources, and there are successful demonstration PAFC systems using gas from landfill sites or sewage farms.

3.2 Transportation

The fuelling problem in transport is more complex than in stationary systems, because there are far more severe size, weight, cost, and performance constraints. Vehicles could be fuelled using pure hydrogen, stored onboard the vehicle. Indeed, this is how most demonstration buses are supplied, making them true zero-emission vehicles. However, there is rarely provision for hydrogen fuelling, so if fuel cells are to be used in cars there may have to be another solution.

Like stationary systems, transport fuel cells (usually PEMFC) can operate on a hydrogen-rich reformate. This is less efficient than using pure hydrogen but may be a pragmatic approach to the fuelling issue. Methanol has been suggested as a good compromise fuel. Although it also requires a supply infrastructure to be developed, it is a liquid and can be handled in a similar way to gasoline, though concerns have been raised regarding its toxicity level. It is also comparatively easy to process into hydrogen. Gasoline can also be reformed using a sequence of autothermal, partial oxidation, and water gas shift reformers, though the resulting reformate stream contains less hydrogen than from methanol and reduces the system performance somewhat more.

The fuelling question remains significant. If methanol turns out to be the fuel of choice, then not only will methanol reformers with sufficiently high performance and low cost have to be integrated into all fuel cell cars, but the problem of supplying methanol to the consumer will also have to be addressed. However, the consensus if opinion in this sector seems to be moving toward hydrogen as the fuel of choice. For this to become a reality, hydrogen storage systems need to be improved, though it is possible to use compressed hydrogen in cylinders designed for compressed natural gas. Equally important are the standards and regulatory decisions that have to be made to allow hydrogen vehicles on the road.

In some cases, fuels other than hydrogen can be used within the fuel cell without reforming into hydrogen. Significant effort, for example, is being applied to the development of a direct methanol fuel cell that can use methanol as a fuel directly without any preprocessing. While this decreases system complexity, it makes the fuel cell more difficult to design and could result in lower efficiency. However, this route is particularly attractive for microfuel cells, which aim to replace battery technology.

4. FUEL CELL APPLICATIONS

There are many areas in which fuel cells could potentially be used to replace conventional power equipment, discussed under the broad headings of stationary power generation, transport, and battery replacement.

4.1 Stationary Power Generation

Even within stationary applications there are a number of distinct divisions, though the most important ones have to do with temperature and the amount of waste heat that can be used. In general, plant sizes of several hundred kWe's (enough for a leisure center or small office block) down to 1 to 5 kWe (a single house or a portable power unit) are under development.

High-temperature systems can be used in more demanding applications where larger systems are required or additional heat is useful. Such systems are also more efficient when operating on fuels such as natural gas, as they enable internal reforming. While heat of 80°C or more can be used for space heating, hot water and possibly absorption chillers to allow for cooling, industrial steam raising, or gas turbine bottoming cycles require temperatures of at least 500°C. This not only allows for the potential of generating extra electrical power and thus improving the overall system efficiency to nearly 70%, but also the possibility of using cogenerated heat and increasing total energy efficiency to 90%. Either of these options brings down the cost per unit of energy even if the capital cost of the system is high, but can only be effectively based around a high-temperature fuel cell variant.

4.2 Transport

Transport applications tend to demand rapid startup and instant dynamic response from fuel cell systems, so a high-temperature fuel cell is unlikely to be competitive as the main engine in applications such as cars and buses. The prime candidate for these vehicle propulsion systems is the PEMFC, which exhibits both of the above characteristics while also having very high power density. This is important as it must also occupy a similar amount of space to an internal combustion engine. Of recent interest has been the development of auxiliary power units for vehicles, in which the fuel cell meets the onboard electric load of the vehicle. Both PEMFCs and ITSOFCs are under development for this application.

AFC systems have traditionally been used in space applications by NASA—in the *Gemini*, *Apollo*, and space shuttle programs—but are also being investigated for certain transport applications, mainly in vehicles with limited duty cycles such as delivery vehicles and fork lifts.

Of course, transport is not confined to the car and aerospace markets—locomotives, ships, scooters, and a whole host of other applications offer potential for a variety of fuel cell systems. For ships and trains, where the application is almost akin to having a stationary power plant running all the time, startup and system dynamics are less important than noise, emissions, fuel consumption, and vibration. Serious investigations are under way as to the benefits of installing SOFCs, for example, on ships to remove the marine diesel—traditionally a source of heavy pollution, very high noise levels, and damaging vibration. However, in these cases the preferred fuel would be heavy fuel oil, one of the most difficult to process for a fuel cell application.

PEMFC systems have also been commissioned for a number of the world's navies—Ballard and Siemens have each been active in their respective countries putting PEMFCs into submarines.

4.3 Battery Replacement

An area in which it is possible that fuel cells may break through to commercialization in the very near future is in the replacement of conventional batteries. Battery power for laptop computers, mobile phones, and many other devices is expensive and often inconvenient if recharging is required every few hours. A small fuel cell with an equally small fuel source could potentially operate for longer than a battery, but with refueling only taking a few minutes instead of many hours. Batteries cost much more for the amount of power they can supply than almost any other application, and this gives the fuel cell a good chance of entering the market, although it is still expensive. The ideal fuel cell for these applications is the PEMFC, which not only has the high power density required for miniaturization, but also has the least challenging electrolyte management issues of the low-temperature fuel cells.

4.4 The Fuel Cell Industry

The recent upsurge of interest in fuel cell systems has led to rapid growth in industries developing fuel cell technology around the world. As well as fuel cell technology developers, there are an even larger number of component suppliers, which are not dedicated to the fuel cell industry but have a significant role to play, for example, in the supply of compressors, pumps, valves, and so forth. Indeed, it is estimated that typically only around one-third of the cost of a fuel cell system is the actual fuel cell stack, with around one-third being balance of plant, and one-third integration, installation, and commissioning costs. Cost issues are discussed in more detail in the following section.

5. FUEL CELL COSTS

The true costs associated with fuel cells are not yet clear—either from a capital or operating perspective. Present costs are well above conventional technologies in most areas, though this depends slightly on the type of fuel cell and the market area in which it may play a part.

The economics of fuel cell systems are also different in different market niches. The fuel cell has the potential to usurp many traditional technologies in a variety of markets, from very small batteries and sensors to multimegawatt power plants. Each system has very different characteristics and will accept very different prices. For example, a laptop battery substitute that could run for 20 h instead of 2 h could command a high price, especially if it could be refueled in seconds from a canister rather than recharged over several hours. At the other end of the scale, the potential for building modular power plants in which maintenance can be carried out on each module without shutting down the system is worth a significant amount of money to the owner.

Traditional economic calculations have suggested that the fuel cell system for large-scale power generation needs to be less then $1500/kWe before it will be competitive, while the fuel cell system for automobiles and mass production must be competitive with the internal combustion engine at $50/kWe or below. That said, it must be remembered other drivers exist for the technology, including environmental benefits, and an issue of increasing strategic importance for many counties, namely a reduced reliance on oil. Some fuel cell systems will sell themselves at $10,000/kWe, however, if they can be installed where there is currently no available technology capable of meeting requirements.

However, it is clear that all fuel cell costs at present—and these are estimated at anything between 500 and 10,000 dollars per kilowatt (a mature technology such as a gas turbine costs about $400/kWe)—are high because they are representative of an emerging technology. Once in mass production, recent estimates predict costs of $40 to $300/kWe for PEMFCs for transport applications, depending on assumptions regarding technology development. It is clear that both further technical innovation as well as mass manufacture will be needed to compete solely on a cost basis with the internal combustion engine.

High-temperature systems tend to be more expensive as they require significant investment in associated balance of plant, but should still be able to be manufactured for close to $600 per kilowatt, not far from the current price for a gas turbine or gas engine.

6. ENVIRONMENTAL BENEFITS

One of the areas in which fuel cells should demonstrate significant advantages is in their potential for minimal environmental impact. As well as offering a high theoretical efficiency, all fuel cells emit low levels of pollutants such as the oxides of sulfur (SO_x) and nitrogen (NO_x). SO_x emissions are

low because low sulfur fuels such as methanol or desulfurized natural gas are used. NO_x emissions are low because even the high-temperature fuel cells such as the molten carbonate fuel cell and the solid oxide fuel cell operate at temperatures well below those needed to form NO_x by the thermal combination of nitrogen and oxygen. The formation of NO_x at high temperatures is a problem for those trying to push up the efficiency of heat engines by increasing their maximum operating temperature. Fuel cell systems are already exempt from permitting requirements in some U.S. states, including New York, meaning that they can bypass one of the planning stages (in itself a useful bonus in reduced cost and time).

The high efficiency of the electrochemical process is an added advantage, since less fuel is required to produce a given amount of power than would otherwise be needed. This means that less fuel is used and, of increasing importance, that less CO_2 is released. Estimates suggest that a fuel cell power plant running on a traditional cycle could produce 20 to 30% less CO_2 than traditional power plants, and that vehicles powered by fuel cells would provide similar benefits.

In the case of vehicles, it is particularly important to examine the fuel on which they run. While fuel cell vehicles powered on gasoline reformer technology will have little or no benefit in reduced greenhouse gas emissions, methanol-powered cars may produce 25% less CO_2. Using hydrogen produced from natural gas will result in cuts of up to 40%, while hydrogen from renewably generated electricity, such as wind or solar, emits no greenhouse gas at any stage of the process.

In the ultimate renewable/zero-emission scenario, fuel cells can be run on pure hydrogen produced from renewable energy, using electrolysis of water. This ensures that there are no polluting emissions at any stage of the fuelling process (though there will inevitably be some from the manufacture and construction of the plant). This scenario is applicable both to stationary energy and to transport, and would enable countries to reduce their dependence on imported energy in various forms, in addition to being very clean. Hydrogen can also be produced from a whole variety of primary resources, including biomass and fossil fuels.

Glossary

autothermal A characteristic of fuel processor design that combines exothermic and endothermic reactions so that the resulting system is close to thermally neutral.

criteria air pollutant An airborne substance regulated according to public health-based standards; key criteria pollutants pertinent to motor vehicles include carbon monoxide, various toxic substances, ozone and fine particulate matter, and their precursors including reactive hydrocarbons and nitrogen oxides.

electrolyte A substance that dissociates into ions, so that it can conduct electricity by means of ion transport (as opposed to electron conduction as in a metallic conductor, for example).

energy density Energy content of a fuel or energy storage device per unit mass.

fuel processor A device that converts a fuel into hydrogen-rich gas and removes impurities so that the resulting gas can supply the anode of a fuel cell; also termed a *reformer.*

platform The primary load-bearing structural assembly that determines the basic size of a motor vehicle and supports its powertrain, body panels, and suspension components.

powertrain The interconnected set of components that drives the wheels to propel a motor vehicle, commonly including engine, transmission, driveshaft and differential, or transaxles.

POX Partial oxidation, a combustion process in which the reactants are only partially oxidized, allowing hydrogen to be dissociated from a fuel without being completely consumed.

PrOx Preferential oxidation, a catalyzed chemical reaction in which species other than hydrogen are oxidized so as to yield a product stream containing maximum amounts of hydrogen with minimum amounts of undesirable constituents (such as CO).

reformate The gaseous output stream from a reformer or fuel processor, containing hydrogen for supplying a fuel cell anode.

reformer A device that converts a fuel into hydrogen-rich gas and removes impurities so that the resulting gas can supply the anode of a fuel cell; also termed a *fuel processor.*

regenerative braking The process of slowing a vehicle by drawing kinetic energy into a generator (typically an electric motor operating "in reverse"), thereby exerting a rotational drag on the wheels.

specific energy Energy content of a fuel or energy storage device per unit volume.

stack A set of individual fuel cells arranged next to each other and connected in series.

ultracapacitor An electrochemical device that stores electricity through capacitive charging and is capable of providing high power in a compact size and mass.

1. INTRODUCTION

A fuel cell is an electrochemical device that directly converts a fuel to electricity by means of reactions on the surfaces of electrodes and transport of ions through an electrolyte. A fuel cell can be thought of as a chemical battery whose reactants are fed from external sources rather than packaged as part of the battery. A key feature of a fuel cell is transformation of the chemical potential energy of a fuel directly into electricity, a high-value form of energy that can be put to many uses. The fuel cell's direct energy conversion process occurs without an intermediate step of heat generation, as involved in combustion engines. Fuel cells designed to operate at relatively low temperatures, as suitable for automotive propul-

sion, need catalysts such as platinum that enable reaction rates sufficient to provide adequate power.

A fuel cell engine couples a fuel cell to an electric motor to provide mechanical power. A fuel cell vehicle is a motor vehicle having a fuel cell engine as its prime mover. Thus, a fuel cell vehicle has the advantages of electrical propulsion while retaining the advantages of carrying its own chemical fuel. Electrical propulsion is quiet and offers high efficiency, through avoidance of many mechanical frictional losses. Another advantage is its controllability, through fully programmable "tuning" of the vehicle's driving characteristics for responsiveness and smoothness. An electric drive system can further increase a vehicle's efficiency by recovering energy during braking, energy that otherwise is lost as low-grade heat in friction brakes. Advantages of an onboard chemical fuel include the relatively low mass occupied by the stored fuel, good driving range between refueling, and ease of refueling. Such advantages are related to a chemical fuel's energy density, or amount of energy per unit mass. Liquid fuels (such as hydrocarbons and alcohols) have higher energy densities than gaseous fuels (such as natural gas and hydrogen), and chemical fuels typically have higher energy densities than rechargeable batteries.

In addition to the fuel cell itself, a fuel cell vehicle requires a variety of additional components. Some are the auxiliary parts needed for a complete fuel cell power system. Others include fuel storage and processing systems, an electric motor, battery, associated electronics, and control systems. The major functional components are illustrated schematically in Fig. 1. The stack consists of a series of individual fuel cells, each consisting of electrodes, electrolyte, plates with channels for supplying the reactants and removing the exhaust products, and connections. Auxiliaries include blowers, pumps, heat exchangers, and other items needed to regulate the heat and mass flows from the stack. Fuel is supplied from the onboard tank, holding a liquid fuel or compressed hydrogen. Some designs entail a fuel processor, or reformer, to convert the fuel to a hydrogen-rich gas for feeding the fuel cell; that process may create pollutants requiring emissions controls for cleanup. The stack produces direct current that is regulated by a power electronics package, which in turn supplies electricity to one or more electric traction motors for driving the vehicle. The motor may recapture braking energy that is fed back through the power electronics to recharge the battery. At minimum, a fuel cell vehicle has a battery for startup; a more powerful battery or other high-power storage device is used to provide supplemental traction power in a hybrid fuel cell vehicle. Thus, a fuel cell vehicle is a complex machine, requiring numerous, high-technology components that must be integrated together and manufactured at the low cost and high reliability expected of mass-produced automobiles.

2. FACTORS SHAPING AUTOMOBILE PROPULSION TECHNOLOGY

Fuel cell vehicles are being developed because they promise to meet the requirements expected of automobiles in a market increasingly constrained by environmental and resource limitations. Air pollution and oil dependence have been persistent challenges for vehicles powered by petroleum fuels (gasoline and diesel). Global warming presents a new challenge in the need to limit carbon dioxide (CO_2) emissions from fossil fuel combustion. It is unclear whether automobiles powered by combustion engines running

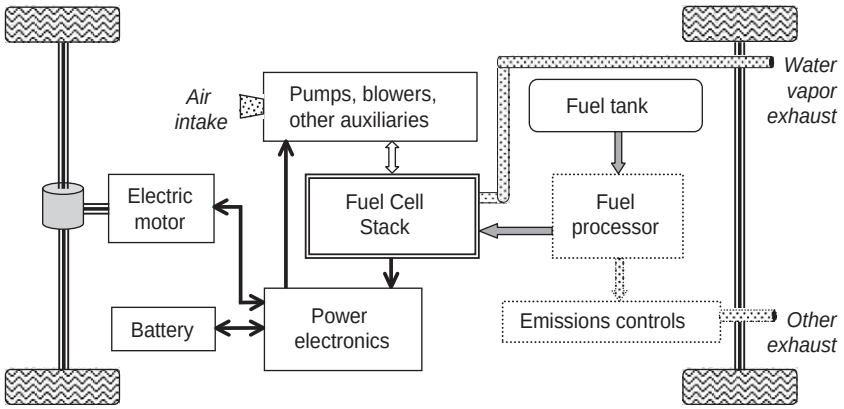

FIGURE 1 Major components of a fuel cell vehicle.

on conventional fossil-derived fuels will be able to meet these challenges. Moreover, electric propulsion has its attractive features of quiet, precisely controllable operation and high efficiency for both powertrain and accessories. The growing number of electrical amenities in automobiles further raises the value of a propulsion system that provides ample electric power capacity. In short, eliminating the internal combustion engine has great appeal and motivates the development of fuel cell vehicles.

Fuel cell vehicles are not the only option for addressing future automotive expectations. Improvements to internal-combustion engines can partially address the challenges, and further refinements can provide additional progress. Hybrid combustion-electric vehicles extend the efficiency horizon of petroleum-fueled designs while boosting onboard electric power capacity. Advanced strategies for controlling criteria air pollutants generated by gasoline vehicles (including sophisticated onboard combustion control and cleanup systems as well as reformulated fuels) make air quality concerns less a driver for technology change than the global warming issue, which presents a more fundamental challenge. Effective control of criteria air pollution is a greater hurdle for diesel engines, which otherwise have an energy-efficiency advantage. Conventional alternative fuels (such as alcohols, ethers, plant oils, and natural gas) also offer partial solutions, but their benefits have not been great enough to overcome the high costs of transition. Using low-CO_2 producing fuels in hybrid vehicles may enhance the prospects for some alternatives. Rechargeable battery electric vehicles have cost and range limitations that inhibit extensive use with existing transportation infrastructure. What makes fuel cell vehicles attractive is their promise for affordably addressing the multiple design requirements likely to be faced by future automobile propulsion systems.

3. FUEL CELL TECHNOLOGIES

Fuel cells are typically classified according to type of electrolyte. While many varieties of fuel cells have been demonstrated in the laboratory, five major types are seeing development for commercial applications:

- Polymer electrolyte membrane (PEM) cells use a plastic (polymer) membrane that becomes electrically conducting when hydrated (saturated with water); they operate near 100°C.
- Alkaline fuel cells use a caustic electrolyte such as potassium hydroxide (KOH); they also operate near 100°C.
- Phosphoric acid fuel cells use that acid as the electrolyte and operate around 200°C.
- Molten carbonate fuel cells use electrolytic mixtures of metal (Li, Na, K) carbonates and operate at 600°C or higher; they are highly efficient and can reform a fuel within the cell.
- Solid oxide fuel cells use zirconium oxide as a solid-state electrolyte and operate at 600°C or higher, and also have advantages of high efficiency and in-cell fuel reforming.

As fuel cell technologies mature, they may see a variety of uses, including battery replacement for portable electronics, large-scale electric power generation, distributed generation, combined heat and power, and transportation. Both PEM and alkaline fuel cells have been used on spacecraft. The first fuel cell vehicle was a farm tractor demonstrated in 1959 using an alkaline cell. Phosphoric acid fuel cells are in limited commercial use for specialized power generation but are too expensive and difficult to manage for vehicle use. Molten carbonate and solid oxide fuel cell technologies are being developed for stationary electric power generation. The need to bring the relatively large quantities of these electrolytes up to a high operating temperature makes these fuel cells unsuitable as a prime mover for motor vehicles, although small solid oxide fuel cells are being investigated as auxiliary power units.

The PEM fuel cell is the focus of automotive development efforts because of its low operating temperature and potential for low-cost mass production. Only PEM cells running on hydrogen have been developed enough to power practical motor vehicles. However, PEM cells that run on methanol are being investigated. It is also premature to dismiss alkaline fuel cells as a long-run option. Figure 2 illustrates the functional elements of a hydrogen PEM fuel cell. Fuel (hydrogen or a hydrogen-rich gaseous mixture) is supplied to the anode (negative electrode) where it diffuses to a catalyst layer. There it dissociates into electrons, supplied to the external electrical load, and hydrogen ions (protons), which are conducted across the polymer electrolyte membrane (also known as a proton exchange membrane) to the cathode. At the cathode, electrons from the returning current and oxygen from the air complete the reaction at a second catalyst layer, forming water vapor that is exhausted from the fuel cell.

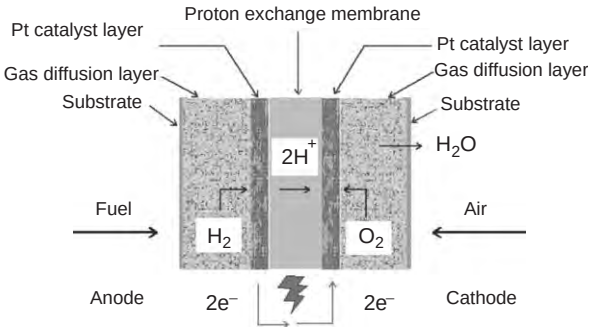

FIGURE 2 Schematic diagram of a polymer electrolyte membrane (PEM) fuel cell. Courtesy of Johnson Matthey Fuel Cells Today Web site (www.fuelcelltoday.com), with permission.

The ideal, open-circuit voltage of a hydrogen-air cell at typical operating conditions is approximately 1.2 volts. Under practical load conditions, a single hydrogen PEM cell might produce 0.7 volts. The voltage produced in part determines the cell's energy efficiency; at 0.7 volts, a hydrogen PEM cell is roughly 60% efficient in converting the chemical potential energy of hydrogen into electricity. Research and development on fuel cell design seeks to obtain a maximum amount of current from a given cell surface area while maintaining voltage, which determines the efficient power output of the fuel cell. A stack of cells connected in series is used to produce the power levels needed for vehicle propulsion.

4. VEHICULAR FUEL CELL SYSTEMS

The components of a fuel cell vehicle, as shown in Fig. 1, draw on a variety of technologies, not all of which are at the same state of development. The particular requirements for fuel cell vehicle systems depend on the configuration. Three categories of components are common to all fuel cell vehicle systems: the fuel cell stack itself, auxiliary equipment that supports the operation of the stack, and the electric drive system. Fuel storage and processing components depend on the choice of onboard fuel; these systems are discussed in Section V of this article.

4.1 Fuel Cell Stacks

It is progress in the development of hydrogen-air PEM stacks that has made fuel cells a contender for powering automobiles of the future. For many years, the energy and power densities of PEM cells were so low and the amount of platinum catalyst required was so high that most commercial applications seemed out of the question. For example, the platinum requirements for the PEM cells used on Gemini space missions of the 1960s were on the order of 100 g/kW, for a cost factor of $1500/kW (assuming a platinum cost of $15/g). A typical automotive fuel cell stack would be 80 kW, implying a cost of $120,000 for the catalyst material alone. By comparison, current automotive catalytic converters require roughly 0.05 g/kW of platinum-group metals, costing on the order of $100 for an average car. More stringent emissions standards are pushing precious metal requirements higher, so that future gasoline vehicles may need 0.1 to 0.2 g/kW of platinum group metals.

During the 1980s, research on electrode catalyst deposition led to large reductions in the amount of platinum needed. By the early 1990s, PEM fuel cell platinum requirements had dropped below 10 g/kW; as of 2002, state-of-the art designs needed less than 2 g/kW, with further reductions still in sight. Such breakthroughs have motivated engineering development work on the other critical elements of a fuel cell stack, such as the membrane, electrode assemblies, and flow fields that supply hydrogen and air and exhaust the reaction products from the cells. Platinum needs remain a cost challenge for PEM fuel cells, however, and ongoing research targets another order-of-magnitude reduction in platinum catalyst requirements as needed to place the technology in the range of affordability and precious metal availability that would make widespread use feasible.

Fuel cell stacks can be designed as compact modules, with connections for their electrical output as well as for feeding fuel and air into the stack and removing exhaust, cooling the stack, and monitoring its operating state. Since PEM cell stacks are built in modular form, a great deal of flexibility will be available to designers in terms of how stacks are placed and arranged in the vehicle. Using current designs, a typical fuel cell stack for automotive applications, delivering 80 kW of peak power, occupies a volume of about 80 liters and weighs roughly 90 kg. However, even more compact designs are likely to evolve as experience is gained. Stacks could be built in modules of specified sizes, so that multiple modules would be arranged and connected to supply the differing power requirements of different sized vehicles while permitting enhanced economies of scale in mass production. A remaining engineering challenge for fuel cells is achieving sufficient membrane durability. Other developmental issues include

freeze protection and further cost reduction for electrodes, membranes, and separator plates.

The latter serve the multiple functions of separating adjoining cells, providing the flow fields that transport fuel-air reactants and exhaust products to and from the cells, and removing waste heat. Early PEM cells have used graphite plates, but these are costly to produce. Coated metallic and composite materials are being developed for separator plates, with goals of meeting low-cost mass production targets while achieving performance and durability requirements in the highly reactive fuel cell environment.

4.2 Fuel Cell Engine Auxiliaries

Numerous other parts are needed for a complete fuel cell engine suitable for motor vehicles. These auxiliary components include many familiar pieces of equipment, such as blowers, pumps, heat exchangers, sensors, and controls. However, fuel cells have specialized performance requirements, so substantial engineering effort is needed to develop auxiliary systems suitable for fuel cell vehicles.

A blower or compressor is needed to supply air to a fuel cell stack, and air compression represents the largest parasitic load in the system. The pressure of the air supplied to the cells influences the stack efficiency, but a trade-off is involved. The higher output that comes with higher pressure entails an energy penalty for running the compressor. Designers are experimenting with various pressure regimes, and although pressure may vary depending on operating conditions, most designs operate at no more than three atmospheres. Compression power requirements approach 10% of stack output at peak power, while other loads (pumps, cooling, controls, etc.) are generally in the 1 to 2% range. Optimized designs can hold the average air compression penalty to 3 to 5% of stack output. Energy in the fuel cell exhaust stream is typically captured in a turbine expander to help power the compressor.

Another critical auxiliary component is an integrated system for moisture control and thermal management. This system maintains membrane moisture, exhausts water vapor, removes heat from the stack, and manages the flow of heat among various components for optimum efficiency. Fuel cell membranes need to be precisely hydrated to function properly. Too much water accumulation blocks the reactions, but the membrane can fail or degrade if it becomes too dry. Fuel cells need to start in very cold weather; motor vehicles are typically designed to be able to start at −40°C. Therefore, special "anti-freeze" hydrating solutions are being developed that do not poison the stack; mechanisms are needed to address the water vapor that is present in the exhaust stream and other fuel cell subsystems as well as quickly bring a stack up to operating temperature.

Heat removal presents its own special challenges, since PEM cells operate at low temperatures and so need to efficiently reject low-trade heat. Ambient pressure designs operate near 80°C. This level is much lower than the over 2000°C flame temperature and roughly 500°C exhaust gas temperature of a gasoline combustion engine. Pressurized PEM fuel cells use only relatively low pressures, so temperatures are under 200°C in any case, offering but a small difference to ambient temperature for driving heat transfer. Even at its high, roughly 50% efficiency, a 80 kW stack must dissipate 5 to 10 kW of waste heat under average loads and as much as 40 kW without risking membrane degradation under peak loads. Some of this heat is carried away in the exhaust stream, but much must still be handled by directly cooling the stack and transferring heat to the ambient air. Thus, sizable heat exchangers and fans are needed.

4.3 Electric Drive Systems

The primary electric drivetrain components for fuel cell vehicles are the same as those for any electric vehicle: traction motors, power electronics, and batteries. Electric drive components require their own sets of auxiliaries and management systems, for control and cooling of the equipment. A fuel cell vehicle may have a hybrid powertrain, in which the fuel cell is sized at less than the vehicle's peak power requirement and additional power is supplied from an electricity storage device, such as a high-power battery or ultracapacitor. Although a hybrid powertrain is more complex than one using a fuel cell alone, it offers advantages of regenerative braking, which helps vehicle efficiency, and the availability of greater power for startup and auxiliary loads. Hybridization also would have an economic advantage if the cost of peak power from the electricity storage device is less than that of meeting the peak power requirement with a fuel cell alone.

The electric drive system for a fuel cell vehicle is comparable to that for a battery electric vehicle or series hybrid, with the traction motor and power electronics scaled to meet the full power needs of the vehicle. This situation contrasts with electric drive system for a parallel hybrid as used for contemporary models (such as the Toyota Prius and Honda Civic Hybrid), in which the electric drive components

supply only a portion of the tractive power with the rest mechanically provided from the combustion engine. The specific components used in an fuel cell vehicle, such as type of motor, depend on the particular electric drive system design, which is itself a new and evolving area of engineering.

Although more developed than fuel cells themselves, electric drive technologies are not mature by automotive standards. As of 2002, hybrid electric vehicle production volumes were still an order of magnitude lower than those of typical mainstream vehicle models, and costs remain high. For fuel cell vehicles, electric drive system costs compound those of the core fuel cell system and its fuel storage or processing components. The cost of electric drive components is expected to fall substantially, with some estimates as low as $30/kW (retail-equivalent, excluding batteries). Time and production experience will be needed for costs to fall to such levels, which are likely to be essential for widespread commercialization of any type of electric vehicle, including fuel cell vehicles. As experience is gained and research progresses, the types of electric drive components used in fuel cell vehicles will also evolve. For example, instead of traditional electric traction motors, compact wheel motors might be used as suggested by GM's Autonomy fuel cell vehicle concept.

5. FUEL SUPPLY, STORAGE, AND PROCESSING

Depending on the fuel they carry, fuel cell vehicles entail various requirements for fuel supply (including production and distribution), fuel storage on the vehicle, and on-vehicle fuel processing that might be needed.

A fuel cell vehicle operated on gasoline may require minimal changes in existing fuel supply infrastructure, but faces special processing requirements onboard the vehicle. A fuel cell vehicle operated directly on hydrogen, on the other hand, does not require a fuel processor, but needs a new fuel supply infrastructure and workable technology for onboard fuel storage. Methanol is also being considered for fuel cell vehicles, since it has the convenience of liquid while being easier to process into hydrogen than gasoline. Table I summarizes the issues and technical status of these three key fuel options for fuel cell vehicles. Ethanol has processing requirements similar to those for gasoline and a long-term potential for production from renewable resources. Natural gas has processing requirements similar to those for methanol and is already widely distributed, but faces the challenges associated with gaseous storage.

The ultimate fuel supply, storage, and processing configuration of fuel cell vehicles will be shaped by how well various fuel-related technologies progress through research and development. The configuration will also be influenced by the broader changes in transportation infrastructure (such as increasing use of intelligent systems) that will occur over the time frame needed to bring these technologies to states of workability and affordability that would enable widespread commercialization.

5.1 Fuel Supply

The auto and oil industries are among the world's largest, and the extensive infrastructure that supplies gasoline and diesel motor fuel is built of years of investment in both equipment and know-how. If practical ways can be found to power fuel cells with

TABLE I

Fuel Options for Fuel Cell Vehicles

	Hydrogen	Methanol	Gasoline
Fuel economy gain	High	Modest	Small/nil
CO_2 reduction (near-term)[a]	Modest	Low	Small/nil
Emissions control need	Zero	Low	Low
Fuel supply	Needs major development	Very limited	Already exists
On-board storage	Needs major development	Readily feasible	Already exists
Fuel processing	Not needed	Under development	Under development
Added car cost/weight	Modest	High	High

[a] Near-term CO_2 reduction assumes hydrogen and methanol derived from natural gas; the long-term potential is greater for all options as renewable resources or carbon sequestration systems for fossil fuels become available.

existing hydrocarbon fuels, or variants of them, adoption of fuel cell vehicles could proceed more quickly than if it were constrained by the rate at which infrastructure can be changed. On the other hand, fuel cells powered directly by hydrogen are already technically workable. Thus, another commercialization path could be niche vehicles that can accept the range restrictions of compressed hydrogen storage using new infrastructure that is constructed incrementally.

Gasoline-like hydrocarbon fuels for powering fuel cell vehicles would have properties tailored to the new technology, just as today's motor fuels are formulated for optimum performance in combustion engines. Impurities such as sulfur would have to be essentially eliminated; this change is already under way as sulfur levels in conventional fuels are being lowered for pollution control reasons. The mix of particular hydrocarbons would also change. But the key characteristics of being an energy-dense, convenient-to-distribute liquid would remain, and that is the attraction. Hydrocarbon fuel supply is also quite energy efficient. The "well-to-tank" efficiency—that is, the amount of fuel energy delivered to a vehicle per unit of primary energy—is typically over 80% for gasoline and over 90% for diesel.

The major problems for use of hydrocarbons in fuel cell vehicles are (1) the fact that hydrocarbons still carry carbon to the vehicle and (2) the difficulties of fuel processing (discussed later). All known hydrocarbon fuel technologies for motor vehicles involve releasing the carbon as CO_2. Practical ways to "scrub" or capture carbon from vehicles do not exist. Thus, even with the fuel cell vehicle's potentially higher efficiency and the possibility of offsets through carbon sequestration, there will be limits to the effectiveness of fossil-derived fuels for addressing global warming. Thus, hydrocarbons supplied by an evolved version of the current motor fuel supply infrastructure are viewed as a possible transitional pathway rather than the ultimate fuel. Hydrocarbons derived from renewable resources could offer a zero or very low net release of CO_2 to the atmosphere (and of course, such fuels could also be used in combustion engine vehicles).

Hydrogen is the ideal fuel for PEM cells and any other low-temperature fuel cell technology. Currently and for the near-term, natural gas is the most economical source of hydrogen. It can be produced by steam reforming at central plants and then distributed to filling stations, or natural gas could be locally reformed at filling stations to provide the hydrogen. The former approach is how most hydrogen is now made. The primary energy efficiency for supplying compressed hydrogen in this manner is typically 70% (that is, the energy content of the compressed hydrogen at its point of distribution is about 70% of the energy content of the natural gas at the well). Local reforming would take advantage of existing natural gas distribution infrastructure and is generally viewed as the most economical way to begin building a hydrogen fuel distribution system. Hydrogen can also be made by reacting coal with water; this approach holds economic promise because coal is so plentiful. Research is under way to find ways to sequester the resulting CO_2 and such a system could enable the use of coal to generate hydrogen for a variety of applications, including vehicles, with lower CO_2 emissions than existing direct use of fossil fuels.

The ultimate attraction of hydrogen is that it is a carbon-free energy carrier which, if produced from renewable resources, offers the potential of an energy system with zero greenhouse gas emissions. If vehicular hydrogen supply systems were initially developed using natural gas, for example, they ultimately might be converted to hydrogen supplied from renewable resources.

Other fuel options have their own supply characteristics, which differ in the near and long term. Methanol is now made from natural gas and that would be the most economical source for the foreseeable future. In the long run it could be produced from coal or biomass, with the latter resource option offering very low greenhouse gas emissions. But methanol also has toxicity issues that are difficult to manage. Ethanol is now made from sugar or starch-bearing crops in an energy- and resource-intensive agricultural system, making it costly and of dubious net environmental benefit even though it is in some sense renewable. However, ethanol can be made through efficient, enzymatic conversion of cellulose from organic wastes and specialized crops, thereby offering near-zero greenhouse gas emissions. Alcohols still carry carbon to the vehicle, so achieving their potential for zero or very low greenhouse gas emissions would require both truly renewable, zero-fossil-fuel input energy crops plus essentially zero-emissions processing, refining, and distribution systems.

Finally, from a long-term fuel supply perspective, it cannot be discounted that the most effective way to use fuel cells to power vehicles might be indirectly, at least for many vehicles in urban and near-urban areas. In this case, the fuel cells are kept off the vehicle, which would be powered by advanced

batteries charged through an intelligent, electrified infrastructure to which electricity is supplied by stationary fuel cells. This approach would represent an even closer coupling of motor vehicles to a power grid than other options for grid-connected vehicles, including vehicles with onboard fuel cells, that could supply power to the grid but would still need a separate fuel infrastructure.

5.2 Fuel Storage

Fuel storage onboard an automobile is straightforward and well established for liquids, but presents cost, range, and packaging challenges for any gaseous fuel. The challenge is particularly acute for hydrogen, which is the least dense of substances. Thus, a fundamental breakthrough in onboard hydrogen storage technology is needed for widespread use of direct hydrogen fuel cell vehicles to become feasible. Even if fuel cells and their auxiliary systems achieve low costs, and hydrogen supply and infrastructure systems become competitive, all known options for storing hydrogen have limitations that would inhibit commercialization of fuel cell vehicles for personal automobiles as used today.

Hydrogen is the least dense of all fuels in spite of its high specific energy of 142 MJ/kg, compared to 46 MJ/kg for gasoline. All vehicular storage options for hydrogen present difficulties, rooted in the specific energy and energy density values shown in Table II. Options include compressed gas, liquid hydrogen and metal or chemical hydrides (which involve chemical reactions to store and release the hydrogen). Devices that react iron oxide with water to produce hydrogen have been explored. Adsorption in carbon nanotubes and high-pressure confinement in glass microspheres have been proposed but remain largely speculative.

Compressed gas storage is well known through experience with natural gas vehicles; most fuel cell demonstration vehicles use compressed hydrogen. Problems with gaseous storage include onboard space requirements and costs inherently higher than those of liquid fuel tanks. Packaging challenges exist even for natural gas, which has an energy density nearly four times higher than that of hydrogen. Development is under way on very-high pressure tanks made of carbon-fiber composites that offer greater shape flexibility than metal cylinders. Automakers have successfully tested tanks rated at 5000 psi, which is higher than the 3000 psi range now typical for compressed gas storage, and designs in the 10,000 psi range are being developed.

TABLE II

Onboard Fuel Storage System Characteristics

Fuel storage option	Specific energy (MJ/kg)	Energy density (MJ/L)
Gasoline (liquid in steel tank)	36	32
Methanol (liquid in steel tank)	18	18
Hydrogen		
Compressed gas (5000 psi/340 atm)	7	2
Cryogenic liquid	15	5
Metal hydride	3	12
Organic hydride	9	7
Sponge iron	5	6
Nanotubes	50	100

Note: Comparisons are made on a higher heating value (HHV) basis: 46 MJ/kg for gasoline, 23 MJ/kg for methanol, and 142 MJ/kg for hydrogen, counting the mass and size of fuel system components but not counting powertrain energy conversion losses. Values for hydride and sponge iron options are fairly uncertain but representative of what is expected through research; the nanotube option is still considered speculative.

Storing hydrogen as a liquid requires very cold, cryogenic temperatures. At atmospheric pressure, hydrogen liquefies at 20 K (−253°C or −423°F); the saturation temperature rises by only 10 K going to 10 atmospheres. Special systems are needed to maintain such low temperatures on a vehicle and safety manage the hydrogen boil-off that occurs while the vehicle is not in use. Liquid hydrogen storage systems have been demonstrated in compact packages suitable for vehicles, along with automated refueling systems that approach gasoline in terms of speed and convenience. A serious handicap is high energy cost of liquefying hydrogen, amounting to roughly one-third of the fuel's energy content. Because it involves unrecoverable low-grade heat rejection, this energy loss is fundamental and degrades the environmental benefits and economics no matter what resource is used for hydrogen production. Further losses occur during distribution, refueling, and storage (due to boil-off), so that the net supply efficiency of liquid hydrogen may be no more than 50%.

Hydrides of various forms are being investigated for storing hydrogen; they are relatively compact but have a high weight penalty. Metal hydrides store roughly 7% hydrogen by weight, not counting

containment, but not all of that is recoverable in practical storage systems (by comparison, gasoline is about 16% hydrogen by weight). Energy penalties are involved in charging (filling) and discharging hydride systems. Some metallic systems (such as magnesium alloys) are costly but compact; other materials (such as sodium borohydride) are less costly but face other technical challenges. Another system under investigation is lithium hydride in an organic mineral oil slurry, and other organo-metallic hydrides may hold promise, although the charging and discharging reactions involve elevated temperatures and catalysts to effectively release the hydrogen. Some systems would have to be refilled by simultaneous pumping of fresh, "charged" hydride into the vehicle while pumping out the hydrogen-depleted chemical for reprocessing. In general, hydride systems are still in early stages of development and have not yet been shown to be workable for automobiles.

5.3 Fuel Processing

The challenges of supplying hydrogen and storing it onboard a vehicle and have prompted efforts to develop onboard fuel processors (reformers) for converting liquid hydrocarbon or alcohol fuels into a hydrogen-rich anode feed gas. In general, such fuel processing involves two major steps: (1) dissociating the hydrogen from the fuel and (2) purifying the resulting gaseous stream to have maximum hydrogen levels and minimal constituents such as CO that can poison the stack. Each step involves multiple reactions and processes and a preliminary cleanup stage is needed if sulfur or other detrimental substances are present in the fuel.

Methanol can be processed by steam reforming, a catalytic process that is endothermic (requiring heat input). Steam reforming is a standard process for large-scale production of hydrogen from natural gas. Low-cost catalysts, such as copper/zinc oxides on alumina for methanol and nickel on alumina for natural gas, can be used for steam reforming. Two reactions are involved: (1) the fuel and water are converted to a synthesis gas containing CO and H_2, and (2) a water-gas shift reaction converts H_2O plus CO into CO_2 plus additional H_2. The resulting reformate is rich in H_2 and low in CO. Since air input is not used in steam reforming, the reformate is not diluted with nitrogen. But because it is not possible to run a complete water-gas shift reaction, further CO cleanup is needed using a catalyzed preferential oxidation ("PrOx") processor (that is, a device that preferentially oxidizes CO rather than H_2). A precious metal catalyst is required for the PrOx processors shown to be effective to date.

Because methanol is a liquid that can be steam-reformed at a relatively low temperature of about 250°C, some researchers consider methanol-based systems more feasible than systems based on hydrocarbons that require reforming temperatures in excess of 650°C. However, steam reforming involves a trade-off between fast, responsive reaction rates needed for driving and the slower reaction rates that are limited by the heat transfer characteristics of the reformers. Slow startup and high cost also remain difficult issues for methanol processing.

Any hydrocarbon can be converted into a H_2 reformate by using a partial oxidation ("POX") process followed by a water-gas shift reaction and then PrOx cleanup of the residual CO. This approach is being developed for gasoline as well as flexible-fuel reformers that could handle alcohols as well as other fuels. Partial oxidation is exothermic, since it involves burning some of the fuel, and the POX process does not itself require a catalyst. However, most hydrocarbon fuel processors use a catalyst to lower the reaction temperature, improve hydrogen yields, and avoid soot formation. Many are designed to be autothermal, using the heat released from the POX as input for the steam reforming process, so that the resulting system is close to thermally neutral. This approach helps the fuel processor achieve a high efficiency.

Startup and transient response are less problematic for POX and autothermal reformers than for steam reformers. However, they face a greater CO cleanup challenge, since their raw reformate can have a CO concentration as high as 10% (from gasoline, for example). Also, nitrogen in the input air dilutes the H_2 in the reformate, thereby lowering the efficiency of the fuel cell, and can produce ammonia, adding to the cleanup requirements. Providing a very clean H_2 reformate is critical, because impurities in the reformate not only poison the fuel cell catalyst, but also cause the fuel cell membrane to degrade. To achieve high effectiveness and durability, most fuel processing catalysts contain noble metals, leading to high catalyst costs.

All approaches to onboard liquid fuel processing have problems of cost, size and weight, startup and dynamic response, and overall workability that need to be resolved before practical designs can be developed. Although the basic processes involved are well known, combining them into an affordable device that would fit into a car is a formidable

challenge. Although size and weight are a lesser concern in nonautomotive applications, many similar technical issues must be resolved even for fuel cells in stationary power generation.

6. PERFORMANCE AND COST

The ultimate appeal of fuel cell vehicles rests on whether they can provide superior environmental performance (low emissions of air pollutants and greenhouse gases) while meeting or exceeding the driving performance and other consumer expectations of competing technologies. At the same time, fuel cell vehicles will need to be affordable in terms of providing such features with customer value sufficient to be marketed successfully.

A fuel cell vehicle's environmental performance advantage is determined largely by the operating efficiency of the stack and associated components. Part of the fuel cell's attraction is its inherently high energy conversion efficiency, exceeding 50% over much of the load range, compared to the 35% or 45% efficiency achieved by gasoline or diesel engines, respectively, only in their ideal operating range. However, net fuel cell system efficiency is strongly influenced by auxiliary systems, particularly air compression. For liquid fueled systems, fuel processing penalties also come into play. Overall vehicle efficiency also depends the balance-of-vehicle parameters that determine mass, aerodynamic drag, tire rolling resistance, and accessory loads. The level of greenhouse gas emissions also depends on the source of the fuel, as it does for all vehicle propulsion options.

The performance and cost of fuel cell vehicles and key competing advanced vehicles is illustrated in relative terms in Fig. 3. While numerous other alternative fuels (such as natural gas, alcohols, synthetic fuels) could also enter into such a comparison, much of what is known can be inferred by comparing direct hydrogen and gasoline-based fuel cell vehicles to evolved versions of gasoline and diesel internal combustion engine vehicles, including hybrid-electric vehicles that retain internal combustion engines. The comparisons of Fig. 3 are normalized, showing both retail price increases and greenhouse gas emissions reductions in percentage terms. The estimates are referenced to a contemporary gasoline car, represented by "Today's Vehicles" at origin of the axes, rated at 28 miles per gallon (mpg) on an average of U.S. EPA regulatory city and highway driving tests. Cost and performance depend on numerous assumptions regarding

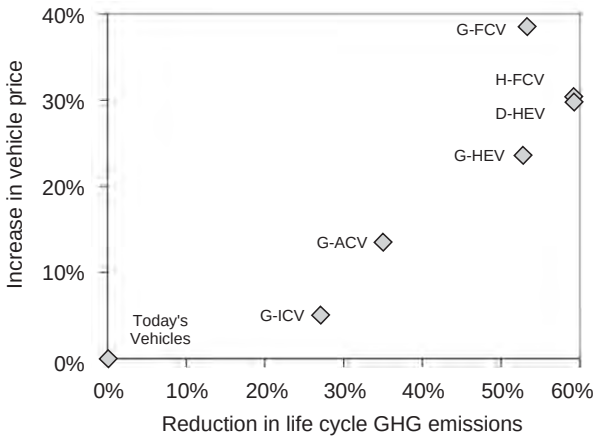

FIGURE 3 Greenhouse gas emissions reductions and retail prices increases of fuel cell vehicles relative to other advanced vehicles. All fuels assume oil or natural gas feedstocks and projections are given relative to today's vehicles as represented as a midsize car rated at 28 miles per gallon on the U.S. EPA composite test cycle. Key: G, gasoline; D, diesel; H, hydrogen, ICV/ACV, improved/advanced conventional vehicle; HEV, hybrid electric vehicle (on advanced platform); FCV, fuel cell vehicle (on advanced platform).

future technologies; the values could change depending on R&D progress. Nevertheless, the ordinal ranking reflects current knowledge of the engineering potential of fuel cell cars compared to other future technologies.

Even using fossil fuel feedstocks (oil for the gasoline and diesel vehicles, natural gas for methanol and hydrogen), fuel cell vehicles and other options all show lower greenhouse gas emissions than today's cars. A good part of this reduction is associated with an advanced vehicle platform having reduced mass, better aerodynamics, and other reductions in the "load," or amount of energy that needs to be delivered by the vehicle's power plant. The comparisons for the fuel cell vehicles, hybrid-electric vehicles, and advanced conventional vehicles assume a uniform advanced platform. This platform has substantial load reduction compared to today's cars, reflected in how the gasoline-powered advanced conventional vehicle (G-ACV) in Fig. 3 achieves a greater GHG emissions reduction than the improved conventional vehicle shown for reference (G-ICV).

Among fuel cell vehicles, the direct hydrogen design (H-FCV) provides the greatest greenhouse gas reduction and has the lowest expected cost, since it avoids the cost and other penalties associated with onboard fuel processing. The H-FCV illustrated in Fig. 3 assumes compressed gas hydrogen storage

which, while technically feasible, may not be practical for mass-market vehicles. The gasoline fuel cell vehicle (G-FCV) represents the highest cost option. Although it may not reduce greenhouse gas emissions more than a hybrid-electric combustion engine vehicle, the G-FCV is being researched because it offers a transition path to hydrogen fuel cell vehicles that make use of existing infrastructure.

The comparisons shown here assume hydrogen produced from natural gas. Substantially lower or even zero greenhouse gas emissions are hypothetically possible with hydrogen produced from solar energy, other renewable resources, or nuclear power. Very low greenhouse gas emissions could be obtained with fossil-derived hydrogen if ways were found to sequester the carbon, since direct use of hydrogen avoids carrying carbon atoms to the vehicle. Similarly, very low greenhouse gas emissions would be feasible with methanol or other fuels that might be processed into onboard hydrogen if they were derived from renewable resources or other feedstocks enabling offset of the carbon.

Because of diesel fuel's high efficiency in piston engines and low energy requirements for production from crude oil, diesel vehicles have lower greenhouse gas emissions than similar gasoline vehicles. A diesel hybrid-electric vehicle (D-HEV) offers lifecycle greenhouse gas emissions reductions as great as those of a H-FCV using hydrogen derived from natural gas. However, it is not yet known whether diesel engines can attain adequately low levels of criteria air pollutants, as already demonstrated for gasoline internal combustion engines and likely to be feasible for any fuel cell vehicle. Costs of an advanced D-HEV are expected to be similar to those of a H-FCV, due to the significant costs premium of diesel engines and their emissions controls compared to gasoline engines.

To put costs into perspective, the average real (inflation-adjusted) price of new cars in the United States has been rising linearly for many years, as a result of consumer features as well as regulatory changes to address safety and environmental hazards. Between 1980 and 2000, average new car real prices rose 34%. Continuing a linear trend over the next 20 years—a plausible early horizon for mainstream commercialization of fuel cell vehicles—implies a further 21% price increase. Current expectations, as reflected in Fig. 3, suggest fuel cell vehicle costs exceeding such a trend. Nevertheless, a combination of research progress (lowering costs) and greater value placed on the environmental or other attributes offered by the technology could yield a situation where fuel cell vehicles are competitive in future market and regulatory contexts. Indeed, the prospects for such a business case underpin the research and development investments now being made by automakers in fuel cell technologies.

7. COMMERCIALIZATION ISSUES

The commercialization prospects for fuel cell vehicles depend not only on their performance and cost, but also on how well they can compete with other technology options that address similar market and policy needs. While market forces have not traditionally motivated design change for reasons of environmental performance, customer values and expectations can evolve and such characteristics could grow in importance. However, inherent market conservatism will favor less disruptive ways to address evolving needs, which might be met by improved gasoline and diesel vehicles, including hybrid-electric versions. Yet looking over the long-run, particularly the need to substantially reducing greenhouse gas emissions, hydrogen fuel cells may well provide a solution that is superior to other alternatives.

While the use in mass-market private vehicles is the prospect that motivates extensive fuel cell R&D, cars and light trucks may not be the initial market for fuel cells vehicles. Fuel cells seem likely to become competitive sooner in urban buses and delivery vehicles. Centrally managed fleets of such vehicles could be serviced by a limited hydrogen refueling infrastructure; onboard hydrogen storage (e.g., with compressed gas) is also more feasible with such vehicles. Engines for buses and other heavy vehicles are produced at lower volumes with higher unit costs than those for light-duty vehicles, enabling fuel cells to compete sooner in this more limited market. Urban operation is well suited for electric drive and causes higher population exposures to exhaust pollution, providing a higher value on the very low or zero emissions offered by fuel cells. The higher cost tolerance, lower infrastructure barriers, and higher value of a very clean technology suggest that buses and other urban vehicles offer greater opportunities for initial fuel cell vehicle commercialization than light duty vehicles. Nevertheless, improvements in diesel emissions control and the emergence of diesel electric hybrid designs will still provide notable competition for fuel cell vehicles.

For light vehicles, the most difficult barriers faced by fuel cell vehicles are those associated with the fuel,

namely, the dual challenges of onboard hydrogen storage and liquid fuel reforming. Both of these technical hurdles present fundamental R&D challenges. Until such challenges are overcome, it will not be possible to confidently project when commercialization of fuel cell cars might proceed. Moreover, electric drivetrain components (motors, controllers, high-power batteries) are just now beginning to see mass production for hybrid vehicles. It is likely to take over a decade to gain experience and reduce costs for such components sufficiently to enable fuel cell vehicles to be affordable to the mass market. Thus, although automakers began introducing fuel cell demonstration vehicles in 2002, widespread commercialization will not be possible for at least another 15 or more years. Even over a 15- to 20-year time frame, building a business case for fuel cell vehicles will require the convergence of three pathways: (1) engineering development and maturation of fuel cell stacks and auxiliary components, (2) cost reduction for electric drive components, and (3) resolution of the barriers related to the right fuel for fuel cell vehicles.

Given such the long time horizon, non-energy-related needs could begin to reshape the personal transportation system. These other needs include issues such as congestion, safety, personal security, and convenience, and the opportunities associated with telecommunications and computer technology. It is not obvious that any "drop in" new fuel and technology, including fuel cells, that does little to address such other needs will provide benefits compelling enough to displace evolved versions of the internal combustion engine running on hydrocarbon fuels. Nevertheless, given the fuel cell's promise for meeting the long-term challenges for motor vehicle energy use, research on the technology has captivated the interests of industry and governments around the world, so that fuel cells may well become the prime mover of choice in a future transportation system whose details are yet to be imagined.

Glossary

advanced vehicle technologies The engineering and design processes that lead to vehicles with high energy efficiencies and low emissions; include direct-injection, hybrid electric, fuel cell, and battery-powered electric vehicle systems.

alternative transportation fuels Energy sources other than petroleum gasoline and diesel for motor vehicle applications. These fuels can be produced from nonpetroleum sources and may have energy and emission benefits.

feedstock stage The first stage of a transportation fuel cycle; the feedstock stage includes fuel feedstock recovery, storage, and transportation.

fuel cycle analysis A procedure used to analyze energy use and emissions during the cycle of energy feedstock production and transportation; transportation fuel production, transportation, and distribution; and transportation fuel use in vehicles (also called well-to-wheels analysis).

fuel stage The second stage of a transportation fuel cycle; the fuel stage includes fuel production, storage, transportation, and distribution, in addition to activities such as fuel liquefaction and compression for long-distance transportation and onboard vehicle storage.

greenhouse gases The by-products of energy use that are believed to have the potential to cause global warming. Although there are many greenhouse gases, the three major greenhouse gases that result from motor vehicle fuel use are carbon dioxide, methane, and nitrous oxide.

life cycle analysis The process of evaluating energy use and emissions of a product from "cradle to grave" (including raw material recovery, material fabrication, product manufacture, product use, product recycling, and disposal). This process is typically used for consumer products; fuel cycle analysis (well-to-wheels analysis) is usually used for transportation vehicles/fuels.

pump-to-wheels stage The second stage of a well-to-wheels analysis (also called vehicle operation stage). It begins with refueling of vehicle fuel tanks. Emissions at this stage may come from fuel combustion or conversion, fuel evaporation, and brake and tire wear.

vehicle operation stage The last stage of a transportation fuel cycle; this stage begins with refueling of vehicle fuel tanks. Emissions at this stage may come from fuel combustion or conversion, fuel evaporation, and brake and tire wear.

well-to-pump stage The first stage of the well-to-wheels analysis (also called the upstream stage), it covers all activities from the wells where fuel feedstock is recovered, to fuels available at the pumps of vehicle refueling stations. In particular, it includes activities associated with the feedstock stage and the fuel stage of a transportation fuel cycle analysis.

well-to-wheels analysis Also called a fuel cycle analysis, this process assesses all activities from the wells where fuel feedstock is recovered, to vehicle wheels where useful energy is generated and used to move vehicles. The analysis focuses in particular on energy use and emissions of energy feedstock production and transportation; transportation fuel production, transportation, and distribution; and transportation fuel use in vehicles.

The spark-ignition and compression-ignition engine technologies that are currently employed in motor vehicles were developed more than 100 years ago. These conventional vehicle technologies are fueled by petroleum-derived gasoline and diesel fuels (the so-called conventional fuels). Over the past 100 years, the conventional technologies have been dramatically improved, reducing cost and increasing performance. Humanity enjoys the mobility provided by these technologies more than ever. However, their use causes negative effects, such as the exclusive dependence on petroleum by the transportation sector, air pollution (especially urban air pollution), and large amounts of greenhouse gas (GHG) emissions. Alternative transportation fuels to replace conventional fuels and advanced vehicle technologies (such as electric drive technologies) to increase vehicle energy efficiency have long been studied and promoted worldwide. Alternative transportation fuels and advanced vehicle technologies could help solve urban air pollution problems, reduce GHG emissions, and reduce U.S. dependence on imported oil. To evaluate the energy and emission effects of alternative fuels and vehicle technologies accurately and adequately, researchers must consider emissions and energy use from fuel production processes as well as from vehicle operations (so-called fuel cycle analysis). This is especially important for technologies that employ fuels with distinctly different primary energy sources and fuel production processes because the emissions and energy use associated with fuel production and distribution can be significantly different.

1. INTRODUCTION

Fuel cycle analysis is requisite when comparing different vehicle technologies powered by different fuels. Figure 1 shows the significantly different greenhouse gas (GHG) emission results obtained by considering only vehicle tailpipe emissions (pump to wheels) versus considering both fuel production (well to pump) and tailpipe emissions (fuel cycle). A number of studies have been conducted to estimate fuel cycle emissions and energy use associated with various transportation fuels and vehicle technologies. The results of those studies were influenced by the assumptions made by individual researchers regarding technology development, emission controls, primary fuel sources, fuel production processes, and many other factors. Because different methodologies and parametric assumptions were used by different researchers, it is difficult to compare and reconcile the results of different studies and to conduct a comprehensive evaluation of fuel cycle emissions and energy use. Computer models for calculating emissions and energy use are needed to allow analysts and researchers to test their own methodologies and assumptions and make accurate comparisons of different technologies.

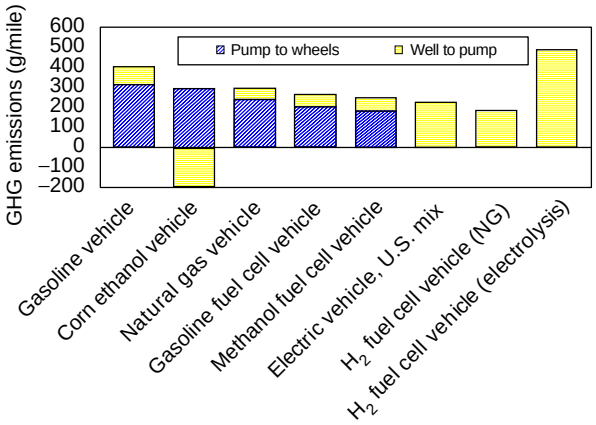

FIGURE 1 Tailpipe vs fuel cycle greenhouse gas emissions of selected vehicle/fuel systems. NG, natural gas.

The effects on energy use and emissions of using advanced vehicle/fuel systems can differ considerably because (1) the production technologies and distribution pathways for the fuels are significantly different and (2) the fuel economy and emissions performance associated with the vehicles powered by these fuels vary. If the energy and environmental effects of vehicle/fuel systems are to be thoroughly examined, the fuels must be evaluated on the basis of a full fuel cycle, including both fuel production and in-vehicle usage.

2. ALTERNATIVE TRANSPORTATION FUELS AND ALTERNATIVE FUEL VEHICLES

2.1 Alternative Transportation Fuels

At present, in the United States and worldwide, motor vehicles are fueled almost exclusively by petroleum-based gasoline and diesel fuels. Since the first oil price shock in 1973, efforts have been made to seek alternative fuels to displace gasoline and diesel fuels and achieve energy and environmental benefits. Some of the alternative fuels that have been researched and used are liquefied petroleum gas (LPG), compressed

natural gas (CNG), liquefied natural gas (LNG), methanol (MeOH), dimethyl ether (DME), Fischer–Tropsch diesel (FTD), hydrogen (H_2), ethanol (EtOH), biodiesel, and electricity. Production processes associated with gasoline, diesel, and each of these alternative fuels differ.

For fuel cycle analyses, gasoline often serves as the baseline fuel to which other fuels are compared. Because of emission concerns, requirements for gasoline quality are in place in many countries to help reduce motor vehicle emissions. In the United States, so-called reformulated gasoline, compared to the gasoline used in the 1970s, has much better quality in terms of emission reduction potential. Oxygen additives such as methyl *tert*-butyl ether (MTBE) or ethanol are often mixed with gasoline. To control emissions of nitrogen oxides (NO_x) and particulate matter of size smaller than 10 μm (PM_{10}) with after-combustion treatments for diesel vehicles, regulations are in place or are being developed to maintain the sulfur content of diesel fuels at a very low level. The demand for both low-sulfur gasoline and low-sulfur diesel requires significant desulfurization efforts in petroleum refineries.

Liquefied petroleum gas, primarily propane, is produced in either petroleum refineries or natural gas (NG) processing plants. In the United States, about 40–50% of LPG is produced in petroleum refineries and the remaining 50–60% is produced in NG processing plants. Natural gas can be delivered to vehicle refueling stations, where it is compressed to above 3600 psi for storage on CNG vehicles, or it can be liquefied in central liquefaction plants and transported to refueling stations for LNG vehicle applications. Compared with compressed natural gas vehicles (CNGVs), liquefied natural gas vehicles (LNGVs) have one distinct advantage, a longer driving range per refueling. However, cryogenic storage of LNG onboard a vehicle presents technical and cost challenges.

Methanol is produced through synthesis of a gaseous mixture of H_2, carbon monoxide (CO), and carbon dioxide (CO_2). Although methanol can be produced from biomass, coal, heavy oil, naphtha, and other feedstocks, the availability of reasonably cheap NG feedstock makes steam methane reforming (SMR) technology an economical way to produce methanol. SMR is a mature technology and is widely used in existing methanol plants. Methanol plants may be located near remote gas fields to take advantage of cheap, remote NG supplies.

Dimethyl ether, which has physical properties similar to those of LPG, has been proposed and tested as an alternative to diesel fuel in compression-ignition (CI) engines. Use of DME in diesel engines offers NO_x and PM emissions reduction benefits. DME is now used predominantly as an aerosol propellant and is produced from methanol through a dehydration process. Research and development efforts have focused on technologies to produce DME directly from coal and NG.

The Fischer–Tropsch (FT) process produces middle distillates containing no sulfur and virtually no aromatics; the process also produces naphtha and wax. Using FT diesel in CI engines helps reduce NO_x and PM emissions. The FT reaction process was used by Germany during World War II to produce diesel fuel from coal and by South Africa during the oil embargo against that country's apartheid. Currently, several major companies are actively pursuing the production of FTD from remotely located ("stranded") natural gas.

Although H_2 can be produced from many feedstocks, most H_2 is currently produced from NG via SMR technologies. Several alternative schemes, such as partial oxidation (POX), autothermal reforming (ATR), and plasma reforming, have been developed and used commercially to produce H_2. Hydrogen plants can generate a significant amount of steam; some of the steam produced is used as process steam within the plant, and the remainder can be exported to nearby chemical plants. The gaseous H_2 ($G.H_2$) produced can be compressed to above 5000 psi for storing on board hydrogen-powered vehicles, or the $G.H_2$ can be liquefied to produce liquid H_2 ($L.H_2$) and used in hydrogen-powered vehicles. Besides production in central plants, H_2 can be produced in refueling stations to avoid construction of expensive hydrogen distribution infrastructure. In addition, H_2 can be produced via electrolysis of water with electricity that is generated by using different energy sources.

Biomass can be used to produce ethanol and biodiesel. Ethanol fuel is currently produced from grains such as corn and sugarcane. Research and development efforts to develop and commercialize technologies to produce ethanol from cellulosic biomass are ongoing. Methyl or ethyl esters that are produced from vegetable oils and animal fats are commonly called biodiesel (BD). Biodiesel, which can be used in diesel engine vehicles, is produced via a transesterification process from natural vegetable oils (soybean oil, cotton oil, and rapeseed oil). Outside the United States production is mainly from rapeseed oil; in the United States, biodiesel is produced primarily from soybeans.

Electricity can be used directly as a transportation fuel in battery-powered electric vehicles (EVs); in

combination with an onboard engine, electricity can supply the motive power for hybrid electric vehicles (HEVs). Also, electricity can be used to produce H_2 via electrolysis of water. The energy use and emission effects of electricity as a transportation fuel are primarily determined by the type of fuels (e.g., coal, NG, or oil) used and the type of fuel combustion technologies (e.g., steam boilers, simple-cycle gas turbines, or combined-cycle gas turbines for NG-fired power plants). Because the electric generation mix is so different from region to region, the energy and emission effects of electricity also vary greatly.

2.2 Alternative Fuel Vehicles

Figure 2 shows the numbers and types of alternative fuel vehicles on the road in the United States. Besides these conventional vehicle technologies, advanced vehicle technologies such as HEVs and fuel cell vehicles (FCVs) are also under development. Past fuel cycle analyses have covered both conventional and advanced vehicle technologies. Some of the alternative fuels (such as methanol, ethanol, and biodiesel) can be blended with gasoline or diesel for vehicle applications.

3. *FUEL CYCLE ANALYSES OF VEHICLES AND TRANSPORTATION FUELS*

The fuel cycle for a given transportation fuel includes the following processes: energy feedstock (or primary energy) production; feedstock transportation and storage; fuel production; fuel transportation, storage, and distribution; and vehicle operations that involve fuel combustion or other chemical conversions (Fig. 3). The processes that precede vehicle operations are often referred to as the well-to-pump (WTP) stage, the vehicle operations are referred to as the pump-to-wheels (PTW) stage, and the entire fuel cycle is referred to as the well-to-wheels (WTW) cycle. Various models have been developed that allow researchers to conduct fuel cycle analyses of vehicle/fuel systems. The GREET (greenhouse gases, regulated emissions, and energy use in transportation) model, developed by Argonne National Laboratory, is in the public domain and, so far, more than 1000 users worldwide have used the model to predict the energy use and emissions associated with alternative fuels and vehicles. The GREET model and its documents are posted on the Internet at http://greet.anl.gov.

Mark Delucchi of the University of California at Davis has developed another transportation fuel cycle models. The model has been used by Delucchi for applications in the United States, Canada, and Europe. Another analytic tool, the TEAM model, developed by Ecobalance, is a commercial model used primarily for life cycle analysis of consumer products. In certain configurations, the model can be used to analyze vehicle/fuel systems. The National Renewable Energy Laboratory in the United States has applied the model to analyze bioethanol and biodiesel. Shell (Royal Dutch Petroleum Company) recently applied the model to analyze FT diesel.

For fuel cycle analysis of vehicle/fuel systems, the results need to be per distance traveled. If the analysis is conducted for each unit of energy produced and used, the energy efficiency and emission differences during the pump-to-wheels (vehicle operation) stage may be excluded, resulting in incomplete analysis of

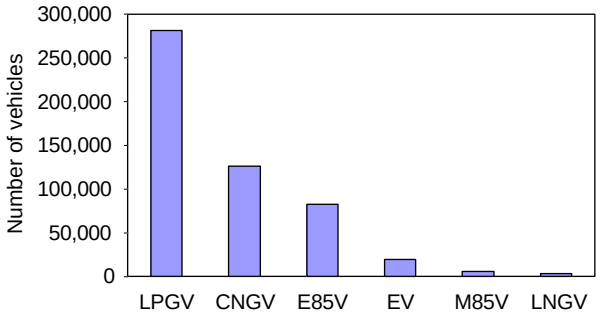

FIGURE 2 Stocks of alternative fuel vehicles in the United States in 2002. LPGV, Liquefied petroleum gas vehicles; CNGV, compressed natural gas vehicles; E85V, vehicles fueled by 85% ethanol/15% gasoline (by volume); EV, electric vehicles (battery powered); M85V, vehicles fueled by 85% methanol/15% gasoline (by volume); LNGV, liquefied natural gas vehicles. FIGURE 3 Coverage of a fuel cycle analysis.

the systems. To estimate well-to-wheels energy use and emissions, the well-to-pump energy use and emissions per unit of fuel available at refueling pumps are estimated first. The WTP estimates take into account energy uses (including use of process fuels and energy losses during WTP activities) and emissions associated with the activities, as discussed in reports prepared by Delucchi and Wang about their models. Estimates of WTW emissions usually include emissions of greenhouse gases [primarily CO_2, methane (CH_4), and nitrous oxide (N_2O)] and criteria pollutants such as volatile organic compounds, CO, NO_x, PM_{10}, and sulfur oxides (SO_x). Emissions occurring during WTP activities include those resulting from the combustion of process fuels and from noncombustion processes such as chemical reactions, fuel leakage, and evaporation. Of these pollutants, CO_2 emissions are relatively easy to estimate because they depend almost exclusively on the carbon content of the fuels used. Emissions of other pollutants are affected by combustion technologies, as well as the amounts and the types of fuels used. To a large extent, emissions estimates for these other pollutants rely heavily on emission factors (in grams per unit of fuel used) for different combustion technologies fueled by different process fuels. These emission factors can be obtained from databases such as the AP-42 document created by the U.S. Environmental Protection Agency (EPA).

Sulfur oxide emissions are calculated by assuming that all sulfur contained in process fuels is converted into sulfur dioxide (SO_2) for combustion technologies fueled with process fuels except for coal and residual oil. The SO_x emissions for these two process fuels are usually subject to after-combustion control devices. PTW energy use and emissions are calculated on a per-mile basis. Usually, energy use per distance traveled is calculated from vehicle fuel economy values, which are available from measurements or vehicle simulations. Vehicle emissions values are available from emission certifications, estimations of on-road vehicle operations, and laboratory tests.

Although fuel economy and emissions for benchmark gasoline vehicles and diesel vehicles are presented as actual values (e.g., miles per gallon for fuel economy and grams per mile for emissions), fuel economy and emissions for alternative fuel vehicles (AFVs) are usually presented as ratios to benchmark vehicles. In this way, differences in vehicle operating conditions can be reduced to some extent, as long as the fuel economy and emission ratios are for similar vehicle types and under similar operating conditions. For criteria pollutants, location (e.g., urban, rural) is also important, and fuel cycle analyses need to be conducted with a special focus on where emissions occur. In the GREET model, criteria pollutant emissions are separated into "total emissions" (those that occur everywhere) and "urban emissions" (those that occur within metropolitan areas, where large populations are exposed to the pollutants).

4. FUEL PATHWAYS AND VEHICLE/FUEL COMBINATIONS

Table I shows different types of vehicle propulsion systems and the transportation fuels that have been studied for their potential to power the vehicles. Gasoline, CNG, LNG, LPG, methanol, ethanol, and hydrogen can be used in vehicles equipped with conventional spark-ignition (SI) engines. Interest in developing efficient, low-emission, spark-ignition direct-injection (SIDI) engine technologies has heightened in recent years. Although vehicles with SIDI engines can be fueled efficiently with liquid fuels (gasoline, methanol, ethanol, and liquid hydrogen), gaseous fuels do not appear to offer inherent fuel economy benefits when used in these engines. Compression-ignition direct-injection (CIDI) engines, which can be fueled by diesel, DME, FT diesel, and biodiesel, help increase vehicle fuel

TABLE I

Potential Combinations of Vehicle Technologies and Transportation Fuels

Vehicle technology[a]	Potential fuels for use[b]
Conventional SI engine	Gasoline, CNG, LNG, LPG, MeOH, EtOH, H_2
SIDI engine	Gasoline, MeOH, EtOH, $L.H_2$
CIDI engine	Diesel, dimethyl ether, Fischer–Tropsch diesel, biodiesel
SIDI engine HEV	Gasoline, CNG, LNG, LPG, MeOH, EtOH, $L.H_2$
CIDI engine HEV	Diesel, dimethyl ether, Fischer–Tropsch diesel, biodiesel
Battery-powered EV	Electricity
FCV	Hydrogen, MeOH, gasoline, EtOH, diesel, CNG, LNG, LPG, naphtha

[a] Abbreviations: SI, spark ignition; CIDI, compression ignition, direct injection; HEV, hybrid electric vehicle; EV, electric vehicle; FCV, fuel cell vehicle.

[b] Abbreviations: CNG, compressed natural gas; LNG, liquefied natural gas; LPG, liquefied petroleum gas; MeOH, methanol; EtOH, ethanol; $L.H_2$, liquid hydrogen.

economy substantially, although they face the challenge of reducing NO_x and PM emissions.

Hybrid electric vehicles achieve significant fuel economy gains compared with conventional vehicle powertrain configurations. HEVs can be equipped with conventional SI, SIDI, or CIDI engines. HEVs can also be designed to obtain electricity from the electric grid and combine it with power from onboard engines. Battery-powered EVs, charged with grid electricity, offer large fuel economy gains and zero tailpipe emissions. The limited driving range, limited performance characteristics, and high battery costs of EVs limit their market penetration, but EVs continue to be promoted.

Major automakers and the government have programs aimed at development of fuel cell vehicles. Although the ultimate fuel for FCVs is hydrogen, hydrocarbon fuels are being considered, at least for a transition period, before expensive hydrogen production and distribution infrastructure is in place. In theory, any hydrocarbon fuel (e.g., methanol, gasoline, ethanol, diesel, CNG, LNG, LPG, and naphtha) can be used to produce hydrogen on board FCVs. Use of hydrocarbon fuels in FCVs requires onboard fuel processors to produce H_2.

5. ENERGY AND EMISSIONS: ITEMS OF INTEREST

A typical life cycle analysis includes analysis of the inventory of environmental releases, evaluation of potential environmental impacts, and interpretation of the inventory analysis and impact evaluation. Environmental releases include emissions to air, water, and solid waste emissions; these are defined in document 14040 of the International Standards Organization (ISO), *Environmental Management, Life-Cycle Assessment—Principles and Framework*. Prior fuel cycle analyses of vehicle/fuel systems have focused primarily on air emissions and energy use. For air emissions, studies often include the following criteria:

1. Greenhouse gas emissions: carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), and several other gases, including hydrofluorocarbons, perfluorocarbons, and sulfur hexafluorides.
2. Criteria pollutant emissions: volatile organic compounds (VOCs), carbon monoxide (CO), nitrogen oxides (NO_x), particulate matter [usually smaller than 10 μm (PM_{10})], and sulfur oxides (SO_x).
3. Emissions of air toxics: acetaldehyde, benzene, 1,3-butadiene, and formaldehyde.
4. Energy use parameters: total energy use, fossil energy use, and petroleum use.

To estimate CO_2-equivalent GHG emissions, the GHGs are often combined with their global warming potentials (GWPs) as described by the Intergovernmental Panel on Climate Change (IPCC) in its 2001 report, *Climate Change 2001: The Scientific Basis, Technical Summary of the Group I Report*. The three major GHGs for evaluating vehicle/fuel systems are CO_2, CH_4, and N_2O. The GWPs of the greenhouse gases vary with the time horizon used to calculate them. With a time horizon of 100 years, GWPs are 1, 23, and 296 for CO_2, CH_4, and N_2O, respectively.

Emissions of criteria pollutants are regulated in the United States by the EPA (the term "criteria pollutants" comes from the EPA's establishment of criteria for ambient concentrations and emissions of these pollutants). These pollutants primarily cause adverse health effects. Thus, the locations in which they are emitted as well as their amounts are important. Total emissions are emissions that occur everywhere, including unpopulated or sparsely populated regions, and urban emissions are those that occur in urban areas with large populations.

Air toxics are hydrocarbons identified by EPA as potential cancer-causing species. Acetaldehyde, benzene, 1,3-butadiene, and formaldehyde are the major air toxics emitted by motor vehicles. Air toxic emissions of various vehicle/fuel combinations have been assessed in a study at Argonne National Laboratory by Winebrake and colleagues.

All complete fuel cycle analyses of energy impacts include total energy use; which means that all energy sources, such as renewable energy and nonrenewable energy (i.e., fossil energy), are taken into account. Some analyses further analyze fossil energy impacts; in these studies, assessments take into account fossil energy, including petroleum, natural gas, and coal. Because fossil energy resources are finite, analyses of fossil energy use reveal the impacts of particular vehicle/fuel systems on energy resource depletion. This aspect of life cycle analysis is especially important for biofuels such as ethanol and biodiesel, for which analysis of total energy impacts may not provide adequate information because the energy in ethanol and biodiesel comes from solar energy during crop growth, and use of solar energy per se is not a concern. Some studies also include analysis of petroleum displacement effects by vehicle/fuel

systems. This is an important issue for countries that rely on imported oil and seek to reduce their oil consumption.

6. ISSUES INVOLVED IN TRANSPORTATION FUEL CYCLE ANALYSES

There are several key issues that transportation researchers need to keep in mind when conducting and using the data that result from life cycle analysis studies.

6.1 Usefulness of Fuel Cycle Analysis Results

ISO document 14040 identifies four areas for using life cycle analysis (LCA) results: (1) identifying opportunities to improve the environmental aspects of products, (2) helping industry, governments, and nongovernmental organizations make sound environmental decisions, (3) selecting relevant environmental indicators for measuring the environmental performance of products, and (4) marketing claims of the environmental performance of products. For transportation fuel cycle analyses (FCAs), the first two areas are important. The results of FCAs of vehicle/fuel systems are helpful in comparing the energy and emissions performance of different systems on a complete basis. Such comparisons help society identify and pursue the technologies that offer the greatest potential energy and emissions benefits; for example, they can be used to rank technologies in relative terms rather than estimating the absolute amount of energy use and emissions for given technologies. FCA results may be less useful for estimating total energy use and total emissions for all the activities associated with a vehicle/fuel system.

As ISO 14040 states, the results of LCAs in general, and transportation FCAs in particular, can be very helpful in identifying opportunities to improve energy performance and environmental conditions. That is, FCA results should be used in a dynamic way to identify the subsystems that can contribute to improved energy and environmental performance of a vehicle/fuel system and to identify potential system improvements, and not in a static way to show simply which systems are better than others.

6.2 Allocation Methods

For processes that produce multiple products, energy and emission burdens have to be allocated to individual products. ISO 14040 advocates reducing the need to allocate by expanding the system boundary. That is, when comparing two systems, the system boundaries for both can be expanded so that all products from both systems are within a newly expanded single system. In transportation FCAs, the system boundary expansion is also called the displacement method (for a full discuss ion, see the 1999 report by Wang, *Transportation Fuel-Cycle Model, Volume 1: Methodology, Development, Use, and Results)*. In practice, however, the system expansion approach can become time and resource intensive. Also, in some cases, systems may be expanded subjectively without considering marketplace effects. Thus, allocation of energy and environmental burdens is still widely used in transportation FCAs. The burdens can be allocated based on shares of output products in terms of energy content, market value, or mass. Of these three options, the energy content basis is appropriate if all products are energy products. The market value basis could be used if the market values of products will drive market behaviors, which can, in turn, affect technologies. The mass basis usually is the least favorable method for transportation FCAs. In any event, all products need to be taken into account in evaluating multiple-product processes and systems. Ignoring coproducts, as some past studies have done, results in unfair treatment of the primary product of a process or a system. Also, the fact that the coproducts indeed have market values is ignored.

6.3 Technology Maturity Levels

In comparative transportation FCAs, different fuels and vehicle technologies are often analyzed together. Comparisons of technologies should take into consideration different commercial maturity levels; some fuels and technologies are already mature and in use, whereas others may still be in the research and development stage. Because FCAs generally do not address technology maturity and commercial readiness, it is important to remember that FCAs and their results cannot be used to assess the commercial viability of fuels and vehicle technologies. FCAs simply provide information on energy and emission effects that would occur if the evaluated fuels and technologies were to be introduced into the marketplace.

The level of technology maturity also affects FCA data quality; For technologies at the research and

development stage, few or no actual operational data are available. Sources of data for these technologies are often limited to engineering analyses, predictions, and simulations. There is typically an abundance of reliable performance data for fuels and vehicle technologies already in the marketplace.

6.4 Uncertainties in Input Parameters and Output Results

Because FCAs cover many activities from wells to wheels, there is a demand for data. Data associated with different activities can come from a wide variety of sources of differing quality, and different engineering designs and facility operation can vary significantly. To address the reality that the data obtained are subject to a large degree of uncertainty, many FCAs have been conducted using sensitivity analyses that change key input parameters. Many researchers now incorporate Monte Carlo simulations in their studies to address uncertainties on a systematic basis. With Monte Carlo simulations, inputs parameters and output results are associated with probability distribution functions.

6.5 Transparency

Transportation FCA results are determined by assumptions regarding input parameters, simulation methodologies, and system boundaries. These assumptions need to be presented explicitly in transparent ways to allow studies to be compared and to make clear whether general conclusions can be drawn from individual studies. Sensitivity analyses can be included in FCA studies to demonstrate the importance of some of the assumptions in determining results. Sometimes, seemingly similar studies are combined to generalize conclusions.

7. COMPLETED STUDIES

Some of the results of past studies are summarized in the following sections. Although many of the studies estimated both (1) absolute energy use and emissions of vehicle/fuel combinations and (2) energy use and changes in emissions of alternative vehicle/fuel systems relative to benchmark technologies (usually gasoline-fueled light-duty vehicles), the summary here presents relative changes only, because they are more comparable than absolute amounts across studies.

Of the vehicle types that use alternative transportation fuels, most completed studies evaluated only passenger car applications. However, many alternative transportation fuels and advanced vehicle technologies can also be applied to heavy-duty trucks. The benchmark vehicles for heavy-duty vehicle comparisons are usually diesel trucks. Because heavy-duty vehicle technologies can be considerably different from light-duty vehicle technologies and because heavy-duty vehicle driving patterns are very different from those for passenger cars, the relative FCA results summarized here are generally not applicable to heavy-duty vehicles.

7.1 Kreucher, Ford Motor Company (1998)

The study by W. M. Kreucher included evaluations of well-to-wheels emissions, energy use, and costs. Vehicle fuel economy for a Ford Escort was simulated by using Ford's proprietary model on the federal test procedure (FTP) cycle. Well-to-pump energy and emissions were simulated with a model developed by Arthur D. Little for the U.S. Department of Energy (DOE). Emissions analysis included CO_2 and criteria pollutants.

7.2 Weiss *et al.*, Massachusetts Institute of Technology (2000)

Weiss and others at the Energy Laboratory at the Massachusetts Institute of Technology (MIT) conducted a study to compare several vehicle propulsion systems fueled by alternative transportation fuels. In conducting the comparison, the researchers projected vehicle and fuel production technologies from 1996 to 2020. Their analysis was primarily for North American applications. Greenhouse gas emissions in that study include CO_2 and CH_4. A midsize passenger car, such as a Toyota Camry, was used for vehicle simulations. Well-to-pump data were based on a critical review of published data. Vehicle fuel economy results were simulated by using an MIT vehicle computer simulation model. One of the study's strengths is vehicle characterization and simulations. The study also presents some detailed information on vehicle performance and technology advancement.

7.3 (S&T)^2 Consultants, Inc., for Methanex (2000)

The (S&T)^2 study was conducted primarily for Canadian well-to-pump conditions, but the results

are somewhat applicable to U.S. WTP conditions. The study included GHG emissions only (CO_2, CH_4, and N_2O) and employed Canadian oil recovery efficiencies and carbon emissions, which are high because a significant amount of oil is recovered from oil sands in Canada. Also, the study assumed low refinery efficiency and high GHG emissions for petroleum refineries. Emissions from vehicle materials cycles were also included. A derivative of the model developed by Delucchi was used for simulating well-to-wheels GHG emissions. The study is unique in its collection and use of Canadian WTP data on GHG emissions and fuel production efficiencies.

7.4 Ishitani, University of Tokyo (2000)

The study by H. Ishitani was conducted assuming Japanese conditions for both WTP activities and vehicle technologies. Vehicle fuel economy was simulated with a model that the author developed. The study included well-to-wheels energy efficiencies only. It appears that well-to-pump and pump-to-wheels efficiency assumptions were more optimistic in this study than in the other studies reviewed here.

7.5 Louis, Shell Global Solutions (2001)

The Shell study estimated well-to-wheels GHG emissions and energy use for 24 vehicle/fuel systems. Greenhouse gas emissions included CO_2 and CH_4. The vehicle technologies that were evaluated were internal combustion engine vehicles (ICEVs), HEVs, and FCVs. The analysis for WTP activities was conducted for the United Kingdom primarily with Shell data. A Mercedes A-class passenger car was chosen for comparison. The GREET model developed by Argonne National Laboratory was used in the study to conduct WTW simulations.

7.6 Delucchi, University of California at Davis (2001)

The study by M. A. Delucchi evaluated motor vehicles, forklifts, and space and water heaters. It included emissions of GHGs and criteria pollutants, but not energy use, although the Delucchi model includes estimation of energy use. The CO_2-equivalent GHG emissions addressed in the study were CO_2, CH_4, N_2O, nonmethane organic compounds (NMOCs), CO, NO_x, SO_x, PM, and hydrofluorocarbon (HFC)-134a and chlorofluorocarbon (CFC)-12. Delucchi included both fuel and vehicle cycles in his analysis. The results summarized in Fig. 3 are fuel cycle results. Delucchi showed that vehicle cycle GHG emissions could be 16% of vehicle tailpipe GHG emissions.

7.7 Arthur D. Little (2002)

Arthur D. Little (ADL) has conducted studies for the DOE and the state of California since the early 1990s. The report cited here was prepared for the DOE to evaluate fuel choices for FCVs. The study considered energy efficiencies, GHG emissions, costs, and safety for use of the following fuels in FCVs, ICEVs, and battery-powered EVs: hydrogen, methanol, ethanol, gasoline, and diesel. The analysis was conducted for year 2010. ADL developed a vehicle model to simulate vehicle fuel economy under different driving cycles. A modified GREET version was used for WTW simulations.

7.8 Summary

Tables II and III summarize changes in WTW energy use (Table II) and GHG emissions (Table III) by vehicle/fuel system relative to baseline gasoline vehicle data from the studies described in the preceding sections. Energy use results from five of the seven studies (the Methanex and Delucchi studies did not address energy use) indicate that, of the nine SI engine vehicle/fuel systems, use of cellulosic ethanol, corn ethanol, methanol, and H_2 in SI engines could lead to increased WTW energy uses, whereas use of LPG and CNG results in reduced energy use. Of the three CIDI engine vehicle/fuel systems, use of FT diesel could result in increased WTW energy use, because of large energy losses during FT diesel production. Use of all of the eight HEVs results in reductions in energy use. Among the FCVs, use of electrolysis H_2, cellulosic ethanol, and corn ethanol could result in increased energy use, because of very large energy losses during WTP activities for these fuels. Of the four studies analyzing gasoline FCVs, only the MIT study concluded that gasoline FCVs could have higher WTW energy use compared to baseline gasoline vehicles. Of the five studies that addressed EVs, two showed increases in energy use by EVs, but three showed reductions.

The WTW GHG emission changes presented in Table III for six of the reviewed studies (the study by the University of Tokyo did not present GHG emission results) reveal that, of the nine fuels for SI engine vehicle applications, NG-based L.H_2 could

result in GHG emissions reductions. All of the 12 FCV and EV types are shown to have GHG emissions reduction benefits, except for electrolysis H_2 and gasoline for FCV applications, for which two studies showed increases (the four studies showed decreases for these two options).

8. FUEL CYCLE ENERGY AND EMISSION RESULTS OF VEHICLE/FUEL SYSTEMS

Because different studies have different system boundaries and parametric assumptions, the studies

described in Section 7 resulted in different magnitudes of changes in energy use and GHG emissions. The GREET model was used to develop the results presented in this section. In conducting the analyses with the GREET model, key assumptions were specified by taking into account the results from various completed studies. Because some of the vehicle/fuel systems are emerging technologies and are not in the marketplace yet, all technologies were analyzed for the time frame around 2010, so that both emerging technologies and technologies already in the marketplace can be compared within the same period.

8.1 Specifications of and Key Assumptions for Fuel Production Pathways

Table IV presents specifications of and key assumptions of fuel production pathways for North American applications. For each fuel pathway, the table presents the fuel pathway (including feedstocks), key parametric assumptions, and main pathway characteristics. Note that the petroleum gasoline pathway is the baseline pathway to which other fuel production pathways are compared.

8.2 Vehicle Fuel Economy Assumptions

Table V lists the fuel economy of baseline gasoline vehicles (GVs) and the fuel economy ratios of alternative vehicle/fuel systems relative to the baseline GV. The values are based on research at Argonne National Laboratory of various vehicle technologies and fuel economy simulations from studies completed at Argonne and elsewhere. The baseline GV fuel economy [27.5 miles per gallon (mpg)) represents the on-road fuel economy value for a typical midsize passenger car produced in 2010 (there is a considerable penalty from laboratory-tested mpg to on-road actual mpg). The mpg ratios for alternative vehicle/fuel systems are based on test results and vehicle simulations. These values were used in the GREET model to conduct WTW simulations.

8.3 Well-to-Pump Energy Efficiencies

Figure 4 shows the energy efficiencies of various fuel production pathways from well to pump. The efficiencies shown are defined as the energy in a given fuel (available at pumps in vehicle refueling stations) divided by total energy inputs during all WTP activities, including the energy content of the fuel. One way to interpret the WTP efficiencies in the figure is as the difference between 100% and the energy efficiencies, which roughly represent energy losses during WTP stages for making a given fuel available at the pump. As stated in Section 3, WTP activities include feedstock production; feedstock transportation and storage; fuel production; and fuel transportation, storage, and distribution.

The reformulated gasoline (RFG) pathway is considered to be the baseline pathway to which other pathways are compared. Figure 4 shows that the baseline RFG pathway has a WTP efficiency of about 80%. There are four fuel pathways, LPG, CNG, LNG, and low-sulfur (LS) diesel, that have WTP efficiencies higher than that of the baseline RFG pathway. These pathways have fuel production efficiencies higher than the gasoline refining efficiency (see Table IV).

Fuel pathways in the next group have energy efficiencies of 50–70%. These pathways include biodiesel from soybeans, DME from NG, methanol from NG, FT diesel from NG, G.H_2 from NG, and ethanol from corn. For renewable biodiesel and ethanol, energy losses from photosynthesis during soybean and corn plant growth are not included because solar energy is abundant. However, energy is consumed for soybean and corn farming and production of biodiesel and ethanol. These effects result in lower WTP efficiencies for these two renewable fuel pathways, compared to the baseline RFG pathway. The NG-based pathways for DME, methanol, FT diesel, and G.H_2 have lower WTP efficiencies because they are subject to considerable energy losses during fuel production.

The next five fuel pathways have WTP energy efficiencies of 30–50%. They include European Union (EU) electricity generation, ethanol from cellulosic ethanol, L.H_2 from NG, U.S. electricity generation, and G.H_2 from EU electricity via electrolysis. Electricity generation with the EU/U.S. generation mix has low WTP efficiencies because electricity generation efficiencies are usually low (see Table IV). Note that for nuclear power generation, an energy efficiency of 100% is assumed here, even though nuclear power plant efficiencies are usually in the range of 35–40%. This is because the energy content in uranium used for power generation is not a concern, because a unit of mass of uranium can generate a large amount of electricity. In a way, nuclear energy could be treated in a manner similar to renewable energy. Because of the way nuclear power and renewable power (such as hydropower)

TABLE IV

Specifications and Key Assumptions for Fuel Production Pathways[a]

Fuel pathway	Key assumptions	Main pathway characteristics
Petroleum to gasoline	Petroleum refining efficiency of 85.5%	For U.S. refineries; 60% crude is imported and 40% domestic; gasoline with sulfur content of 30 ppm and with EtOH as the oxygenate.
NG to CNG	NG compression efficiency of 93%	NG is recovered in North America
NG to LNG	LNG production efficiency of 90.5%	NG is recovered outside of North America; LNG is produced outside of North America and transported to North America
Petroleum and NG to LPG	NG to LPG production efficiency of 96.5%; petroleum to LPG production efficiency of 93.5%	Of the total LPG produced for North American use, 60% is from NG and 40% from petroleum
NG to MeOH	MeOH production efficiency of 68%	Methanol is produced outside of North America and transported to North America
Corn to EtOH	Energy use for ethanol production of 45,500 Btu/gal; ethanol yield of 2.6 gal per bushel of corn	Both dry and wet milling EtOH plants are included; coproducts (primarily animal feeds) are considered
Herbaceous biomass to EtOH	EtOH yield of 92 gal per dry ton of biomass	Cogenerated electricity in cellulosic ethanol plants is considered
Petroleum to LSD	Petroleum refining efficiency of 87%	For U.S. refineries; 60% crude is imported and 40% domestic; diesel with sulfur content of 15 ppm
NG to DME	DME production efficiency of 70%	DME is produced outside of North America and transported to North America
NG to FTD	FTD production energy efficiency of 63% and carbon efficiency of 80%	FTD is produced outside of North America and transported to North America
Soybeans to biodiesel	Biodiesel yield of 1.36 gal per bushel of soybeans	Coproducts (animal feeds and glycerine) are considered
U.S. average electricity	Coal-fired power plant efficiency of 36.5%; NG-fired power plant efficiency of 41%; oil-fired power plant efficiency of 35%	The U.S. electricity generation mix: 54% coal; 15% NG; 1% oil; 18% nuclear; 12% others
European union average electricity	Coal-fired power plant efficiency of 36.5%; NG-fired power plant efficiency of 41%; oil-fired power plant efficiency of 35%	The European Union electricity generation mix: 25% coal; 18% NG; 7% oil; 34% nuclear; 16% others
NG to G.H_2	G.H_2 production efficiency of 71.5%; gaseous H_2 compression efficiency of 85%	G.H_2 is produced in North America with North American NG
NG to L.H_2	G.H_2 production efficiency of 71.5%; H_2 liquefaction efficiency of 71%	L.H_2 is produced outside of North America and transported to North America
Electricity to G.H_2 via electrolysis	G.H_2 production efficiency of 71.5%; G.H_2 compression efficiency of 86%	G.H_2 is produced at refueling stations
Electricity to L.H_2 via electrolysis	G.H_2 production efficiency of 71.5%; H_2 liquefaction efficiency of 66%	L.H_2 is produced at refueling stations

[a] Fuels are for use in North America. Abbreviations: EtOH, ethanol; NG, natural gas; CNG, compressed natural gas; LNG, liquefied natural gas; LPG, liquefied petroleum gas; MeOH, methanol; LSD, low-sulfur diesel; DME, dimethyl ether; FTD, Fischer–Tropsch diesel; G.H_2, L.H_2, gaseous and liquid hydrogen.

are treated here, the EU generation mix has a higher WTP efficiency compared to the U.S. generation mix (the EU generation mix has higher shares of nuclear power and hydropower). L.H_2 from NG has an energy efficiency of about 42% because this pathway is subject to large energy losses during H_2 production and liquefaction. The G.H_2 from EU electricity via electrolysis has an energy efficiency of 32% because of the energy losses during electricity generation and H_2 production.

The last three pathways are electrolysis-based H_2 production pathways (G.H_2 from U.S. electricity, L.H_2 from EU electricity, and L.H_2 from U.S. electricity). They have WTP efficiencies of 23–30%. These pathways are subject to large energy losses during electricity generation, H_2 production, H_2

TABLE V

Gasoline Vehicle Fuel Economy and Fuel Economy Ratios of Alternative Vehicle/Fuel Systems

Vehicle[a]	Fuel economy ratio (relative to baseline GVs)
Baseline GVs (mpg)	27.5
CNGV	1.05
LNGV	1.05
LPGV	1.08
M90 vehicle	1.08
E90 vehicle	1.08
LS diesel CIDI vehicle	1.21
DME CIDI vehicle	1.21
FTD CIDI vehicle	1.21
BD20 CIDI vehicle	1.21
Gasoline HEV	1.43
LS diesel HEV	1.63
EV	3.50
H_2 FCV	2.36
Methanol FCV	1.60
Gasoline FCV	1.50

[a] Abbreviations: GV, gasoline vehicle; CNGV, compressed natural gas vehicle; LNGV, liquefied natural gas vehicle; LPGV, liquefied petroleum gas vehicle; E90, blend of 90% ethanol/10% gasoline (by volume); LS, low sulfur; CIDI, compression ignition, direct injection; DME, dimethyl ether; BD20, blend of 20% biodiesel/80% petroleum diesel (by volume); EV, electric vehicle.

compression (for $G.H_2$), and H_2 liquefaction (for $L.H_2$). The WTP energy efficiency of 23% for $L.H_2$ from U.S. electricity implies that, if FCVs are to be powered with $L.H_2$ produced this way, they need to achieve vehicle efficiencies at least four times as high as conventional GVs in order to have equal energy effects—a formidable challenge.

8.4 Well-to-Wheels Total Energy and Fossil Energy Results

The combination of well-to-pump results and the energy use and emissions associated with vehicle operation (also called the pump-to-wheels stage) results in full well-to-wheels energy and emission results for vehicle/fuel systems. The energy efficiencies of 19 fuel pathways were presented in the preceding section. The well-to-wheels energy use and emissions results for 23 representative vehicle/fuel systems, combined with some of the vehicle technology options listed in Table I, are now considered.

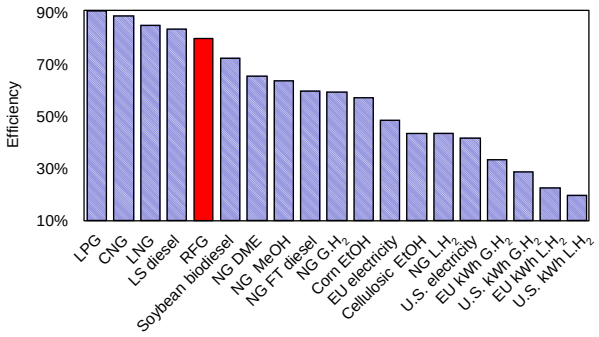

FIGURE 4 Well-to-pump energy efficiencies of fuel production pathways. LPG, Liquefied petroleum gas; CNG, compressed natural gas; LNG, liquefied natural gas; LS diesel, low-sulfur diesel; RFG, reformulated gasoline; NG DME, natural gas (dimethyl ether); NG MeOH, natural gas (methanol); NG FT diesel, natural gas (Fischer–Tropsch diesel); NG $G.H_2$, natural gas (gaseous hydrogen); corn EtOH, corn-derived ethanol; EU, European Union; cellulosic EtOH, cellulosic-derived ethanol; NG $L.H_2$, natural gas (liquid hydrogen).

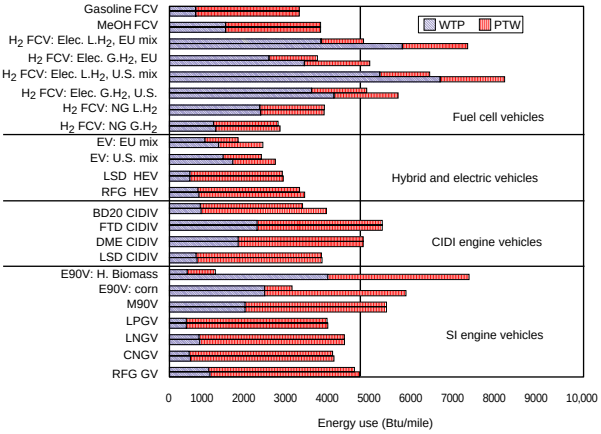

FIGURE 5 Well-to-wheels total energy use and fossil energy use of vehicle/fuel systems. WTP, Well to pump; PTW, pump to wheels; FCV, fuel cell vehicle; LSD, low-sulfur diesel; HEV, hybrid electric vehicle; BD20, blend of 20% biodiesel/80% petroleum (by volume); CIDIV, compression-ignition, direct-injection vehicle; SI, spark ignition; FTD, Fischer–Tropsch diesel; E90 V, vehicles fueled by 90% ethanol/10% gasoline (by volume); M90 V, vehicles fueled by 90% methanol/10% gasoline (by volume); GV, gasoline vehicle; see legend to Fig. 4 for other abbreviations.

Figure 5 shows WTW results for total energy use and fossil energy use. Total energy use includes both fossil and renewable energy sources. Fossil energy use includes three fossil energy sources, petroleum, NG, and coal. In this and the following six figures, the 23 vehicle/fuel systems are separated into four groups by vehicle technologies: SI engine vehicles, CIDI engine vehicles, HEVs and battery-powered EVs, and FCVs. For each system, the bottom bar represents total energy use and the top bar represents

fossil energy use. Also, for each bar, the results are separated into well-to-pump and pump-to-wheels components.

For total energy use, of the seven SI engine vehicle options, use of methanol and ethanol could increase total energy use relative to baseline RFG vehicles. The increases are caused by high amounts of energy use during the WTP stage. On the other hand, use of CNG, LNG, and LPG results in reduced total energy use, because of lower WTP energy use. Among the four CIDI vehicle options, use of DME, and especially FT diesel, could lead to increases in total energy use. But, because of high CIDI engine efficiencies, use of LS diesel and a blend of LS diesel and biodiesel (BD20; a blend of 20% biodiesel and 80% LS diesel) results in reduced total energy use. All four HEV and EV options reduce total energy use, because HEVs and EVs have much higher vehicle efficiencies compared to vehicles with SI engines (see Table V). The eight FCV options have diversified WTW energy results. The four electrolysis-based H_2 pathways actually increase total energy use, even though FCVs are much more efficient compared to SI engine vehicles. This is because electrolysis-based H_2 pathways have much lower efficiencies than the baseline RFG fuel pathway (Fig. 4) has. The two NG-based H_2 pathways and the two hydrocarbon fuels (gasoline and methanol) achieve energy benefits.

For fossil-energy-based fuels (i.e., fuels produced from petroleum and gasoline), WTW fossil energy results are similar to total energy results. However, renewable fuels (ethanol and biodiesel) achieve great fossil fuel benefits, even though they have potential total energy use penalties. Also, H_2 produced from both EU and U.S. electricity has much smaller increases in fossil fuel use because a significant portion of electricity is generated from nonfossil energy sources.

8.5 Well-to-Wheels GHG Emissions

Figure 6 shows WTW GHG emissions of the 23 vehicle/fuel systems. For each system, the bottom bar represents CO_2-equivalent emissions of CO_2, CH_4, and N_2O, combined with their global warming potentials (GWPs). The top bar represents CO_2 emissions only. For the two ethanol pathways (corn and cellulosic ethanol), there are some negative emissions. They represent carbon uptake during biomass growth. The carbon is eventually emitted to the air during ethanol combustion. Thus, the net results from the two ethanol pathways are the difference between the bars on the right of the axis

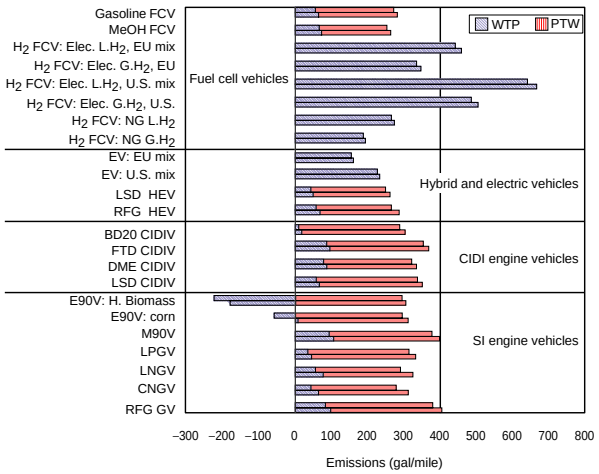

FIGURE 6 Well-to-wheels greenhouse gases and CO_2 emissions of vehicle/fuel systems; see Figs. 4 and 5 for abbreviations.

and the bars on the left. SI engine vehicles fueled with cellulosic ethanol have the lowest GHG emissions because a large amount of carbon is sequestered during biomass growth. Furthermore, biomass, not fossil fuels, is used in cellulosic ethanol plants to provide heat and steam for plant operations.

The group with the next lowest GHG emissions includes battery-powered EVs and FCVs fueled with $G.H_2$ made from NG. In the EV case, the very high efficiency overwhelmingly outweighs the low efficiency of electricity generation. In addition, some of the electricity used by EVs is generated from zero-emission sources such as nuclear power and hydropower. In the FCV case, the vehicle efficiency outweighs the inefficiency of $G.H_2$ production and compression. The third group with low GHG emissions includes HEVs, FCVs fueled with $L.H_2$ from NG, FCVs fueled with methanol and gasoline, and CIDI vehicles fueled with BD20. These vehicle/fuel systems achieve moderate GHG emissions reductions either because of efficiency gains of the vehicle technologies or because of reduced WTP GHG emissions for fuel production and distribution. The fourth group achieves some GHG emission reductions. This group includes SI engine vehicles fueled with CNG, LNG, LPG, M90 (a blend of 90% methanol and 10% gasoline, by volume), and E90 (a blend of 90% ethanol and 10% gasoline, by volume) with ethanol from corn; CIDI vehicles fueled with LS diesel, DME, and FT diesel; and FCVs fueled with $G.H_2$ from EU electricity. The last group includes FCVs fueled with $L.H_2$ from EU and U.S. electricity and $G.H_2$ from U.S. electricity. These vehicle/fuel systems actually increase GHG emissions because of

the high energy losses during electricity generation, H_2 production, H_2 compression (for gaseous H_2), and H_2 liquefaction (for liquid H_2).

For most vehicle/fuel systems, CO_2 emissions are slightly lower than GHG emissions, because CH_4 and N_2O emissions are excluded in the former. In a few cases, such as with ethanol and NG-based fuels, the differences between CO_2 and GHG emissions could be significant. In these cases, exclusion of CH_4 and N_2O emissions could give the evaluated fuel options unwarranted benefits.

8.6 Well-to-Wheels VOC Emissions

Figure 7 shows total VOC emissions of the evaluated vehicle/fuel systems. For each technology option, the bottom bar represents total VOC emissions (emissions that occur everywhere), whereas the top bar represents urban emissions (emissions that occur within urban areas). Urban emissions, a subset of the total emissions, are determined by information on locations of facilities within the United States. For vehicle operation emissions, urban emissions are estimated by using the vehicle distance traveled within U.S. urban areas. The separation of criteria pollutant emissions is intended to provide information for potential human exposure to the air pollution caused by these pollutants. Because the major concern with criteria pollutants is human health effects, the results of urban emissions are discussed here, even though there are large differences between total and urban emissions for many technology options.

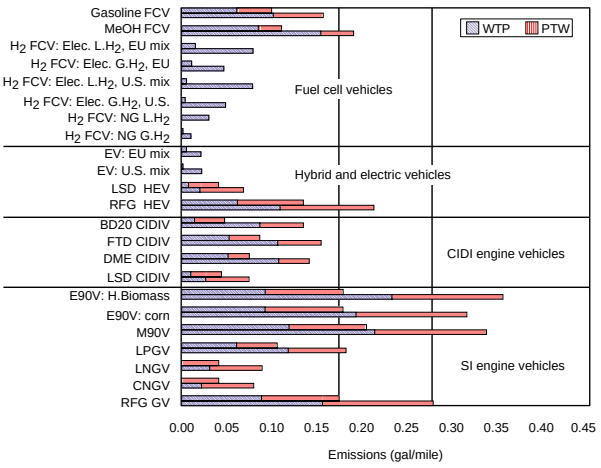

FIGURE 7 Well-to-wheels total and urban volatile organic compound emissions of vehicle/fuel systems; see Figs. 4 and 5 for abbreviations.

Of the seven SI engine technology options, CNGVs, LNGVs, and LPGVs achieve large urban VOC emissions reductions. These fuels generally have lower vehicle emissions. The E90 vehicles have VOC emissions equivalent to those of baseline GVs; M90 vehicles have a little higher VOC emissions, mainly because of high emissions from WTP stages. The four CIDI engine vehicle options have much lower urban VOC emissions compared to baseline GVs. Of the two HEV options, RFG HEVs have somewhat lower VOC emissions. Low-sulfur diesel HEVs (equipped with CIDI engines) have much lower VOC emissions. EVs and FCVs fueled by H_2 have the lowest urban VOC emissions: these vehicles are zero-emission vehicles. WTP urban VOC emissions from these options are usually small. FCVs fueled with methanol and gasoline do not achieve VOC emissions reductions as high as those offered by EVs and H_2-powered FCVs, although they offer considerable emissions reductions. This is because WTP urban VOC emissions for methanol and gasoline are relatively large, and production of H_2 from methanol and gasoline used to fuel FCVs generates VOC emissions.

8.6 Well-to-Wheels CO Emissions

Figure 8 presents the WTW CO emissions of the evaluated systems. Internal combustion engines produce a large quantity of CO emissions. Consequently, the technologies powered by these engines have high CO emissions. Also, the two FCV options with onboard fuel processors produce a significant amount of CO emissions. EVs and direct H_2 FCVs

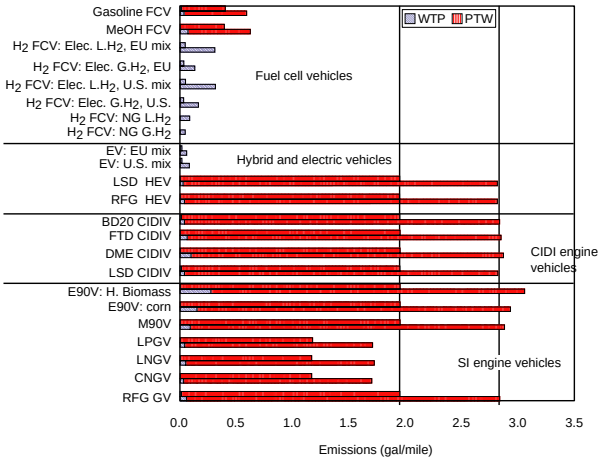

FIGURE 8 Well-to-wheels total and urban CO emissions of vehicle/fuel systems; see Figs. 4 and 5 for abbreviations.

have much lower CO emissions than the baseline GVs do.

8.7 Well-to-Wheels NO_x Emissions

Figure 9 shows NO_x emissions for the 23 vehicle/fuel systems. The differences between total and urban NO_x emissions for all technology options are large. Of the seven SI engine vehicle options, all options fueled by alternative fuels achieve significant urban NO_x emissions reductions, primarily because of low WTP urban NO_x emissions for these fuels. This is due to the plan to locate production facilities for alternative fuels outside of U.S. urban areas, in contrast to the siting of a large proportion of U.S. petroleum refineries within U.S. urban areas.

The five CIDI engine technology options and the two EV options (including LS diesel HEVs) offer small or no urban NO_x emissions reduction benefits. These technology options have high vehicle emissions. Their lower WTP NO_x emissions are not enough to offset high tailpipe NO_x emissions to achieve large WTW NO_x emissions reduction benefits. In the two EV cases, because some electric power plants are located in urban areas, NO_x emissions from these power plants cause urban NO_x emissions similar to those of baseline GVs.

FCVs fueled with H_2 from NG and with methanol and gasoline have lower urban NO_x emissions as compared to baseline GVs. The nonzero urban NO_x emissions for these vehicle options are caused primarily by their WTP urban NO_x emissions. The four electrolysis H_2 production options with EU and U.S. electricity actually increase urban NO_x emissions, even though FCVs do not generate any NO_x emissions.

8.8 Well-to-Wheels PM_{10} Emissions

Figure 10 shows PM_{10} emissions for the evaluated vehicle/fuel systems. The majority of urban PM_{10} emissions are from vehicle operations. Of these, a large proportion is from brake and tire wear. This will be especially true when future stricter tailpipe PM_{10} emission standards take effect. On the other hand, for total PM_{10} emissions, the technologies relying on electricity as the ultimate fuel have much higher PM_{10} emissions because of the high PM_{10} emissions from coal-fired power plants.

8.9 Well-to-Wheels SO_x Emissions

Figure 11 presents SO_x emissions of the evaluated systems. Because SO_x emissions are a regional as well as local air pollutant, both total and urban SO_x

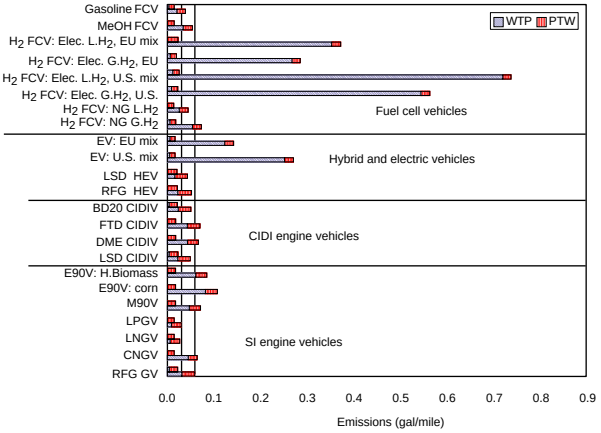

FIGURE 10 Well-to-wheels total and urban PM_{10} emissions of vehicle/fuel systems; see Figs. 4 and 5 for abbreviations.

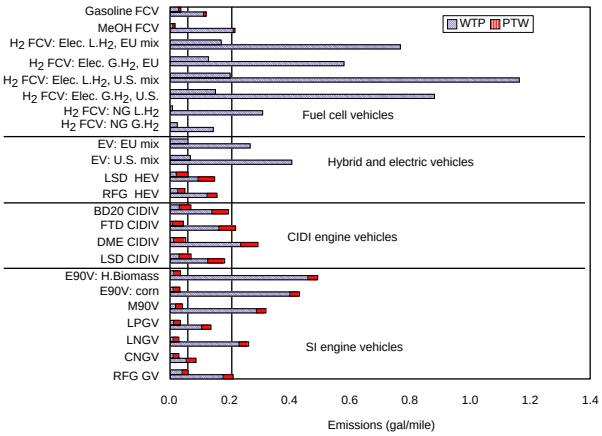

FIGURE 9 Well-to-wheels total and urban NO_x emissions of vehicle/fuel systems; see Figs. 4 and 5 for abbreviations.

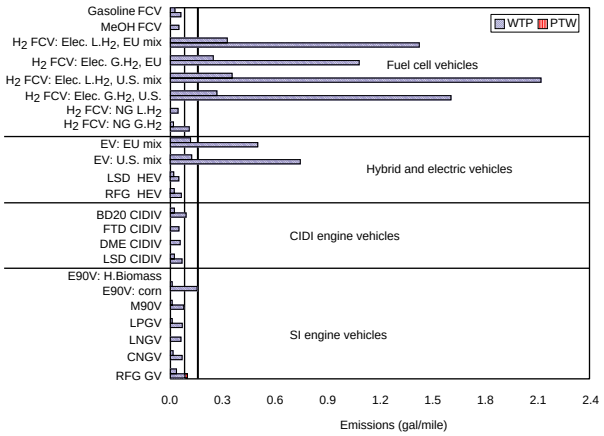

FIGURE 11 Well-to-wheels total and urban SO_x emissions of vehicle/fuel systems; see Figs. 4 and 5 for abbreviations.

emissions could be important. All the alternative vehicle/fuel systems achieve SO_x emissions reduction benefits because RFG (used in the baseline vehicle) has a higher sulfur content than do other fuels, resulting in high tailpipe SO_x emissions. Also, petroleum refineries generate considerable SO_x emissions.

All the options that rely on electricity generate very high total SO_x emissions. Corn-based ethanol and FCVs fueled with $G.H_2$ from NG generate somewhat high SO_x emissions. In the case of corn ethanol, this is because a significant amount of steam in ethanol plants is generated from coal combustion.

9. CONCLUSIONS

To evaluate the energy and emissions impacts of advanced vehicle technologies and new transportation fuels fully and accurately, researchers must conduct well-to-wheels analyses for two reasons: (1) fuel production pathways can be significantly different for new transportation fuels, resulting in different WTP energy and emission effects, and (2) vehicle tailpipe emissions, especially emissions of criteria pollutants, continue to be controlled and could become a smaller portion of the WTW emissions associated with vehicle/fuel systems.

In general, advanced vehicle/fuel systems achieve energy and emissions benefits relative to the benchmark gasoline vehicle. However, certain fuel pathways must be avoided to achieve the energy and emission benefits of some vehicle/fuel systems. Emission controls for criteria pollutants need to be considered for well-to-pump activities, as well as pump-to-wheels stages, so that advanced vehicle/fuel systems can help solve urban air pollution problems.

Glossary

driving cycle A carefully measured trip that is defined by the vehicle speed during every second of the trip over a specified distance; using a driving cycle allows different vehicles to be tested and compared in a consistent manner.

fuel economy A measure of vehicle fuel efficiency expressed as distance traveled divided by fuel consumed (e.g., miles per gallon, kilometers per liter).

hybrid drivetrains (hybrid vehicles) Generally refers to vehicles that combine a conventional fuel-driven engine with an electric drivetrain, that is, a battery (or other means of storing electricity) and a motor/controller.

light-duty vehicles Automobiles, compact passenger vans, sport utility vehicles, and pickup trucks; in the United States, statutes regulating light-duty vehicles generally restrict these to vehicles less than 8500 pounds "gross vehicle weight" (i.e., curb weight plus carrying capacity of passengers plus cargo).

top runner A means of setting vehicle efficiency, emissions, or other standards by identifying representative vehicles that excel in the characteristic being targeted and using their performance as the basis for setting standards for an entire class of vehicles.

This article describes initiatives aimed at improving the fuel economy of light-duty passenger vehicles—automobiles and light trucks (sport utility vehicles, pickup trucks, and small passenger vans). The article's primary focus is on direct measures that create fuel economy targets for national and/or corporate fleets of new vehicles.

1. OVERVIEW

Reducing the growth of fuel consumption and greenhouse emissions from light-duty vehicles (LDVs) is a critical component of attempts to prevent global warming and to reduce the vulnerability of national economies to the adverse effects of oil price volatility. In the United States, where travel by LDVs is most intensive, LDVs consume nearly 8 million barrels of oil per day, or 40% of U.S. oil consumption, and account for nearly 17% of U.S. emissions of carbon dioxide. According to the U.S. Department of Energy's Energy Information Administration, energy use and greenhouse emissions from LDVs in the United States are expected to grow by nearly 2% per year over the next few decades. Although the rest of the world is, on average, far behind the United States in vehicle ownership and use (nearly 800 vehicles/1000 population in the United States vs $\sim$120 vehicles/1000 population for the world average and $\sim$30 vehicles/1000 population for the developing world), growth rates of both vehicle ownership and fuel use are much higher outside the United States and especially in the developing world. It is unlikely that U.S. levels of vehicle ownership and per capita personal travel will become the global norm, but it appears inevitable that vehicle ownership and personal travel will continue to grow rapidly throughout the world.

Restraining the growth of greenhouse emissions and oil use of LDVs can be accomplished by improving vehicle efficiency (fuel economy), substituting nonpetroleum fuels (with lower lifecycle greenhouse emissions), reducing travel demand

 © 2004 Elsevier Inc. All rights reserved.

(e.g., by raising the cost of travel or promoting compact development), and promoting shifts in travel to other modes that are more efficient and/or use nonpetroleum fuels (e.g., rapid transit). All of these approaches are worth pursuing.

In addition to reducing oil consumption and greenhouse emissions, improvements in fuel economy will affect emissions that directly affect human and ecosystem health. The primary positive effect is through the reduced need to produce, refine, and distribute vehicle fuels, yielding a proportional reduction in so-called "upstream" emissions and fewer hydrocarbon emissions from vehicle refueling. However, the effect on vehicle tailpipe emissions is decidedly mixed and may well be negative. On the one hand, reductions in fuel consumption generally yield a proportional reduction in emissions from the engine. On the other hand, this may make little practical difference in actual tailpipe emissions if emissions regulations are written in terms of maximum allowed weight of emissions per unit of distance driven (as they are in the United States, Europe, and Japan). In this case, manufacturers are likely to use fewer emissions controls on those vehicles with inherently lower emissions, yielding the same emissions outcome—with the important caveat that, if vehicle emissions controls malfunction, the more efficient vehicles will then tend to have lower tailpipe emissions than their less efficient counterparts. A decidedly negative impact is associated with any increase in travel caused by the lower per mile fuel costs associated with improved efficiency (the so-called "rebound effect"); this will increase emissions. The overall net impact on health-related emissions of these several effects is not clear.

The three major markets that currently have active fuel economy initiatives—the United States, Japan, and the European Union (EU)—have approached the pursuit of higher levels of fuel economy in different ways. The United States has pursued what some consider to be a contradictory policy, combining an economic policy that maintains low fuel prices with a regulatory policy that demands attainment of fixed fuel economy levels. U.S. standards have remained at 27.5 mpg for passenger cars and between 20 and 21 mpg for light trucks since 1985 (although there is a pending proposal to increase the light truck standard to 22.2 mpg by model year 2007). At the same time, U.S. gasoline prices have been half or less than half the prices prevailing in Europe and Japan (due to much lower tax rates in the United States), and this has provided minimum economic incentive for U.S. motorists to seek out vehicles with high fuel economy. On the other hand, until recently neither Japan nor the EU had used formal standards to stimulate higher levels of fuel economy, apparently relying on high fuel prices (generally $3.00/gallon and up) to maintain efficient fleets. However, Japan recently introduced a set of "weight class standards" that require attainment of fuel economy targets in each of nine weight categories, with an estimated fleet fuel economy improvement (from 1995 levels) of about 23%—to approximately 35 mpg—by 2008. Also, the EU accepted a voluntary commitment from its vehicle manufacturers associations for a reduction in "per vehicle" CO_2 emissions of 25% percent—to 140 g CO_2/km—by 2010 (2009 for the Japanese and Korean associations), also from a 1995 baseline. If fuel composition does not change, this corresponds to a fuel economy improvement of 33%—to about 41 mpg.

In addition to fuel taxes and fuel economy standards, approaches to improving LDV fuel economy include

- vehicle purchase and ownership taxes, tax credits, and direct purchase subsidies rewarding high efficiency;
- government requirements for public access to information about fuel economy and fuel costs, allowing vehicle purchasers to appropriately incorporate these factors into their purchase decisions;
- government sponsorship of research and development (R&D) on higher efficiency vehicles;
- government requirements for fleet purchase of high-efficiency vehicles.

Although this article does not address regulations controlling health-related vehicle emissions, many developing nations are beginning to adopt emissions standards based on those of the industrialized nations, especially recent EU standards. Complying with these standards may require adoption of improved engine controls and fuel injection, both of which should yield improved fuel efficiency.

2. *FUEL ECONOMY STANDARDS*

2.1 Overview

The most direct way in which to improve LDV fuel economy is to establish clear targets for new vehicle fuel economy or CO_2 emissions (although the latter

can theoretically be attained partly, or even solely, by switching to lower carbon fuels). In 1974, U.S. automakers voluntarily agreed to achieve a 40% improvement in fuel economy by 1980. This voluntary agreement was superseded by mandatory standards promulgated in 1975, aiming for still higher gains by 1985. Canada followed the U.S. example with a set of voluntary fuel economy targets mimicking the United States' mandatory ones. Within the past few years, both the EU and Japan have established new targets, the EU through a voluntary commitment with its automobile manufacturers associations and Japan through a set of mandatory fuel economy targets based on vehicle weight classes.

Setting fuel economy or CO_2 emissions targets for future vehicles or fleets raises a number of important concerns. Some of the key concerns include the following:

- *Economic efficiency and impacts.* Many in the environmental community have championed new fuel economy standards because they appear to guarantee results and perhaps because the U.S. standards appear to have been quite successful. However, economists have generally not supported fuel economy standards because they fear that such standards may force manufacturers to produce vehicles that consumers will not want, they do not address the demand for vehicle travel (and actually will tend to boost travel by reducing fuel costs, thereby offsetting some of the fuel savings associated with the increased efficiency—the rebound effect), and they inevitably create strong incentives for manufacturers to "game play" to take advantage of quirks in the regulations. A number of studies have compared fuel economy standards with other means of reducing oil consumption and greenhouse gas emissions, and others have examined the economic impacts of new standards, particularly the impact on employment. A thorough examination of these studies would require a separate discussion, but they can be summarized with extreme brevity as follows. First, standards generally are less efficient than direct economic incentives, in particular fuel taxes, which will suppress travel as well as stimulate higher fuel economy. However, there is little agreement about the magnitude of the difference in economic efficiency among the different approaches due to the wide range in estimates of the fuel price sensitivity of travel and fuel economy and similar disagreements about the actual costs of new standards. Second, employment impact studies sponsored by the vehicle manufacturers generally conclude that new standards will reduce employment, whereas studies sponsored by the environmental community conclude that new standards will increase employment. These differences are driven primarily by very different underlying assumptions about the success and costs of new standards as well as about the approach that manufacturers will take to comply with the standards.
- *Selection of targets and assumptions about future technological and market development.* Unless fuel economy targets are quite modest and short term, the process of developing reasonable standards requires a set of assumptions about how automotive technology will change within the time frame of the standards, how consumer tastes will change (or not change), and how manufacturer market behavior will change (e.g., whether companies will go after new markets, whether companies will produce new classes of vehicles). Analyses leading to new standards have tended to avoid these questions by assuming little or no change, for example, no change in vehicle attributes such as weight and power (except possibly to address existing emissions and safety standards). All aspects of the vehicle marketplace have changed substantially over time, with strong impacts on fuel economy improvement potential.

Those who might wish to apply any of the existing standards to their own markets, or who simply wish to understand how ambitious the targets are, should pay careful attention to a variety of factors that affect the fuel economy potential of a particular market. The more important factors include the following:

- *Fuel taxes.* All else equal, higher fuel taxes and prices will mean that vehicle purchasers will have greater incentive to buy more fuel-efficient vehicles and manufacturers will have greater incentive to make them. Although raising fuel prices may be a desirable strategy for increasing fleet fuel efficiency (and reducing vehicle miles driven), higher fuel taxes might not be politically viable. In any case, attaining a given fuel economy target should generally be easier in markets with high fuel prices.
- *Driving cycles and conditions.* The driving cycle over which fuel economy is measured can strongly influence the performance of fuel economy technologies such as improved engines and use of lightweight materials. In general, regulators try to measure fuel economy on a driving cycle that corresponds well to actual driving conditions in their market. For example, Japanese driving conditions are best represented by congested city driving, and

the official Japanese "10.15" driving cycle used to measure fuel economy for regulatory purposes is a slow, stop-and-go cycle. (10.15 refers to the two sets of speed profiles in the cycle: one with 10 and the other with 15 separate driving modes—acceleration, deceleration, or constant speed driving. The 10-mode portion of the cycle is driven three times, followed by one 15-mode portion.) The U.S. regulatory cycle uses much faster speeds, with the European cycle somewhat in between, and these cycles represent average driving conditions in their markets reasonably well. One effect of these differences is to reward certain key technologies that focus on improving "low-load" efficiency—variable valve timing, hybrid drivetrains, idle–off, and the like—with significantly higher fuel economy "boosts" on the Japanese cycle than on the U.S. cycle. In contrast, improvements in aerodynamics are well rewarded on the U.S. cycle, and are nearly irrelevant on the Japanese cycle, because aerodynamic drag forces are much more important at high speeds than at low speeds. A critical effect of differences in driving cycles among the different markets is that the fleet fuel economy value and targets in each market are not directly comparable to those in the other markets. In general, if the current fuel economy levels in each market were to be measured on the U.S. driving cycle, the European fleet would have its measured fuel economy levels raised a bit (from their value on the European cycle) and the Japanese fleet would be raised even more. However, the percentage changes needed to "normalize" the fleets to a single driving cycle will change over time as technology changes.

- *Emissions regulations.* Emissions regulations can affect the performance and cost of key engine technologies and in extreme circumstances can prevent certain technologies from being used. Currently, emissions standards in the three markets with fuel economy standards are strictest in the United States and most lenient in Japan. Unless excellent progress is made in lean burn NO_x control technology, strict U.S. NO_x standards might serve to ban or significantly limit diesel use in the LDV fleet and reduce the fuel economy performance of direct injection gasoline engines. In contrast, European and Japanese standards allow for such "lean technologies" and, moreover, do not hold diesel-fueled vehicles to NO_x emissions levels as stringent as those for gasoline-fueled vehicles.
- *Vehicle taxes.* High vehicle taxes can serve to make new fuel economy technologies more expensive because they apply to the price of the total vehicle. For example, EU countries have "value-added" taxes that apply to the total price of the vehicle. On the other hand, countries may impose taxes on vehicle sales and/or ownership that vary with fuel efficiency or with factors that are likely to affect fuel efficiency, especially engine power or displacement, and these taxes would provide a positive incentive for high-efficiency vehicles. Several EU countries and Japan have such taxes. Also, some countries may give tax credits or deductions for certain kinds of high-technology vehicles, increasing the cost-effectiveness of these vehicles and making it somewhat easier for fleets to achieve high fuel economy. For example, the United States gives tax deductions to purchasers of hybrid electric vehicles.
- *Vehicle miles driven.* More driving means higher annual fuel savings from new technologies, thereby improving the cost-effectiveness of these technologies. For example, LDVs are driven farther in the United States ($\sim$13,000 miles/year for the first 5 years) than in Europe (8000–9000 miles/year), and much farther than in Japan ($\sim$6000 miles). This tends to raise the cost-effectiveness of new technologies in the United States versus that in the other markets.
- *Average vehicle efficiency.* In considering how high a percentage increase in current fuel economy might be sought, a high current fuel economy will mean that a particular percentage increase will save less fuel than would be saved if current fuel economy was low. In other words, a 20% increase would save more fuel in the United States than in Europe or Japan because the current U.S. fuel economy level is lower than in the other markets.

2.2 U.S. Corporate Average Fuel Economy Standards

In the United States, all major automakers are subject to Corporate Average Fuel Economy (CAFE) standards requiring their new vehicle fleets to meet specific fuel economy targets. The standards were established by the Energy Policy and Conservation Act of 1975 in response to the 1973 oil embargo and subsequent oil price shock. Under the act, each manufacturer's fleet of new vehicles is subdivided into passenger cars and light trucks (including pickup trucks, vans, and sport utility vehicles) and the passenger car fleet is further subdivided into domestic and import vehicles, where vehicles with less than 75% U.S./Canadian content are considered to be imports. Each individual fleet must then meet a separate target. In 2002, each manufacturer's domestic and import passenger car fleet had to average at

least 27.5 mpg and each manufacturer's light truck fleet had to average at least 20.7 mpg. Manufacturers that do not comply with these standards are liable for a civil penalty of $5.50 for each tenth of 1 mpg its fleet falls below the standard, multiplied by the number of vehicles in the noncomplying fleet. The U.S. government has enforced the standards; for example, in calendar year 2001, manufacturers paid civil penalties totaling more than $33 million for failing to comply with the standards in model years 1999 and 2000.

Additional important characteristics of the standards are as follows:

- *Low-volume manufacturers.* The standards can be waived for low-volume manufacturers, that is, those producing fewer than 10,000 passenger cars annually worldwide.
- *Vehicle weight limits.* The standards apply only to vehicles whose gross vehicle weight rating (GVWR) is 8500 pounds or less. A number of large sport utility vehicles have GVWRs above this level and are not subject to the standards.
- *Setting and amending standards.* The U.S. Congress set the original schedule for passenger car standards and authorized the National Highway Traffic Safety Administration (NHTSA), in the Department of Transportation, to set the light truck standards. Manufacturers were required by Congress to comply with the 27.5-mpg standard for passenger cars by 1985, and the standard has remained unchanged since (except for a brief reduction from 1986 to 1989). NHTSA is authorized to amend the passenger car and light truck standards.
- *Testing responsibility.* Manufacturers are responsible for measuring their own fleet fuel economy. They test preproduction prototypes of their new vehicle models and submit the results to the U.S. Environmental Protection Agency (EPA). EPA retests approximately 10% of the tested vehicles to confirm the manufacturer's tests.
- *Test procedure.* The procedure for testing vehicle fuel economy consists of having a professional driver drive the vehicle on a dynamometer through two driving cycles designed to simulate city and highway driving. Each vehicle is driven in the same manner on the same type of equipment, so that results can be compared with confidence. The city test begins with a cold start (as if the vehicle had been parked overnight) and simulates an 11-mile, stop-and-go trip at mostly low speeds (although the maximum speed is 56 mph), averaging 20 mph. The trip takes 31 min with 23 stops and a total of about 5.5 min of idle time. The highway test begins with the engine warmed up and simulates a 10-mile combined highway/rural road trip at an average speed of 48 mph and a maximum of 60 mph. The resulting two fuel economy values are averaged by assuming that 55% of driving is city driving and 45% is highway driving, with the average calculated by the following formula:

$$1/\text{vehicle mpg} = 0.55/(\text{city mpg}) + 0.45/(\text{highway mpg}).$$

Calculating CAFE. Each manufacturer's CAFE is the sales-weighted average of the tested fuel economy levels of its vehicles. This average is calculated in a manner similar to the preceding formula, that is, the inverse of the fuel economy level (the fuel consumption level) of every vehicle in the manufacturer's fleet is added, with the sum divided by the total number of vehicles. To clarify, if a manufacturer sold two types of vehicles with annual sales of 100,000 and 300,000, its fleet average fuel economy (CAFE) would be calculated using the following formula:

$$1/CAFE = [100,000/(\text{mpg of vehicle 1}) + 300,000/(\text{mpg of vehicle 2})] \div 400,000.$$

Credits. Manufacturers can earn credits if they exceed the standards, and these credits can be applied to any of the subsequent or preceding 3 years to offset shortfalls. Also, a manufacturer failing to meet the standard for a given model year can avoid paying the civil penalties by submitting a compliance plan to NHTSA demonstrating that it will earn enough credits within the next 3 model years to offset the penalties. Manufacturers also earn credits by producing and selling alternative fuel vehicles, with greater credits awarded for dedicated vehicles than for dual-fuel vehicles (which can burn either gasoline or an alternative fuel). Although each alternative-fuel vehicle obtains a high fuel economy value based on the theoretical amount of oil-based fuel it consumes (theoretical because dual-fuel vehicles may burn gasoline exclusively), total credits awarded to a manufacturer cannot increase its official CAFE value by more than 1.6 mpg.

- *Original schedule.* Although the passenger car CAFE targets have remained constant since 1990 and the light truck targets have remained constant since 1996, the original legislation was crafted to allow companies to raise their fleet fuel economy levels gradually, taking into account the impossibility of redesigning entire corporate fleets simultaneously as

well as the time needed to develop improved technology. Thus, for passenger cars, the 1978 standard was 18.0 mpg, with yearly increases thereafter (to 19.0 mpg in 1979, 20.0 in 1980, 22.0 in 1981, 24.0 in 1982, 26.0 in 1983, and 27.0 in 1984), leading to the 27.5-mpg target in 1985.

Although there have been arguments about whether increases in U.S. LDV fuel economy after 1975 were caused mostly by the CAFE regulations or were instead caused largely by market forces, the U.S. fleet has generally complied with the regulations and has maintained fuel economy values above the required levels despite low gasoline prices and shifts in consumer tastes toward larger, more powerful vehicles. However, since attaining the standards, U.S. fleet fuel economy has essentially stopped improving, and the combined car and truck fuel economy has actually declined due to increasing market shares of (less efficient) light trucks. Over the past two decades, the U.S. fleet has used a continuing influx of new technology to allow fleet fuel economy levels to be maintained while other factors—weight, acceleration time, luxury features, and the like—moved in directions that would otherwise have reduced fuel economy. EPA has estimated that the tested fuel economy (not adjusted downward for onroad conditions) of the model year 2001 fleet of cars and trucks, which was 23.9 mpg, would have instead been 30.3 mpg had the weight mix and 0-to-60 mph acceleration times of the fleet been the same as that of the 1981 model year. In other words, the fleet traded away between 6 and 7 mpg for higher weight and better acceleration during that 20-year period.

A number of controversies have arisen over the CAFE standards. Probably the most important is the claim that size and weight reductions demanded by the standards have had an adverse impact on overall vehicle safety. This claim has tended to dominate discussions about raising future CAFE standards. The National Research Council's (NRC) Committee on the Effectiveness and Impact of Corporate Average Fuel Economy Standards concluded in 2002 that the change in size and weight of the fleet between 1976 and 1993 caused about 2000 additional traffic fatalities in 1993. There was a strong dissent to the committee's conclusions from within the committee itself as well as from other analysts. Furthermore, an earlier national academy panel concluded that the available analyses showing vehicle weight/traffic fatality correlations should not be used to project fatalities caused by fleetwide weight changes because the analyses could not adequately control for various confounding factors such as driver age. The issue is complicated by the fact that fuel economy can be improved without weight reduction and that the distribution of weight within the fleet is likely to be more important to safety than the average weight. A reanalysis of traffic fatality data sponsored by Honda, using more recent data but the same analytical method cited by the NRC committee, found essentially no impact on traffic fatalities from a 100-pound reduction in the average weight of the fleet.

Manufacturer responses to some provisions of the standards have caused some controversy. For example, the division into domestic and import fleets has created incentives for manufacturers to alter the domestic "content" of individual models to move them into one fleet or the other depending on circumstances. The original purpose of the division was to create an incentive for manufacturers to produce small cars within the United States so as to boost domestic employment (manufacturers needed the smaller cars to provide a counterweight to larger, less efficient models that previously had been their major market focus for domestic production). The division succeeded in stimulating domestic small car production, but it also created an incentive to add import content to larger domestic models so as to get them out of the domestic fleet and into a fleet of more efficient import models that could more easily offset their low fuel economy. For example, Ford temporarily made its full-size (and relatively low-fuel economy) Crown Victoria model into an "import" to get it out of the domestic fleet, thereby aiding that fleet in complying with its CAFE standard.

In 2002, the State of California passed legislation (Assembly Bill 1493) that requires the California Air Resources Board to establish greenhouse gas standards for vehicles in model year 2009 and beyond, applying to corporate fleet averages. Although automakers will be able to partially comply with the standards by reducing greenhouse gas emissions from nonvehicle sources and by shifts in fuels, the standards will essentially have an effect similar to that of fuel economy standards. The bill has been challenged in the courts by the vehicle manufacturing industry on the basis that the standards will be fuel economy standards and that only the federal government can set such standards.

2.3 Japanese Weight Class Standards

The Japanese government has established a set of fuel economy standards for gasoline- and diesel-

powered light-duty passenger and commercial vehicles, with fuel economy targets based on vehicle weight classes. Table I shows the vehicle targets for gasoline- and diesel-powered passenger vehicles, as measured on the Japanese 10.15 driving cycle. The targets for gasoline-powered vehicles are to be met by 2010, and 2005 is the target year for diesel-powered vehicles. Figure 1 illustrates the percentage improvements required for each weight class of gasoline-powered vehicles as well as the market share for each class at the time the regulations wave created. The original regulations demanded that the targets be met by each automaker for each weight class; that is, automakers could not average across weight classes by balancing a less-than-target vehicle in one class with a better-than-target vehicle in another class. Revisions to the regulations in January 2001 allow automakers to accumulate credits in one weight class and use them in another class, with important limitations.

Assuming no change in vehicle mix, these targets imply a 22.8% improvement in gasoline passenger vehicle fuel economy (15.1 km/L in 2010 vs 12.3 km/L in 1995) and a 14.0% improvement in diesel passenger vehicle fuel economy (11.6 vs 10 km/L) compared with the 1995 fleet. In other words, compliance with

TABLE I

Japanese Weight Class Fuel Economy Standards for Passenger Vehicles

	Vehicle weight class (kg)								
	750	875	1000	1250	1500	1760	2000	2250	2500
A. Gasoline-Fueled Passenger Vehicles for 2010									
Vehicle curb weight (kg)	–702	703–827	828–1015	1016–1265	1266–1515	1516–1765	1766–2015	2016–2265	2266–
Vehicle curb weight (pounds)	1548	1550–1824	1826–2238	2240–2789	2791–3341	3343–3892	3894–4443	4445–4994	4997–
Fuel economy target (km/L)	21.2	18.8	17.9	16.0	13.0	10.5	8.9	7.8	6.4
Fuel economy target (mpg)	49.9	44.2	42.1	37.6	30.6	24.7	20.9	18.3	15.0
B. Diesel-Powered Passenger Vehicles for 2005									
Vehicle weight (kg)	–1015	1016–1265	1266–1515	1516–1765	1766–2015	2016–2265	2266–		
Vehicle weight (pounds)	–2238	2240–2789	2792–3341	3343–3892	3894–4443	4445–4994	4997		
Target standard (km/L)	18.9	16.2	13.2	11.9	10.8	9.8	8.7		
Target standard (mpg)	44.5	38.1	31.0	28.0	25.4	23.0	20.5		

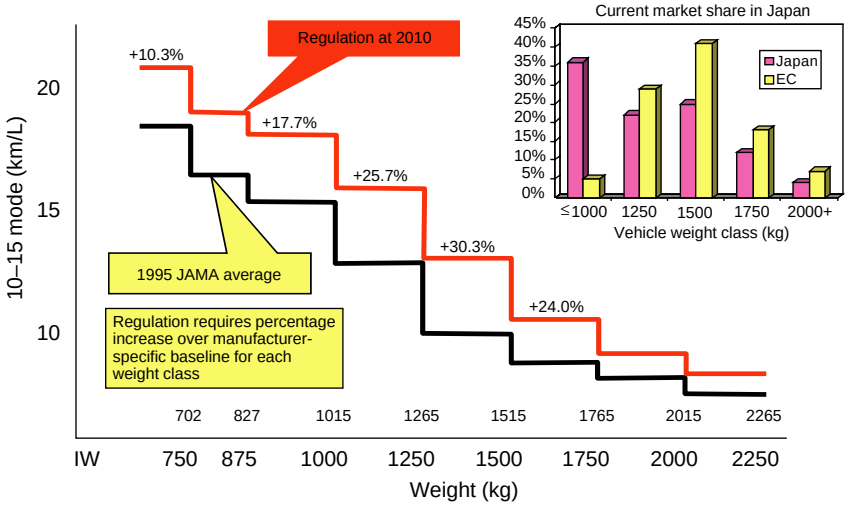

FIGURE 1 New Japanese fuel economy regulations. (Source: Japan Ministry of Transport.)

these standards will produce a Japanese gasoline-fueled, light-duty passenger vehicle fleet of 35.5 mpg and a diesel fleet of 27.3 mpg by 2010 and 2005, respectively, as measured using the Japanese 10.15 driving cycle (and assuming no changes in the market shares of the various weight classes). The Japanese 10.15 driving cycle is substantially slower than the combined U.S. city/highway cycle, and the U.S. equivalent miles per gallon for this fleet would be significantly higher.

The regulations call for civil penalties if the targets are not met, but these penalties are very small. The formal enforcement procedure includes a government assessment of whether the automakers have taken the necessary steps to comply with the targets, recommendations by the regulating agencies about steps they might take, and another assessment by the agencies of the adequacy of the automakers' compliance with the recommendations, with the procedures taking more than 1 year. Realistically, enforcement will come from pressure from the government and the auto companies' desire to avoid public embarrassment, not from the financial penalties.

The fuel economy targets were selected by identifying representative "best in class" fuel economies in each weight class and demanding that the average new vehicle meet that level in the target year. The Japanese call this the "top-runner" method of selecting fuel economy targets. The actual top-runner fuel economy target might not be the highest in the weight class. As described in the next subsection, some vehicles will not be candidates for top-runner status so as to avoid saddling the automakers with impractical targets based on exotic technology or nonrepresentative characteristics.

As noted previously, manufacturers may accumulate credits in a weight class by achieving levels of fuel economy higher than the target levels. These credits, measured as (difference in fuel consumption between the vehicle and the target fuel consumption rate) * (number of vehicles sold), can be applied to vehicles in another weight class at a 50% rate; that is, two credits are needed to offset one unit of underperformance. However, the credits can be applied only if the automakers' performance in the failed weight class meets the threshold values of fuel efficiency shown in Table II (for gasoline vehicles).

The fuel economy regulations have additional requirements over and above the actual fuel economy targets. These are as follows:

1. For new vehicles, fuel economy and major efficiency technologies onboard must be recorded in catalogs and displayed at exhibits.
2. Government is charged with providing education and other incentives for vehicle users and manufacturers, making sure that fuel economy regulation proceeds in harmony with other regulations (especially new emissions and fuel quality standards), reviewing manufacturers' efforts to improve fuel economy, and trying to harmonize this regulation with similar efforts in Europe and the United States.
3. Manufacturers are expected to develop new efficiency technologies, design vehicles of outstanding efficiency, and help to educate the public.
4. The public is charged with selecting efficient vehicles and using them in an efficient manner.

Although the Japanese standards do not take effect until 2010, some concerns have already arisen. First, changes in the weight composition of the Japanese fleet may change the degree of improvement in fuel economy demanded by the standards. Figure 2 shows how the weight distribution of the fleet has changed between 1995 and 2000. Primary changes include a large reduction in the lightest (750-kg) market segment and substantial increases in the heavier segments. If the year 2000 weight distribution is applied to the fuel economy standards, the expected improvement in fleet fuel economy over the 1995 baseline would be 18.0% versus the 22.8% percent projected by the Japanese government based on the 1995 weight distribution. Conceivably, future changes in the fleet's weight distribution might drive down the expected improvement even further.

TABLE II

Fuel Economy Thresholds for Use of Credits (Japanese Weight Class Standards)

Weight class (kg)	750	875	1000	1250	1500	1760	2000	2250	2500
Fuel economy threshold (km/L)	20.2	18.5	17.1	14.1	12.6	9.8	8	6.8	6.1
Target fuel economy (km/L)	21.2	18.8	17.9	16	13	10.5	8.9	7.8	6.4

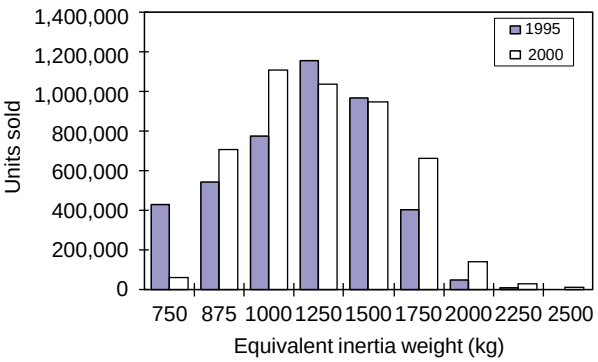

FIGURE 2 Weight distribution of the Japanese new LDV fleet, 1995–2000. (Source: Kiyoyuki Minato, Japan Automobile Research Institute.)

Another concern is the limitation on averaging fuel economy across weight classes. This allowed "50% averaging" still leaves manufacturers with far less flexibility than if full averaging were allowed. This lack of flexibility particularly affects European and U.S. manufacturers that export into the Japanese market and that are likely to have limited numbers of models, and possibly only one model, in a weight class.

2.3.1 The Japanese Top-Runner Selection Process

The new Japanese weight class standards for LDV fuel economy are based on identifying top runners—vehicles with exemplary fuel economy—in each weight class and requiring future vehicles in that class to attain similarly high fuel economy. According to Japanese industry sources, the top-runner selection process is more nuanced than simply selecting the highest fuel economy vehicle in each class and establishing that as the standard. Instead, the regulators—the Ministry of International Trade and Industry (MITI) and the Ministry of Transportation (MOT)—with the consultation of the Japanese Auto Manufacturers Association (JAMA), select top-runner targets based on their judgment of the relevance of class-leading vehicles and their technology to the class as a whole. For example, because the large majority of personal vehicles use automatic transmissions, only vehicles with automatic transmissions are considered as top-runner candidates for personal vehicles. For commercial vehicles, separate goals are established for vehicles with automatic and manual transmissions. Top-runner candidates that have very small sales volumes and/or very expensive technology are not likely to be considered because the regulators are interested in technologies that have been shown to be practical for the class as a whole. For example, the hybrid electric vehicles currently in the Japanese marketplace were not used as top runners.

2.4 ACEA Voluntary Commitment to the EC on Vehicle Carbon Emissions

The European Automobile Manufacturers Association (ACEA) has offered, and the European Commission (EC) has accepted, a voluntary commitment to reduce the CO_2 emissions from new light-duty passenger vehicles, with firm fleetwide targets of 140 g CO_2/km (~41 mpg for gasoline) by 2008, measured under the new European test cycle (Directives 93/116/EC and 99/100/EC). This represents approximately a 25% reduction from the 1995 average of 187 g/km (~30 mpg) on this cycle. The European cycle is likely to produce lower fuel economy ratings than the U.S. combined urban/highway cycle, so the "U.S. equivalent" miles per gallon ratings of the year 2008 European fleet will likely be higher than 41 mpg if the targets are met.

Note that the 140-g CO_2/km goal is a collective target, not a target for each individual company. The ACEA participants in the voluntary commitment—BMW, Fiat, Ford of Europe, GM Europe, DaimlerChrysler, Porsche, PSA Peugeot Citroen, Renault, Rolls-Royce, Volkswagen, and Volvo—have not publicly committed to individual objectives.

The voluntary commitment applies to light passenger vehicles classified as M1 in European Council Directive 93/116/EC, which includes vehicles with no more than eight seats in addition to the driver. The commitment includes a promise to introduce some models emitting 120 g/km (~48 mpg) or less by 2000 and a nonbinding 2003 target range of 165 to 170 g/km (~34–35 mpg). In addition, the commitment was to be reviewed in 2003 with the aim of moving toward a fleet goal of 120 g/km by 2012. Finally, ACEA agrees to monitor compliance with the commitment jointly with the EC.

In exchange for their commitment to meet the 2008 CO_2 emissions goal, industry members insisted that the voluntary commitment be contingent on a number of conditions, including the following:

- *Clean fuels availability.* Because the industry believes that direct injection engines will play a key role in achieving the targets, the commitment requires "full-market availability" of clean fuels needed for this technology by 2005—gasoline with 30 ppm sulfur content and less than 30%

aromatics, diesel fuel at 30 ppm sulfur and cetane number greater than or equal to 58. The low sulfur level is needed to avoid poisoning the catalysts needed for NO_X control.
- *Protection against unfair competition.* Non-ACEA members must commit to similar goals, and the European Community will agree to try to persuade other car manufacturing countries to embrace equivalent efforts. The latter is designed to protect ACEA members from suffering in world market competition for their European efforts.
- *Regulatory ceasefire.* There are no new regulatory measures to limit fuel consumption or CO_2 emissions.
- *Unhampered diffusion of technologies.* The companies assume that the EC will take no action that would hamper the diffusion of efficiency technologies, particularly direct injection gasoline and diesel engines. Presumably, this could include tighter emissions standards on NO_x and particulates. ACEA assumes that up to 90% of the new vehicle fleet will use direct injection engines by the 2008 compliance date, and tighter standards for these pollutants might interfere with the diffusion of this technology.

The voluntary commitment also incorporates a statement that might be seen as an escape hatch for the companies:

> *On the basis of the outcome of the monitoring, or if the impacts of this commitment on the European automotive industry, particularly its employment situation and its global competitive environment, are detrimental, ACEA and the [European] Commission will review the situation and make any necessary adjustments in good faith.*

Both JAMA and the Korean Automobile Manufacturers Association (KAMA) have agreed to a revised version of the ACEA targets—achievement of the 2008 target levels in 2009.

A concern with the voluntary commitment is that it does not specify individual corporate targets, nor does it define mechanisms to guarantee attainment of the fleet target. The flexibility afforded by the lack of specified individual targets theoretically could lead to an efficient market solution if companies could agree among themselves to attain levels of fuel economy improvement that represent approximately equal marginal net value (value of fuel savings minus technology cost). However, it is not clear that there is any agreement among the companies defining their individual targets, and there is no guarantee that all companies will make a fair effort toward meeting the fleet target. The lack of specified corporate targets might tempt companies to provide less than their full effort and might make it difficult for the EU to assess responsibility if the industry fails to meet the target.

3. FUEL TAXES

3.1 Overview

Economists have overwhelmingly favored fuel taxes over fuel economy standards as a means to reduce fuel consumption because taxes give maximum flexibility to both vehicle manufacturers and purchasers and because they influence fuel consumption through both fuel demand and vehicle supply by making travel more expensive (thereby reducing vehicle miles traveled) and by creating an economic incentive for manufacturers to build efficient vehicles and for consumers to purchase them. However, it is important to note that the presumed superior effectiveness of fuel taxes over CAFE standards depends on the assumption that markets for fuel economy and travel are very efficient. This assumption about an efficient market, especially as it pertains to the market for fuel economy, is debatable, and the interested reader is urged to examine the considerable literature on this subject.

Because analyses of future light-duty transportation energy use require estimates of the impact of fuel prices on travel and fleet fuel economy, estimates of the fuel price elasticity of travel, fuel economy, and fuel consumption are ubiquitous in the literature. However, there is substantial disagreement about the magnitude of these elasticities because travel volumes, fuel economy, and fuel consumption are dependent on several variables other than fuel price and because fuel prices have tended to be volatile during the past few decades, thereby complicating attempts to estimate long-run elasticities. Thus, the magnitude of the effect of changes in fuel taxes on fleet fuel economy and on travel volumes and fuel consumption is also subject to considerable disagreement. For the United States, recent studies by D. L. Greene and others imply that a 10% gasoline price increase would cause at most approximately a 2% increase in average fuel economy, a 2 or 3% decrease in travel, and a 4% decline in gasoline consumption (compared with a baseline, and increasing, level) over the long term. However, others conclude that the decline in gasoline consumption would be higher—as much as 6 or 8%. The effect elsewhere will be different. For example, in Europe and Japan, fuel prices make up a larger share of the total cost of

travel, implying that fuel price elasticities there will likely be higher than those in the United States.

3.2 United States

In the United States, motor vehicle fuel taxes have generally been viewed as "user taxes" at the federal and state levels. In other words, the federal government and most state governments set their per gallon tax rate at a level that will pay for a substantial share of road-building requirements. In addition, states and localities add sales taxes as a percentage of fuel prices. Federal taxes in 2000 were $0.184/gallon for gasoline and $0.244/gallon for diesel fuel. Gasohol, a blend of 90% gasoline and 10% ethanol by volume, was taxed at only $0.131/gallon. State taxes averaged about $0.20/gallon plus sales taxes, the latter of which vary between 1 and 7%. In addition, 12 states allow localities to add their own taxes.

The result is that taxes on gasoline and diesel fuel in the United States have been quite low in comparison with those in Europe and Japan. In 2000, the average U.S. gasoline price (less local taxes) was $1.48/gallon, of which 28% was federal and state taxes. The average total gasoline price in 2001 was $1.63/gallon, and the average diesel price was $1.52/gallon.

3.3 Japan and Europe

Europe and Japan have traditionally taxed gasoline at high rates, so that gasoline prices have been much higher than those in the United States. These higher prices, along with differences in land use patterns and other factors, play an important role in the strong differences in average per vehicle miles traveled among Europe, Japan, and the United States; over their first 5 years of life, LDVs are driven approximately 13,000 miles in the United States, 8000 miles in Europe, and 6000 miles in Japan.

In 2001, Japanese gasoline prices averaged $3.80/gallon as compared with $3.68/gallon in France, $3.74/gallon in Germany, and $4.63 in the United Kingdom. With the exception of the United Kingdom, diesel prices were substantially lower—$2.70/gallon in Japan, $2.80/gallon in France, and $2.91/gallon in Germany. U.K. diesel prices were virtually the same as gasoline prices—$4.42/gallon.

In Europe, the price differences among the various countries and the gasoline/diesel price difference are due nearly entirely to differences in taxation. Table III displays the gasoline and diesel taxes in the several European countries. As shown by the table, every European country but the United Kingdom taxes diesel fuel substantially less than it does gasoline on a volumetric basis despite diesel fuel's higher volumetric energy content. This differential has stimulated sales of diesel-powered vehicles, which have soared in Western Europe—to nearly 40% of new vehicle sales during the first 6 months of 2002.

TABLE III

European Taxes on Gasoline and Diesel Fuel as of 2001 [(Euros/Liter)/(Euros/Gallon)]

Country	Gasoline	Diesel	Value-added tax (percentage)
Austria	0.408/1.55	0.283/1.07	20.0
Belgium	0.507/1.92	0.290/1.10	21.0
Denmark	0.524/1.98	0.367/1.39	25.0
Finland	0.552/2.09	0.300/1.14	22.0
France	0.571/2.16	0.374/1.42	19.6
Germany	0.593/2.25	0.409/1.55	16.0
Greece	0.297/1.13	0.245/0.93	18.0
Ireland	0.348/1.32	0.249/0.94	20.0
Italy	0.520/1.97	0.382/1.45	20.0
Luxembourg	0.372/1.41	0.253/0.96	15.0
The Netherlands	0.402/1.52	0.339/1.28	19.0
Portugal	0.289/1.09	0.246/0.93	17.0
Spain	0.372/1.41	0.270/1.02	16.0
Sweden	0.528/2.00	0.356/1.35	25.0
United Kingdom	0.765/2.90	0.765/2.90	17.5

Figure 3 shows the average gasoline prices in Canada, France, Germany, Japan, the United Kingdom, and the United States for the years 1990 and 2001, illustrating the importance of taxes in the overall prices.

4. VEHICLE TAX INCENTIVES PROMOTING HIGHER FUEL ECONOMY

4.1 Overview

A number of countries have tax programs designed to reward purchasers and owners of fuel-efficient vehicles (or to penalize purchasers and owners of fuel-inefficient vehicles) by tying vehicle purchase and/or ownership taxes either directly to fuel economy or to vehicle features associated with fuel economy (e.g., engine displacement). Aside from taxes aimed specifically at fuel economy or associated vehicle characteristics, all countries in the major auto markets have vehicle taxes that are based on the total purchase

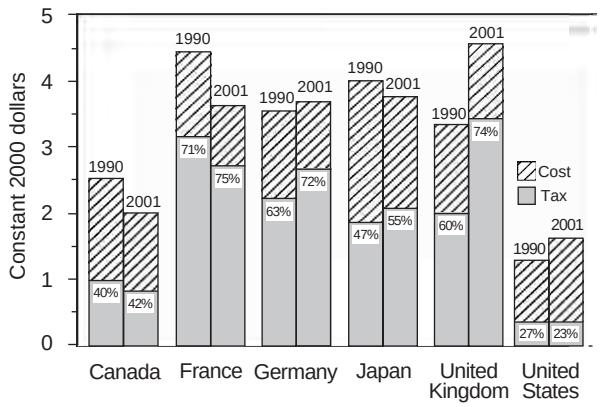

FIGURE 3 Gasoline prices for selected countries, 1990 and 2001, showing effect of taxes. From Oak Ridge National Laboratory. (2002). "Transportation Energy Data Book," 22nd ed.

price of the vehicle (e.g., sales taxes in the United States, value-added taxes in Europe). This latter form of taxes can actually serve as an impediment to higher fuel economy to the extent that increased efficiency is attained with high-cost technology, such as continuously variable automatic transmissions, hybrid electric drivetrains, and variable valve controls, and such taxes add to the cost of these technologies. Of course, such taxes, by making vehicles more expensive, reduce sales and so limit fuel consumption in this manner.

4.2 United States

The United States has two distinct tax-based programs aimed at improving vehicle efficiency. The first is the well-known "gas guzzler tax," established by the Energy Tax Act of 1978, which adds a substantial purchase tax to the price of passenger cars (light-duty trucks are not subject to the gas guzzler tax) whose fuel economy falls below an EPA test value of 22.5 mpg. The current tax rate begins at $1000 U.S. for cars with fuel economy between 21.5 and (less than) 22.5 mpg, and it escalates to $7700 U.S. for cars with fuel economy of less than 12.5 mpg. For the 2001 model year, there were 35 models subject to the tax, and all of these were expensive luxury or performance cars such as the Dodge Viper, Mercedes SL500, Rolls-Royce Corniche, and BMW 750IL. Most analysts believe that mass market manufacturers have tried hard to keep their larger models above the tax's minimum fuel economy, not only to avoid the payment but also to avoid having these vehicles subject to the stigma attached to being identified as "guzzlers."

The second U.S. program is a substantial tax deduction from federal income taxes of up to $2000 U.S. (i.e., $2000 U.S. may be deducted from reported net income before calculating taxes) for hybrid vehicles. The tax credit was originally established as a "Clean Fuel" program designed to promote the use of alternative nonpetroleum fuels, but the U.S. government's Internal Revenue Service determined that the program applies to hybrids. This program is scheduled to phase out between 2004 and 2006, although Congress might extend the deadline.

4.3 Japan

Japan has instituted a number of tax incentives for higher fuel economy or for characteristics that are associated with higher fuel economy. They are as follows (with U.S. dollar values calculated at 120 yen/dollar):

- Regarding taxes directly promoting hybrid vehicles, the vehicle acquisition tax is reduced to 2.2% for hybrid vehicles (the national acquisition tax for conventional vehicles is 5%). For example, the purchaser of a Toyota Prius would save about $400. Second, there is better tax treatment of corporate income tax for company purchases (this applies to all vehicles meeting 2010 fuel economy targets and generating 25% less emissions than current standards). Third, there are purchase incentives for private individuals and special government loans for company purchases. The private incentive is half the price difference between the hybrid and equivalent conventional vehicles. For a Prius, the incentive is worth about $1800.
- The annual tax of vehicles meeting both low emissions standards and fuel economy standards is reduced. A Toyota Prius owner would save approximately $120/year for the first 2 years of ownership.
- The vehicle tax is based on weight and assessed at inspection (6300 yen or ~$53/half ton).

4.4 Europe

As in Japan, many members of the EU have passenger car taxes that either directly reward high fuel efficiency or reward vehicle characteristics that are associated with high fuel efficiency. Table IV shows the variety of taxes on both vehicle purchase and ownership in the 15 European countries that have such taxes. Of particular interest are yearly taxes in Denmark that vary inversely with fuel

economy—at approximately $30/vehicle/year for gasoline vehicles with fuel economy above 20 km/L (47 mpg), approximately $330/vehicle/year for vehicles at about 23 mpg, and more than $1100/vehicle/year for vehicles below 10.6 mpg.

The United Kingdom has introduced a number of economic incentives for higher fuel economy, including a vehicle purchase tax based on CO_2 emissions ranging from 60 to 160 pounds (~$95 to $250 U.S. at 2002 exchange rates), tax credits for companies purchasing vehicles with 120 g/km or less CO_2 emissions, and 1000-pound (~$1600 U.S.) grants to consumers purchasing hybrid vehicles.

Another example of a tax program based directly on fuel economy is the tax rebate program adopted by the Netherlands in January 2002 that awarded a purchase tax rebate of 1000 euros for cars with an "A" fuel economy rating (at least 20% more efficient than other cars of similar size) and 500 euros for cars with a "B" rating (10–20% higher fuel economy than cars of similar size). However, this program ended after its first year in existence due to a change in governments.

TABLE IV

Taxes on Vehicle Purchase and Ownership Based on Fuel Economy-Related Variables: European Union and United Kingdom

Country	Sales tax	Ownership tax
Belgium	Based on cc	Based on cc
Denmark		Fuel economy, weight
Germany		cc
Spain	<1.6 L: 7% >1.6 L: 12%	Horsepower
Finland		
France		
Greece		cc
Ireland	<1.4 L: 22.5% 1.4–2 L: 25% >2 L: 30%	cc
Italy		Horsepower
Luxembourg		cc
The Netherlands		Weight
Austria	Fuel economy Maximum 16%	Horsepower
Portugal	cc (e.g., 1.6 L): 5032 euros	cc
Sweden		Weight
United Kingdom		CO_2 emmissions

Note: cc, cubic centimeters of engine displacement.

4.5 Measures in Other Countries

We know of no studies that have examined vehicle taxation programs elsewhere in the world, but it seems likely that there are a number of tax regimes that affect vehicle fuel economy, albeit indirectly. For example, Brazil reduces its 25% tax on industrialized products to 10% for automobiles with engines less than 1 L in size, greatly encouraging sales of low-powered vehicles that are likely to be fuel efficient.

5. INFORMATION PROGRAMS TO PROMOTE HIGHER FUEL ECONOMY

5.1 Overview

A variety of information programs exist in the major automobile markets to assist potential purchasers of new cars in comparing fuel economy characteristics (and other attributes) among competing vehicles. However, there is no evidence that the existence of such systems plays a significant role in consumer choice of vehicles. For example, in 1995, the light-duty fleets in the two European countries with fuel economy labeling systems (Sweden and the United Kingdom) were the least efficient in Europe (according to International Energy Agency data).

5.2 United States

The fuel economy information program in the United States is the oldest and most highly developed of the major vehicle markets. The current system includes a label on the window of all new cars and light trucks available for sale that lists the approximate fuel economy the average driver can expect to obtain in city and highway driving (obtained by adjusting the fuel economy test values obtained on the official EPA city and highway test cycles downward by 10% for the city cycle and 22% for the highway cycle) and other relevant information. More specifically, the label includes the following:

- a description of the vehicle sufficient for the customer to distinguish it from other similar models, including the identical model with a different engine or transmission;
- the (adjusted) city and highway fuel economy values;
- the statement of the likely range of fuel economy values obtained by the majority of drivers,

estimated at 15% below to 15% above the city and highway fuel economy values;
- a statement of the range of fuel economy levels obtained by comparable vehicles;
- an estimate of the annual fuel cost.

The second component of the system is a fuel economy guide, available at automobile dealers and on a Web site (www.fueleconomy.gov), that offers an extensive menu of information about fuel economy and other vehicle attributes. Main features include the following:

- for every vehicle marketed, identified by manufacturer, model, engine option, and transmission type: city and highway fuel economy, annual fuel cost (assuming 15,000 miles/year [45% highway driving and 55% city driving]), annual greenhouse gas emissions (with the same assumptions), and an EPA air pollution score;
- on the Web site, a search engine that allows selection by market or size class, by manufacturer, or by fuel economy;
- on the Web site, capability to display competing vehicles side by side;
- identification of "best" and "worst" vehicles, on the basis of fuel economy, for each size class;
- compilation of advice on driving more efficiently;
- simple information about advanced technology vehicles (e.g., hybrid electric vehicles).

EPA also offers a "Green Vehicle Guide" at its Web site (www.epa.gov/autoemissions) that lists, for each new vehicle, its fuel economy value and a ranking from 0 to 10 based on its emissions of air pollutants.

In addition to the consumer information available in the Fuel Economy Guide and on the Web site, EPA publishes a yearly compilation of fuel economy trends that provides guidance to policymakers and analysts about national progress in fuel efficiency. The 2001 version of the report, *Light-Duty Automotive Technology and Fuel Economy Trends 1975 through 2001,* is available on the Web (www.epa.gov/oms/cert/mpg/fetrends/rdtrnd01.htm). The report highlights key fuel economy and technology trends in the U.S. LDV fleet, including trends in vehicle attributes, such as horsepower and weight, that affect fuel economy. Fuel economy information is broken down in a variety of ways (e.g., total fleet, all cars, all light trucks) by size and weight class, by manufacturer, by marketing group (e.g., Ford Group—Ford, Mazda, Volvo, Jaguar, Land Rover), and the like. Also, the report shows the difference in fleet fuel economy using the standard EPA assumption of 55% city driving and 45% highway driving and shows actual measured values of city and highway driving (the "actual" fuel economy values are about 2% lower than the estimated values using the 55/45 split). Trends in technology (e.g., four-wheel drive, four valves per cylinder) and vehicle characteristics (e.g., horsepower, weight) are shown in tables and figures. One interesting feature is a series of analyses that show how the fleet fuel economy would change if all of the vehicles in each size class or weight class attained the fuel economy of the best vehicles in that class. Finally, the report includes an analysis of what fleet fuel economy would have been had there been no change in average vehicle weight and acceleration capabilities over the past 10 or 20 years. This analysis shows the impact on fuel economy of changes in vehicle weight and acceleration capability. The analysis is then repeated with size class substituted for weight.

5.3 Japan

The government of Japan does not require fuel economy labels on new cars, although it has started to consider introducing such labeling. However, the Ministry of Land, Infrastructure, and Transport does publish a fuel economy guide (and maintains the guide on its Japanese-language Web site) that includes information for each vehicle on fuel economy and CO_2 emissions and highlights vehicles that already meet 2010 fuel economy standards. Also, manufacturers must list fuel economy values in sales brochures and vehicle specification sheets at car dealerships.

5.4 Europe

Two European countries, Sweden and the United Kingdom, have had vehicle fuel economy labeling systems in place for the past two decades or so. The United Kingdom's system has been mandatory, with fines set for noncompliance, but the Swedish system generally has not been enforced.

The EC has established (in Directive 1999/94/EC) consumer information requirements for new passenger cars that demand the following:

- fuel economy labels on all new cars that include both fuel economy and CO_2 emissions rates;
- ready availability of a fuel economy guide containing fuel economy ratings of all new vehicles sold in that market;

- posters in new vehicle showrooms listing the fuel economy ratings of all vehicles for sale at those locations;
- incorporation of fuel economy/fuel consumption values in advertising material.

The official labeling program in the Netherlands complies with the EC directive in that labels contain fuel consumption and CO_2 emissions values, and it goes a step further in giving each vehicle a CO_2 emissions rating, from "A" (>20% more efficient) to "G" (>30% less efficient), that compares the car with others of similar size (defined as car width × car length) as well as with the average of all cars. The rating is 75% dependent on the comparison with cars of similar size and 25% dependent on the comparison with the average of all cars. This feature was adopted as a compromise, on the one hand, to ensure that small cars that are rather inefficient for their size are not always labeled as if to appear superior to larger cars that are quite efficient for their size and, on the other, to avoid giving large cars the same rating as small cars of similar technical efficiency even though the large cars have much higher CO_2 emissions.

6. GOVERNMENT SPONSORSHIP OF RESEARCH AND DEVELOPMENT

6.1 Overview

Although the automotive industry is a vigorous sponsor of research and development—worldwide, nearly $20 billion U.S. worth in 1997—governments throughout the world sponsor additional automotive R&D, both separately from and in partnership with the industry. This work focuses primarily on four areas: emissions, safety, fuels, and fuel economy. Within the past few years, government sponsorship of automotive R&D has moved sharply in the direction of attempting to advance the performance and cost-effectiveness of automotive fuel cells, which address three of the four areas: emissions, fuels, and fuel economy. Aside from large programs in the three major market areas—the United States, Japan, and Western Europe—there is a significant fuel cell program in Canada and there are small efforts in South Korea and elsewhere.

Aside from direct sponsorship, governments promote R&D in the automotive industry (and elsewhere) through generous tax credits for R&D. Although the actual amount of tax credits taken by automakers in the various markets is proprietary information, Japanese vehicle companies (excluding parts producers) had approximately $190 million U.S. available to them in 1999 and $122 million in 2000. U.S. companies (including parts producers) had approximately $540 million available to them in 1997 and $617 million available in 1998 in U.S. R&D tax incentives.

6.2 United States

The U.S. government has sponsored R&D in vehicle efficiency technology for decades, primarily through the Department of Energy, whose Electric and Hybrid Vehicle Program, begun in 1976, spent about $500 million from its inception to the beginning, in 1992, of the Partnership for a New Generation of Vehicles (PNGV). PNGV was a joint R&D program between the federal government and the U.S. Council for Automotive Research (USCAR), an R&D partnership of Ford, General Motors, and DaimlerChrysler. For approximately a decade, PNGV was the centerpiece of the government's vehicle research efforts, with one of its key goals being the demonstration of a family car that could obtain 80 mpg while meeting all safety, emissions, performance, and affordability requirements. Research areas included engine powertrain systems (including lean-burn engines and emissions controls), advanced materials, electric energy storage and electric motors and controllers (for electric hybrids), and vehicle manufacturing. Federal research dollars were spread among the USCAR companies and their suppliers, the national laboratories, and other R&D performers such as universities.

In January 2002, the FreedomCAR Partnership superseded the PNGV, with the research focus shifting to the development of hydrogen as a primary fuel for cars and trucks. In fiscal year 2002, the Department of Energy spent approximately $150 million on FreedomCAR-related research, with $60 million focused on fuel cell and hydrogen infrastructure R&D. Despite the shift in primary focus, FreedomCAR's research goals retain some of PNGV's focus on materials and engine powertrain systems.

6.3 Japan

The Japanese government is sponsoring extensive research activity in high-efficiency vehicle technology for both conventional and fuel cell drivetrains. The 2001 Prime Minister's Action Plan calls for a $155

million R&D program (among other initiatives such as vehicle purchase subsidies, tax incentives, and low-interest loans) aimed at putting 10 million low-emissions vehicles (including fuel cell, hybrid, and alternative-fuel vehicles) on the road by 2011, with 50,000 of these being fuel cell vehicles. The plan further calls for 5 million fuel cell vehicles to be on the road by 2020. More recent recommendations from senior ministers of the key transportation and environment ministries call for increased fuel cell R&D funding, more rapid vehicle deployment than is called for in the action plan, and additional measures to achieve global fuel cell leadership.

Prior to the new focus on fuel cells, the major government/industry R&D project for high-efficiency vehicles was the Advanced Clean Energy Vehicle (ACE) Project. The ACE Project's primary goal was to develop vehicles using clean fuels that would double energy efficiency with ultra-low emissions vehicle (ULEV) emissions. The total government plus private funding over the project's lifetime was approximately $175 million, but the LDV part of this was substantially smaller (the project included development of technologies for buses and cargo trucks).

6.4 Europe

Both European auto manufacturers and the EU responded vigorously to the U.S. PNGV program, the manufacturers by forming the European Council for Automotive R&D (EUCAR) to coordinate R&D among the companies and the EU by initiating the Car of Tomorrow program. EU funding for EUCAR starting with the initiative was $2.3 billion for 5 years.

Fuel cell funding by European governments was approximately $60 million in 2001, with half from the EU and half from individual countries. However, the majority of these funds is aimed at transit projects. Key research areas are component cost reduction, development of a cost-effective hydrogen supply infrastructure, and development of vehicle systems. At the national government level, France and Germany have the most robust programs at approximately $11.5 million and $8 million, respectively (for fiscal year 2000). The Netherlands, Spain, Denmark, Italy, and the United Kingdom have programs at or above $2 million per year, with Switzerland, Sweden, and Norway having smaller programs. In addition, individual governments have initiated more generalized efficiency R&D programs. For example, the United Kingdom's Foresight Vehicle Initiative, with nearly $20 million of government money invested, has focused on hybrid, electric, and alternative-fuel vehicles; advanced materials and structures; and powertrain technology—a program quite similar to that of the PNGV. However, even this program's focus is shifting more to fuel cell technology.

6.5 Canada

The Canadian government's R&D support has focused strongly on fuel cell research, in which it is a global leader. Canadian fuel cell research began in 1983 at Ballard Power Systems through a defense contract to further develop General Electric/National Aeronautics and Space Administration technology developed for the U.S. space program. Canadian government fuel cell support was approximately $40 million in 2001, about one-third of the U.S. government's effort.

Glossary

fitness function A mathematical expression transforming a certain combination of several input values into one output value, representing the evaluation of the input, often in relation to the optimum.

fuzzy logic A soft computing method to carry out logic operations; uses verbal expressions described by fuzzy sets generated from membership functions.

genetic algorithms A soft computing method that uses biological processes of evolution for optimization.

linguistic variable A variable for which the values are linguistic terms (for instance, "small") instead of numbers. Fuzzy sets generated by membership functions build the connection between the linguistic expression and the numerical information.

membership function A mathematical expression that represents to what degree an element belongs to a mathematical set, considering that these memberships do not have to be total memberships.

operator A mathematical manipulation on numbers or terms. Classical examples are addition, multiplication, differentiation, etc. In soft computing, other operators are needed, e.g., fuzzy or genetic operators such as aggregation, accumulation, crossover, mutation, and reproduction.

soft computing Mathematical methods of calculating, developed mainly within the past 30 years, and not necessarily operating on classical functions and numbers, but taking into account the human kind of information processing and principles of biological operating.

sustainable development A goal for the future development of mankind under intragenerational and intergenerational justice. The negotiated road map for future economical, ecological, and societal sound development is the Agenda 21, from the United Nations Conference for Environment and Development held in Rio de Janeiro in 1992.

technology assessment An interdisciplinary scientific and societal approach to the questions of what impacts technology application and the technological progress have on mankind, and what technologies are needed and preferred.

The energy supply system is crucial to the further development of humans. Evaluations concerning the impact of energy conversion technologies on this development are difficult due to the complexity of the problem. This leads to different conclusions about how to proceed. Using soft computing techniques, both technically measurable quantities and nontechnical evaluation criteria can be taken into account to obtain an objective evaluation, to discover hidden evaluation criteria, and to formulate a goal for a future sustainable development.

1. INTRODUCTION

Current global development increasingly calls attention to the realities of population growth, extended mobility, and increasing energy demands and their contribution to environmental problems. This collision between civilization and the ecosystem illuminates two dilemmas: (1) The goals of maintaining society's prosperity and protecting the environment are not independent. Rather, they are competing goals, because technological applications increasingly

 © 2004 Elsevier Inc. All rights reserved.

require extensive use of nonrenewable resources. (2) The globally increasing demand for nonrenewable resources necessitates even more technology application and development. Thus, guided by the vision of sustainability, the concept of technology assessment (TA) must deal with the question of technology's ability to enable sustainable development. To avoid increasing both resource use and risk, new technologies should be appropriate to address developmental needs, yet ecologically "reasonable." Designing such technologies requires improved information on and knowledge of technical systems. This knowledge encompasses development and application of technical systems and the connections among economic, social, and political systems, as well as impacts on the environment. Such knowledge should be used when evaluating both existing and new technologies within decision support systems. Problems characteristically encountered in making such evaluations involve multicriteria decision making, aggregation of facts, weighting of goals, uncertain information, and integrating people into the decision-making process. The overall problem is not a lack of data, but the difficulty in generating knowledge from a vast amount of partially uncertain, partially fuzzy data and information, often structured in such a way as to be rather useless. The global energy supply system, for example, is structured to consist of different primary energy carriers. This leads inherently to different evaluations of the system (for instance, due to the different ranges or durations of the primary energy carriers, or to the differences in the dangers of operating different conversion technologies), thus the present structure cannot be the most desirable one. An essential question for the future, concerning technology assessment studies, is how to achieve a sustainable energy supply. Under the present energy supply structure, evaluations for each applied energy conversion technology are needed.

Approaches to this entire problem are possible using a hybrid method of the soft computing techniques, fuzzy logic and genetic algorithms, first introduced by the author. This approach of recursive optimization considers different technical and nontechnical evaluation criteria to achieve optimum primary energy percentages that form the best energy mix. The aim is to reduce the multidimensional decision-making problem to a comparison of aggregated one-dimensional numbers. This should be achieved by combining the advantages of human thought-process structures and processes of biological development with the logical and analytical accuracy of computers.

2. METHODICAL ASPECTS

Examining such problems analytically requires cognitive information processing. The desired systematic procedures require application of methods to organize and to extend our knowledge on complex systems. Generally, problem-specific combinations of methods are applied. Methodical problems and deficits usually emerge due to the complexity of the processes or of the impacts. Problems in describing complex dynamical systems are due to nonlinear impacts and boundary conditions, to boundary conditions that are time dependent and/or solution dependent, and to different time constants within the subsystems.

2.1 Deficit Analysis

Knowledge about technical systems is commonly gained by analyzing the underlying interactions. This is mainly characterized by the building of models. These are mainly mathematical models that allow systematic simulations to identify potential reactions of the system.

In the case of a holistic and systemic view, the system border is extended to all participating and impacting areas. Thus, interactions and impacts have to be considered, but often resist analysis using a description with classical mathematics—say, a formalistic handling. These entities have one of the following properties: unique basic variables are not identifiable, unique causalities are not recognizable among them, or measurable indicators cannot be determined in case of known interactions. This plays a considerable role in the discussion of sustainability, because the entities could be impacts such as risk, quality of life, or diversity. These are hardly measurable quantities. Mainly they are considered in models by boundary conditions or verbal discussion. Neglecting these entities or disaggregating them to other available variables leads, in any case, to an information loss, so the complexity of the system is not represented completely by the model.

2.2 Deficit Synthesis

Complex systems in practice are handled, or at least are made more accessible, by composite numbers or indicators. This is familiar, for instance, in process or chemical engineering. In contrast to the information content of single-measurement data, composite indicators generate new knowledge by aggregating single data and information. The procedure of

aggregation varies depending on the indicators. Nevertheless, indicators of different aggregation levels always provide the same information content. Indicators are especially important in environmental discussions. Assessing or evaluating a situation or guiding a decision requires differently aggregated indicators that characterize a process or a state.

The aggregation problem points out the following dilemma: the methodical deficits of assessments are due to problems of comparison because of the transformation of indicators to highly aggregated assessment measures. On the other hand, this procedure is necessary, which becomes obvious, for instance, if entities such as environmental pollution are to be quantified. This property allows less aggregated indicators to be used at the beginning of systems analysis (for instance, within an inventory analysis of modern environmental management approaches) and enhances transparent aggregation procedures.

2.3 Deficit Assessment

A multidimensional assessment problem can be considered as a logical measurement operation. The assessment problem then is the optimal arrangement of a set of possible alternatives, with respect to the relevant aims and to the preferences of the decision makers, considering given restrictions. The aim of an assessment is to determine a particular value for any alternative so that its relative advantages are represented in only a single expression. The solution of this selection problem will be especially difficult if the problem structure is complex (that is, when many objectives are to be considered, different assessment scales emerge, objectives are weighted differently, information is at least partially uncertain, the problem is time-dependent, many participants are to be involved in the decision-making process, or no unique criterion exists for decision making). Contributing variables could be factors such as risk or diversity, which represent heterogeneous fuzzy expressions that cannot be broken down any further, often with many different impacts. This makes comparability of these variables difficult, especially when factors of different aggregation degree are involved, and makes any evaluation subjective. Nevertheless, to describe real systems, these influences are indispensable quantities.

2.4 Goal

Designing innovative technologies, considering widespread aspects such as sustainable development, requires environmental information for design, assessment, and decision processes. The difficulties mainly emerge during recording and assessing of entities. The problem is caused by aggregated system variables that are incomparable. More adequate methodical approaches maintain the complexity of these variables. Necessary subjective inputs during a system analysis then have to be made absolutely clear to maintain transparency, and they have to be introduced as early as possible in an algorithmic procedure to avoid a conscious manipulation of the solution.

3. MODELING APPROACH WITH SOFT COMPUTING

At a level of thinking that does not have to be conscious, humans use a kind of knowledge that is not sharp and is hard to formulate explicitly. This fuzziness is not a property of reality, but of perception. This kind of knowledge is characterized by the handling of incomplete and not well-structured patterns and information. Here the question emerges as to how and with what language we can model such uncertainties. The methodical deficits mentioned previously can be softened by application of the techniques of soft computing. Apart from artificial neural nets, these are primarily fuzzy logic and genetic algorithms; their usefulness is due to their potential to integrate complexity into calculation.

3.1 Fuzzy Logic

Within the context of this discussion, only fuzzy set theory, one branch of fuzzy logic, is of interest for application to technology assessment, because the important questions of TA do not deal with maintaining states of operation, the subject of control theory, but with fuzzy information processing. Fuzzy logic enables the handling of verbal and indeterminate information using exact mathematics.

Traditional binary logic is part of fuzzy logic, as a special case operating only with two values of interpretation. A set is fuzzy limited if not all the members of the set are assigned a value of 1, or 100%, which means total membership. A fuzzy set is defined by the generalized characteristic function, called the membership function μ. This real function can take on any values, but usually it is normalized into the interval [0, 1].

The key notion when modeling with fuzzy logic is the linguistic variable. In contrast to mathematically precise quantifiable equations, verbal descriptions of

activities contain terms of properties with smooth gradation transitions. Linguistically formulated variables are generally more intelligible, but have a higher aggregated information content. These entities are therefore more difficult to quantify without an information loss. The values of a linguistic variable are verbal expressions, called linguistic terms (for instance, the term "small"). The content of each linguistic term is identified with one fuzzy set and is assigned to the related numerical scale of the basic variable by a particular membership function. Thus, the fuzzy sets build the connection between the linguistic expression and the numerical information.

To process fuzzy formulated knowledge, several linguistic variables must be linked by linguistic operators. The connecting rules represent the knowledge, which is stored in a rule base or knowledge base, similar to expert systems. The procedure consists of the sequential steps fuzzification, inference, and defuzzification.

3.2 An Assessment Method Using Fuzzy Logic

Along with the preceding remarks, a general assessment method using fuzzy logic has been developed. An assessment is a determination of the goodness of a considered issue. This will be made by a function that systematically integrates knowledge into the procedure of modeling and also handles the aggregation procedure. The assessment procedure is based on a multidimensional vector of criteria containing all knowledge input, which characterizes the matter to be evaluated related to the chosen degree of aggregation. The aim is to get statements of the form "*s*th is good, fair, satisfying, to introduce, desirable, etc." This kind of statement can be understood as a result of logic operations.

The concept of linguistic variables enables the formulation of scales of values with linguistic terms as gradations. The essential and critical process is the formalistic assignment of human knowledge to fuzzy sets. However, through this procedure, existing subjective preferences are integrated transparently at each stage, so a conscious manipulation has only a limited impact on the final result.

The general five-step top-down procedure is as follows:

1. Definition of a scale for evaluation.
2. Definition of subordinate criteria for ranking onto this scale. The question concerning which of the possibly independent criteria and impacts will influence the superior scale from step 1 has to be answered.
3. Stepwise disaggregation of these basic criteria. The subordinate impacts are disaggregated to further arbitrary substages, depending on the given knowledge. The result is an aggregation hierarchy of the different impacts. Generally, steps 2 and 3 answer the question of which of the less aggregated and possibly independent impacts are impacting on the next higher aggregation level. Depending on the character of an impact, it can be described by a measurable quantity on a less aggregated level. Otherwise, it keeps the character of an aggregated entity. Both kinds of characters can be considered simultaneously.
4. Fixing the specifications of the fuzzy system parameters. This includes fixing the numbers of linguistic terms and the verbal connotations of all attendant variables, the shape of the membership functions (default: triangular), and the logic operators for aggregation (default: minimum) and for accumulation (default: maximum), as well as the defuzzification method (default: center of gravity). It is recommended to choose an odd number of linguistic gradations for each input variable (default: three) to ensure a certain resolution, with the additional possibility of naming a medium term. The number of linguistic terms of all superior aggregated variables then can be taken as determined in order to get an objective rule base (see step 5).
5. Formulation of the rule base. The phenomenological dependencies between the variables are stored in the rule base. The rules state which combination of linguistic input terms is connected with which linguistic output term. To achieve a definite assignment in the rule base, the number of linguistic terms of a superior aggregated variable then is determined by all possible combinations of input linguistic terms of all related subordinate variables.

This is carried out by a numerical codification. The N linguistic terms of a subordinate variable are assigned to numbers in the interval $[-(N-1)/2,...,-1, 0, 1, ..., (N-1)/2]$ ($N = 3, 5, 7, ...$), where the medium term is assigned to zero. For instance, a variable with $N_{In} = 3$ linguistic terms (small, medium, large) would be assigned to $(-1, 0, 1)$. Thus, we can determine the number N_{Out} of linguistic terms of an output variable from its M input variables ($M = 1, 2, 3, ...$) with their $N_{In,1}, ..., N_{In,M}$ linguistic terms as follows [Eq. (1)]:

$$N_{Out} = 1 + 2\sum_{i=1}^{M} \frac{N_{In,i-1}}{2} \tag{1}$$

For instance, an output variable aggregated from $M = 2$ input variables with $N_{In,1} = 3$ and $N_{In,2} = 5$

linguistic terms would then have $N_{Out} = 1 + 2(1 + 2) = 7$ linguistic terms.

The rules can be derived from the following procedure. The conditions of all rules that are the permutations of all linguistic input terms can be written numerically codified. The conclusion is then represented by the linguistic term of the output variable (numerical codification is assigned by the sum of the numerical input codifications). For instance, considering one three-term input variable with the terms (small, medium, large) codified as (−1, 0, 1), and a second input variable with five terms (very small, small, medium, large, very large) codified as (−2, −1, 0, 1, 2), the particular rule may be written as follows:

$$\text{IF Input}_1 = \text{small AND Input}_2 = \text{medium}$$
$$\text{THEN Output} = ? \quad (2)$$

which is codified as

$$\text{IF Input}_1 = -1 \text{ AND Input}_2 = 0$$
$$\text{THEN Output} = -1 + 0 = -1 \quad (3)$$

According to Eq. (1), the output variable has seven terms codified as (−3, −2, −1, 0, 1, 2, 3). Therefore, the conclusion Output = −1 means that the result is the linguistic output term that is located one term smaller than the medium term, whatever the verbal connotation may be.

3.3 Genetic Algorithms

The idea of technology assessment to point out alternatives to any problem solution can be taken as an optimization problem, where optimization of an application is aimed at, for instance, its energy efficiency, its material intensity, or its sustainability. The application of usual optimization procedures is limited. Restraints can be nonlinear problems or problems with many parameters or many restrictions due to the programming effort and memory demand.

Genetic algorithms, instead, refer to a behavior that would be similar to a biological process of evolution. These techniques do not have requirements for linearity, differentiation, or a certain structure, and often require less programming effort. Problem solutions are kept or changed due to the principle of survival of the fittest. The point is that the search for more capable solutions takes place with a high probability at sites of the solution space, where an enhancement higher than average is required. These features are used in genetic algorithms to evaluate systematically created solutions. A genetic algorithm can be defined as an iterative procedure maintaining a population of structures that are candidate solutions to specific domain challenges. Each candidate solution is called a chromosome. As in biological systems, a chromosome can make a copy of itself. The copy might be slightly different from its parent. During each temporal increment, called a generation, the structures in the current population are rated for their effectiveness as domain solutions, and on the basis of these evaluations, a new population of candidate solutions is formed using specific "genetic operators," which are used by most genetic algorithms, such as reproduction, crossover, and mutation:

1. *Reproduction:* Through reproduction, genetic algorithms produce new generations of improved solutions by selecting parents with higher fitness ratings or by giving such parents greater probability to be contributors.
2. *Crossover:* Usually genetic algorithms use binary strings to represent solutions. Crossover means choosing a random position on the binary string (that is, after a certain digit) and exchanging the segments either to the right or to the left of this point with another string partitioned similarly.
3. *Mutation:* This genetic operator is an arbitrary change of a single bit of a chromosome. It is needed to keep the algorithm from getting stuck. This operator changes a 1 to 0 or a 0 to 1.

The natural optimization techniques can be distinguished by their main operators. In case of genetic algorithms, the main operator is crossover, which is chosen with a probability of 80–100%. Mutation, in contrast, is a very subordinate operator. Such a bit change occurs at a low probability of 1–10%. Genetic algorithms use a three-step iterative process: (1) test a solution to see how good it is, (2) select the best parents, and (3) generate offspring. Genetic algorithms provide a set of efficient, domain-independent search heuristics. Information that enables rejection of inferior solutions and accumulation of good ones is received. Only genetic algorithms and their derivatives provide methods powerful enough for optimizing complex problems. Traditional optimizing tools are not applicable.

4. APPLICATION TO THE ENERGY SUPPLY

Decreasing resources of fossil primary energy carriers and globally increasing mean per capita energy demand and population growth bring to view the

question how and by which technologies the future energy supply can be guaranteed. Of primary concern here is the evaluation of the sustainability of the energy supply system. An energy supply system provides energy via different conversion technologies. In the present global energy supply system, 90% of the demand is still provided by fossil fuel-based primary energy carriers. Increasing energy demands and increasingly urgent global impacts require development of a new supply system, keeping in mind future generations and threshold countries with vastly growing economies; this is referred to as intergenerational and intragenerational justice. Due to the requirement for sustainability of a new energy supply system, one of the most important questions to be answered concerns which primary energy carriers can be and should be used, and to what extent in consideration of limited resources and potential risks. This question concerns the optimal structure of percentages of the different primary energy carriers, of the different energy conversion technologies, or the optimal energy mix. The applied recursive optimization is a two-step iterative procedure. First, a given energy supply structure must be evaluated, considering the technologies involved, with regard to certain evaluation criteria. Second, the input structure will be varied to find the best rated energy mix.

4.1 Assessment: The Fuzzy Fitness Function

To evaluate a given primary energy structure, the fuzzy logic assessment method described previously is used. The assessment procedure is based on a multidimensional vector of criteria that characterizes a conversion technology. The method is applied as follows, according to the previous description:

1. Definition of a scale for evaluation. The interesting entity is the sustainability of an energy conversion technology, here reduced to the related primary energy carrier.

2. Definition of subordinate criteria for the ranking onto the scale sustainability. In case of energy conversion technologies, the independent criteria duration of the primary energy carrier and ecological relevance of the technology are chosen.

3. Stepwise disaggregation of these subordinate criteria. In this case (Fig. 1), the ecological relevance could be considered as being made up from the basic criteria climate impact, area demand, and risk. Area demand is composed of the value and the size of the used area. Duration, for instance, may depend on the level of technology, on the reserve of the primary energy carrier considered, and on social factors. The climate impact can be specified with technical quantities such as emissions and global warming potential. However, both are not differentiated further here. Risk in this approach should specify the potential danger in case of an accident.

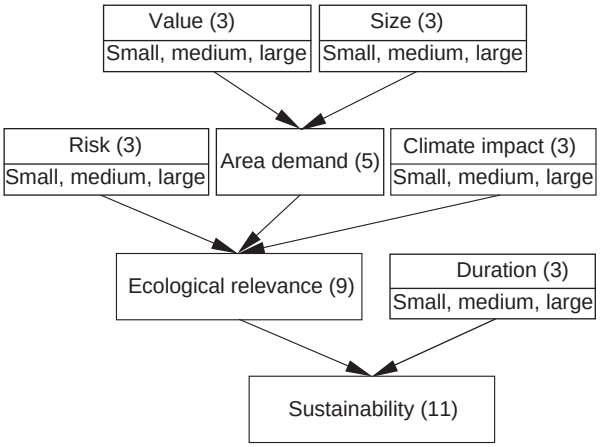

FIGURE 1 Aggregation hierarchy of the assessment function. The number of linguistic terms of each variable determined with Eq. (1) is in parentheses. Reproduced with permission from the Society of Automotive Engineers, SAE 1999-01-2708. Copyright 1999, SAE.

4. Fixing the specifications of the fuzzy system parameters. Here, for all specifications, the default standard parameters are chosen. Each input variable has been aligned to three linguistic terms (small, medium, large). According to Eq. (1) and the hierarchical aggregation structure (Fig. 1), the numbers of linguistic terms for the superior variables given in Fig. 1 are obtained. All fuzzy sets at the edges of the intervals of the basic variables are performed in such a way that defuzzification of the minimum (maximum) linguistic term would provide the value of 0 (1) of the basic variable. Therefore, the membership functions of these linguistic terms of the input basic variables have to be defined symmetrical to 0 (1).

5. Formulation of the rule base. With the preceding procedure, the objective rule bases for the three aggregation levels (for area demand with 9 rules, for ecological demand with 45 rules, and for sustainability with 27 rules) are obtained. For example, the aggregation levels would have the following formulations:

$$\begin{aligned} &\text{First aggregation level:}\\ &\text{IF Value} = \text{medium}\\ &\text{AND Size} = \text{small}\\ &\text{THEN Area Demand} = \text{small} \end{aligned} \tag{4}$$

Second aggregation level:
IF Risk = small AND
Area Demand = small
AND Climate Impact = small
THEN Ecological Relevance = very very small (5)

Third aggregation level:
IF Ecological Relevance = very very small
AND Duration = large
THEN Sustainability = very very very large. (6)

Each primary energy carrier being considered can now be characterized by the vector of criteria (elements are the values of the inputs, each on a specific aggregation stage). The assessment result can be a verbal or a numerical value of the highest aggregated output variable, "sustainability." In case of an energy mix, different technologies are considered with their relative percentages. An input value for the mix then has to be built by the sum of the values of the single technologies weighted with the percentage within the mix. This assessment procedure operates as the fitness function of the genetic algorithm.

4.2 The Optimization Procedure

The optimization problem consists of determining the percentages of each considered technology that participates in supplying the energy demand. During the optimization procedure, the following fitness function F has to be optimized:

$$F = F(\alpha, \beta, \gamma) \rightarrow \max \quad (7)$$

where α represents the contribution of fossil-fuel-based primary energy carriers, β represents that one of the regenerative (renewable)-energy-based primary energy carriers, and γ represents the contribution of nuclear-energy-based primary energy carriers. The boundary condition, of course, is $\alpha + \beta + \gamma = 1$, or 100%. First, the aggregated inputs to the fuzzy block are determined (Fig. 2). Therefore, each single, specific evaluation of a technology taken from Table I is weighted by its percentage and then summarized. This resulting vector of criteria for a considered energy structure serves as input vector for the fuzzy fitness function that determines the total goodness of the structure. The genetic algorithm now varies the input vector of percentages of a given energy structure until the maximum fitness is achieved (Fig. 2).

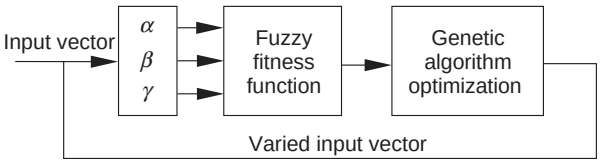

FIGURE 2 Recursive optimization, where the contributions of primary energy carriers are α, fossil fuels; β, regenerative (renewable) energy; and γ, nuclear energy. Reproduced with permission from the Society of Automotive Engineers, SAE 1999-01-2708. Copyright 1999, SAE.

5. RESULTS AND DISCUSSION

Vectors of criteria for different technologies and sustainability results are shown in Table I. The current energy mix has been determined twice, first considering the nuclear percentage based on uranium-235 (mix 1) and second based on the breeder technology (mix 2). A separate control calculation with the analytical hierarchy process method has resulted in the same ranking tendency. Although fossil energy carriers use oil and gas in addition to coal, oil and gas have not been differentiated here, which should be done for more precise results. Also, in reality, hydro energy is the most significant

TABLE I

Vectors of Criteria for Different Primary Energy Carriers

	Criteria[a]					
Vector	CI	Value	Size	Risk	D	S
Test cases[b]						
Max	0	0	0	0	1	1
Min	1	1	1	1	0	0
Technologies[c]						
Fossil (coal)	1.0	1.0	0.01	0.01	0.3	0.439
Nuclear (uranium-235)	0.1	1.0	0.01	0.95	0.1	0.400
Nuclear (breeder)	0.1	1.0	0.01	1.0	0.8	0.510
Regenerative (solar)	0.1	0.01	1.0	0.01	1.0	0.780
Mix 1995[d]						
(1)	0.906	0.968	0.042	0.079	0.308	0.444
(2)				0.082	0.359	

[a] Data from SAE 1999-01-2708. CI, climate impact; D, duration; S, sustainability.
[b] The two test cases verified the algorithm.
[c] The single values for the technologies were determined from the literature.
[d] Evaluation of the 1995 energy structure in Germany: (1), standard nuclear energy; (2), fast breeder technology.

contributor to regenerative energy supplies, but the percentage in Table I has been taken as consisting entirely of solar energy (photovoltaics). Therefore, the values in Table I for climate impact, value, and size of area are not calculated properly. Nevertheless, the results allow the following statements:

1. The assessment procedure provides correct results for given vectors of criteria.
2. Maximum sustainability cannot be achieved.
3. The traditional nuclear energy conversion technology has been ranked worst because of the high risk and the simultaneous short duration.
4. The current energy mix is debatable, considering this evaluation.
5. The best sustainability is achieved for regenerative energies, and is strongly dependent on the value of the size of area used.

Not surprisingly, the optimization procedure provides 100% regenerative energy carriers as the best solution if risk is considered, and 100% nuclear energy if not. Far more interesting are results evaluated as being a little worse than the pure regenerative solution, but better than today's mix. In this case, the dominant regenerative part decreases with decreasing evaluation values, which also start to oscillate. Simultaneously, the percentages of fossil-fuel-based and nuclear-based primary energy carriers increase alternately, also with increasing oscillations. However, there are obviously several solutions with the same evaluation result.

Using a linguistic notion of arrangement, fuzzy logic allows simultaneous consideration of entities and technically measurable quantities by a verbal description of interactions. The evaluation results for the current energy mix and for certain other possibilities with respect to meeting the worldwide future energy demand show that this kind of consideration is useful to discover hidden evaluation criteria and to formulate a goal for a future sustainable development.

1. Implications for Gas Hydrates
2. Gas Hydrate Technical Review
3. Energy Resource Potential of Gas Hydrates

Glossary

clathrate A class of compounds characterized by cages of molecules that encapsulate other molecules; from the *Latin clathratus*, meaning to encage.
dissociation A chemical process by which temperature and/or pressure changes cause a group of molecules to be separated into simpler groups.
methane A colorless flammable gas consisting of carbon and hydrogen.
methanol Methyl alcohol; a colorless, flammable liquid derived from natural gas.
permafrost Ground (soil or rock) that remains at or below 0°C for at least 2 years.
seismic reflectors An interface between two media with different elastic properties as shown on a seismic profile.
well log A graphic record of the measured physical characteristics of a subsurface rock section as encountered in a well.

Gas hydrates, composed of water and gas, are crystalline substances in which solid lattices of water molecules trap gas molecules in a cagelike structure, or a clathrate. Gas hydrates occur in sedimentary deposits under conditions of pressure and temperature present in permafrost regions and beneath the sea in outer continental margins. Despite the fact that relatively little is known about the ultimate resource potential of natural-gas hydrates, it is certain that they are a vast storehouse of natural gas. There is much to learn about these compounds before this potentially enormous resource can be turned into an economically producible reserve.

1. IMPLICATIONS FOR GAS HYDRATES

The combined information from Arctic gas hydrate studies shows that, in permafrost regions, gas hydrates may exist at subsurface depths ranging from about 130 to 2000 m. Anomalous seismic reflectors, known as bottom-simulating reflectors (BSRs), have been mapped at depths below the seafloor ranging from about 100 to 1100 m. The presence of gas hydrates in offshore continental margins has been inferred mainly from these BSRs. Although methane, propane, and other gases can be included in the clathrate lattice structure of gas hydrates, methane hydrates appear to be the most common in nature. The amount of methane sequestered in gas hydrates is probably enormous, but estimates of the amounts are speculative and range over three orders of magnitude, from about 3114 trillion to 7,634,000 trillion cubic meters, which represents a very large potential energy resource.

Gas hydrates also represent a significant drilling and production hazard. Russian, Canadian, and American drilling engineers have described numerous problems associated with gas hydrates, including blowouts and well-bore casing failures. Seafloor stability is also an important issues related to gas hydrates. Seafloor stability refers to the susceptibility of the seafloor to collapse and slide as the result of gas hydrate disassociation. It is possible that both natural and anthropogenic changes can contribute to *in situ* gas hydrate destabilization, which may convert a hydrate-bearing sediment to a gassy water-rich fluid, triggering seafloor subsidence and catastrophic landslides. Evidence implicating gas hydrates in triggering seafloor landslides has been found along the Atlantic Ocean margin of the United States. However, the mechanisms controlling gas hydrate-induced seafloor subsidence and landslides are not well understood.

Recent studies indicate that atmospheric methane, a greenhouse gas, is increasing at a rate such that the current concentration will probably double in the next 50 years. Because methane is 21 times more radiatively active than carbon dioxide, it is predicted that methane will surpass carbon dioxide as the predominant atmospheric greenhouse gas in the second half of the next century. The source of this atmospheric methane is uncertain; however, numerous researchers have suggested that destabilized natural-gas hydrates may be contributing to the buildup of atmospheric methane.

2. GAS HYDRATE TECHNICAL REVIEW

Under appropriate conditions of temperature and pressure (Fig. 1), gas hydrates usually form one of two basic crystal structures (Fig. 2). Each unit cell of Structure I gas hydrate (Fig. 2A) consists of 46 water molecules that form two small dodecahedral voids and six large tetradecahedral voids. Structure I gas hydrates can hold only small gas molecules such as methane and ethane, with molecular diameters not exceeding 5.2 Å. The chemical composition of a Structure I gas hydrate can be expressed as $8(Ar,CH_4,H_2S,CO_2)46H_2O$ or $(Ar,CH_4,H_2S,CO_2)5.7H_2O$. The unit cell of Structure II gas hydrate consists of 16 small dodecahedral and 8 large hexakaidecahedral voids formed by 136 water molecules. Structure II gas hydrates may contain gases with molecular dimensions in the range of 5.9 to 6.9 Å, such as propane and isobutane. The chemical composition of a Structure II gas hydrate can be expressed as $8(C_3H_8,C_4H_{10},CH_2Cl_2,CHCL_3)136H_2O$ or $(C_3H_8,C_4H_{10},CH_2Cl_2,CHCL_3)17H_2O$. At conditions of standard temperature and pressure (STP), one volume of saturated methane hydrate (Structure I) will contain as much as 189 volumes of methane gas; because of this large gas storage capacity, gas hydrates are thought to represent an important source of natural gas.

The geologic occurrence of gas hydrates has been known since the mid-1960s, when gas hydrate accumulations were discovered in Russia. Cold surface temperatures at high latitudes on Earth are conducive to the development of onshore permafrost and gas hydrates in the subsurface (Fig. 3). Onshore gas hydrates are known to be present in the West Siberian Basin and are believed to occur in other permafrost areas of northern Russia, including the

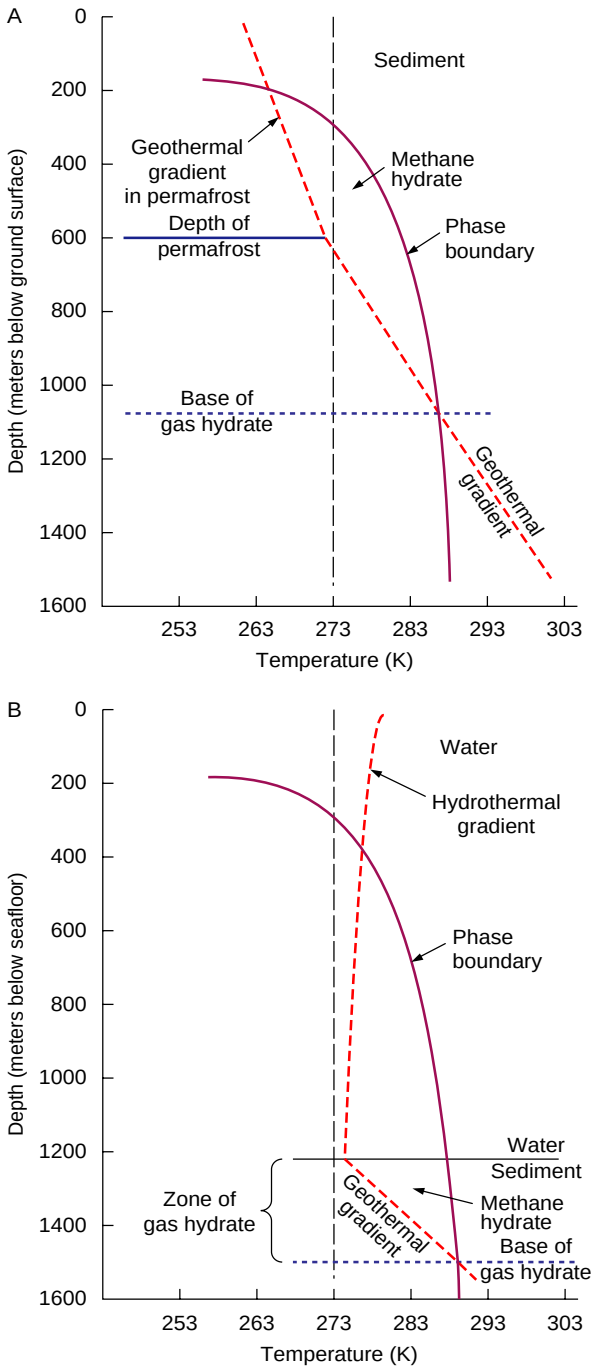

FIGURE 1 Graphs showing the depth–temperature zone in which methane hydrates are stable in (A) a permafrost region and (B) an outer continental margin marine setting.

Timan-Pechora province, the eastern Siberian Craton, and the northeastern Siberia and Kamchatka areas. Permafrost-associated gas hydrates are also present in the North American Arctic. Direct evidence for gas hydrates on the North Slope of Alaska comes from a core test in a gas hydrate exploration well, and

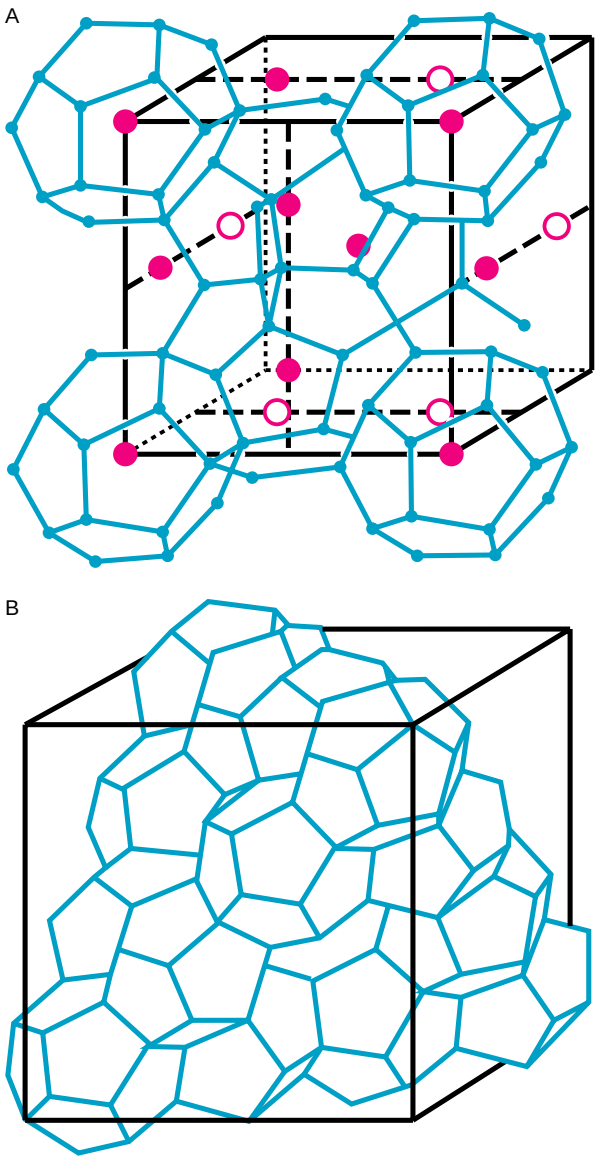

FIGURE 2 Two gas hydrate crystal structures: (A) Structure I and (B) Structure II.

indirect evidence comes from drilling and open-hole industry well logs that suggest the presence of numerous gas hydrate layers in the area of the Prudhoe Bay and Kuparuk River oil fields. In Canada, well-log responses attributed to the presence of gas hydrates have been obtained in about one-fifth of the wells drilled in the Mackenzie Delta, and more than half of the wells in the Arctic Islands are inferred to contain gas hydrates. The recently completed Mallik 2L-38 gas hydrate research well confirmed the presence of a relatively thick, highly concentrated, gas hydrate accumulation on Richards Island in the outer portion of the Mackenzie River Delta.

In marine environments, gas hydrates have been recovered in gravity cores within 10 m of the seafloor in the sediment of the Gulf of Mexico, the offshore portion of the Eel River Basin of California, the Black Sea, the Caspian Sea, and the Sea of Okhotsk. Also, gas hydrates have been recovered at greater subbottom depths during research coring along the southeastern coast of the United States on the Blake Ridge, in the Gulf of Mexico, in the Cascadia Basin near Oregon, in the Middle America Trench, on offshore Peru, and on both the eastern and western margins of Japan.

3. *ENERGY RESOURCE POTENTIAL OF GAS HYDRATES*

World estimates for the amount of natural gas in gas hydrate deposits range from 14 trillion to 34,000 trillion cubic meters for permafrost areas and from 3100 trillion to 7,600,000 trillion cubic meters for oceanic sediments. Current estimates of the amount of methane in the world's gas hydrate accumulations are in rough accord at about 20,000 trillion cubic meters. If these estimates are valid, the amount of methane in gas hydrates is almost two orders of magnitude larger than the estimated total remaining recoverable conventional methane resources, estimated to be about 250 trillion cubic meters.

The 1995 National Assessment of United States Oil and Gas Resources, conducted by the U.S. Geological Survey, focused on assessing the undiscovered conventional and unconventional resources of crude oil and natural gas in the United States. This

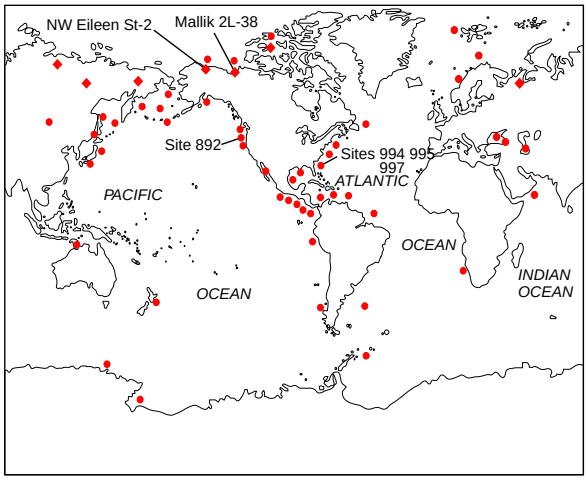

FIGURE 3 Locations of known and inferred gas hydrate occurrences.

assessment included for the first time a systematic resource appraisal of the in-place natural gas hydrate resources of the onshore and offshore regions of the United States. In this assessment, 11 gas hydrate plays were identified within four offshore and one onshore gas hydrate provinces. The offshore gas hydrate provinces assessed lie within the U.S. Exclusive Economic Zone adjacent to the lower 48 states and Alaska. The only onshore province assessed was the North Slope of Alaska. In-place gas resources within the gas hydrate regions of the United States are estimated to range from about 3200 trillion to 19,000 trillion cubic meters of gas, at the 0.95 and 0.05 probability levels, respectively. Although this wide range of values shows a high degree of uncertainty, it does indicate the potential for enormous quantities of gas stored as gas hydrates. The mean in-place value for the entire United States is calculated to be about 9000 trillion cubic meters of gas, which is a very large volume of gas, when it is considered that the United States has only about 7 trillion cubic meters of conventional natural gas reserves.

Even though gas hydrates are known to occur in numerous marine and Arctic settings, little is known about the technology necessary to produce gas hydrates. Most of the existing gas hydrate "resource" assessments do not address the problem of gas hydrate recoverability. Proposed methods of gas recovery from hydrates (Fig. 4) usually deal with dissociating or "melting" gas hydrates *in situ* by (1) heating the reservoir beyond hydrate formation temperatures, (2) decreasing the reservoir pressure below hydrate equilibrium, or (3) injecting an inhibitor, such as methanol or glycol, into the reservoir to decrease hydrate stability conditions. Gas recovery from hydrates is hindered because the gas is in a solid form and because hydrates are usually widely dispersed in hostile Arctic and deep marine environments. First-order thermal stimulation computer models (incorporating heat and mass balance) have been developed to evaluate hydrate gas production from hot water and steam floods; the models have shown that gas can be produced from hydrates at sufficient rates to make gas hydrates a technically recoverable resource. However, the economic cost associated with these types of enhanced gas recovery techniques would be prohibitive. Similarly, the use of gas hydrate inhibitors in the production of gas from hydrates has been shown to be technically feasible, but the use of large volumes of chemicals such as methanol comes with a high economic and environmental cost. Among the various techniques for production of natural gas from *in situ* gas hydrates, the most economically promising method is considered to be the depressurization technique. However, the extraction of gas from a gas hydrate accumulation by depressurization may be hampered by the formation of ice and/or the reformation of gas hydrate due to the endothermic nature of gas hydrate dissociation.

The Messoyakha gas field in the northern part of the Russian West Siberian Basin is often used as an example of a hydrocarbon accumulation from which gas has been produced from *in situ* natural-gas hydrates. Production data and other pertinent geologic information have been used to document the presence of gas hydrates within the upper part of the Messoyakha field. It has also been suggested that the production history of the Messoyakha field demonstrates that gas hydrates are an immediately producible source of natural gas, and that production can be started and maintained by conventional methods. Long-term production from the gas hydrate part of the Messoyakha field is presumed to have been achieved by the simple depressurization scheme. As production began from the lower free-gas portion of the Messoyakha field in 1969, the measured reservoir pressures followed predicted decline relations; however, by 1971, the reservoir pressures

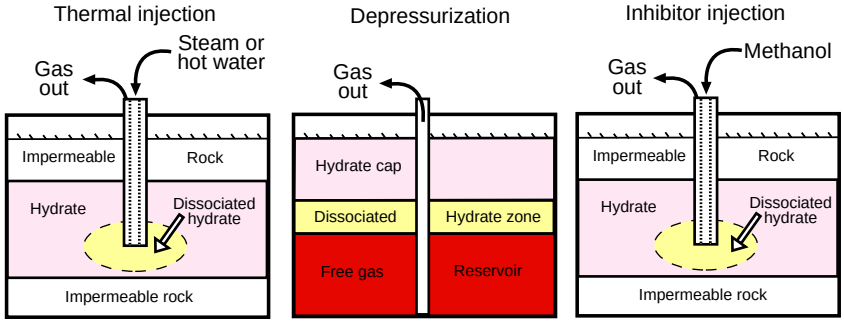

FIGURE 4 Schematic of proposed gas hydrate production methods.

began to deviate from expected values. This deviation has been attributed to the liberation of free gas from dissociating gas hydrates. Throughout the production history of the Messoyakha field, it is estimated that about 36% (about 5 billion cubic meters) of the gas withdrawn from the field has come from the gas hydrates. However, several recent studies suggest that gas hydrates may not be significantly contributing to gas production in the Messoyakha field.

It should be noted that the current assessment of proposed methods for gas hydrate production does not consider some of the more recently developed advanced oil and gas production schemes. For example, the usefulness of downhole heating methods such as *in situ* combustion, electromagnetic heating, or downhole electrical heating have not been evaluated. In addition, advanced drilling techniques and complex downhole completions, including horizontal wells and multiple laterals, have not been considered in any comprehensive gas hydrate production scheme. Gas hydrate provinces with existing conventional oil and gas production may also present the opportunity to test relatively more advanced gas hydrate production methods. For example, in northern Alaska, existing "watered-out" production wells are being evaluated as potential sources for hot geopressured brines that will be used to stimulate gas hydrate production thermally.

It has been suggested that some of the methane liberated from a producing gas hydrate field could be lost to the atmosphere; methane is believed to be a significant greenhouse gas. It is possible that large-scale production of gas from hydrates could contribute methane to the atmosphere; however, the rates of gas release from a hydrate accumulation would probably be similar to those associated with conventional natural gas fields. In addition, any modern gas hydrate field completion plan would attempt to monitor and remediate any potential accidental release of gas.

Because of uncertainties about the geologic settings and feasible production technology, few economic studies have been published on gas hydrates. The National Petroleum Council (NPC), in its major 1992 study of gas, published one of the few available economic assessments of gas hydrate production (Table I). This information assessed the relative economics of gas recovery from hydrates using thermal injection and depressurization. It also benchmarked the cost of gas hydrate production with the costs of conventional gas production on Alaska's North Slope. Since the 1992 NPC report, the cost of conventional gas production has declined. However, within countries with considerable production of cheaper conventional natural gas, hydrates appear not to be an economically viable energy resource in a competitive energy market. However, in certain parts of the world with unique economic and/or political motivations, gas hydrates may become a critical sustainable source of natural gas within the foreseeable future.

TABLE I

Economic Study of Gas Hydrate Production

Economic factor[a]	Thermal injection[b]	Depressurization	Conventional gas
Investment ($\times 10^6$\$)	5084	3320	3150
Annual cost ($\times 10^6$\$)	3200	2510	2000
Total production (MMcf/year)[c]	900	1100	1100
Production cost (\$/Mcf)	3.60	2.28	1.82
Break-even wellhead price (\$/Mcf)	4.50	2.85	2.25

[a] Mcf, thousand cubic feet; MMcf, million cubic feet.

[b] Assumed process: injection of 30,000 barrels/day of water at 150°C.

[c] Assumed reservoir properties: h (reservoir thickness) = 7.3 m, ϕ (reservoir porosity) = 40%, k (reservoir permeability) = 600 md.

University of Illinois at Chicago
Chicago, Illinois, United States

1. Introduction to Gasoline Additives
2. Human Health Effects of Methyl Tertiary-Butyl Ether (MTBE)
3. Human Health Effects of Other Ether Compounds
4. Human Health Effects of Ethanol
5. Conclusions and Recommendations

1. INTRODUCTION TO GASOLINE ADDITIVES

Since 1979, oxygenates as gasoline additives have been used in limited areas of the United States as octane enhancers to replace lead at levels around 2 to 8% by volume. During the 1980s, oxygenates came into wider use as some states implemented oxygenated gasoline programs for the control of carbon monoxide air pollution in cold winter. Oxygenates were added to conventional gasoline nationally at higher percentages with the passage of the 1990 Clean Air Act (CAA), which required that oxygenates be added either seasonally (15% MTBE by volume) or year-round (11% MTBE by volume) to gasoline in specific parts of the country where carbon monoxide in the winter or concentrations of ozone in the summer exceed their respective National Ambient Air Quality Standards (NAAQS). Title II of the 1990 CAA addresses mobile sources and mandates the following two types of oxygenated fuel programs:

- Section 211 (m) of the CAAA of 1990 directed the EPA to mandate that states establish a wintertime oxygenated fuel program in 42 geographic areas designated as moderate or serious CO nonattainment areas (i.e., areas with CO concentrations exceeding the CO NAAQS) by November 1, 1992. The oxygenated fuel program was mandated during the winter months of November through February based on the fact that gasoline combustion is less efficient at colder temperatures, resulting in increased CO emissions, and that pollutants stay closer to ground level in winter. During these months, the oxygen content requirement for gasoline sold in the designated areas is a minimum of 2.7 percent.
- Title II of the 1990 CAA under Section 211(k) specified that only reformulated gasoline (*RFG*) with a 2% oxygen weight requirement can be sold in metropolitan areas with populations more than 250,000, classified as extreme or severe for ozone pollution. These included Los Angeles, New York, Baltimore, Chicago, Milwaukee, Houston, San Diego, Sacramento, Philadelphia, and Hartford. Less-polluted nonattainment areas for ozone opted to implement the RFG program since its initiation in January 1995. During Phase I of the RFG program, refiners were required to reduce vehicle emissions of ozone-forming volatile organic compounds (VOCs) and air toxics by 15 to 17% annually, compared to 1990 baseline averages. The benzene and the aromatic content of RFG could not exceed 1.0% and 25% by volume, respectively. Nitrogen oxides (NO_x) emissions were not allowed to increase relative to conventional "baseline" gasoline. During Phase II, a 25 to 29% reduction in VOC was required, as well as a 20 to 22% reduction in air toxics and a 5 to 7% reduction in NO_x emissions from the 1990 baseline.

Among the available oxygenates in the marketplace, methyl tertiary butyl ether (MTBE) is the most widely used because of its low vapor pressure, compatibility with the blending and distribution system for gasoline, high octane rating, availability

 © 2004 Elsevier Inc. All rights reserved.

and ease of production, and low cost. MTBE had the second highest volume of all chemicals produced in the United States in 1997.

On the other hand, ethanol is the predominant oxygenate used in gasoline in some areas, particularly in the Midwest. Other fuel oxygenates that are in use or may potentially be used to meet the 1990 CAA oxygenated fuel requirements include ethyl tertiary butyl ether (ETBE), tertiary-amyl methyl ether (TAME), diisopropyl ether (DIPE), tertiary-butyl alcohol (TBA), and methanol. This article assesses the human health effects of MTBE, ETBE, TAME, DIPE, and ethanol based on potential for exposure to these compounds as a result of using oxygenates in the U.S. gasoline supply. The priority is given to human studies in analyzing health effects information related to each of these compounds in gasoline.

In the 1992–1993 CO season, MTBE-blended gasoline accounted for approximately two-thirds of the demand, with ethanol providing the remainder. According to the EPA, ethanol is the predominant oxygenate used in the oxyfuel program (about 7.5% and 15% by volume for ethanol and MTBE, respectively) to meet the 2.7% by weight oxygen requirement. On the other hand, MTBE at 11% by volume is the primary oxygenate used in RFG to meet the 2% by weight oxygen requirement. The EPA's Office of Mobile Sources estimated in 1994 that approximately 30 million people live in areas using wintertime oxygenated gasolines and about 45 million live in high ozone RFG areas. Later estimates by SRA Technologies suggest that 70 and 57 million people live in areas using oxyfuel and RFG, respectively. It is also reported that about 109 million Americans live in counties where MTBE is used as oxygenate in gasoline. There is some overlap between the areas implementing the winter oxyfuel program and the areas implementing the year-round RFG program. Estimated oxygenated volume consumed in RFG areas in the United States is 237 (MTBE), 0.3 (ETBE), 14.6 (TAME), and 24.2 (ethanol) thousand barrels per calendar day. These estimates suggest that a large fraction of the U.S. population may get exposed to oxygenates on a daily basis.

2. HUMAN HEALTH EFFECTS OF METHYL TERTIARY-BUTYL ETHER (MTBE)

Acute health symptoms attributed to methyl tert-butyl ether (MTBE) were reported in various parts of the United States soon after the addition of oxygenated compounds to gasoline during the winter of 1992–1993. Such complaints were not anticipated but have subsequently focused attention on possible health risks due to oxygenated gasoline. The health complaints were accompanied by complaints about reduced fuel economy and engine performance and by controversial cancer findings in long-term animal studies.

2.1 Epidemiological Evidence for Air Exposures

Following the introduction of MTBE-oxygenated gasoline in Fairbanks, Alaska, in November 1992, about 200 residents reported headaches, dizziness, irritated eyes, burning of the nose and throat, coughing, disorientation, nausea, and other acute health symptoms. The Alaska Department of Health and Social Services and the Center for Disease Control (CDC) conducted a number of field epidemiology studies to investigate the potential relationship between MTBE oxyfuel exposure and acute health symptom responses. A two-phase study was performed in Fairbanks, with Phase I occurring while MTBE-oxyfuel was in use and Phase II occurring 6 weeks after MTBE-oxyfuel use had been terminated. In this study, the relationship between MTBE oxyfuel exposure and blood levels of MTBE and a major metabolite of MTBE, tertiary butyl alcohol (TBA), was also investigated. The occupational and non-occupational exposure groups answered a questionnaire inquiring about the presence of certain symptoms, including the seven key complaints of headache, eye irritation, burning of nose/throat, cough, nausea, dizziness, and spaciness. Occupationally exposed individuals reported a greater prevalence of health complaints during Phase I compared to Phase II. Overall, the CDC's analysis of Fairbanks data showed that there was a statistically significant difference between the number of cases among the individuals who were exposed to higher concentration of MTBE (e.g., taxi drivers) compared to people exposed to lower exposure levels (e.g., students). The CDC cautioned that the results did not provide definitive evidence that the use of MTBE oxyfuels caused the reported symptoms due to potential confounding factors (e.g., negative publicity about MTBE-oxyfuel effects, small sample size, strong odor associated with MTBE, and lack of controls) and called for further research to determine whether there actually is an increase in acute health symptoms and, if so, whether they are causally associated

with MTBE-oxyfuel. However, the governor of Alaska suspended the program in Fairbanks within 2 months of the introduction of oxyfuel and a switch from MTBE-oxyfuel to ethanol-oxyfuel occurred in following years.

A desire to conduct a study similar to the Fairbanks study in the absence of confounding factors observed in Alaska (especially negative publicity) led to a field study in another part of the country. The CDC compared the prevalence of acute health symptom reports in Stamford, Connecticut, in April 1993 (where MTBE-oxyfuel was used) and Albany, New York, in May 1993 (with no oxyfuels). There were no known consumer health complaints in either location. For the Stamford study, CDC in cooperation with the State of Connecticut Health Department selected 221 individuals from four groups of workers and administered a questionnaire similar to that used in Fairbanks. The CDC reported that the 11 individuals with the highest blood MTBE levels were statistically significantly more likely to report one or more key symptoms than the other 33 people with lower blood levels. However, there was no apparent relationship between symptom prevalence by occupational category and the median blood MTBE or the TBA concentrations associated with each category. CDC again cautioned that the small numbers of subjects studied, the wide range of blood MTBE and TBA levels within each category, and the wide variability of response prevented a definitive conclusion. For the Albany study, 264 individuals were nonrandomly selected and categorized into three groups presumed to have tiered levels of exposure. Overall, the results indicated that the Albany residents with no MTBE-oxyfuel exposure had symptom prevalence as high as those in Stamford residents with MTBE-oxyfuel exposure. It was suggested that this outcome could potentially be attributed to the high prevalence of symptoms due to allergies and viruses at the time of the study in Albany.

In New Jersey, the EOHSI evaluated 237 state-employed garage workers from two groups in 1993: (1) 115 northern New Jersey workers sampled during the wintertime oxyfuel program and (2) 122 southern New Jersey workers sampled 10 weeks after the phase-out of the program in that area. All participants were asked to complete questionnaires about symptoms and their severity over the previous 30 days and about preshift and postshift symptoms. Essentially no differences in symptom reports were found between the northern (high-exposure) and southern (low-exposure) groups. In a separate study, 11 workers who pumped MTBE-oxyfuel for more than 5 hours per day were matched with 11 workers from the south who had low or nondetectable exposures to MTBE. No differences in symptom prevalence were found between the groups.

Another EOHSI study attempted to identify a sensitive subpopulation for the effects of MTBE-oxyfuel exposure. This involved 13 subjects with multiple chemical sensitivities (MCS), five subjects with chronic fatigue syndrome (CFS), and six healthy controls. Through a symptom questionnaire, these subjects were asked to assess symptoms associated with situations in which they could be exposed to MTBE such as refueling and driving. On a total symptom score range of 0 (no discomfort) to 28 (severe discomfort), the MCS subjects scored 5.3, compared to 4.8 for the CFS subjects and 1.2 for the healthy subjects. It was not possible to draw any definitive conclusions from this study due to (1) lack of evidence to support that an unusually high rate of symptoms or an increase of symptoms was occurring uniquely where MTBE was most prevalent, (2) small sample sizes, and (3) inability to distinguish between those subjects using and not using MTBE oxyfuel.

In response to variety of health concerns of Milwaukee citizens after the beginning of the RFG program in January 1995, the state of Wisconsin conducted a random-digit-dial telephone survey of 500 residents of the Milwaukee metropolitan area and equal numbers of residents in Chicago and in non-RFG areas of Wisconsin. In Milwaukee, oxygenates in the RFG samples were 49% MTBE, 38% ethanol, and 14% ETBE. Symptom prevalence was significantly higher in Milwaukee than in either Chicago or elsewhere in Wisconsin (23% compared to 6%). In Milwaukee, persons were more likely to report symptoms if they had experienced a cold or flu, smoked cigarettes, or were aware that they had purchased RFG. Because overall symptom prevalence was essentially equivalent in Chicago and non-RFG areas of Wisconsin, the authors concluded that factors other than RFG use such as an increase in price of gasoline, odors of MTBE, and negative media coverage significantly contributed to the differences in symptom prevalence between Milwaukee and the other two areas. However, due to study design limitations, the study could not "rule out subtle effects of RFG exposure, or the possibility that a relatively small number of individuals may have a greater sensitivity to RFG mixtures."

Hakkola and his coworkers investigated neurological effects reported by 101 Finnish male tank drivers with exposure to gasoline containing 10%

MTBE. Drivers with longer exposure scored higher for fatigue and hostility changes as compared to drivers with shorter exposure. In addition, 20% of drivers reported the following symptoms in the order of decreasing frequency: headache, nausea, increased salvation, dizziness, and dyspnea.

2.2 Controlled Human Inhalation Exposure Chamber Studies

Assessment of humans exposed directly in a chamber to MTBE was hoped to answer whether there was a direct causal relation between MTBE exposure and acute health symptoms, particularly in view of the inconclusive evidence gathered from the field epidemiology studies. In an EPA investigation, 37 healthy nonsmoking individuals were exposed for 1 h to both clean air and 1.4 ppm (5 mg/m^3) "pure" MTBE in air at 75° F and 40% humidity. The endpoints selected, based on observations from Alaska, were the types of symptoms associated with organic solvent exposure: (1) nonspecific symptoms including headache, nasal irritation, throat irritation, cough, eye irritation, odor quality, and dizziness; (2) measures of behavioral response (neurobehavioral evaluation system test battery); (3) indicators of upper airways inflammation (nasal lavage); and (4) indicators of eye irritation. The study found that MTBE exposure had no statistically significant effects on any of the endpoints. Yale University researchers replicated the EPA study, with few minor modifications—that is, 43 subjects, slightly higher MTBE concentration of 1.7 ppm (6 mg/m^3), and an additional experiment involving a 1-h exposure to a complex mixture of 16 VOCs commonly found in gasoline at a concentration of 7.1 ppm without MTBE. Similar to the EPA study, it was found that MTBE exposure had no statistically significant effects on any of the endpoints studied as compared to clean air exposure. The VOC exposure caused an increase in inflammatory cells in the nasal lavage on the day following exposure when the VOC exposure compared to clean air exposure. Taken together, the EPA and Yale investigations showed that controlled exposure of a small number of healthy humans to MTBE in air under the conditions studied did not cause increased symptoms or measurable responses. Exposure concentrations utilized in these controlled exposure studies (1.4 and 1.7 ppm) did not represent the worst-case exposure conditions based on measurements from the customer breathing zone samples taken in air during refueling (median exposure range: 0.3 to 6 ppm, occasionally higher). Nor were subjects chosen who were seemingly susceptible to MTBE based on their complaints.

Another controlled exposure chamber study exposed normal subjects to much higher concentrations of MTBE (5, 15, and 25 ppm compared to 1.4 and 1.7 ppm) and a longer exposure duration (2 hours) than the EPA or the Yale study (1 hour). This study did not include neurobehavioral assessments. No effects associated with MTBE exposure were identified. In a separate study, 13 healthy male subjects were exposed to 25 and 75 ppm MTBE in air in an exposure chamber. Subjects with 75 ppm exposure developed irritation of mucous membranes and nonspecific symptoms indicative of effects on mood.

A controlled exposure study was conducted at the EOHSI to investigate the symptoms, psychophysiologic and neurobehavioral effects of exposure to the MTBE. The exposures were conducted at concentrations similar to those found while refueling a vehicle using both control subjects and those individuals self-described as sensitive to MTBE. In the double-blinded repeated-measures controlled exposure study, subjects were exposed for 15 min each to clean air, gasoline alone, gasoline with 11% MTBE, and gasoline with 15% MTBE. Relative to the control group ($n = 19$), sensitive individuals ($n = 12$) reported significantly more total symptoms only when exposed to gasoline with 15% MTBE and not to gasoline with 11% MTBE or clean air. However, the sensitive group did not exhibit significant differences in psychophysiologic responses from the control group at any exposure level. This study did not identify a dose-response relationship for MTBE exposure and symptoms were specific to MTBE. The EOHSI research group also studies the driving habits and vehicle maintenance patterns of these two study groups. Results showed that the individuals who had self-reported heightened sensitivity to oxygenated gasoline vapors drove their vehicles more often and fueled their vehicles more frequently than the control group. In addition, sensitive individuals more frequently drove their vehicles with compromised body integrity that could lead to higher exposures.

2.3 Health Effects Associated with Oral Exposure to MTBE

In the mid-1990s, the focus on MTBE began to shift from questions about air quality-related health risks and benefits to questions about water quality risks. The change was triggered by a number of

factors including the USGS studies demonstrating contamination of the nation's water supply with MTBE, and discovery of underground storage tank (UST) leaks resulting in high concentrations of MTBE in water causing the closure of drinking water wells in Santa Monica, South Tahoe, and San Jose, California. The emergence of widespread reports of MTBE-impacted drinking water resources in other states (e.g., New Jersey, Maine, Vermont, New York, Virginia) heightened interest in protection of water resources from MTBE. The presence of MTBE in ground water and in reservoirs used for drinking water in other parts of the country is now relatively widespread.

Faced with an acute potential public health problem and degradation of water quality (e.g., strong odor and taste associated with MTBE) resulting in loss of water supplies for consumer consumption, the California legislature enacted a number of bills calling to address issues pertaining to oxygenates including risks and benefits to human health and the environment of MTBE and its combustion byproducts in air, water, and soil and alternate oxygenates like ethanol and ETBE. In response to these legislative bills, the Office of Environmental Health Hazard Assessment (OEHHA) of the California Environmental Protection Agency proposed a Public Health Goal (PHG) of 14 ppb for MTBE in drinking water in June 1998 to protect consumers against health risks over a lifetime of exposure. The proposed PHG for MTBE was based on carcinogenic potency of 1.7×10^{-3} (mg/kg-day)$^{-1}$, which is the geometric mean of the cancer slope factor estimates obtained from three cancer sites: combined male rat kidney adenomas and carcinomas in the 1992 inhalation study of Chun *et al.*, the male rat Leydig cell tumors and the leukemia, and lymphomas in female rats in the 1995 oral study by Belpoggi *et al.* In July 1998, the Department of Health Services (DHS) adopted a secondary maximum contaminant level (SMCL) for MTBE of 5 ppb based on available data on odor and taste thresholds. Another product was a University of California (UC) report on "Health and Environmental Effects of MTBE," submitted to the governor and legislature of the state of California on November 12, 1998. The UC report states "For the general population, the risk of exposure to MTBE through ingestion of MTBE-contaminated water is currently low." However, because MTBE is highly soluble in water, poorly adsorbs to soil, readily transfers to groundwater from LUSTs, and pipelines, travels much further than plumes commonly associated with gasoline spills, and is highly resistant to biodegradation, the report concluded that "There are significant risks and costs associated with water contamination due to the use of MTBE." Most importantly, the UC scientists recommended phasing out MTBE over an interval of several years instead of an immediate ban. Based on significant risk to California's environment associated with the continued use of MTBE in gasoline, Governor Davis, on March 25, 1999, directed appropriate state regulatory agencies to devise and carry out a plan to begin immediate phase out of MTBE from California gasoline, with 100% removal achieved no later than December 31, 2002.

Faced with another MTBE problem, in 1996, the EPA began working on revising the 1992 drinking water lifetime health advisory for MTBE of 20–200 ppb to meet the needs of states that were struggling to endorse safe levels that ensure both consumer acceptability of MTBE-laden drinking water and public health protection against potential adverse health effects of ingested MTBE. Meanwhile, in the absence of enforceable federal drinking water standards, individual states began to adopt action levels or cleanup levels for MTBE in water. In December 1997, the EPA's Office of Water published "Drinking Water Advisory: Consumer Acceptability Advise and Health Effects Analysis on Methyl Tertiary-Butyl Ether (MTBE)." The advisory recommended that keeping MTBE levels in the range of 20 to 40 ppb or below to protect consumer acceptance of the water resource would also provide a large margin of safety from potential adverse health effects. The EPA could not develop a RfD for MTBE due to the persisting limitations of health effects data (e.g., lack of a pharmacokinetic model for converting inhalation exposure data for MTBE to oral exposure, limited reported pathology and historical tumor incidence, no toxicity studies with oral exposure to water). A blue-ribbon panel convened by the United States Environmental Protection Agency (EPA) recommended that Congress should act to provide clear federal and state authority to regulate or eliminate the use of MTBE and other gasoline additives that threaten drinking water supplies.

2.4 Carcinogenic Effects of MTBE

There are no human data on which carcinogenicity of MTBE can be evaluated. However, the evidence from chronic exposure by inhalation and oral exposure routes demonstrate that MTBE is

carcinogenic in rats and mice. Two chronic animal cancer bioassays with inhalation exposure to MTBE resulted in rare kidney tumors and testicular tumors in the mid- and high-dose groups of male rates, and liver tumors in mice at the high-dose group. Sprague-Dawley rats exposed to MTBE in olive oil as the vehicle for oral gavage for 2 years showed dose-related increases in lymphomas and leukemias in females and in interstitial cell tumors of the testes in males. The biological mechanism responsible for MTBE cancer production in animals is not known. The lack of mechanistic information limits our ability to determine whether the MTBE bioassay results are relevant to humans. In 1998, IARC found insufficient evidence to establish that MTBE poses cancer risks to humans. The EPA has also concluded that potential for MTBE's carcinogenicity for humans is of concern and requires further study.

3. HUMAN HEALTH EFFECTS OF OTHER ETHER COMPOUNDS

The other aliphatic ethers, ethyl tertiary butyl ether (ETBE), tertiary amyl methyl ether (TAME), and diisopropyl ether (DIPE) are proposed as potential alternatives to MTBE as an oxygenate in gasoline. In particular, TAME was considered to be an attractive alternative due to its lower vapor pressure as compared to MTBE despite its lower octane content. These compounds are being used in varying percentages in gasoline in the United States (e.g., 19.90% TAME in Sussex County, Delaware, 1.6% TAME in San Diego, California, in 1999).

Although a number of toxicity studies in animal models for other ether oxygenates of ethyl tertiary butyl ether (ETBE), tertiary amyl methyl ether (TAME), and diisopropyl ether have been conducted and published, human relevance of these findings is not known. There appears to be qualitative similarities to the MTBE health effects, with kidney and liver being the most sensitive target organs. Biotransformation and pharmacokinetics of these compounds in animals and human volunteers have been studied except DIPE. A summary of animal studies and pharmacokinetic studies in animals and humans can be found in Ahmed's 2001 research.

The EPA has not been able to establish any quantitative cancer potency factor or noncancer toxicity values (i.e., reference dose [RfD] or reference concentration [RfC]) to date due to inability to establish dose-response relationships from the animal data in a scientifically defensible manner. To fill this data gap, the EPA mandated the manufacturers to perform toxicity testing of evaporative emissions of these compounds under the CAA Section 211(b) by 2004. The EPA also called for "comprehensive evaluation of multimedia, life-cycle environmental impacts" of different fuels to assess viability of TAME, ETBE, and DIPE to be a safe replacement for ethanol or MTBE. A number of scientific bodies convened to evaluate health effects of oxygenated gasolines more than two decades also repeatedly called for more research into understanding the health effects of these compounds alone and in combination with gasoline. The California DHS proposed to add ETBE and TAME to the list of unregulated chemicals for which monitoring is required by public water systems.

4. HUMAN HEALTH EFFECTS OF ETHANOL

Ethanol used as oxygenate in gasoline is produced from grains or other renewable agricultural and forestry feedstocks. The U.S. Congress has approved a 5.4 cents/gallon federal subsidy for this biomass-based source of fuel in nations' gasoline supply. Ethanol production in 2000 was 1.5 billion gallons. Approximately 30% of this amount is used in RFG during the summer in ozone nonattainment areas. About 20% is used in the winter oxygenate program to control CO air pollution. The remainder 50% is used in conventional gasoline in the United States to enhance octane and extend fuel supplies. Ethanol is highly volatile when spilled; it will evaporate five times faster than MTBE. However, it is commonly used in many modern day products including pharmaceuticals, mouthwash products, alcoholic beverages, and cleaning products. Because humans frequently ingest fermented beverages containing 12% ethanol by volume, ingestion-related health effects of ethanol are well known. The Health Effects Institute (HEI) in its assessment of health effects of oxygenates stated that our knowledge on health effects of ethanol emanates from ingestion exposures. Ethanol was shown to be associated with increased rates of tumors of digestive track with oral exposure to moderate levels of alcohol when other carcinogens were present. Ethanol is classified as a Class I carcinogen by IARC based on human data for alcoholic beverage consumption. There is no data of such association for inhalation exposures. However,

ethanol, when blended in gasoline increases volatility of other compounds, results in an increase in evaporative emissions of VOCs, including benzene. Many of these VOCs are known or suspected carcinogens and also have adverse health effects associated with noncancer health endpoints. Ethanol exposure is also associated with cancers in the liver, esophagus, oral cavity, pharynx, and larynx. There have been reports of adverse reproductive and developmental effects of associated with exposure to ethanol in animal and human studies. Irvine analyzed the relevance of the developmental toxicity of ethanol in occupational settings and concluded that while developmental toxicity may result from drinking alcoholic beverages for which threshold levels have yet to be determined there was no evidence for developmental toxicity in occupational environment.

With the executive order to phase out of MTBE in gasoline distributed in California by December 31, 2002, Governor Davis also directed CARB and the State Water Resources Board to conduct an environmental fate and transport analysis of ethanol in air, surface water, and groundwater and the OEHHA to prepare an analysis of health risks associated with exposure to ethanol in gasoline. In terms of air quality effects, the substitution of ethanol for MTBE in CA's fuel supply was found to have not significantly impact air quality as long as RFG regulation in CA addressed the potential for ethanol to increase evaporative emissions and to cause more rail and truck traffic to bring ethanol to the state. The CA analysis found no substantial differences in the air-related public health impacts of different non-MTBE fuel formulations including ethanol. Although the replacement of MTBE by ethanol is expected to have some benefits in terms of water contamination due to ethanol's relative toxicity and rapid biodegradation, these could not be quantified. The overall estimated health risks for exposure scenarios with ethanol, MTBE, and nonoxygenated fuel did not differ between fuel formulations, but showed a significant improvement for 2003 in comparison to 1997.

The Northeast States for Coordinated Air Use Management (NESCAUM) also prepared an analysis in response to potential phase-out of MTBE in Northeast States due to adverse water quality impacts of MTBE and the need to protect environmental resources. The NESCAUM estimated that the use of ethanol instead of MTBE would increase emission rates of acetaldehyde, a combustion by-product, into the atmosphere in the Northeast by 50 to 70%. Acetaldehyde is also a probable human carcinogen. Ambient levels of acetaldehyde in the Northeast exceed the health-protective levels of acetaldehyde at majority of the air monitoring locations throughout the northeastern states. NESCAUM estimates that ethanol at 10% by volume in conventional gasoline would increase the VOC emissions significantly. Therefore, NESCAUM stressed the importance of studying health effects of ethanol alone, in combination with gasoline, but importantly, its lifecycle, its degradation products, and concurrent VOC emission increases. Schifter *et al*. also estimated an increase of about 80% in acetaldehyde emissions with 6% by volume ethanol as a substitution for 5% by volume MTBE accompanied by 16% decrease in CO and a 28% decrease in formaldehyde motor vehicle emissions in Mexico City. However, according to the CARB analysis on impact of use of ethanol-containing gasoline on air quality in Denver, Colorado, Albuquerque, New Mexico, Brazil, and other areas, acetaldehyde levels were substantial only in Brazil, where the fuels contained either pure ethanol or 22% ethanol, much greater than the maximum 10% ethanol allowed in CA gasolines.

There are no EPA toxicity values established for cancer (cancer slope factor) or noncancer (RfD or RfC) health endpoints for ethanol. There is also no safe drinking water standard for ethanol. The lack of toxicity values for ethanol for various exposure routes and lack of exposure information in various exposure media do not enable us to quantitatively estimate health risks associated with exposure to ethanol under different exposure conditions for public exposed to ethanol due to its circulation in the environment related to its widespread use in gasoline. Such analysis should not only include ethanol, but also all environmental degradation products of ethanol, and health risks and benefits analysis focusing on multimedia exposures is essential for not repeating the history of MTBE episode.

5. CONCLUSIONS AND RECOMMENDATIONS

There have been significant air quality benefits since the implementation of the oxygenated fuels program. Although some of the improvement in air quality indices may be simply due to fleet turnover, increase in fuel efficiency over time, and improvements in vehicle testing and maintenance programs, the oxygenates have also been credited for air quality

benefits. For example, 10 to 14% reduction in ambient CO concentrations has been attributed to use of oxygenated in winter months in CO nonattainment areas. Although the National Research Council concluded that little air quality impact in terms of ozone reduction can be gained from the use of oxygenates in RFG, the EPA's blue ribbon panel acknowledged major reductions in VOCs, especially, some of the carcinogenic air toxics (e.g., benzene, 1,3-butadiene) in many urban environments where RFG is used during the summer months. However, health complaints associated with exposure to MTBE containing gasoline and discovery of degradation in water quality in national scale with contamination of groundwater, surface water, and drinking water resources with MTBE overshadowed the potential air quality benefits and associated air-quality-related health benefits in the decade since the enactment of the oxygenated fuel programs by the Congress. The course of the national debate on oxygenates has shifted to potential alternatives to MTBE. We know more about the potential human health effects associated with exposure to MTBE alone or in combination with gasoline than about its potential substitutes. Quantitative assessment of the public health inhalation risks of MTBE-oxyfuel in comparison to conventional gasoline has been difficult, in part due to uncertainties and data deficiencies in toxicity combined with the paucity of the population-specific human exposure data. Although both short-term field epidemiological studies and a few controlled human laboratory studies of healthy adults provide a better understanding of human exposures to MTBE and MTBE-oxyfuel, the large differences in terms of confounding parameters, study design, exposure conditions, and exposure parameters greatly complicate the interpretation of the results of these few studies. Although more animal toxicity data for MTBE have become available and have increased our scientific understanding of the toxicity of MTBE (especially the pharmacokinetics of MTBE), there are insufficient data to answer questions about the relevance of these animal data to humans. Additionally, in the absence of oral toxicity studies, health effects of ingested MTBE cannot be determined. Although neither the epidemiological studies nor the controlled human exposure studies of normal and sensitive subjects have been, in majority, inconclusive, they cannot rule out the possibility that for a small percentage of the population, those claiming that they were affected by MTBE, there is a causal relationship between their exposure and their symptoms. In conclusion, the human health effects of MTBE are still unclear. For some other oxygenates, animal testing has not been thoroughly conducted and published yet. Any alternatives to MTBE, including TAME, ETBE, DIPE, and ethanol, should be studied with well-designed experiments to assess potential environmental and public health implications of using these compounds in large scale. This requires a substantial commitment and well-coordinated research effort by government and industry. The EPA scientists have evaluated retrospectively the governmental decision making with MTBE and concluded that

> *The most valuable lesson to be gained from the MTBE experience may be the importance of obtaining comprehensive understanding of the many and varied risks and benefits potentially offered by any given fuel option. This should entail a consideration of all facets of the life cycle of a fuel or additive, including the environmental fate of any emissions or releases, because the by-products of a chemical may be of greater toxicological or environmental significance than the parent compound itself.*

Given the fact that ethanol has increasingly gained oxygenate market share in the absence of such comprehensive evaluation should remind the EPA and the scientific community about the importance of critical findings gleaned through the MTBE experience.

Glossary

econometric analysis A test of economic theory with linear or nonlinear regression and other multivariate statistical methods using socioeconomic and technical data.

geography of energy The study of energy development, transportation, markets, or use patterns and their determinants from a spatial, regional, or resource management perspective.

location theory Spatial theory developed to solve optimization problems for selecting a preferred zone or location for a facility, which involves trading off transportation costs with production and processing costs, production balances, and market-delivery levels.

mathematical programming model An operations research technique designed to determine an optimal solution to a well-defined problem by maximizing or minimizing an objective function subject to technical, economic, and often environmental constraints.

regional input–output analysis An analysis of the economy at the urban, state (provincial), or multistate (provincial) levels based on a fundamental identity that equates supply and demand using fixed proportions of intermediate inputs.

Three Mile Island (TMI) The name of the nuclear power plant near Harrisburg, Pennsylvania, that was the site of the most serious nuclear accident in the United States on March 28, 1979.

Since the field of geography encompasses broad study of interactions between humans and the environment, the concept of energy has been operationalized and studied in several ways. These approaches have included energy balance studies in geographical climatology, energy resource availability and conservation in applied climatic research, cultural geography, and economic geography of energy resources. In the past few decades, new geographic perspectives on energy have been introduced from spatial analysis and modeling to applied, political, transportation, hazards, geographic information systems, global environmental change, and ecological economics. Some of these areas are even considered separate fields.

Understanding and modeling solar radiation and the energy budget of the climate at a variety of spatial scales have long been central concerns of several types of climatological studies: modeling, synoptic and dynamic climatology, climate change, and applied climatology. Analytical approaches have become increasingly mathematical over time, and this work has been somewhat separate from other branches of geography. It is consequently more convenient to trace the evolution of the energy concept in geographic thought by focusing on the contributions of human geography, which initially considered energy from economic and cultural perspectives. The article begins with a discussion of pre-World War II studies of the coal industry.

 © 2004 Elsevier Inc. All rights reserved.

Subsequent sections consider the rise of petroleum as a global political force, commercial nuclear power, and additional work on the location and spatial distribution of fossil fuels. A new period in geographic thought followed the Three Mile Island nuclear power plant accident in 1979, when geographers gave attention to technological hazards and risks of energy systems, the back end of the nuclear fuel cycle, the diffusion of energy conservation technologies, and the increasing scarcity of fossil fuels. The article concludes with a discussion of the growing need to develop sustainable energy resources in the context of concerns about global climatic change and rising energy demands in developing nations.

1. EARLY RESEARCH ON THE COAL INDUSTRY, 1934–1955

Coal, as the fossil fuel of greatest abundance and widest distribution, has long attracted attention from geographers. In the early years, this attention focused on the location of deposits and their transport and much of it mirrored the major coal fields of Britain, Germany, Poland, and the United States. The accounts in geography journals were largely descriptive, economic, and cartographic. Little or no interest was evident regarding the environmental costs. Later, when the public mood shifted and impacts were widespread, more attention was paid to environmental impacts, especially air pollution and its dispersal, impacts of acid rain, landscapes altered by strip mining and waste heaps, and the forced relocation of residents. This emphasis came with the increasing knowledge not only of the damage that was created by our demand and use of coal but also that we should and could do something to reduce or reverse the impact it was having on air, land, and water. From this point forward, research articles were much more widely dispersed, within a range of environmental journals and books, and the type of writing was more analytical.

2. FOSSIL FUELS AND ELECTRIC POWER GENERATION, 1955–1971

Parallel to the growth and development of the oil and natural gas industries in the United States and other advanced economies, geographers began to give more attention to the other fossil fuels, their development, and use patterns in the mid-1950s. Another exciting new energy source gained attention with the commercialization of atomic power plants in Britain, Russia, and the United States during this period. Nuclear power development attracted considerable attention among geographers in North America and Europe. This topic is considered separately since the economics, spatial diffusion, risks, social acceptance, waste problems, and other dimensions of nuclear power were highly uncertain in the 1950s and thus it was treated differently.

Although a quantitative revolution in geography first appeared in the mid-1950s there was little evidence of a change in methods in energy research until the early 1960s. Indeed, most geographical publications on energy issues in the 1950s were studies on the regional geography of energy (i.e., "areal differentiation"). Although important, this work was overly descriptive and often handicapped by scant understanding of the complex interplay between resources and technical, economic, and social factors in energy markets. Several detailed analyses were completed on the oil, gas, and electric power industries of the United States, Britain, Europe, and the former Soviet Union during this time. A few researchers went beyond the single-region scale and assessed the development of power interconnections in Europe, North America, and the Soviet Union. A 1960 paper addressed the conflict between hydroelectric power generation and salmon fisheries in the Pacific Northwest, which is still relevant today. This study suggested the use of (but did not apply) optimization criteria to help resolve the conflict. The same year marked the inaugural publication of *Soviet Geography: Review and Translation*, which was to become a major scholarly outlet for energy studies of the former Soviet Union and its various regions.

Neoclassical studies of the regional geography of energy continued throughout the 1960s at a variety of spatial scales. Several books and articles on the economic geography of the oil and gas industries analyzed national and international patterns of location, economic growth, development, and trade but did not suggest general market patterns. The first truly international energy study, a book on the economic geography of the world oil industry by the British geographer Peter Odell, was published in 1963, just a few years after the formation of the Organization of Petroleum Exporting Countries (OPEC). Articles on coal geography also assessed economic growth and development but considered

declining or less prosperous coal fields and their socioeconomic effects as well. Political factors (i.e., national policies, government regulation, political stability, etc.) began to be mentioned more frequently in this literature but were still secondary to economic considerations.

Of special significance was the work by Gerald Manners in the 1960s to incorporate location theory into energy geography. General locational principles were identified and applied to the oil, gas, and electric power sectors. Transportation costs were shown to be of fundamental importance because they determine the energy facility location between a resource market(s) and final demand center(s). Also important are factor costs of production, resource availability, weight and quality, scale economies, technical efficiency, modal and interfuel competition, and the load factor(s). Similar principles were used to explain the changing pattern of pit location within a coal field. The first such analytical, general approach for studying the industrial geography of energy was published in book form by Manners in 1964. (A 1950 book on the geography of energy by Pierre George received little notice outside of France.) Owing to data availability and the scale of the economies, his research focused on Western Europe and North America. National studies and atlases for the United States and United Kingdom were to come later.

As the 1960s closed, a few prominent authors completed seminal works on the international patterns of energy geography. A landmark book by Odell addressed oil and world power; this book was first published in 1970 and updated seven times. The monograph considered this leading industry's production, economic growth, and trade in the context of its prominent role in national and international political affairs. By analyzing the global structure of the oil industry along with regional perspectives and company–nation state relationships, Odell provided the most complete story of this vital resource. Three more general energy papers by geographers in the September 1971 issue of *Scientific American* showed the close connection between energy resource type and technology at the various life-cycle stages and the pattern of energy flows in primitive and advanced industrial economies.

Two final (although brief) energy books from the perspective of world economic geography closed out this period, both of which were written by Nathaniel Guyol. One of these monographs provided, for the first time, a system of energy accounting that made it possible to compare energy statistics in multiple countries on a consistent basis, a subject he had worked on since the late 1940s. An accounting worksheet, suggestive of a first cut of a simple input–output table, was developed for The Netherlands as an example. The other volume was narrower but more detailed: a systematic survey of the electric power industry in 162 nations. Important observations were made by Guyol on the regional variations in electricity supply and use.

3. THE BIRTH OF COMMERCIAL NUCLEAR ENERGY, 1951–1973

The use of commercial nuclear power grew up as the stepchild of the military program. After spending an enormous amount of money to develop and construct the three bombs that were detonated in 1945, there was a concerted effort to turn this research to peaceful use. There followed almost a decade of research and development that led to the construction of electrical generating stations at Calder Hall, England, Shippingport, Pennsylvania, Eureka, California, and eventually more than 400 other commercial units.

Geographers showed little interest in the dispersed siting of the nuclear research program of the war years, but afterwards they addressed the possibility of using nuclear bombs to reshape the earth's surface, the location of nuclear fuels, and the siting of nuclear power plants. It was electricity generation that was to achieve the greatest momentum as commercial enterprises began appearing in several countries: Britain, the United States, the Soviet Union, and later France, Germany, and Japan. Researchers during this period published a steady, if thin, series of geographical studies, only rarely turning their attention to the spatial pattern of the fuel cycle or dispersal of the technology.

For more than 15 years, there seemed little uncertainty or public misgivings about the wisdom of a nuclear power program, and the geographic literature did not contradict this trend. Industry, government, and the public seemed to all be moving in the same direction, one that looked to nuclear power to generate a growing, perhaps dominant, proportion of the great amounts of new generating capacity that many countries were demanding. With U.S. growth rates for electricity exceeding 7% per year in the 1960s, nuclear power not only seemed like the most likely supplement to coal-fired power plants but also seemed to be the eventual replacement

technology as concerns grew over the pollution that such fossil power plants produced. Moreover, it was recognized that by themselves coal stations would not be able to keep ahead of the tidal wave of demand for electricity. The public, bolstered by the reassurances of government and contractors, regarded the use of nuclear power as the only way to meet the steep rise in need.

During the early civilian period, power plant siting was influenced mostly by seismic stability and the availability of cooling water. Little consideration was given to isolating power plants from urban areas; indeed, many were located close to load centers, the better and more conveniently to service their needs. Thus, the pattern that was emerging favored the densely settled northeastern United States and Chicago. Gradually, additional power plants appeared in the southeast. In Britain, all but one (in Wales) were sited along coasts. France used both coastal and riverine sites, starting mostly with the latter locations, and in contrast to the United States and the United Kingdom, the distribution of nuclear power plants had no obvious locational concentration. However, the benign public reaction to nuclear power was to be short-lived.

4. MODELING THE SPATIAL DEVELOPMENT AND TRANSPORTATION OF FOSSIL FUELS AND POWER PLANT SITING

By the early 1970s, the quantitative revolution was firmly entrenched in energy geography. Researchers began to apply several mathematical and statistical techniques to problems of spatial energy resource development and transportation, power plant siting, and socioeconomic and environmental impact analysis. These important research developments, spanning the 1970s through the mid-1990s, are discussed in turn.

4.1 Resource Development and Transportation

Beginning in the 1970s, geographers developed and applied a variety of simulation, mathematical programming, and econometric models to oil and gas issues. Among the early work was a rather extensive analysis of North Sea oil development through 2080. A less ambitious study assessed the optimal oil pipeline network in the British sector of the North Sea. North American oil industry studies also used mathematical programming models, with the site selection and storage levels at the Strategic Petroleum Reserve in Louisiana as an example. Since the mid-1980s, a series of related papers have used econometric methods to update the oil industry models of geologist M. King Hubbert. This work often differentiated resource quality and used more than 50 years of historical data to assess the bleak future prospects of the U.S. oil industry. Somewhat less attention has been given to oil development in other regions. A few econometric studies have analyzed foreign investment, locational analysis, and resource-based industrialization in the Middle East, other developing countries, and the former Soviet Union. Additional studies have highlighted the main result of these developments for the United States: growing dependence on foreign sources of oil.

Mathematical programming methods also began to dominate research on the development and marketing of natural gas in North America and the Soviet Union. Since the production of this fossil fuel generally lagged that of petroleum in the United States and was decontrolled starting in the late 1970s, new research opportunities were pursued for modeling greater development, especially in Alaska, and trade with Canada and Mexico. Similarly, natural gas emerged as the fuel of choice in the Soviet Union in the 1980s. In order to advance this research area, it was necessary to improve upon previous models of the pipeline network and capacities. Following the decline in oil and gas prices and plentiful gas supplies in the United States since 1986 this research area has been largely abandoned. Only one major analysis of U.S. natural gas development has been completed since then, an econometric analysis of the declining yield per effort and resource scarcity.

Not surprisingly, the quantitative research methods that were first used in the 1970s for oil and gas studies also were applied to coal problems, along with the use of cluster analysis and spatial interaction models. Given the wide distribution of coal reserves in the United States and their often long distances from markets, transportation bottlenecks have occasionally arisen. Such problems are ideal cases for the use of operations research methods, such as linear, nonlinear, mixed integer, and multiobjective programming. An early 1970s study of the Great Lakes region was a landmark in the modeling of the whole coal resource delivery system. This was followed by a series of coal studies: regional industry analyses, such

as for Britain, western U.S. states, and Pennsylvania; transshipment problems involving railroads and ports; coal exports; competition for water resources; other environmental constraints; and structural and technological change.

Geographers, along with scholars in other fields, have also studied the development potential of synthetic fuels from fossil fuels. This work has analyzed the spatial distribution patterns and development potential of coal gasification and liquefaction plants, oil shale, tar sands, and alcohol fuels. The huge water and other resource requirements and environmental effects were given prominent attention. These studies tracked the government policy interest and short-lived massive subsidies to potential synthetic fuels industries in North America in the late 1970s and early 1980s, which were briefly considered a viable alternative to the growing dependence on foreign oil supplies. Among these resources, only alcohol fuels (from ethanol and methanol) and the Canadian tar sands industry have established commercial viability.

4.2 Power Plant Siting

The siting patterns of electric power generating stations have been a major research area among energy geographers. Although early papers on this subject were published in 1960, the vast majority of these studies were done in the mid-1970s through the mid-1980s. Perhaps surprisingly, a retrospective discriminant analysis of U.S. power plant siting patterns from 1912 to 1978 showed that fuel choice was more important than regional differences in the siting process. Development of site suitability models for fossil-fueled and nuclear power plant location analysis was pioneered at the Oak Ridge National Laboratory in the late 1970s. These and later siting models were applicable to efforts to avoid or mitigate inevitable locational conflicts surrounding proposals for many new energy facilities. Geographers developed land use screening procedures to generate local site suitability scores by estimating a land use compatibility index and using importance weights offered by decision makers. A large range of engineering, ecological, and socioeconomic criteria were analyzed. These models were applied to the Mid-Atlantic states. Despite the value of these methods for initial site screening, it has been noted that the approach largely failed to be implemented because of a lack of need for new power plant sites at that time. On the other hand, the screening models amount to a stepwise heuristic and can select inferior sites. Improvements to the method were made through the development and application of optimal transshipment and multiobjective programming models, which were also applied to the Mid-Atlantic region. Another study considered the challenges in siting coal-fired power plants in western states, where there are stricter air quality standards.

The siting and safety of nuclear power plants received the most attention by geographers of energy during the early to mid-1980s. Ironically, following the Three Mile Island (TMI) accident in 1979, North American energy geographers shifted their research from power plant siting to reactor decommissioning and waste disposal, whereas British colleagues focused on nuclear plant siting. Computer programs were written in England to analyze alternative power plant siting criteria while emphasizing remote areas and the potential human dose from radioactive releases during accidents. Government policy was shown to downplay the siting criterion of proximity to human population centers, and thus arguably safety, despite the existence of ample remote sites in Britain. Cluster analysis was used to show that local population density received greater attention with regard to siting in the United States than in Britain. Broadening this discussion from a Canadian perspective, it was shown that existing nuclear power expansion plans in the mid-1980s were not as robust as construction of small-scale hydroelectric stations. Expansion of cheap hydroelectric power in eastern Canada, whether small or large, fits in well with plans for increased electricity trading with the United States. Indeed, further study has highlighted the parallel socioeconomic and environmental challenges accompanying the recent "outsiting" of nonnuclear power plants in Mexico and Canada that have been dedicated to U.S. markets.

Since U.S. electric utilities had a greatly diminished need for power plant siting in the late 1980s as independent power producers and demand-side management picked up the slack, energy geographers abandoned regional siting analysis and developed broader, more detailed, and sophisticated industry resource planning models. A few major, large linear programming (LP) models were built with a full range of technical options for meeting future electricity demand under environmental constraints. One of these used multicriteria decision making and applied it to demand-side management planning in British Columbia, Canada. Most of the LP models

were applied to sulfur dioxide (SO_2) emissions control. There was some limited regional detail to them, which overlapped with the work of regional scientists and regional economists.

4.3 Socioeconomic and Environmental Effects

Research by geographers on the mixed effects of coal mining dates back to at least the early 1950s. Initially, this work focused on the eastern United States, but by the late 1970s and 1980s it had shifted to the arid West (along with an increasing share of the coal production). This research analyzed the potential socioeconomic impacts of "boomtown" development of coal or synthetic fuels. The declining economic fortunes of some of the eastern coal mining areas such as anthracite towns of Pennsylvania continued to receive attention in the 1980s. Regional input–output (IO) analysis was demonstrated to be an especially useful tool for analyzing economic effects of spatial shifts in the coal industry. Similarly, most coal research in Britain during this period focused on the uneven economic development or shift between declining and developing regions and a short-lived effort to revive the industry. When U.S. western energy resource development plans were scaled back, research emphasis shifted to the economic and ecological effects and control of acid rain emissions of SO_2 and NO_x. This subject continued to receive the attention of a few geographers through the 1990s as the Acid Rain Program of the Clean Air Act Amendments was implemented, including (interstate) SO_2 allowance trading.

Many energy geographers have examined the socioeconomic and environmental effects and planning issues surrounding petroleum development in disparate regions such as the Middle East, Scotland, Norway, and the U.S. Gulf Coast. The U.S. studies have also considered impact mitigation in the context of the National Environmental Policy Act and the macroeconomic effects of a future large supply disruption by OPEC. Econometric analyses by geographers for the United States have shown since 1989 that policies to expand domestic oil production would have adverse economic and ecological effects. Although less sweeping in its findings, a regional economic analysis in Canada of potential oil resource development in the nearby Beaufort Sea found that little or none of the net economic benefits would accrue to Canada's Northwest Territories. This research used a multiregional IO model.

5. HAZARDS, RISKS, AND TECHNOLOGICAL DIFFUSION: BEHAVIORAL RESEARCH BY GEOGRAPHERS SINCE THE TMI ACCIDENT

Public disinterest in nuclear power was shaken by the successful campaign to raise awareness about its purported safety risks. It was a movement that slowly gained momentum, but by 1976 an antinuclear referendum in California received ample public notice and approximately 40% of the votes. Although the referendum failed, it was a watershed for the nuclear industry because it raised many more questions than the industry could successfully answer about the safety and the financial feasibility of the technology. In addition, it prompted more restrictive and demanding siting criteria, and more than anything else it put nuclear power on the map of regular public debate. Like colleagues from other disciplines, geographers became more involved, and it was a natural topic of interest because most of the issues were spatial in nature.

The increased attention by geographers first manifested itself in questions about the adequacy of the siting criteria that had been unquestioned during the previous decade. Since much of the impetus for the nuclear debate had come from California, it was not surprising that the strongest opposition to power plant siting appeared there as well. Geographers played a quiet role at first, mostly related to siting, but their participation grew as the public debate expanded to other spatial issues, such as radioactive waste transport and disposal, dispersal of radioactivity by air currents, and identification of evacuation routes that might be needed in the event of an accident. These developments were all part of a simmering debate about nuclear power in the United States and elsewhere, but they would come to a boil with the TMI Unit 2 accident near Harrisburg, Pennsylvania, on March 28, 1979. Ironically, Pennsylvania had enthusiastically commissioned the earliest U.S. nuclear power plant 22 years earlier.

It was the TMI accident that firmly placed geographers within the nuclear power debate. For several years, many geographers turned their attention to the myriad questions that the accident raised, including siting criteria, the dispersal pattern of possible contamination, evacuation behavior, and the adequacy of emergency planning and preparedness. The effects that the accident had on nuclear power were fundamentally geographical. Most

noticeably, no new operating licenses were granted afterward, largely because of the elevated public concerns about the appropriateness of virtually every suggested site. Emergency requirements that were promulgated became so demanding that power plants already completed (e.g., the Shoreham plant on Long Island) were unable to develop an approvable evacuation plan.

Geographers participated in these studies and were most heavily involved in evaluating and measuring public risk perceptions. They asked questions about relative risk, the level of risk required to trigger evacuation, and the use of distance as a buffer to risk. These issues came into play because of the obvious inadequacy of emergency preparations at TMI, but the interests of geographers were not limited to them. Issues that had long been beneath the surface came into full view, and they included all forms of "nuclear geography," including a striking increase in the attention paid to radioactive waste transport and disposal.

Although attention to these matters was initially concentrated in the United States, it did not remain within its borders. Geographers in other countries, particularly Britain, heard the call as well, and geographers there had been making similar intellectual preparation to participate. There was a different attitude in the United Kingdom, however, in large part because their system of government had not been as receptive to an open debate on nuclear power as in the United States. As it soon became clear, its citizens had more practical reason for concern. Great Britain is a country smaller than Arizona, without the vast distances and isolation possible in the United States. Moreover, when the inquiry into the 1957 Windscale accident in northwest England confirmed public suspicions about nuclear hazards and ill-considered official secrecy, a phalanx of geographers was to lead the charge for a much wider nuclear debate.

All the nuclear plants that currently exist in the United States had already been sited by 1979, but this was not the case everywhere. In the United Kingdom, for instance, great attention was paid to siting and safety issues of the planned addition to the Sizewell nuclear station on the Suffolk coast. There was already a Sizewell A, but Sizewell B was to be a pressurized-water reaction of American design, ostensibly safer than the Magnox and Advanced Gas-Cooled reactors that comprised all the early British reactors. In response to the work of many groups, and especially geographers in the United States and Britain, the government conducted the longest and most detailed public inquiry in the history of the country.

Like the TMI accident, the Sizewell inquiry galvanized geographical attention. Soon, geographers in England were writing about waste transport through London, waste disposal under the Irish Sea, and elevated leukemia frequencies in Cumbria. Perhaps due to the smaller size of the country, much of the work of geographers in Britain attracted more attention than similar work did in the United States. Geographers regularly appeared on TV and in various newspapers and magazines, which gave their comments more visibility. Eventually, geographers from Britain and the United States began collaborating on articles and books. Even France, which operates nuclear power plants that are closer to London than those in Wales, was not immune from criticism, and although the debate was more subdued there, geographers tracked and reported on various acts of public opposition.

Attention of geographers to nuclear issues peaked in the early 1980s and then began to subside, only to be shaken into a higher degree of agitation 7 years later by the accident at the Chernobyl nuclear power plant in Ukraine. This was a far more serious accident, and it had global implications. Climatologists tracked the movement of radioactive materials, but access to data was difficult owing to long-standing policies of the Soviet Union. Nevertheless, several geographers focused their attention on the disaster, with some examining issues of the power plant's location adjacent to the vulnerable Pripyat Marshes and 90 miles upwind from the heavy concentration of humans around Kiev, others observing how land had to be reshaped and forests leveled for safety reasons, and still others focused on the forced evacuation of more than 135,000 people who lived near the plant. Others were intent on observing the various political ramifications, including how the accident helped hasten the collapse of communism.

The Chernobyl accident also pounded several more nails in the nuclear coffin. In 1988, Swedish voters reaffirmed that nation's decision to phase out nuclear power, and Germans voted to take much the same direction. The RBMK design used at Chernobyl was largely abandoned, and many of those that had been built in the former Soviet Union and satellite countries have been closed. Moreover, attention to the various elements of nuclear power plant decommissioning gained increasing momentum.

Although it was obvious that nuclear plants would eventually be "turned off," the questions were when, by what process, and to what effect. There had been

little public attention to these questions prior to 1985, but geographers helped bring attention to them during the next decade, emphasizing postoperational land use, transport and storage of the resulting low-level radioactive waste, the spatial and temporal sequence of targeted plants, and the socioeconomic consequences of the decommissioning process.

At approximately the time that interest in nuclear power was on the decline among geographers, attention was increasing in the area of energy conservation and efficiency. It was not causative, but when problems began appearing and proliferating with nuclear power, several electric utility demand-side management strategies were waiting in the wings. The logic was that if the electricity that nuclear power had been expected to supply was not actually going to be available, shortfalls would occur unless demand could be cut. It was cut, across the board and across the country, in every end-use sector, with the most noticeable changes occurring in the commercial and industrial parts of the economy and gradual progress in the residential sectors as well. Geographers worked with other professions to identify where these changes could be made and evaluated program effectiveness. There were several obvious uses to emphasize, including increased efficiency in lighting, insulation, appliances, and transportation.

6. DEVELOPMENT OF SUSTAINABLE ENERGY RESOURCES

Although physical geographers have long included solar energy in its various manifestations in their work, only since the late 1970s have geographers actively researched renewable forms of energy. Even so, this research interest tapered off in the late 1980s, seemingly coincident with the crash in world oil prices in 1986. This hiatus was short-lived because by the early 1990s, there was renewed interest in fossil fuel scarcity, namely that of oil and gas. Geographers also began to explore the energy policy implications of the growing concern regarding global climate change, with an emphasis on energy efficiency and renewable energy development.

6.1 Oil and Gas Scarcity

Although acknowledgment of the ultimate scarcity of petroleum resources dates back to the 1956 work of M. King Hubbert, who predicted with startling accuracy the ultimate size and production peak of oil resources for the United States and the world, there is much greater concern with its "net energy" from production rather than ultimate depletion. Cutler Cleveland and Robert Kaufmann, among others, in a series of papers since 1991 have convincingly forecast using econometric analyses that the amount of oil added to proven reserves per effort from additional well drilling (yield) in the United States will cease to be a net energy source early in this century. This line of research builds on the work of Hubbert, who was the first to recognize that the historical production pattern would follow a classic bell-shaped curve, reflecting the interplay of resource depletion, real oil prices, technical innovation, and political decisions on long-term production costs. Consequently, domestic oil discovery, production, and proven oil reserves are on an inexorable downward path. These findings call into question energy policy decisions based on assumptions that these geophysical realities of the U.S. resource base can be altered.

With the conventional oil resource base increasingly scarce and dependence on it unsustainable, the cleaner option of natural gas has received more attention, especially since estimates of its proved reserves were greatly increased in the early 1990s. Here too, analysis by Cleveland and Kaufmann is instructive. Using a double-log econometric model of yield per effort of gas drilling in the United States, they found an exponential decline for gas discoveries not associated with oil fields in the lower 48 states from 1943 to 1991. Their model accounts for cumulative drilling, real gas price, changes in drilling effort, and shifts between onshore and offshore gas. Thus, natural gas development lags oil but is subject to similar factors controlling its scarcity.

6.2 Greenhouse Gas Reduction and Renewable Energy Development and Use

Coal, the third fossil fuel, is well-known to have the highest emission rate of carbon dioxide (CO_2), the principal greenhouse gas. By the early 1990s, a growing cadre of geographers began to actively work on energy policy responses to the threat of planetary warming and climate change. Indeed, they recognized that many preferred policy options also reduce conventional air pollutants and have a variety of other ancillary benefits. These energy options include switching to gas, energy efficiency and energy conservation, and rapid development of renewable and possible nuclear energy sources (although no

major energy geographers have promoted the latter option through their research).

Three major types of greenhouse-related energy studies have dominated the work of energy geographers in the past few years: detailed technology assessments at the U.S. national level, sectoral-specific studies, and foreign case studies. One leading study provided an integrated assessment of the potential benefits of advanced energy technologies for greenhouse gas reductions in the United States. The authors found that large CO_2 reductions are possible at incremental costs below the value of energy saved, especially efficiency measures. Many sectoral-specific studies by geographers have highlighted the technological improvements and potential roles of energy efficiency, wind, solar, and solar–hydrogen technologies in buildings, transportation, manufacturing, and electric power. Much of this research has been conducted at the Oak Ridge National Laboratory.

Since global warming and climatic changes do not respect political boundaries, case studies of other nations can be valuable. For instance, several geographers have studied the broad range of policies that would be required to significantly reduce CO_2 emissions in Germany, Canada, and China. These studies not only highlight the great difficulty of significant emission reductions but also emphasize the necessity to implement policy reforms outside of the energy sectors (e.g., addressing urban design and transportation policies). To accelerate the process of emissions reduction in developing countries and economies in transition, the 1992 Framework Convention on Climate Change approved a pilot program in joint implementation of the treaty, whereby two or more nations cooperatively reduce or sequester emissions in their countries. Implementation of this pilot program was slowed, however, by concerns among developing countries that national sovereignty would be violated and that Western nations or Japan would gain a competitive economic advantage. Geographers have generally been sympathetic to these concerns, questioning the policy's fairness and cost-effectiveness, while identifying constructive solutions that involve compromises by the applicable countries.

Renewable energy technologies have different spatial characteristics than those of fossil or nuclear fuels (e.g., with respect to availability, transportability, reliability, and storage), which have yet to be fully explored. Among conventional energy resources, the two renewable sources that are well established are hydroelectricity and biomass. Hydroelectric installations, however, are not always sustainable because gradual siltation of their reservoirs may limit facility lifetime to 50–200 years. Since the 1990s, hydroelectric power has attracted increasingly negative attention in the United States and elsewhere, where the large part of its potential has already been tapped. Identified shortcomings include forced migration of people, displacement and destruction of salmon stocks, and downstream ecological changes.

Geographers have written a modicum of papers and monographs on hydropower facility construction in the past decade, which have focused on trends in North America and a few mammoth dam projects in developing countries such as Brazil, China, and India. Research emphasis in the United States has shifted from dam construction to dam removal and downstream restoration. Several dams have been suggested for demolition, especially smaller structures. Of the large dams, the most attention has been given to the proposed removal or "neutralization" of Glen Canyon Dam, located upstream from the Grand Canyon.

Biomass has long been the major (potentially) renewable energy source in developing nations, and it has received the most attention among the renewables from geographers. It has also received research attention in Scandinavia, where it is commonly used but somewhat controversial in Sweden. Along with its relative abundance, biomass also has challenging limitations owing to its wide variety of forms, ranging from wood to crops and garbage.

Wind energy has been the fastest growing energy source in the world in the past decade, and in the late 1990s Germany overtook the United States as the global leader. An important book printed in 2002 includes 10 chapters by geographers that compare and critique the varying prospects and policy approaches to renewable energy development, especially wind, biomass, and solar energy, in the United States and northern Europe. Wind energy use and public perception in California, the location of its most extensive U.S. development, have been examined by geographers in articles and a 2002 book that examines the issue of aesthetic intrusion on the landscape. Extensive study of wind energy has also been conducted by climatologists. For example, a 1997 paper analyzed the influence of climatic variability on wind resources in the U.S. Great Plains, the area of greatest wind power potential.

Like wind and hydropower, immobility presents geographic challenges for the development of geothermal energy, particularly the pressure it puts

on natural resources. Geographers have given the least research attention among the renewable energy sources to geothermal (because this research area is dominated by geologists and engineers), after significant contributions were made by Pasqualetti in the late 1970s and 1980s.

6.3 Energy in the Developing World

Faster than other professions, geography is predisposed to grasp differences between the developed and the developing world—differences that are particularly apparent in considerations of energy. The developed world relies on fossil fuels, whereas the developing world relies on renewables. The developed world searches for energy to maintain a high standard of living, whereas the developing world must sell its resources to stave off poverty. The developed world worries about the environmental impacts of energy supply, whereas the developing world worries about having any energy supply at all. The developed world has achieved a high standard of living by consuming prodigious amounts of energy, whereas the developing world resents any attempts to curtail their upward mobility by doing the same, even though the environmental impacts are now so much more obvious, troubling, and dangerous. The developed world is in the minority, whereas the developing world is in the majority. Such differences form the basis for much of the work geographers have pursued in developing countries.

Although many developing countries share a need to trade environmental quality for energy supply, they are in other ways profoundly different. For example, China and Mexico are industrial countries, whereas Haiti and Ghana have primarily agrarian economies. In the former, government concentrates on how to increase gross domestic product; in the latter, government tends to worry more about matters of day-to-day survival. The work of geographers has focused on issues of environmental quality, economic growth, equity, and sustainable development and in a more speculative mode the consequences of bringing per capita energy consumption in these countries closer to that of the United States or the European Union.

The work of energy geographers in developing countries is often closely tied to environmental considerations. China, for example, is intent on using its great reserves of coal to help fuel its climb toward greater economic prosperity. As a consequence of pursuing this goal, air pollution has increased in many locations within the country, as has concern about the possible impact of such additional coal burning on global warming. Geographers, among many scientists, have monitored such trends and have expressed opinions ranging from how one might minimize such impacts to suspecting that the impacts on climate change are insignificant.

Other topics of interest to geographers include energy trade and transportation; the use and scarcity of biomass; hydropower development; and the development of geothermal, wind, and solar power. Of these topics, energy transport and trade have had perhaps the most natural and longest interest. The focus of such attention by geographers evolved from matters of shipping routes and port facilities to the location of lines for the movement of energy by rail, pipe, and wire. Shipping routes tend to change infrequently, and then usually as the result of military conflicts and new discoveries. Modern examples include the closing of the Suez Canal and the development of oil fields in the Gulf of Campeche, both in the 1970s.

Geographers continue to track the discovery and development of new sources of energy, although such activities trend toward the expansion of existing areas of extraction rather than new developments. Exceptions to this rule include oil developments in African countries such as Chad and South American countries such as Ecuador, Peru, and Bolivia. In the latter country, interest has been drawn especially to natural gas fields on the eastern side of the Andes, with the prospect of piping through Chile to the Pacific Coast for liquefaction and transport to markets. One market is the United States, and Bolivia is considering shipping to a planned regasification facility in Baja, California, and then piping the gas to California. In so doing, they will be avoiding the environmental encumbrances of trying to locate regasification plants within the United States while still having a U.S. market. In all cases, these and similar projects hold the hope for improving the economic prosperity of citizens of the producing countries, although the usual questions exist as to whether a significant proportion of the extracted wealth will remain local. Geographers have noted this ethical issue and in a few cases have proffered recommendations.

Although these examples rest on matters of resource sales and environmental impacts, geographers have sustained an interest in the transportation routes, including the economic costs and benefits of the developing countries that are physically touched along the way. Chad needs to move its oil through

Nigeria, for example, and the vast resources of the landlocked Caspian Sea must cross through several countries to gain access to the sea, which is a diplomatic challenge. Locally, Mexico and the United States have been working to establish closer ties through increased land-based trade of electricity, coal, oil, and natural gas, in both directions, across their common border. This has caught the attention of geographers in both countries, who have pointed to the shared advantages. They have also identified some of the shared environmental costs when the impacts of energy development cross international borders, such as when air pollution wafts northward from power plants in the Salinas district south of Eagle Pass, Texas.

Hydropower projects always hold a particular appeal for developing countries. Not only do they provide electricity, flood protection, and, often, irrigation water but also they create jobs and national pride. In developing countries, however, they also produce some problems that have not been as publicized elsewhere. Often, these problems have been associated with the displacement of large numbers of people as reservoirs fill. In the past, the most notable examples of this pattern have been in Africa and Brazil, but currently world attention has focused on the Yangtze River in China, the Naranda River in India, and the Euphrates River in Turkey. Even in places where few people live, hydroelectric projects are often controversial, either for reasons of environmental disruption, such as on the border of Uruguay and Brazil, or for reasons of native land claims (as with the huge projects on James Bay in Canada). Although all these hydro projects have inherently geographic applicability, only a few geographers are involved in studying them.

The oldest and most traditional energy resource is biomass, usually in the form of wood from shrubs and trees, crops, and animal dung. Biomass can be used for heating, cooking, and transportation. Wood fuel use and sustainable development have been extensively researched in case studies of India, Pakistan, Tanzania, Kenya, Zimbabwe, Ghana, and Haiti. Brazil, in contrast, has supplemented wood and charcoal use with sugarcane and bagasse for ethanol fuel and cogeneration. The heat content of biomass is low by weight compared to coal and other fossil fuels, so for areas of quickly growing population many geographers have reported how such dependency quickly transforms landscapes, which often do not recover their original appearance or productivity. The relentless and growing dependency on such resources has secondary impacts on soil erosion, microclimates, and other aspects of local and regional ecological balance, which geographers have long noted and studied, especially as it pertains to the creation and implementation of government policies.

Developing countries are among the most logical candidates for the development of renewable energy resources, especially direct solar and wind power. From a geographical perspective, direct solar power, either for hot water or for electricity, holds the greatest advantage because it is not site specific; photovoltaic panels can be installed and used with little need for local technical competence or development of a delivery infrastructure. Geographers have written about the relative advantages of such sources of power for isolated people in India and several other developing countries in Latin American and Africa, and the experiences in these locations can be transferred to just about any place in the tropics. Regarding wind power, some developing countries, such as Mongolia, have great potential, but wind (like geothermal) is spatially concentrated and immobile. The number of studies should increase in the coming decades as the quest for sustainable development continues.

Glossary

Anthropologic Belonging to the scientific study of the origin, behavior, and physical, social, and cultural development of humans.
biomass Plant material, vegetation, or agricultural waste used as a fuel or an energy source.
carbon intensive Having a high content of carbon, a primary element that when burned produces carbon dioxide, which in great amounts can produce changes to the global climate.
externality An intended or unintended cost resulting from a government policy or market operation, coming or obtained from an independent source.
fossil fuel Fuel formed from the geological past and dug out of the earth.
monopoly Exclusive possession in the trade of some commodity.
monopsony Near exclusive possession in the trade of some commodity held by a small group.
Organization of Petroleum Exporting Countries (OPEC) A cartel of oil-producing countries that work together as a group to regulate oil market prices.
renewable Able to be renewed; not depletable.
sustainable productive capacity The daily amount of oil that an individual oilfield or a group of oilfields can produce at a rate that can be sustained for more than 90 days.

World energy use is expected to increase dramatically over the next three decades, reaching some 15.3 billion tons of oil-equivalent (toe) by 2030, up from 9.2 billion toe in 2000, according to the International Energy Agency's *World Energy Outlook 2002*. This increase is the equivalent of two-thirds of current demand and will be driven by strong economic growth in the developing world, especially Asia, and by population growth, which is expected to expand by one-third during the same time period. The developing countries' share of world demand will rise from roughly one-third today to 40% by 2030. Meeting such huge requirements will be a major challenge, requiring massive investment at every stage of the energy supply chain, much of it in developing countries that currently lack adequate resources to meet their current needs. Mobilization of this investment will be a major test for policymakers into the future.

1. INTRODUCTION

More than a quarter of the world's population has no access to electricity, and close to half of the world's people rely on traditional biomass—wood, crop residues, and animal waste—as their main cooking and heating fuels. This situation is unlikely to change, barring the development of a cheap breakthrough energy technology. Current projections are that fossil fuels will remain the primary sources for energy, at approximately 90% of the increase of demand, for at least the next three decades, potentially with dire environmental consequences. Energy emissions of carbon dioxide (CO_2) are expected to grow roughly in line with energy demand unless there is faster deployment of more efficient and cleaner technologies or a larger than expected, policy-driven shift toward less carbon-intensive fuels.

According to projections made in 1993 by the Australian Bureau of Agriculture and Research Economics (ABARE), the growth in CO_2 emissions

 © 2004 Elsevier Inc. All rights reserved.

for the developing world is projected to increase by five times that for the developed world in the next decade or so. Currently, the developed countries emit approximately 60 to 70% of total anthropologic CO_2 emissions and are also responsible for 80% of current concentrations. During the coming decades, the contribution to emissions from the developing world will gain pace, even in the event that Western industrial countries begin to curb emissions in line with the Kyoto accords. In particular, the per capita emissions of four key developing countries—China, India, Indonesia, and Brazil—are expected to grow rapidly during the coming decade and beyond. In 1995, the per capita emissions of these four countries represented only 5 to 10% of the per capita emissions of the United States and were significantly lower than the world average. Over the long term, rising energy use in these countries can be expected to have a dramatic effect on global greenhouse gas (GHG) emissions (Table I).

The desire to wean the global economy—industrial and developing worlds alike—off of fossil fuels to safeguard the environment and provide a fuel source affordable across the globe poses many barriers, including technical cost, available infrastructure, and long lead times for new investments. Many forecasts predict a lowering of the growth in coal demand during the coming three decades as some societies, such as China and India, favor a switch to other sources (e.g., natural gas) for environmental reasons. But coal remains in ample supply in much of the developing world, and production costs are low. World coal reserves are enormous and, compared with oil and natural gas, are widely dispersed. Faced with the insecure nature of imported oil supply and potentially rising prices, even countries seeking environmental improvement may find themselves unable to move away from heavy reliance on coal in power and industrial sectors. As natural gas and crude oil prices have risen during the past few years, a reemergence of rising coal use has been registered. So, although it is expected that coal use will wane during the coming decades for environmental reasons, such forecasts may be deemed too optimistic (Fig. 1).

Environmental advocates would like to see global energy politics move in the direction of renewable fuels such as solar, wind, and hydropower. According to the International Energy Agency's (IEA) *World Energy Outlook 2002* (*WEO 2002*), whereas natural gas is expected to see its world share rise from 23% today to close to 30% by 2030, renewable energy is unlikely to capture a large part of the world energy market during the coming two decades or so (Fig. 2).

The reality is that even with massive investment, renewable resources are unlikely to overtake fossil fuels to any significant extent during the coming decades. Within the "green" community, advocates would like to see the relationship between oil and renewable energy flip during the next 50 years or so such that oil becomes a marginal fuel and renewable energy becomes the major supply source (Fig. 2). But such a green scenario would require massive government intervention and incredible investments of capital to level the current playing field, where fossil fuels maintain a pivotal price advantage in most markets. Thus, without major changes from technological advances or policy intervention, investment in renewables, although highly beneficial to environmental concerns, is unlikely to emerge at large enough rates to make a significant dent in rising demand for oil and natural gas.

TABLE I

Projected Emission Levels in 2010 (Millions of Metric Tons of Carbon)

Country	Year	Residential/ Commercial	Transport	Industrial and other	Final consumption	Primary requirement	Per capita metric tons of CO_2
China	1995	131.77	36.97	487.90	656.64	798.17	2.44
	2010	222.42	92.55	826.24	1141.21	1387.48	3.77
India	1995	18.14	32.77	85.95	136.86	228.28	0.90
	2010	39.14	60.23	153.78	253.15	422.49	1.37
Indonesia	1995	9.91	12.55	14.48	36.94	59.39	1.13
	2010	17.68	21.64	24.47	63.79	102.59	1.59
Brazil	1995	4.27	25.70	26.97	56.94	64.68	1.49
	2010	8.17	43.26	42.03	93.46	110.24	2.13

Source. Hartley, Medlock, Warby: Rice University, Baker Institute.
Note. U.S. per capita emissions in metric tons of CO_2 were 19.13 in 1992 and 19.69 in 1996.

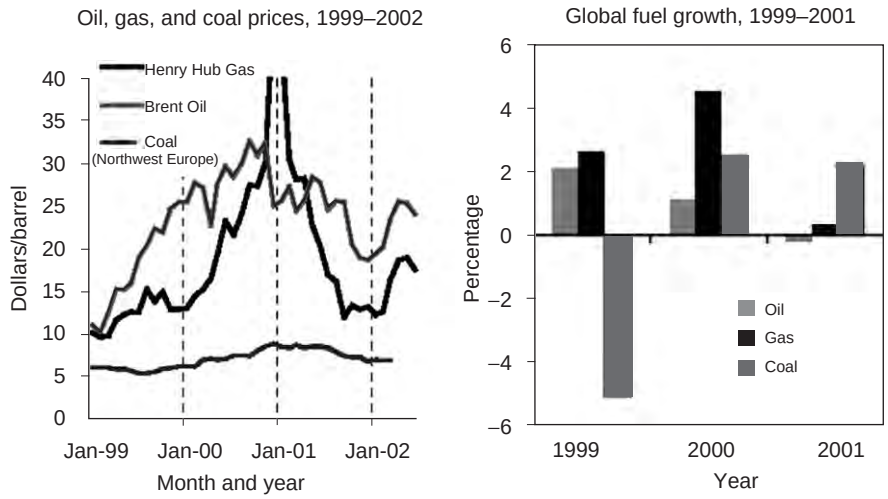

FIGURE 1 Graphs illustrating the reemergence of coal through the process of rising demand. From BP.com.

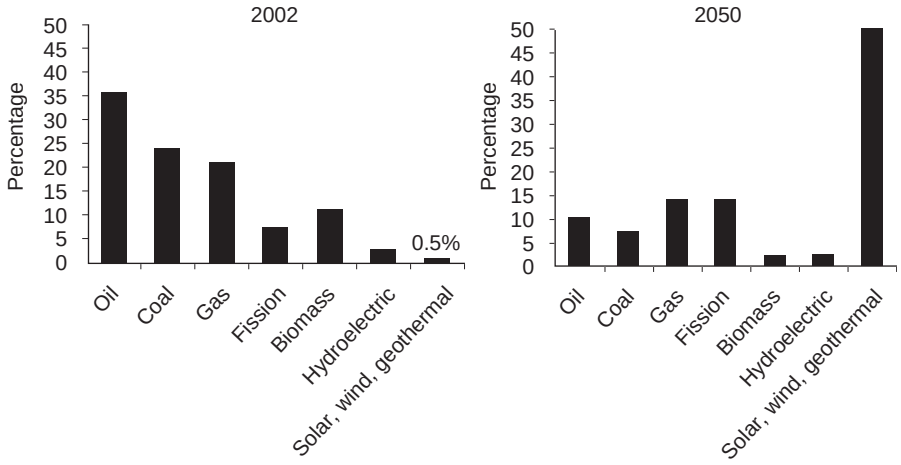

FIGURE 2 Bar graphs depicting the environmental vision for 2050. From Rice University.

For example, the share of nonhydro renewable resources in Organization for Economic Cooperation and Development (OECD) electricity generation, despite relatively proactive green policies by world political standards, is expected to rise from 2% in 1997 to only 4% in 2020 under current programs and is likely to achieve only a 9% share with significant government intervention. According to the IEA's *World Energy Outlook 2001* (*WEO 2001*), to accomplish this 9% share would require new investments of $228 billion and would result in a reduction of CO_2 emissions of only 6% over the period. Wind power capacity has grown by more than 70% since 1997 but still represents less than 1% of the world's total installed electricity capacity, and 69% of world wind facilities are located in Europe.

Nuclear power could be a significant contributor to the long-term global sustainable energy mix, but to play this role successfully, nuclear power will have to overcome serious economic and political challenges, including concerns over nuclear waste, safety, and nonproliferation. In many countries where nuclear power plays a major role, governments are exiting the generation business, with some exceptions (e.g., Finland, South Korea). As electricity markets become increasingly deregulated, nuclear facilities will have to compete on commercial grounds with generators using other fuel sources, and this may be increasingly difficult given the long lead times for siting, design, and other regulatory approvals and grassroots plant costs.

Although third-generation nuclear reactors will continue to play a major role for the next decade or so, the future rests with new fourth-generation designs that might be able to provide safer, more reliable nuclear power through smaller modular units that

will better conform to commercial needs and competitive pressures. In the meantime, until nuclear power is able to offer a competitive challenge to traditional fuels, it is assumed that the bulk of the increase in energy demand will be met with a rise in oil and natural gas production. According to *WEO 2001,* global oil demand is expected to rise by approximately 1.6% per year, from 77 million barrels/day in 2002 to 120 million barrels/day by 2030. Near three-quarters of this increase in demand will come from the transport sector, where renewable energy and nuclear energy are not expected to play a significant role, barring a major technological breakthrough.

2. THE STUBBORN REALITY OF THE MIDDLE EAST

Much ink has been spilled chronicling the world's rising dependence on Middle East oil. According to *WEO 2001,* more than 60% of the world's remaining conventional oil reserves are concentrated in the Middle East. A quarter of these reserves sit in Saudi Arabia alone. The Middle East is currently supplying more than one-third of world oil demand (Fig. 3).

This percentage could rise significantly in the future, depending on policies in consumer countries and on the pace of development of new resources and technologies. The IEA forecasts that the Middle East share of world oil supply will rise to more than 40% by 2020 under its *World Energy Outlook 2000* (*WEO 2000*) reference case. The U.S. Department of Energy, in one forecast, even predicts that the need for OPEC oil could rise from 28 million barrels/day in 1998 to 60 million barrels/day in 2020, with the majority of supply coming from the Middle East, especially Saudi Arabia.

Iran, Iraq, Syria, Sudan, and Libya currently produce approximately 8 million barrels per day or roughly 10% of the world oil supply. Saudi Arabia alone is responsible for nearly 10% of the world oil supply and holds a unique position in oil markets. It maintains the largest share of spare idle production capacity of any other nation in the world. The kingdom is the only oil producer in the world that can single-handedly replace, within a short period of time, the total loss of exports for any other oil producer on the globe. No other nation currently has enough spare capacity to claim this role. Saudi Arabia is also the world's largest exporter, in past years selling nearly 100% more than its next largest export competitor, Russia (Fig. 4).

Saudi Arabia's cushion of spare capacity, which represents more than two-thirds of all global spare capacity, has provided security and stability to world oil markets for two decades. The kingdom derives its international clout from this custodial role and is unlikely to relinquish it, especially in the face of weakening oil market trends. The kingdom must worry about market share considerations in the face of rising investment in Russia, Africa, Iran, and Canada as well as long-term economic considerations. Oil revenues are critical to the health and well-being of the Saudi economy. Therefore, Saudi Arabia can ill afford to jeopardize its coveted position as a stable and reliable supplier from which its geopolitical influence and long-term economic interests derive.

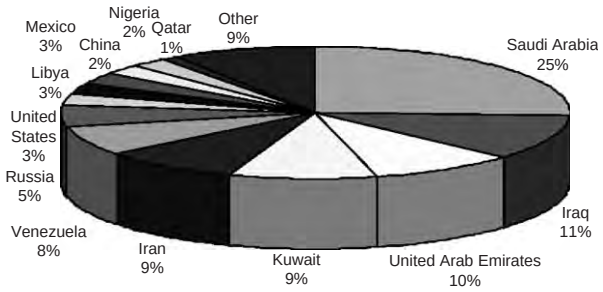

FIGURE 3 Pie chart depicting countries containing proven world resources in the year 2000.

3. WORLD DEMAND TRENDS

World oil demand is expected to rise at a rate of roughly 1.5 to 2.0% per annum over the next two decades, from about 76.4 million barrels/day in 2001

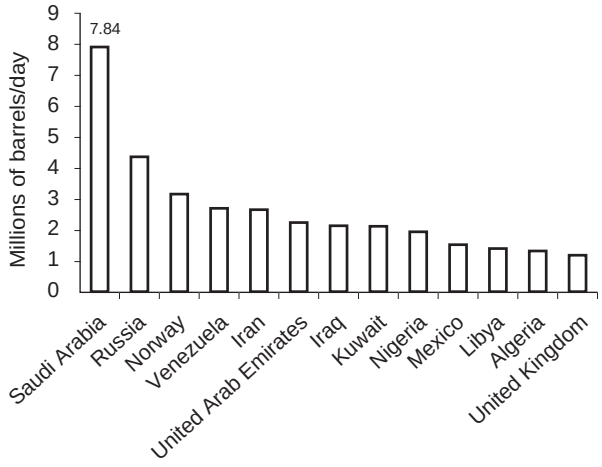

FIGURE 4 Bar graph depicting top world oil net exporting countries for the year 2000.

to 89 million barrels/day in 2010 and 104 million barrels/day by 2020, according to *WEO 2002*. During this same period, Asian demand is anticipated to increase from 28 to 35% of total world demand. Asia's oil consumption, at more than 19 million barrels/day, already exceeds that of the United States. Currently, only approximately 40% of Asia's oil supplies are produced inside the region.

By 2010, total Asian oil consumption could reach 25 million to 30 million barrels/day, of which 18 million to 24 million barrels/day will have to be imported from outside the region. Asian oil demand averaged 21.5 million barrels/day during the first half of 2003, whereas local oil production totaled only some 6.2 million barrels/day, leaving a gap of more than 15.3 million barrels/day that was met by imports, mainly from the Middle East and to a lesser extent from Africa, according to the *Petroleum Intelligence Weekly* database. This is up from a gap of more than 11 million barrels/day in 1998. As Asia develops, oil demand is expected to grow two to three times more rapidly than in the industrialized West, reaching approximately 29 million barrels/day by 2010, according to the "business as usual" forecast scenario of the IEA. Regional oil supplies are not expected to keep pace in any corresponding fashion. The IEA forecasts that Asian oil production will average only 6.4 million barrels/day by 2010, only a modest gain from current levels. In a study by Jaffe and Barnes, analysts expected somewhat larger gains of 1 million barrels/day or so but far less than the 6 million to 11 million barrels/day projected gain in demand.

More than 60% of Middle East exports already go to Asia and nearly 70% of all Asian imports come from Middle East oil producers. Some 84% of all crude oil refined in Singapore comes from the Middle East, whereas 78% processed in Japan originates from that region. The IEA projects that the Asia Pacific region will be importing 20 million to 24 million barrels/day from the Middle East by 2020. These oil linkages could present new political and strategic challenges in light of the emerging geopolitics of the post-September 11, 2001, period. The defense of oil supplies from the Persian Gulf is now achieved nearly single-handedly by the United States. Although it is hard to predict how the U.S. "War on Terror" will affect this role during the coming decades, expanding oil ties between major Asian powers and Middle East exporters will certainly influence East Asian strategic thinking, especially in relation to regional sea lanes issues. The result is likely to be some alteration in big power relations in East Asia during the coming years that might test traditional relationships.

Saudi Arabia and other Middle East oil producers have already grasped the growing importance of the Asian markets and have been building bridges to the region. In July 2001, Saudi Arabia overtook the United Arab Emirates as Japan's primary supplier of oil. Saudi Arabia's exports to Japan grew by 20.7% to 27.40 million barrels that month, whereas the United Arab Emirates' exports to Japan dropped by 19.7% to 26.25 million barrels, according to a *Kyodo News Service* report. Pricing flexibility will be key to the kingdom's strategy to win over any market to which it lays claim.

China's current refinery configurations are currently not suitable to refine large amounts of the lower quality supplies that are produced in Persian Gulf countries such as Iraq, Iran, Saudi Arabia, and Kuwait. This explains the relatively small amount of crude imports from these countries (Fig. 5). Without refinery upgrades, China is projected to have only a little more than 1.35 million barrels/day of capacity to process this lower quality Persian Gulf oil by 2005 (Table II).

However, low-sulfur supplies from Yemen and Oman are expected to fall during the coming years as production from older reservoirs begins to decline. Thus, China is seeking light crude oil supplies from other sources, including Africa, and is seeking to make new upstream investments to lock up such supplies. The state oil company, CNOOC, secured Indonesian supplies recently with its $585 million purchase of the Widuri and Cinta fields in Indonesia from Repsol-YPF, thereby adding 100,000 barrels/day of light crude oil that can be processed quickly through China's existing refinery capacities.

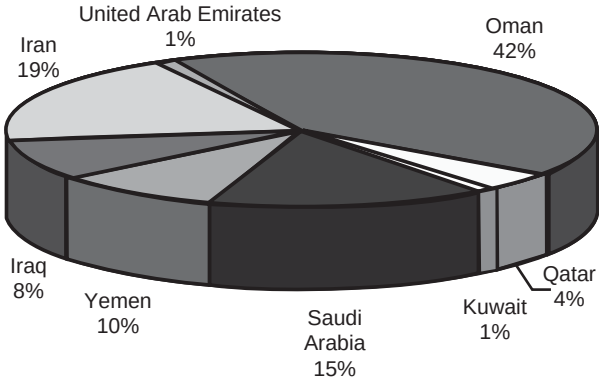

FIGURE 5 Pie chart depicting Chinese oil imports from Middle East countries for the year 2000.

TABLE II

China Refinery Capacity by Crude Tolerance (Thousands of Barrels/Day)

Crude Type	1998	2002	2005
Sweet: <0.9% S	4350	4050	3700
Medium sweet: 0.90–1.15% S	160	550	750
Sour: 2% S or higher	240	600	750–1350
Total	4750	5200	5200–5800

SINOPEC is expected to follow suit and has been negotiating for an exploration deal in Nigeria. Chinese state firms are also seeking exploration and production deals in other African states as well as Libya.

To protect its piece of the growing Chinese market, Saudi Arabia has shown a willingness to help China upgrade its refining capacity to use more Saudi crude oil. In late 2001, Saudi Aramco, ExxonMobil, and Fujian Petrochemical took another step toward the ultimate completion of a 240,000-barrels/day upgrade of a major Fujian refinery by signing an agreement for a joint feasibility study.

In addition, Saudi Aramco is now the largest shareholder in the Thalin refinery and has been negotiating with SINOPEC to expand the refinery at Maoming. Also, China has made a deal for 10 million tons of Saudi oil annually for a 50-year period, with SINOCHEM processing part of the oil at the new joint venture Qingdao refinery and the rest at its Dalian facility, signaling a close and growing import/export relationship between the two countries.

4. ENTER RUSSIA

Mirroring an important international trend, Saudi and other Middle East producers will find competition for growing Asian markets from Russia, which in the aftermath of the September 11 attacks has made clear its intentions to increase oil and gas production with an eye to enhancing exports to the West and Northeast Asia.

Russian firms have been able to marshal capital on their own to revive the Russian oil industry, and Russian oil production rose by more than 640,000 barrels/day from September 2000 to September 2001. The following year, Russian production rose nearly 600,000 barrels/day, from 6.95 million barrels/day in December 2001 to 7.55 million barrels/day in August 2002. Russian production continued to rise to 8.385 million barrels/day by September 2003. Moscow's political leaders, as well as leaders from Russia's corporate oil and gas sector, are portraying the country's oil firms as stable sources of supply, willing to add output to the market to sustain reasonable prices. In the view of Russian leaders, this new geopolitics of energy "can help Moscow gain both economically and politically," according to Morse and Richard.

If concrete plans of the Russian oil firms and their Central Asian counterparts come to fruition during the coming years, rising oil exports from the former Soviet Union could rise by another 2 million barrels/day during the next 5 years or so and move closer to rivaling those of Saudi Arabia. This threat has grabbed the imagination of Middle East policymakers inside OPEC, who called on Russia late in 2001 to cease and desist from stealing OPEC's market share. Moscow initially responded with conciliatory talk toward the end of 2001 and again in March 2002, but Russian oil production rose 600,000 barrels/day during the first three quarters of 2002 versus 2001 levels. And Russian officials have publicly announced Moscow's intentions to increase its oil production during the coming years to help the West diversify its oil supply. Russian government officials and private company chairmen also posited the possibility of Russia establishing an international strategic stockpile of Russian oil that could be used to serve countries that are not currently able to amass strategic stocks. The Russian stockpile would be used to supply markets during times of market emergency and to dampen price run-ups.

Four Russian oil giants have announced plans to build a proposed $2 billion pipeline and deepwater year-round port at Murmansk, in the north of Russia, that could be used to export oil in very large crude carriers (VLCCs) to distant markets such as the United States. A feasibility study of the port project, which is slated to handle up to 1 million barrels/day of exports, is being financed by Lukoil, Yukos, Sibneft, and TNK. The project has been considered for U.S. Exim Bank support. Russian companies see the U.S. sales as a means to diversify its markets so as to avoid oversupplying Europe with growing sales from the former Soviet Union.

Traditionally, Russian oil exports have been bound for Europe and have not confronted Middle East oil producers' efforts to build market share in the United States and Asia. But more recently, there has been a political push in both Moscow and Beijing

to facilitate growing cooperation between Russian and Chinese firms in oil and gas investments and trade. A similar warming of relations on energy trade issues has taken place between Russia and Japan.

The view from Beijing now is that Russia is a key future hydrocarbon supplier. China hopes to receive supplies from new investments by Western firms at Sakhalin and from new field developments within Russia, especially by Yukos. A natural gas pipeline plan involves some 9.5 billion cubic meters (bcm)/year of hydrocarbon exports to Japan and potentially Korea and China from the Sakhalin Islands. Within the next 5 years or so, Russian supply to East Asia from the Sakhalin oilfields under current development are also likely to provide upward of 500,000 barrels/day of incremental supply.

Beyond Sakhalin, there are other prospects from East Siberia, where Yukos, the Russian firm holding perhaps the largest potential reserves in the area, is already in discussion with CNPC/Sinopec on joint projects.

TABLE III

Importance of U.S. Growth to Oil Producers

	1991	2000
U.S. and Asia Pacific share of world oil demand		
United States	24%	25%
Asia Pacific	22%	28%
U.S. net oil imports as a share of global oil trade		
Total	32.34 million barrels/day	42.67 million barrels/day
Net U.S. imports	6.79 million barrels/day	10.20 million barrels/day
U.S. share of increase in global oil trade, 1991–2000	33.02%	
U.S. share of increase in OPEC's output, 1991–2000	55.58%

5. THE IMPORTANCE OF U.S. GROWTH TO OIL PRODUCERS

So much attention has been paid to the increase expected from Asian markets that analysts often forget to note the continued importance of the U.S. market to OPEC. U.S. net oil imports rose from 6.79 million barrels/day in 1991 to 10.2 million barrels/day in 2000, while global oil trade (i.e., oil that was exported across borders from one country to another) rose from 32.34 million to 42.67 million barrels/day. The U.S. share of the increase in global oil trade over the period was a substantial 33%. In OPEC terms, the U.S. import market was even more significant—more than 50% of OPEC's output gains between 1991 and 2000 (Table III).

Saudi Arabia, in particular, has been keenly aware of the importance of the U.S. market and careful to keep nagging political issues between the United States and the kingdom on a separate track from oil policy. The kingdom has been diligently maintaining its U.S. market share during recent years and threw down the gauntlet in 1997 to punish Venezuela for challenging its grip on the important U.S. market. Following the oil price collapse of 1997–1998, newly elected Venezuelan President Hugo Chavez rescinded state oil firm PDVSA's plans to expand capacity to 7 million barrels/day by 2007. Instead, Venezuela announced revised plans to grow its production more gradually, to 5.5 million barrels/day by 2006. However, prolonged political strife inside the country and a major oil workers strike in 2003 not only discouraged further investment by foreign companies (which were already discouraged by rising tax rates) but also left much of Venezuela's oil industry infrastructure damaged, lowering its potential to produce and refine crude oil. Venezuela's oil production capacity was already dropping during recent years given constraints on investment capital and a tough geological decline curve at aging fields, but damage sustained during the oil workers strike and near civil war in the country led to a more rapid reduction in sustainable capacity to 2.2 million barrels/day at the end of 2003, down from a peak of 3.7 million barrels/day in 1998.

Saudi Arabia may face a new challenge to its U.S. market share from a regional exporter, but this time north of the border. Analysts for the kingdom's oil industry say that they are watching with concern the rising output profile for Canada. The start-up of new tar oil sands projects and other offshore projects has put Canada on track for the largest jump in oil output in several years, despite lower capital spending by industry that is often cited as evidence that production will decline. Canada's production has increased from 2.155 million barrels/day in 2000 to 2.3 million barrels/day in mid-2003.

Companies have spent more than $7 billion in oil sands projects since 1996 and are expected to

allocate an additional $25 billion by 2007. Production, which has already reached 800,000 barrels/day, could rise to 1.5 million barrels/day or more by 2010 if currently proposed projects meet their targets (Table IV).

The potential for Canadian heavy crude and oil sands development is huge. Of the 2.5 trillion barrels of crude bitumen (oil sands) resources in place in Canada, approximately 12% (or 300 billion barrels) is thought to be recoverable, a figure comparable to the proven reserves of Saudi Arabia. This is in addition to extra heavy oil resources. In Venezuela, where some U.S. oil companies are working on heavy crude upgrading projects, more than 1.2 billion barrels of bitumen are thought to exist.

During past decades, the high costs of mining and processing tar sands and extra heavy crude oil were somewhat prohibitive at approximately $21 per barrel. But engineering and technological advances are lowering costs rapidly. Analysts estimate that oil sands projects "all in" costs (i.e., investment and operating) have fallen to as little as $8 to $9 per barrel and could fall to $6 to $7 per barrel during the coming years as industry continues to make new advances. However, cost variables in Canada have been somewhat unstable given a tight labor market, and cost overruns have been seen at several of Canada's top existing oil sands projects, including Syncrude, Athabasca, and Millennium.

African supply may also become a key focus of efforts by the West to diversify away from the Middle East. Of the 14.5 million barrels/day of exports projected to be needed from Africa or the Middle East by 2010 in the Atlantic Basin market to fill its supply gap, at least half will be able to be sourced from Africa and North Africa. Angola, a non-OPEC producer, is projected to see increased production, from 750,000 to more than 2 million barrels/day by 2010, as new fields are developed in its deep offshore zone at full-cycle costs of between $3 and $5 per barrel. Chinese national oil companies are also showing interest in African upstream investment, with CNPC already firmly planted in Sudan and Chinese companies showing expanded interest in Nigeria, Chad, Niger, Equatorial Guinea, Algeria, Tunisia, and Libya.

TABLE IV

Approved Canadian Oil Sands Projects

Project	2001	2002	2005	2010
Syncrude	225	250	350	465
Suncor	130	220	260	400

6. OPEC CAPACITY EXPANSION

Over the past few years, there has been a dramatic shift in the internal politics of OPEC, reflecting changes of political leadership at the highest levels and of broader policies of key members. The result has been greater cohesion inside the producer group and a clearer articulation and implementation of goals and aspirations.

The mid-1990s were characterized by OPEC disunity and overproduction, so much so that the cartel members themselves were questioning the future viability of the organization. Venezuela's ambitious campaign to increase oil productive capacity from 2.8 million barrels/day in 1991 to 7 million barrels/day by 2010, combined with the gradual rise in Iraqi oil export rates through the auspices of the UN Oil for Food program, made it nearly impossible for the producer group to agree on a workable production sharing agreement.

During this period of the mid-1990s, market share considerations were paramount for most OPEC countries with spare capacity. Saudi Arabia, in particular, had to concern itself with both the short- and long-range implications of Venezuela's market expansion plans, which were expected to have a significant bearing on the kingdom's ability to maintain its sales to the United States. Venezuela's government was committed to supplementing state revenue by increasing oil exports and in 1992 began a new policy to allow international oil companies (IOCs) to invest in the country's once nationalized oilfields. This campaign contributed to a rise in Venezuelan output, from roughly 2.5 million barrels/day through the 1980s to between 3.5 million and 3.7 million barrels/day by 1997. Venezuela refused to comply with any OPEC production sharing agreements, greatly damaging the producer group's ability to manage oil markets and providing a strong disincentive for Saudi Arabia to contribute a large cutback in output to defend oil prices.

This political stumbling hit a dramatic snag in during 1997–1998 when an unexpected economic

meltdown hit much of Asia and precipitated an unexpected drop in Asian oil use. Asian oil demand fell to 18.18 million barrels/day in 1998, down from 18.53 million barrels/day, a drop of 1.9%. This compared with a 4.5% rise in Asian oil demand between 1996 and 1997. The slowdown in Asia contributed to a major change in the global oil supply–demand balance, limiting the growth in worldwide oil demand to 74.24 million barrels/day in 1998, up only 0.5% from 1997 compared with more typical annual growth rates of 2 to 3% during the mid-1990s (Table V).

TABLE V

Oil Demand per Region, 1996–1998 (Million Barrels/Day)

	1996	1997	Percentage change	1998	Percentage change
World	72.03	73.9	2.6	74.24	0.5
United States	18.25	18.62	2.0	18.7	0.4
European Union	13.03	13.10	0.5	13.39	2.2
Asia	17.74	18.53	4.5	18.18	−1.9
China	3.55	11.5	11.5	3.95	−0.3

By 1997–1998, these circumstances led oil prices to collapse below $10, requiring extraordinary efforts by both OPEC and non-OPEC countries such as Mexico and Norway. The intense financial suffering of nearly all OPEC countries and key changes in government leadership in Venezuela paved the way for a major agreement among oil producers to trim output and propel oil prices back above $22 per barrel. OPEC set a price band of $22 to $28 per barrel as its target that remained in place as of this writing.

OPEC's new, more unified dynamic is rooted in several factors:

- A rise in democratization, freedom of the press and political debate, and a growing tide of anti-Americanism are bringing a greater concern for popular opinion inside OPEC countries, especially in the Middle East Gulf region, than was the case in the past. This new concern for popular sentiment is restricting the options of regional leaders to accommodate Western interests. Populations, as well as some leaders, remain bitter about the suffering that took place when oil prices collapsed during the late 1990s.
- Rising populations and economic stagnation in many OPEC countries indicate that revenue pressures have been taking precedence over other considerations.
- Lack of investment in infrastructure and oilfields over the years due to tight state treasuries and rising social pressures has greatly curtained OPEC's spare productive capacity, rendering it much easier for cartel members to agree to restrain output, at least in the short term.

Given this new dynamic and colored in part by the rise of Chavez as president of Venezuela, OPEC rhetoric during recent years has taken a more strident turn, with oil ministers defending their choices to attain a "fair" price for OPEC oil despite ramifications for global economic growth rates. The debate has become one of economic struggle for "rents" between oil producers who demand high revenues and major consumers whose economies can grow faster with low oil prices.

OPEC's rhetoric has generally been directed at OECD consumer governments that capture rents from oil sales through high national energy taxes. OPEC's anti-tax, anti-Western rhetoric comes against the backdrop of popular domestic sentiment inside OPEC countries that their governments are not doing enough to deliver economic benefits to a substantial portion of their populations. Leaders in OPEC countries cannot be seen as delivering benefits to Western consumers at the expense of their own citizens because such perceptions would leave regimes more vulnerable to public attack and more susceptible to the efforts of opposition parties and groups.

Although political factors have contributed to OPEC's unity over the past 2 years, the more limited amount of spare capacity that has to be held back by most member states is also a supportive factor. Indeed, oil prices tend to track changes in OPEC spare capacity quite closely (Fig. 6).

In 1985, when oil prices collapsed, OPEC was estimated to have some 15 million barrels/day of shut-in production capacity, equal to perhaps 50% of its theoretical capacity (Iran and Iraq were at war with one another at the time) and 25% of global demand. By 1990, when Iraq invaded Kuwait, spare capacity globally was still 5 million to 5.5 million barrels/day, the amount of oil taken off the market by the UN embargo. That was approximately 20% of OPEC's capacity, and 8% of global demand, at the time. During the winter of 2003, before OPEC's seasonal cuts, spare capacity was a negligible 2% of global demand, a level that left oil markets highly susceptible to disruption and supported a run-up in prices to more than $30 per barrel.

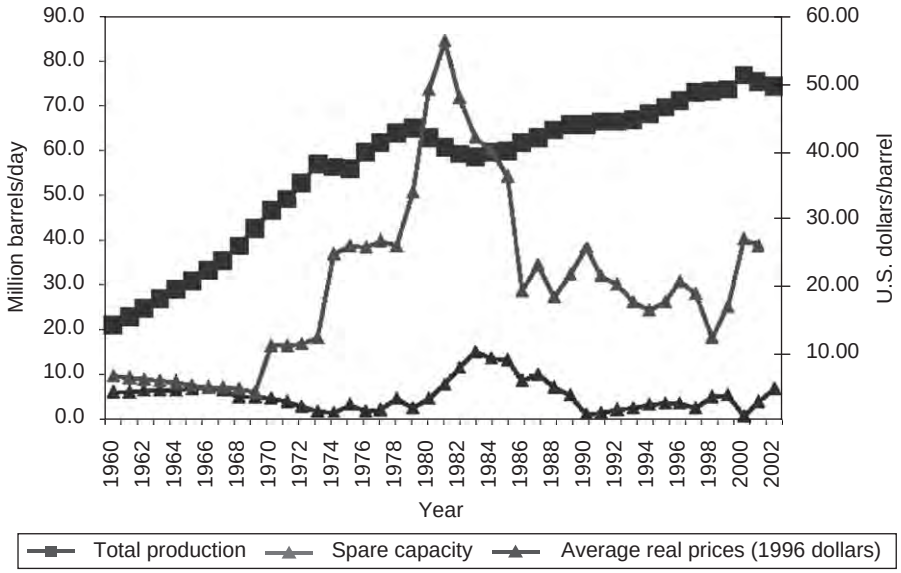

FIGURE 6 Line graph depicting the relationship between oil prices and the OPEC spare capacity. From Hetco Trading.

OPEC has been helped during recent years by irregularity in Iraqi production rates given the regime in Baghdad's aggressive posture to use the withdrawal of its UN-monitored oil exports as a political tool. In 2003, the U.S. military campaign in Iraq greatly curtailed the country's oil exports when facilities were looted and sabotaged in the immediate aftermath of the war. Iraq's export rates fell from just over 2 million barrels/day prior to the U.S. campaign to approximately 500,000 barrels/day in late 2003. In addition, other OPEC members have also benefited from a drop in capacity in Venezuela and Kuwait, both of which have been struggling against technical problems and natural declines in key fields. Venezuelan oil production capacity has fallen from 3.7 million barrels/day in 1998 to approximately 2.2 million barrels/day currently. Kuwait has lost capacity in certain western and northern fields such as Raudhatain, limiting its output capacity by several hundreds of thousands of barrels per day. Sustainable Kuwait capacity has recently been pegged at 2 million barrels/day.

However, the challenge to OPEC will increase during the coming years as OPEC member countries begin to anticipate an expected restoration of Iraqi capacity over time. Several individual OPEC countries have a backlog of new fields that can be brought on line soon. Several countries, such as Nigeria, Algeria, and Iran, have been quietly expanding capacity and anticipate possible production rises over the next few years. Countries such as Algeria and Nigeria, whose new fields involve foreign oil company investment, will increasingly be under additional pressure from these IOC investors to obviate OPEC agreements and allow new fields to move forward at optimum production rates. Meeting these pressures will be difficult for OPEC if market demand for its oil does not increase significantly as expected due to a slowdown in economic growth or other inhibiting factors.

Iran is forging ahead with capacity expansions and could reach more than 5 million barrels/day by 2008 based on investments through buy-back agreements with IOCs and National Iranian Oil Company investment. However, this ambitious plan will be dependent on the success of major IOC field developments, including Azadegan, South Pars, Sirri, Gagh Saran, and the Ahwaz area. Nigeria has plans to expand production in its offshore area, and this could (if successful) raise production to more than 3.5 million barrels/day by 2006.

Prior to the U.S. campaign in early 2003, Iraq had commercial export capacity of approximately 2.2 million barrels/day via Turkey and the Gulf, with additional smuggling capacity through Syria, Iran, and Jordan. U.S. officials were hopeful that Iraq would be able to resume exports at prewar levels by late 2003. Iraq has expressed a desire to expand its productive capacity to 6 million barrels/day, and analysts believe that Iraq could quickly raise its oilfield productive capacity back to 3.6 million barrels/day if security can be restored across the

country and Iraq's upstream oilfield sector were opened to foreign oil company investment. However, for Iraq to be able to export these higher volumes, extensive repairs will be needed to both its oilfields and its export infrastructure.

There will be pressure inside OPEC to bring Iraq back into the production quota system as its production capacity is restored. Key members may insist that Iraq be initially limited to its historical allocation of a quota at parity with that of Iran and then hold its export increases to levels in line with market demand. However, Iraq will have pressing economic reconstruction needs to take into consideration as well, raising questions, depending on the future politics inside the country, as to whether it will be in a position to opt for policies that emphasize solidarity with OPEC.

OPEC's current capacity is estimated at 29.5 million barrels/day but could rise to as much as 36.4 million barrels/day by 2005 if new fields under development come on-line as expected. If OPEC were to expand access to foreign IOC participation, particularly in key countries now off limits to Western investment, capacity could expand to as much as 44 million barrels/day by 2010, leaving very little room for growth from non-OPEC supplies to take place without pressuring oil prices over the next 8 years or so.

7. CONSUMER COUNTRY POWER IN A DEREGULATED SETTING

As discussed previously, the United States is a major buyer of imported crude oil, and its imports represent a large share of the market for internationally "traded" oil. Given the large scale of U.S. purchases, incremental U.S. acquisitions of oil affect the overall international market price of oil. Stated another way, the cost of each marginal barrel is higher than the price paid for that barrel given that this additional purchase affects the costs of all oil consumed. From the perspective of the United States, this constitutes an externality in the sense that consumers will base their decisions regarding the quantity of oil (and oil products) purchased on the average, rather than the marginal, cost of oil. On the other hand, the fact that the United States faces a rising supply curve for oil gives it monopsony power. To the extent that the United States—or a group of consuming countries that include the United States or is of a comparable scale—take concrete actions to reduce the size of its purchases, it can lower the market price of oil.

It has been well established that OPEC frequently changes its price targets in response to changes in market demand. Discussion of the size of a monophony (power) wedge that is the "difference between the current price of oil and the marginal cost of adding a barrel of demand" was the subject of an Energy Modeling Forum working group and other exercises.

OPEC's response to efforts by the OECD to reduce oil demand has varied over time. Initially, during the 1980s as the OECD demand receded, OPEC maintained its output path, letting oil prices decline. This result produced the highest buying power wedge size and reinforced the viability of consumer country policies that sought to exercise this monopsony power. However, OPEC can also maintain its price preference path and allow its market share to decline. This appears to be its strategy during recent years. But the continuation of the production sharing discipline needed to maintain this approach may become harder to sustain in the future.

Consuming countries have implemented two key approaches to dealing with OPEC given the increasing trend toward oil price deregulation inside the OECD. One is that governments have organized to hold strategic stocks of oil. The second is the imposition of consumer taxes on oil, thereby reducing demand for oil. As discussed previously, OPEC has engaged in a public relations battle against Western consumer taxes on oil.

Prior to deregulation, during the 1970s, crude oil was sold mainly through exclusive, long-term, fixed-priced contract arrangements with a handful of major suppliers. Crude prices throughout the world were regulated by national governments at fixed levels. Under this system, oil sellers could pose a clear threat to any individual buyer. A clear thread linked a disruption in supply to the shortfall of actual deliveries. A particular barrel lost in exports was neatly matched to a particular barrel lost to a particular buyer that had a contract for that barrel. Little recourse was available. Barrels were moved around the world like pieces on a chessboard, and there was no other *deus ex machina* to mitigate or alter the impact of any supply cutoff if one's particular barrels were lost. Lucky buyers whose supply chains remained intact could continue to receive their oil at prices locked by long-term fixed-price contracts at precrisis levels. In a word, some buyers were safe and others were not. This system created a psychology that enhanced OPEC's monopoly power and left individual consuming nations vulnerable to the possibility of a supply cutoff. The

oil crisis of 1973 confirmed fears that oil producers might use this leverage to adverse political ends.

Given the high costs of a cutoff under this fixed price system (i.e., regulated price system), large consumers, oil distributors, and middlemen had direct incentives to carry ample inventories of spare supplies. The possibility that oil from any particular supplier could be disrupted without recourse was reason enough to pay the costs to carry extra supplies on hand. Prices that could be passed on to consumers were in many cases inflexible and regulated, and competitors that were not subject to a cutoff would have a clear cost advantage.

Today's world is radically different. Crude oil prices have been "deregulated," that is, set by market forces through market auction practices that allocate supplies to the highest bidder. Price arbitrage will ensure that a price increase for one buyer or location will be a price increase for all buyers and locations.

In the new free-wheeling marketplace for oil, buyers cannot insulate themselves from price jumps by holding long-term contracts given that prices in these contracts are pegged to the spot market. But in today's market, one can always get the oil one desires, even in a major supply disruption, by simply paying a higher price.

At the end of the day, as the market clears, such as it did during the Iraqi invasion of Kuwait in 1990, buyers with imports from countries that were not subject to disruption are in no better position than buyers that had all of their imports subject to interruption. In an unfettered spot market, shortages will manifest themselves not in a physical inability to find supplies but rather in the rising price of oil. The market will "clear" or allocate available physical supplies to the highest bidder.

In this new commodicized market, commercial players such as distributors and middlemen have less incentive to carry inventory, especially if supply disruptions are infrequent. Higher costs during times of supply cutbacks can simply be passed on to end users, reducing the business risks that motivated the accumulation of commercial inventories previously. Although the existence of a large spot market trading at unregulated prices certainly appears to work against OPEC's ability to "blackmail" any particular buyer, structural reductions in commercial inventories can augment the producer group's power to the extent that alternative supplies from countries outside of OPEC are reduced.

The "public goods" aspect of oil market stability elevates the accumulation of oil inventories to a domain beyond the commercial industry. Individual players in the oil market will not take into account the externalities of low commercial stocks such as increased energy price volatility and its negative distributive effects on poorer consumers or its aggregate negative macroeconomic effects. Thus, government plays a role in ensuring that adequate inventories are on hand to maintain orderly markets and to counter the temptation of suppliers with monopoly power from taking advantage of short-term tightness in oil markets. To achieve these ends, government-held stock levels must be credible to convince oil producers that efforts to exploit temporary market tightness by further cuts in production to achieve even higher oil prices will not be successful. Such attempts to extract additional rents from consuming countries would be countered by the release of sufficient inventories to offset any cuts in production contemplated by producers. The larger the government-held stocks and the more consuming governments that participate in such a stock holding program, the more effective it is likely to be in serving as a deterrent to OPEC's monopoly power in deregulated markets.

Market deregulation has left consumers more susceptible to the ill effects of energy price volatility. However, consuming country governments have been able to reduce the negative effects of price variability by increasing energy efficiency and reducing dependence on oil through the use of hefty consumer taxes on oil. The net effect of such taxes is to discourage wasteful use of energy by consumers while collecting some of the rents that would otherwise accrue to oil producers. Furthermore, large oil consumption taxes can force OPEC to accept lower prices, as occurred throughout most of the late 1980s and 1990s.

When OPEC's monopoly power strengthens due to short-term market tightening, the incentive to exploit that power is tempered by the fact that increases in monopoly rents will not accrue entirely to producers but rather must be shared with consuming countries that have high energy taxes.

8. CONSUMER COUNTRY STRATEGIES

OPEC's ability to raise prices in the short run to levels that may be damaging to the economies of major consuming countries poses a major policy challenge to the governments of consuming countries. Rising oil prices threaten consumer country national interest in several ways. Oil price volatility

can inhibit investment, inhibit economic growth, and spur inflation in major economies that purchase consumer country exports.

The burden of rising energy import costs also threatens social stability in key regional consuming countries such as India and Pakistan and the Southeast Asia region. Moreover, supply constraints also make it easier for governments or subnational groups to threaten vital interests of the United States, Japan, and their allies.

Thus, consuming countries have a clear interest in undertaking policies that will undermine OPEC's short- and long-term ability to act as a cartel to inflate oil prices. Policies undertaken in conjunction with other consuming nations are likely to be more effective than policies undertaken individually by increasing the strength of the monopsony wedge.

Policy options include the following:

- Expand and restructure the IEA to better reflect the change in consumer country demand trends.
- Encourage investment in diverse non-OPEC oil resources.
- Develop and deploy alternative energy technologies.
- Develop federal policies to continue enhancing energy efficiency.
- Maintain or expand taxes on oil and gasoline.

The IEA was created a quarter of a century ago as a mutual protection society of OECD countries. Designed as a political grouping to prevent any oil-producing countries from using oil exports as a political instrument to influence the foreign policies of IEA members, the IEA was formed at a time when the OECD countries dominated global energy consumption. Today, the IEA excludes the most rapidly growing energy-consuming countries in the world, including China, India, and Brazil. And, as a result, these new consumers become vulnerable economically during times of disruptions and become potentially vulnerable to political pressures of producers.

During recent years, there has been discussion about increasing the number of member countries inside the IEA, and South Korea has joined the organization. Other countries, such as China and India, are investigating creating national strategic oil stockpiles. The IEA invited both China and India to participate as observers in recent meetings and is pursuing options for finding mechanisms for major non-IEA oil-consuming countries to participate in joint stockpiling emergency programs.

However, the extent of effectiveness of the IEA system will depend on oil market developments, including Asian demand trends. The member countries of the IEA now represent a smaller portion of the oil market than they did at the time of the IEA's formation in 1977. As oil demand growth in Asia expands during the coming decade, new strains could come to the international system if new policies are not put into place. The omission of key consumer countries from Asia in the global emergency stockpiling system will increasingly put pressure on the effectiveness of limited existing stocks in the OECD countries. Moreover, tensions created by Asian "free riding" or possible "hoarding" actions during a crisis could hinder the IEA's ability to stabilize international oil markets in the future.

The OECD countries comprising the IEA accounted for 42.3 million barrels/day out of a total world oil use of 60.6 million barrels/day in 1977 or approximately 70% of world oil demand. The United States alone consumed 30% of the world's oil used in 1977. Asia Pacific demand at that time, at 10.1 million barrels/day or roughly 16% of world oil demand, was a less critical component in the world oil use situation.

By 2001, the OECD share of world oil use had declined to 62% of total world demand, while Asia Pacific use had grown to 28%, overtaking the U.S. share of 25%. Asian economic powers Japan, South Korea, Australia, and New Zealand are OECD members and, as such, are part of the IEA system now. A few Asian countries, such as Pakistan and China, have announced plans to create strategic stocks, but other key Asian oil consumers, such as India, Taiwan, Thailand, and The Philippines, are not. As their share of world oil demand grows, this disconnect between Asia's size and importance as a consumer region and its lack of energy policy coordination with other large oil-consuming countries (and/or the IEA) will create new problems and challenges for international oil markets and the international economic system. In particular, it is important that large Asian consuming countries not purchase and "hoard" oil during an IEA stockpile release because this activity would reduce the effectiveness of a stock release to calm markets and prevent oil supply shortages. The best possible win–win scenario would be for new links to develop between the IEA and other large consumer countries or consumer country groups.

Despite the obvious benefits from an Asian stockpiling group or system, Asian countries have been reluctant to commit to the expense involved in creating such a system. Although an Association of Southeast Asian Nations (ASEAN) delegation visited

Japan in 2000 to study the industrialized country's emergency stockpiling system, the cost per capita was considered "high" by many ASEAN delegates. Press reports indicate that ASEAN energy ministers have focused on security of sea lanes and international gas pipelines, rather than on joint stockpiling arrangements, at recent meetings.

Meetings between IEA officials and Chinese state planning officials have similarly failed to produce an agreement of coordination. The Chinese government has announced its intention to build a strategic petroleum reserve, but so far the government has failed to define the reserve's size or possible location publicly. It is considering requiring state oil companies to hold stocks comparable to 10% of their import levels. There has also been no official verification that China would like to work cooperatively with its Asian neighbors or OECD countries to develop measures to safeguard against disruptions in oil supplies from the Middle East. In March 2001, the State Council and the State Development Planning Commission included a "strategic petroleum reserve" as a key project in the 10th 5-year plan, but continued debate about its size, location, and funding among party leaders, State Council agencies, National People's Congress deputies, and the three central-owned state oil and gas companies has called into question the quick construction of such a reserve.

Although informal programs to encourage stockpiling by developing world countries would have a positive impact, such efforts cannot replace the more effective tool of centralized coordination with the IEA. Centralized efforts are needed so that international norms and standards can be met during a crisis. The United States and Japan are reviewing ways in which the IEA can work with key countries that are not members of the IEA to encourage them to define their strategic oil stockpile requirements and to build strategic stocks (or create minimum inventory requirements for industry). Russia has also made pronouncements recently, offering to establish a Russian strategic oil stockpile to be used to supply countries lacking in their own strategic stocks. This concept was aired at the U.S.–Russia Energy Summit in Houston, Texas, in October 2002.

In the post-September 11 climate, consumer governments are increasingly discussing enhancing development of backstop technologies or promoting alternative energy sources that can serve to reduce the need for fossil fuel. In this practice, backstop technologies create an incentive for oil producers to avoid oil price shocks and supply disruptions for fear that the new technologies would be released and used, permanently eliminating sales markets. Alternative energy supplies provide ready substitutes if an increase in the price of oil is too extreme, and they can shield the economy from the negative impact from disruption of any one fuel source.

The deployment of improved car technology could have a dramatic effect on future oil demand trends as well as play a major role in lowering CO_2 emissions by advancing fuel efficiency. The benefits to the role that enhanced energy efficiency has played in protecting the domestic Japanese economy from oil price variability are well known. Japan did not experience a severe recession after the 1979–1980 price shock, whereas the United States, United Kingdom, and Germany, all of which were less energy efficient at the time, did experience a painful loss in economic output.

It has been shown that the lower a country's energy consumption to gross domestic product (GDP) ratio or the shorter the period that oil prices will remain higher, the lower the cost of the trade-off between inflation and GDP loss. New technologies on the horizon could allow more gains in energy efficiency. Such technologies may include microturbines for distributed power markets, improved car technologies, and household solar technologies. OECD governments should encourage the deployment of these technologies in the marketplace through tax incentives or other vehicles in an effort to reduce their individual exposure to OPEC's monopoly power.

3. Economic Considerations
4. Future Developments

Glossary

agribusiness application Agriculture and aquaculture developments; in this article, it includes the heating of the various applications, such as greenhouses and fish ponds.
aquaculture pond/raceway heating Heat energy provided to ponds and raceway in order to optimize the growing of fish, shrimp, alligators, or other aquatic species.
balneology The use of mineral waters for therapeutic purposes.
direct use The use of the heat energy rather than its conversion to other forms such as electricity; for example, a furnace used for space heating.
district heating Energy provided to a group of buildings or even to an entire community, generally in the form of hot water or steam supplied from a central plant to customers through a pipeline distribution system.
energy cascading The multiple use of an energy source by various applications, with each successive one using an increasingly lower temperature in order to maximize the efficiency of the system.
geothermal energy Energy that can be extracted from the earth's internal heat. The heat is produced by the radioactive decay of thorium, potassium, and uranium that exist in the earth's molten core.
greenhouse heating Heat energy provide to a glass or plastic enclosure in order to optimize the growing of tree seedlings, flowers, and vegetables.
heat pumps A device used to transfer heat from a low-temperature resource to a high-temperature reservoir, thus providing the higher temperature for space heating. The process can be reversed to provide space cooling.
industrial application Manufacturing, machining, assembling, and producing products for consumption; in this article, it includes the heating of the various applications.
space heating Energy provided to a room and building for heating purposes.

Direct or nonelectric utilization of geothermal energy refers to the immediate use of the heat energy rather than to its conversion to some other form such as electrical energy. The primary forms of direct heat use are for swimming, bathing, and balneology (therapeutic use); space heating and cooling, including district heating; agriculture (mainly greenhouse heating and some animal husbandry), aquaculture (mainly fish pond and raceway heating), and industrial processes; and heat pumps (for both heating and cooling). In general, the geothermal fluid temperatures required for direct heat use are lower than those for economic electric power generation.

Most direct use applications use geothermal fluids in the low to moderate temperature range between 50 and 150°C, and in general, the reservoir can be exploited by conventional water well drilling equipment. Low-temperature systems are also more widespread than high-temperature systems (above 150°C), so they are more likely to be located near potential users. In the United States, for example, of the 1350 known or identified geothermal systems, only 5% are higher than 150°C; whereas 85% are lower than 90°C. In fact, almost every country in the world has some low-temperature systems, whereas only a few have accessible high-temperature systems.

1. UTILIZATION

Traditionally, direct use of geothermal energy has been on a small scale by individuals. Recent developments involve large-scale projects, such as district heating (Iceland and France), greenhouse complexes (Hungary and Russia), or major industrial use (New Zealand and the United States). Heat exchangers are also becoming more efficient and better adapted to geothermal projects, allowing use of lower temperature water and highly saline fluids. Heat pumps utilizing very low-temperature fluids have extended geothermal developments into

TABLE I

Summary of Regional Geothermal Use in 2000

	Direct use			
Region	MWt	%	GWh/year	%
Africa	125	0.8	504	1.0
Americas	4,355	28.8	7,270	13.7
Central	5		38	
North[a]	4,308		7,013	
South	42		219	
Asia	4,608	30.4	24,232	45.7
Pacific Rim	3,489		18,242	
Central/Mid-East[b]	1,119		599	
Europe	5,715	37.7	18,905	35.7
Central/east	1,284		4,405	
West/north[c]	3,872		11,307	
CIS[d]	559		3,463	
Oceania	342	2.3	2,065	3.9
Total	15,145		52,976	

[a] Includes Mexico.
[b] Includes Turkey.
[c] Includes Azores and Guadeloupe.
[d] Includes Russia, Georgia, and Armenia.

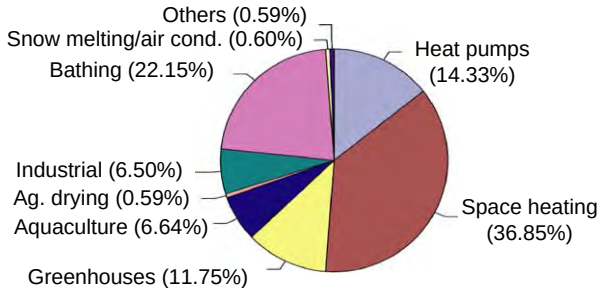

FIGURE 1 Distribution of geothermal energy use throughout the world.

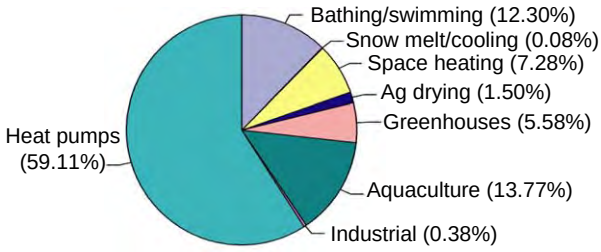

FIGURE 2 Distribution of geothermal energy use in the United States.

traditionally nongeothermal countries, such as France, Switzerland, and Sweden, as well as areas of the midwestern and eastern United States. Most equipment used in these projects is of standard, off-the-shelf design and needs only slight modifications to handle geothermal fluids.

Worldwide in 2002, the installed capacity of direct geothermal utilization was 15,145 MWt and the energy use was approximately 190,699 TJ/year (52,976 GWh/year) utilizing at least 52,746 kg/s of fluid distributed among 58 countries. A summary by region is presented in Table I. This amounts to saving an equivalent of 13.5 million tonnes of fuel oil per year (TOE). The distribution of the energy use among the various types of use is shown in Fig. 1 for the world, and for comparison that of the United States is shown in Fig. 2. The installed capacity in the United States (2000) is 4000 MWt and the annual energy use is 20,300 TJ (5640 GWh), saving 3.94 million TOE. Internationally, the largest uses are for space heating (37%) (three-fourths of which is due to district heating) and for swimming, bathing, and balneology (22%), whereas in the United States the largest use is for geothermal heat pumps (59%). In comparison, Iceland's largest geothermal energy use (77%) is for space heating [15,600 TJ/year (4,334 GWh/year)], primarily with district heating systems.

The Lindal diagram, named after Baldur Lindal, the Icelandic engineer who first proposed it, indicates the temperature range suitable for various direct use activities (Fig. 3). Typically, agricultural and aquacultural uses require the lowest temperatures, from 25 to 90°C. The amounts and types of chemicals in the geothermal water, such as arsenic and dissolved gases such as boron, are a major problem with regard to plants and animals; thus, heat exchangers are often necessary. Space heating requires temperatures in the range of 50–100°C, with 40°C useful in some marginal cases and ground-source heat pumps extending the range to 4°C. Cooling and industrial processing normally requires temperatures higher than 100°C. In terms of market penetration, the leading user of geothermal energy is Iceland, where more than 86% of the population enjoys geothermal heat in their homes from 26 municipal district heating services and 50% of the country's total energy use is supplied by direct heat and electrical energy derived from geothermal resources.

1.1 Historical Development

Although the direct use of geothermal energy has a much longer history than that of electric power generation, the data on utilization has been under

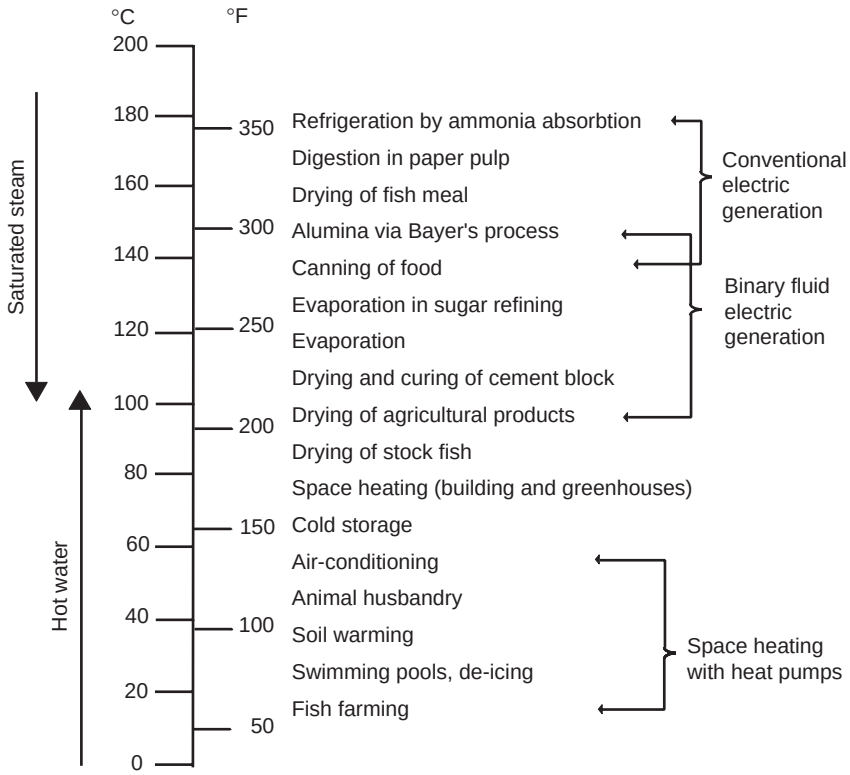

FIGURE 3 Lindal diagram.

reported. In fact, it is difficult to compare installed capacity and annual use due to the inclusion or exclusion of bathing, swimming, and balneology data. This has not been consistent; in the past, this use was not included, but in current reports it is included but not in a consistent manner. Also, values prior to 1970 were not summarized and up to 1980 could only be estimated from country descriptions in rapporteur reports. The early reports did not include China, a large user of geothermal energy for direct use, due to the political situation at the time, and they also did not include the United States even though a geothermal district heating system had been installed in Boise, Idaho, in 1892 and individual wells had been utilized in Klamath Falls, Oregon, since the 1930s for home heating. Finally, since many direct uses are small and not concentrated in one place, they are often overlooked by researchers reporting on their own country.

As a result, the 1961 United Nations (UN) conference in Rome reported only developments in Iceland, New Zealand, Italy, Japan, and Kenya. This report described district heating of 45,000 houses in Reykjavik; use of 1000 wells in Rotorua, New Zealand, for space heating; heating of 95,000 m^2 of greenhouses in Iceland; production of 21,000 tons/year of salt in Japan; the pulp and paper plant at Kawerau, New Zealand; the chemical industry at Larderello, Italy; pig raising in New Zealand; and chicken hatching in Kenya. The 1970 report of the UN meeting in Pisa included descriptions from Hungary, Iceland, Italy, Japan, New Zealand, and the USSR. As mentioned previously, China and the United States were not included. The data in Table II are based on information from the 1970 UN conference in Pisa, a report by Lawrence Livermore Laboratory in 1975, the second UN conference in San Francisco, papers by Lund in 1979 and 1982, and reports from the Geothermal Resources Council (GRC) annual meetings in 1985 and 1990, the 1995 World Geothermal Congress in Italy, and the 2000 World Geothermal Congress in Japan. Starting in 1995, geothermal heat pumps (ground-source heat pumps) were included in the reports and now comprise a significant percentage of the totals.

The large increase in installed capacity between 1980 and 1985 is due to the inclusion of pool heating at spas in Japan (onsen) and the first available data from China. The annual growth rate (based on MWt) from 1970 to 1980 was 9.3%, from 1980 to

TABLE II

Worldwide Development of Geothermal Direct Heat Utilization

	Installed energy			
Year	MWt	GWh/year	No. of countries	Participants reporting
1960			5	Iceland, Italy, New Zealand, Japan, and Kenya
1970	800 est.	2,200 est.	6	+ Hungary, and USSR
1975	1300 est.		10	+ France, the Phillipines, Turkey, and the United States
1980	1950		14	+ Austria, Czechoslovakia, Germany, and Taiwan
1985	7072	23,960	24	+ Australia, Canada, China, Columbia, Denmark, Mexico, Poland, Romania, Switzerland, and Yugoslavia
1990	8064		30	+ Algeria, Belgium, Bulgaria, Ethiopia, Greece, Guatemala, Thailand, and Tunisia; some countries not reporting
1995	8664	31,236	30	Argentina, Georgia, Israel, Macedonia, Serbia, Slovakia, and Sweden; some countries not reporting
2000	15,145	52,976	58	See Lund and Freeston (2001)

1990 it was 15.2% (which was strongly influenced by data from Japan and China), and from 1990 to 2000 it was 6.5%. The overall growth rate during the past 30 years has averaged 10.3% annually. The large increases from 1970 to 1990 (average annual increase of 12.2%) and the reduction from 1990 to present were influenced by the availability of cheap fossil fuels and the economic slowdown in Southeast Asia.

1.2 Swimming, Bathing, and Balneology

Romans, Chinese, Ottomans, Japanese, and central Europeans have bathed in geothermal waters for centuries. Today, more than 2200 hot springs resorts in Japan draw 100 million guests every year, and the "return-to-nature" movement in the United States has revitalized many hot spring resorts.

The geothermal water at Xiaotangshan Sanitarium, northwest of Beijing, has been used for medical purposes for more than 500 years. Today, the 50°C water is used to treat high blood pressure, rheumatism, skin disease, diseases of the nervous system, ulcers, and generally for recuperation after surgery. In Rotorua, New Zealand, at the center of the Taupo Volcanic Zone of North Island, the Queen Elizabeth Hospital was built during World War II for U.S. servicemen and later became the national hospital for the treatment of rheumatic disease. The hospital has 200 beds, an outpatient service, and a cerebral palsy unit. Both acidic and basic heated mud baths treat rheumatic diseases.

In Beppu on the southern island of Kyushu, Japan, hot water and steam meet many needs: heating, bathing, cooking, industrial operations, agriculture research, physical therapy, recreational bathing, and even a small zoo. The waters are promoted for "digestive system troubles, nervous troubles, and skin troubles." Many sick and crippled people come to Beppu for rehabilitation and physical therapy. There are also eight Jigokus ("burning hells") in town that show various geothermal phenomena that are used as tourist attractions.

In the area of the former Czechoslovakia, the use of thermal waters has been traced back before the occupation of the Romans and has had a recorded use of approximately 1000 years. Today, there are 60 spa resorts located mainly in Slovakia that are visited by 460,000 patients annually, usually for an average stay of 3 weeks each. These spas have old and well-established therapeutic traditions. Each sanitarium is designated for the treatment of specific diseases depending on the chemical composition of the mineral waters and spring gas, availability of peat and sulfurous mud, and climatic conditions. The therapeutic successes of these spas are based on centuries of healing tradition (balneology), systematically supplemented by the latest discoveries of modern medical science.

Bathing and therapeutic sites in the United States include Saratoga Springs, New York; Warm Springs, Georgia; Hot Springs, Virginia; White Sulfur Springs, West Virginia; Hot Spring, Arkansas; Thermopolis, Wyoming; and Calistoga, California. These sites were originally used by Indians for bathing and recuperating from battle. There are more than 115 major geothermal spas in the United States with an annual energy use of 1500 TJ.

1.3 Space Conditioning

Space conditioning includes both heating and cooling. Space heating with geothermal energy has widespread application, especially on an individual basis. Buildings heated from individual wells are popular in Klamath Falls, Oregon; Reno, Nevada; and Taupo and Rotorua, New Zealand. Absorption space cooling with geothermal energy has not been popular because of the high temperature requirements and low efficiency. Geothermal heat pumps (groundwater and ground coupled) have become popular in the United States, Sweden, and Switzerland for both heating and cooling.

An example of the use of space heating and cooling with low- to moderate-temperature geothermal energy is the Oregon Institute of Technology in Klamath Falls, Oregon (Fig. 4). Here, 11 buildings (approximately 62,000 m^2 of floor space) are heated with water from three wells at 89°C. Up to 62 liters/s of fluid can be provided to the campus, with the average heat utilization rate more than 0.53 MWt and the peak at 5.6 MWt. In addition, a 541-kW (154 tons) chiller requiring up to 38 liters/s of geothermal fluid produces 23 liters/s of chilled fluid at 7°C to meet the campus cooling base load (recently decommissioned).

1.4 District Heating

District heating originates from a central location and supplies hot water or steam through a network of pipes to individual dwellings or blocks of buildings. The heat is used for space heating and cooling, domestic water heating, and industrial process heat. A geothermal well field is the primary source of heat; however, depending on the temperature, the district may be a hybrid system, which would include fossil fuel and/or heat pump peaking.

Geothermal district heating systems are in operation in at least 12 countries, including Iceland, France, Poland, Hungary, Turkey, Japan, and the United States. The Warm Springs Avenue project in Boise, Idaho, dating back to 1892 and originally heating more than 400 homes, is the earliest formal project in the United States. The Reykjavik, Iceland, district heating system (Fig. 5) is probably the most famous. This system supplies heat for approximately 160,000 people. The installed capacity of 830 MWt is designed to meet the heating load to approximately −10°C; during colder periods, the increased load is met by large storage tanks and an oil-fired booster station.

In France, production wells in sedimentary basins provide direct heat to more than 500,000 people from 61 projects (200,000 housing units). These wells provide 40–100° C water from depths of 1500–2000 m. In the Paris basin, a doublet system (one production and one injection well) provides 70°C water, with the peak load met by heat pumps and conventional fossil fuel burners (Fig. 6).

1.5 Agribusiness Applications

Agribusiness applications (agriculture and aquaculture) are particularly attractive because they require

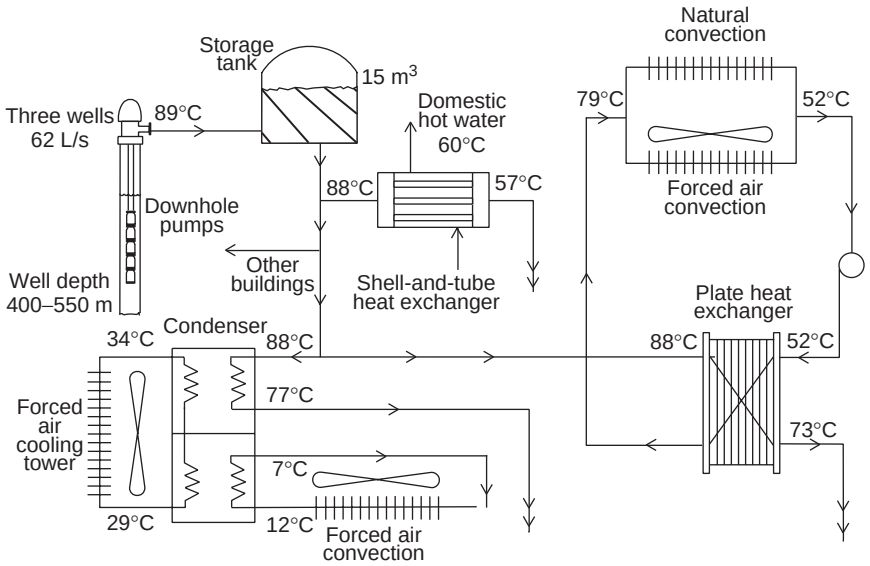

FIGURE 4 Oregon Institute of Technology heating and cooling system.

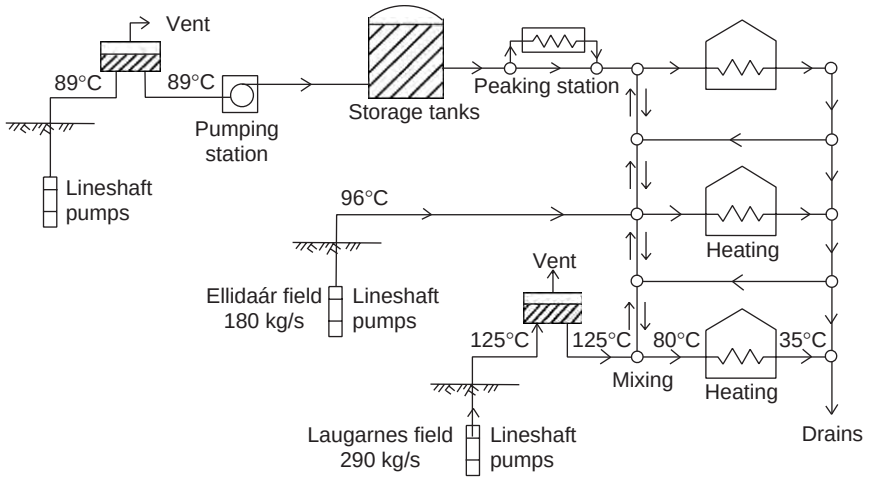

FIGURE 5 Reykjavik district heating.

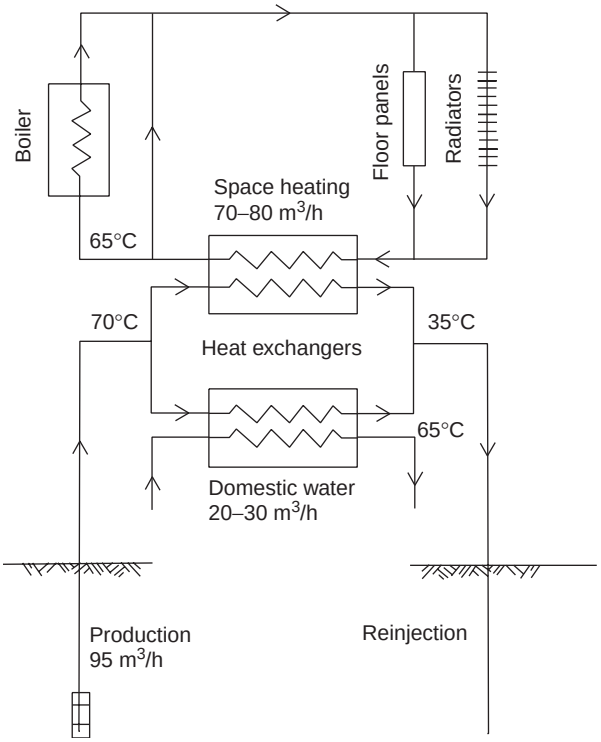

FIGURE 6 Melun l'Almont (Paris) doublet heating system.

heating at the lower end of the temperature range, for which there is an abundance of geothermal resources. Use of waste heat or the cascading of geothermal energy also has excellent possibilities. A number of agribusiness applications can be considered: greenhouse heating, aquaculture and animal husbandry, soil warming and irrigation, mushroom culture, and biogas generation.

Numerous commercially marketable crops have been raised in geothermally heated greenhouses in Tunisia, Hungary, Russia, New Zealand, Japan, Iceland, China, and the United States. These include vegetables such as cucumbers and tomatoes, flowers (both potted and bedded), house plants, tree seedlings, and cacti. Using geothermal energy for heating reduces operating costs (which can account for 35% of the product cost) and allows operation in colder climates where commercial greenhouses would not normally be economical.

The use of geothermal energy for raising catfish, shrimp, tilapia, eels, and tropical fish has produced crops faster than by conventional solar heating. Using geothermal heat allows better control of pond temperatures, thus optimizing growth (Fig. 7). Fish

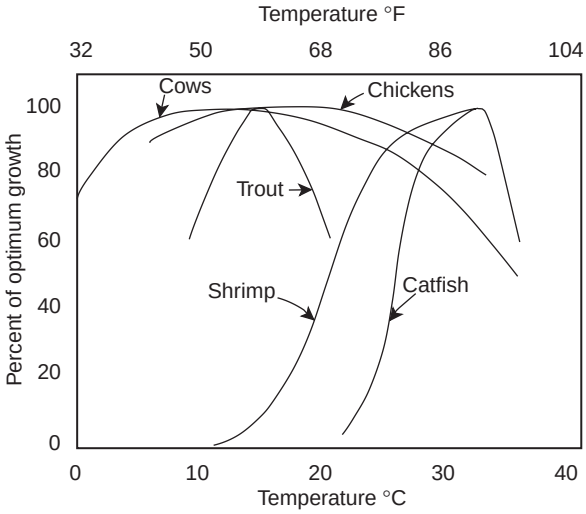

FIGURE 7 Effect of temperature on animal and fish growth.

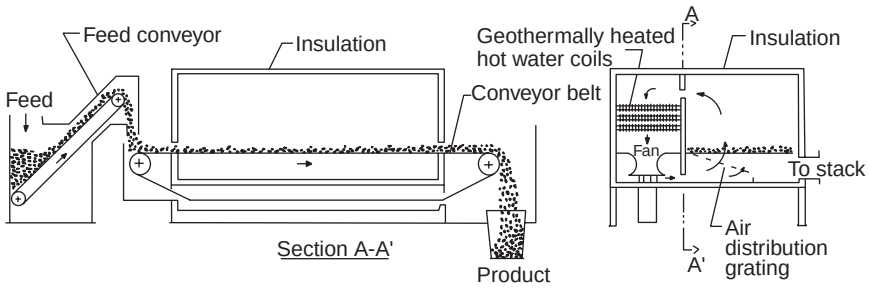

FIGURE 8 Continuous belt dehydration plant.

breeding has been successful in Japan, China, and the United States. A very successful prawn-raising operation, producing 400 tons of giant Malaysian freshwater prawns per year at $17–27/kg, has been developed near the Wairakei geothermal field in New Zealand. The most important factors to consider are the quality of the water and disease. If geothermal water is used directly, concentrations of dissolved heavy metals, flurorides, chlorides, arsenic, and boron must be considered.

Livestock-raising facilities can encourage the growth of domestic animals by a controlled heating and cooling environment. Use of an indoor facility can lower the mortality rate of newborns, enhance growth rates, control diseases, increase litter size, make waste management and collection easier, and, in most cases, improve the quality of the product. Geothermal fluids can also be used for cleaning, sanitizing, and drying of animal shelters and waste as well as assisting in the production of biogas from the waste.

1.6 Industrial Applications

Although the Lindal diagram shows many potential industrial and process applications of geothermal energy, the world's uses are relatively few. The oldest industrial use is in Larderello, Italy, where boric acid and other borate compounds have been extracted from geothermal brines since 1790. Today, the two largest industrial uses are the diatomaceous earth-drying plant in northern Iceland and a pulp, paper, and wood processing plant in Kawerau, New Zealand. Notable U.S. examples are two onion dehydration plants in northern Nevada and a sewage digestion facility in San Bernardino, California. Alcohol fuel production has been attempted in the United States; however, the economics were marginal and thus the industry has not been successful.

Drying and dehydration are important moderate-temperature uses of geothermal energy. Various vegetable and fruit products are feasible with the use of continuous belt conveyors (Fig. 8) or batch (truck) dryers with air temperatures from 40 to 100°C. Geothermally drying alfalfa, onions, pears, apples, and seaweed is an example of this type of direct use. A new development in the use of geothermal fluids is the enhanced heap leaching of precious metals in Nevada by applying heat to the cyanide process. Using geothermal energy increases the efficiency of the process and extends the production into the winter months.

2. EQUIPMENT

Standard equipment is used in most direct-use projects, provided allowances are made for the nature of geothermal water and steam. Temperature is an important consideration, as is water quality. Corrosion and scaling caused by the sometimes unique chemistry of geothermal fluids may lead to operating problems with equipment components exposed to flowing water and steam. In many instances, fluid problems can be designed out of the system. One such example concerns dissolved oxygen, which is absent in most geothermal waters except perhaps the lowest temperature waters. Care should be taken to prevent atmospheric oxygen from entering district heating waters, for example, by proper design of storage tanks. The isolation of geothermal water by installing a heat exchanger may also solve this and similar water quality-derived problems. In this case, a clean secondary fluid is then circulated through the user side of the system as shown in Fig. 9.

The primary components of most low-temperature, direct-use systems are downhole and circulation pumps, transmission and distribution pipelines, peaking or backup plants, and various forms of heat-extraction equipment (Fig. 9). Fluid disposal is either surface or subsurface (injection). A peaking

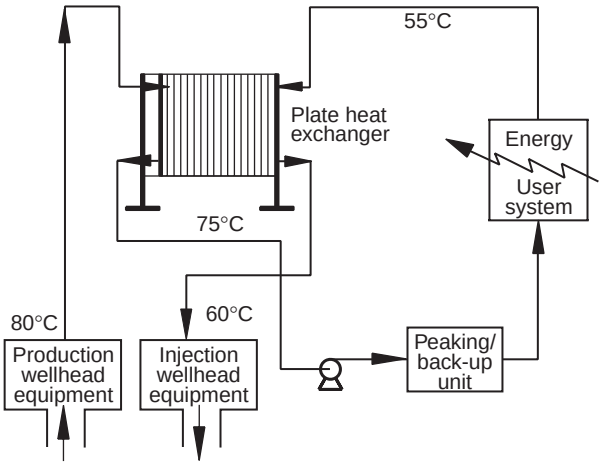

FIGURE 9 Geothermal direct-utilization system using a heat exchanger.

system may be necessary to meet maximum load. This can be done by increasing the water temperature or by providing tank storage (such as is done in most of the Icelandic district heating systems). Both options mean that fewer wells need to be drilled. When the geothermal water temperature is warm (<40°C), heat pumps are often used.

The equipment used in direct-use projects represents several units of operations. In the following sections, the major units are described in the order in which they are used to transform geothermal waters for district heating.

2.1 Downhole Pumps

Unless the well is artesian, downhole pumps are needed, especially in large-scale, direct utilization systems. Downhole pumps may be installed not only to lift fluid to the surface but also to prevent the release of gas and the resultant scale formation. The two most common types are lineshaft pump systems and submersible pump systems.

The lineshaft pump system (Fig. 10) consists of a multistage downhole centrifugal pump, a surface-mounted motor, and a long driveshaft assembly extending from the motor to the pump. Most are enclosed, with the shaft rotating within a lubrication column, which is centered in the production tubing. This assembly allow the bearings to be lubricated by oil since hot water may not provide adequate lubrication. A variable-speed drive set just below the motor on the surface can be used to regulate flow instead of simply turning the pump on and off.

The electric submersible pump system (Fig. 11) consists of a multistage downhole centrifugal pump, a downhole motor, a seal section (also called a protector) between the pump and motor, and electric cable extending from the motor to the surface electricity supply.

Both types of downhole pumps have been used for many years for cold water pumping and, recently, in geothermal wells (lineshafts have been used on the Oregon Institute of Technology campus in 89°C water for 45 years). If a lineshaft pump is used, special allowances must be made for the thermal expansion of various components and for oil lubrication of the bearings. Lineshaft pumps are preferred over the submersible pumps in conventional geothermal applications because lineshaft pumps cost less and they have a proven track record. However, for setting depths exceeding approximately 250 m, a submersible pump is required.

2.2 Piping

The fluid state in transmission lines of direct-use projects can be liquid water, steam vapor, or a two-phase mixture. These pipelines carry fluids from the wellhead to either a site of application or a steam–water separator. Thermal expansion of pipelines heated rapidly from ambient to geothermal fluid temperatures (which may vary from 50 to 200°C) causes stress that must be accommodated by careful engineering design.

The cost of transmission lines and the distribution networks in direct-use projects is significant. This is especially true when the geothermal resource is located a great distance from the main load center; however, transmission distances of up to 60 km have proven economical for hot water (e.g., the Akranes project in Iceland, where asbestos cement covered with earth has been successful).

Carbon steel is the most widely used material for geothermal transmission lines and distribution networks, especially if the fluid temperature is higher than 100°C. Other common types of piping material are fiberglass-reinforced plastic (FRP) and asbestos cement. The latter material, used widely in the past, cannot be used in many systems today due to environmental concerns; thus, it is no longer available in many locations. Polyvinyl chloride (PVC) piping is often used for the distribution network and for uninsulated waste disposal lines in which temperatures are well below 100°C. Conventional steel piping requires expansion provisions, either bellows arrangements or by loops. A typical piping installation has fixed points and expansion points approximately every 100 m. In addition, the

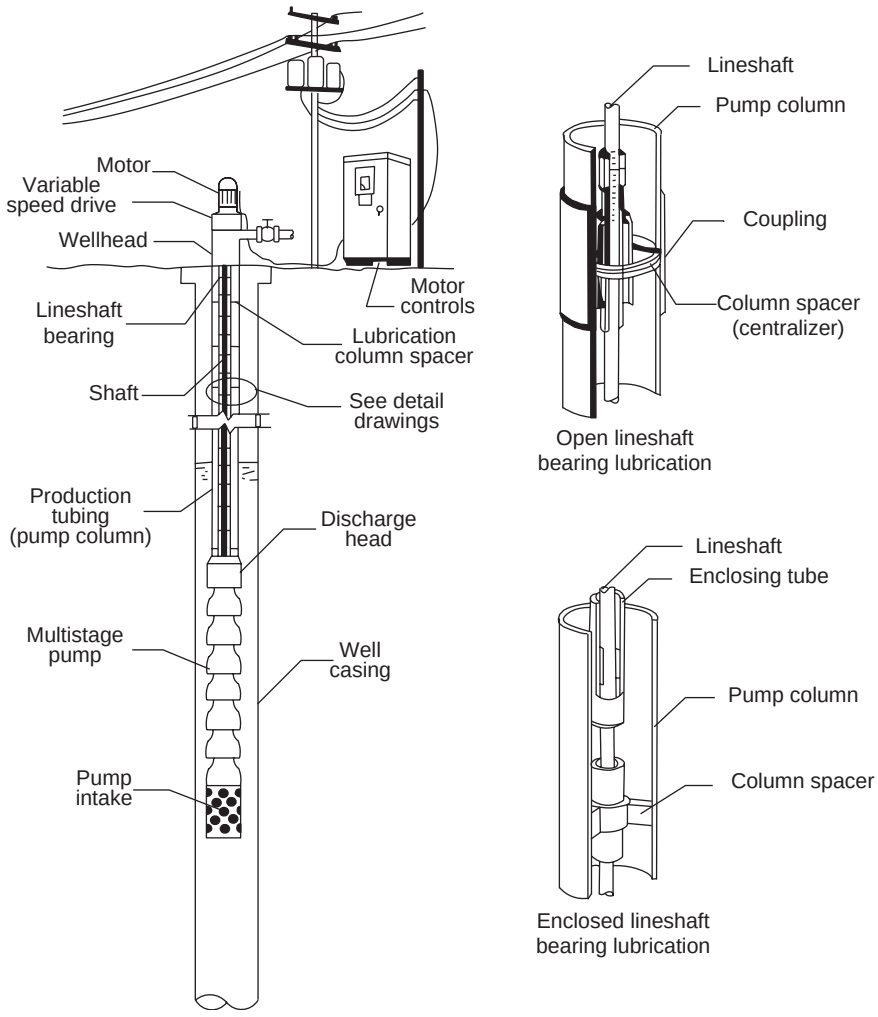

FIGURE 10 Lineshaft pump.

piping has to be placed on rollers or slip plates between points. When hot water pipelines are buried, they can be subjected to external corrosion from groundwater and electrolysis. They must be protected by coatings and wrappings. Concrete tunnels or trenches have been used to protect steel pipes in many geothermal district heating systems. Although expensive (generally more than $300 per meter of length), tunnels and trenches have the advantage of easing future expansion, providing access for maintenance and a corridor for other utilities, such as domestic water, waste water, electrical cables, and phone lines.

Supply and distribution systems can be either single-pipe or two-pipe systems. The single-pipe system is a once-through system in which the fluid is disposed of after use. This distribution system is generally preferred when the geothermal energy is abundant and the water is pure enough to be circulated through the distribution system. In a two-pipe system, the fluid is recirculated so that the fluid and residual heat are conserved. A two-pipe system must be used when mixing of spent fluids is necessary and when the spent cold fluids need to be injected into the reservoir. Two-pipe distribution systems typically cost 20–30% more than single-piped systems.

The quantity of thermal insulation of transmission lines and distribution networks depends on many factors. In addition to minimize the heat loss of the fluid, the insulation must be waterproof and watertight. Moisture can destroy any thermal insulation and cause rapid external corrosion. Aboveground and overhead pipeline installations can be considered in special cases. Considerable insulation is achieved by burying hot water pipelines. For example, burying

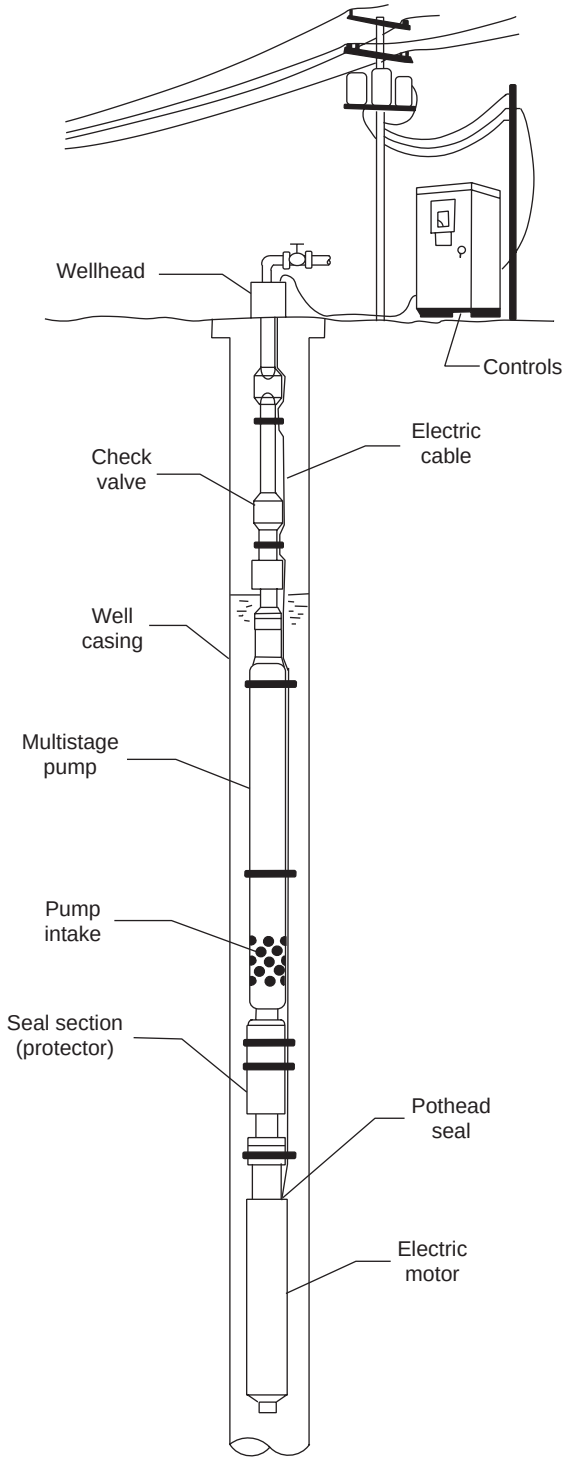

FIGURE 11 Submersible pump.

bare steel pipe results in a reduction in heat loss of approximately one-third compared to aboveground steel pipes in still air. If the soil around the buried pipe can be kept dry, then the insulation value can be

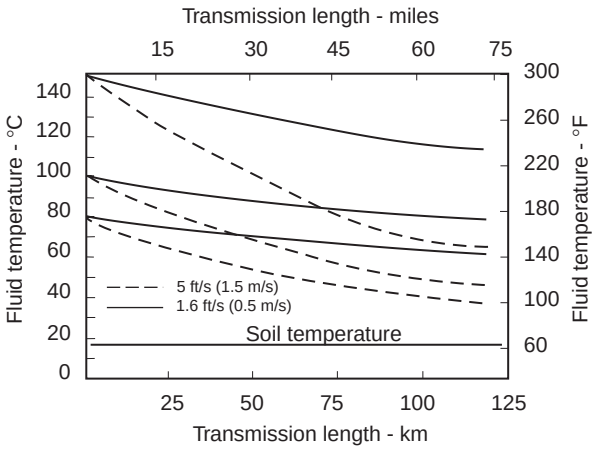

FIGURE 12 Temperature drop in hot water transmission line.

retained. Carbon steel piping can be insulated with polyurethane foam, rock wool, or fiberglass. Belowground, such pipes should be protected with PVC jacket; aboveground, aluminum can be used. Generally, 2.5–10 cm of insulation is adequate. In two-pipe systems, the supply and return lines are usually insulated, whereas in single-pipe systems only the supply line is insulated.

In flowing conditions, the temperature loss in insulated pipelines is in the range of 0.1–1.0°C/km, and in uninsulated lines the loss is 2–5°C/km (in the approximate range of 5–15 liters/s flow for 15-cm diameter pipe). It is less for larger diameter pipes; for example, a <2°C loss is experienced in the aboveground, 29-km long and 80- to 90-cm-diameter line (with 10 cm of rock wool insulation) from Nesjavellir to Reykjavik, Iceland. The flow rate is approximately 560 liters/s and 7 h are required to cover the distance. Uninsulated pipe costs approximately half that of insulated pipe and thus is used where temperature loss is not critical. Pipe material does not have a significant effect on heat loss; however, the flow rate does. At low flow rates (off-peak), the heat loss is higher than that at greater flows. Figure 12 shows fluid temperatures, as a function of distance, in a 45-cm-diameter pipeline insulated with 50 mm of urethane.

Several examples of aboveground and buried pipeline installations are shown in Fig. 13. Steel piping is used in most cases, but FRP or PVC can be used in low-temperature applications. Aboveground pipelines have been used extensively in Iceland, where excavation in lava rock is expensive and difficult. In the United States, belowground installations are more common to protect the line from vandalism and to eliminate traffic barriers.

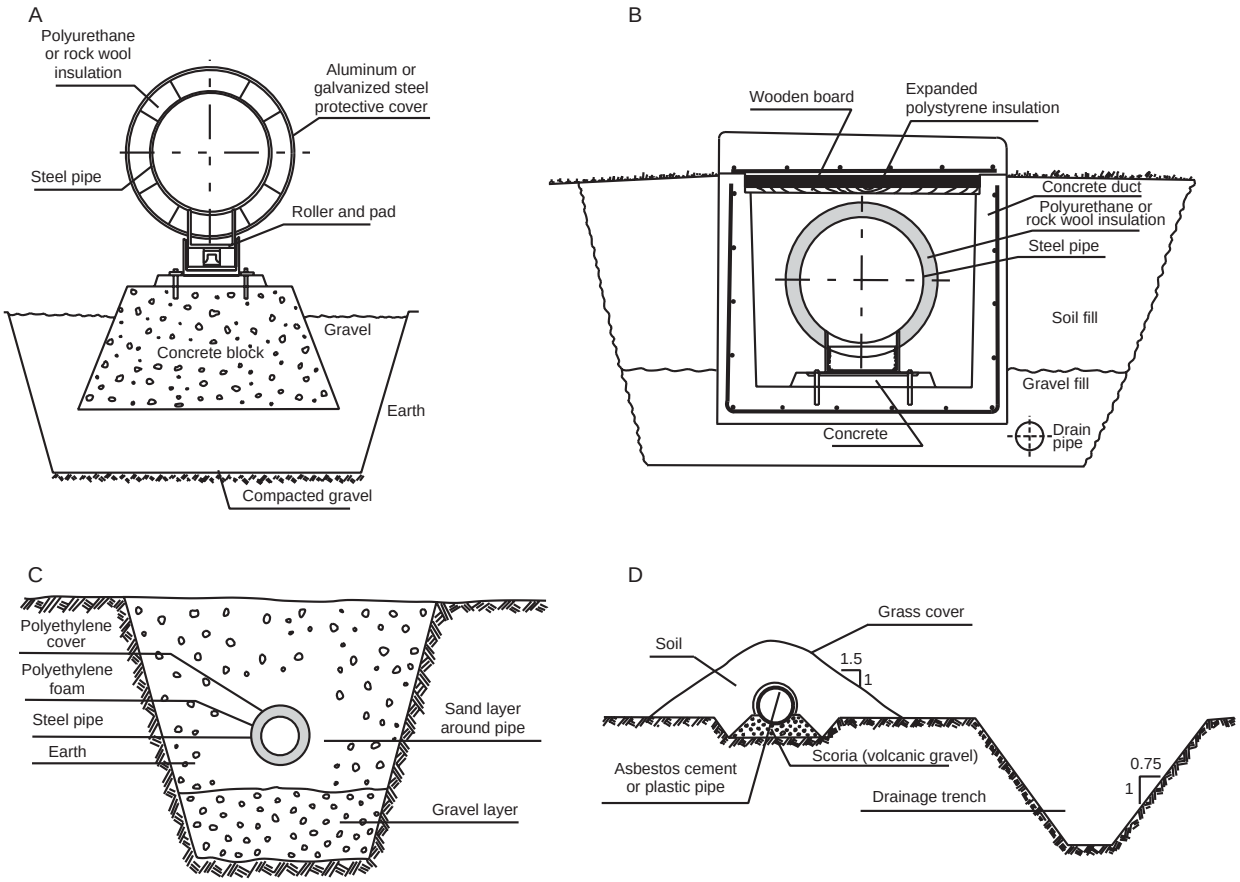

FIGURE 13 Examples of above- and belowground pipelines: (A) aboveground pipeline with sheet metal cover; (B) steel pipe in concrete tunnels; (C) steel pipe with polyurethane insulation and polyethylene cover; and (D) asbestos cement pipe with earth and grass cover.

2.3 Heat Exchangers

The principal heat exchangers used in geothermal systems are the plate, shell-and-tube, and downhole types. The plate heat exchanger consists of a series of plates with gaskets held in a frame by clamping rods (Fig. 14). The countercurrent flow and high turbulence achieved in plate heat exchangers provide for efficient thermal exchange in a small volume. In addition, compared to shell-and-tube exchangers, they have the advantages of occupying less space, are easily expandable when addition load is added, and cost 40% less. The plates are usually made of stainless steel, although titanium is used when the fluids are especially corrosive. Plate heat exchangers are commonly used in geothermal heating situations worldwide.

Shell-and-tube heat exchangers may be used for geothermal applications but are less popular due to problems with fouling, greater approach temperature (the difference between incoming and outgoing fluid temperature), and larger size.

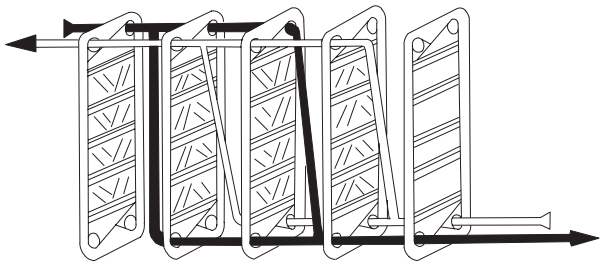

FIGURE 14 Plate heat exchanger.

Downhole heat exchangers eliminate the problem of disposing of geothermal fluid since only heat is taken from the well. However, their use is limited to small heating loads, such as heating of individual homes, a small apartment house, or business. The exchanger consists of a system of pipes or tubes suspended in the well through which secondary

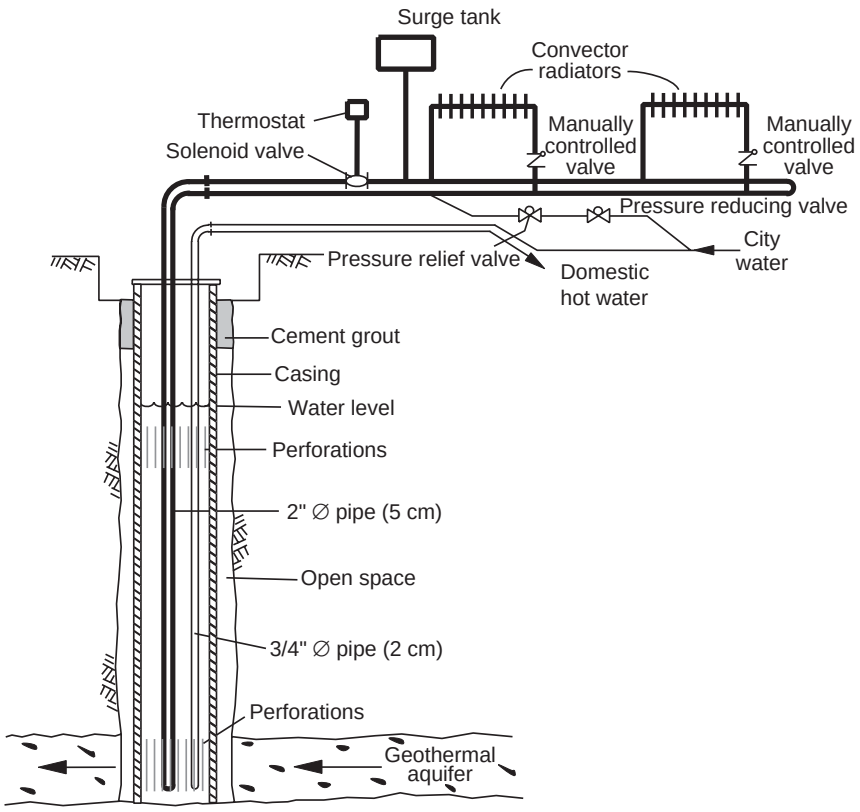

FIGURE 15 Downhole heat exchanger (typical of Klamath Falls, OR).

water is pumped or allowed to circulate by natural convection (Fig. 15). In order to obtain maximum output, the well must have an open annulus between the wellbore and casing, and perforations above and below the heat exchanger surface. Natural convection circulates the water down inside the casing, through the lower perforations, up into the annulus, and back inside the casing through the upper perforations. The use of a separate pipe or promoter to increase the vertical circulation has proven successful in older wells in New Zealand.

2.4 Heat Pumps

Ground-coupled and groundwater (often called ground-source or geothermal) heat pump systems are being installed in great numbers in the United States, Sweden, Switzerland, and Germany. Groundwater aquifers and soil temperatures in the range of 5–30°C are being used in these systems. Ground-source heat pumps utilize groundwater in wells or by direct ground coupling with vertical heat exchangers (Fig. 16). Nearly every state in the United States, especially in the midwestern and eastern states, utilizes these systems, which are in part subsidized by public and private utilities. It is estimated that approximately 70,000 groundwater systems, and more than 210,000 closed-loop vertical and 170,000 horizontal systems, are in use.

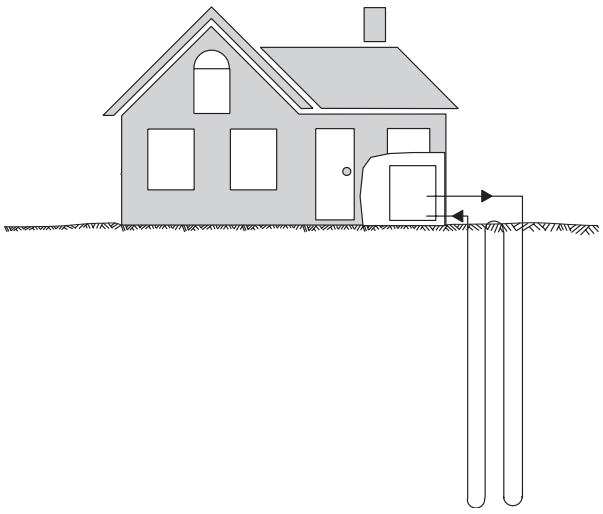

FIGURE 16 Typical ground-source heat pump installation.

Like refrigerators, heat pumps operate on the basic principle that fluid absorbs heat when it evaporates into a gas and likewise gives off heat when it condenses back into a liquid. A geothermal heat pump system can be used for both heating and cooling. Water-to-air and water-to-water heat pumps are adaptable to geothermal energy. Heat pumps with heating capacities ranging from less than 3 kW to more than 1500 kW are available.

2.5 Convectors

Heating of individual rooms and buildings is achieved by passing geothermal water (or a heated secondary fluid) through heat convectors (or emitters) located in each room. The method is similar to that used in conventional space heating systems. Three major types of heat convectors are used for space heating: forced air, natural air flow using hot water or finned tube radiators, and radiant panels (Fig. 17). All these can be adapted directly to geothermal energy or be converted by retrofitting existing systems.

2.6 Refrigeration

Cooling can be accomplished from geothermal energy using lithium bromide or ammonia absorption refrigeration systems. The lithium bromide system is the most common because it uses water as the refrigerant. However, it is limited to cooling above the freezing point of water. The major application of lithium bromide units is the supply of chilled water for space and process cooling. They may be either one- or two-stage units. The two-stage units require higher temperatures (approximately 160°C), but they also have high efficiency. The single-stage units can be driven with hot water at temperatures as low as 77°C (such as at Oregon Institute of Technology; Fig. 4). The lower the temperature of the geothermal water, the higher the flow rate required and the lower the efficiency. Generally, a condensing (cooling) tower is required, which will add to the cost and space requirements.

For geothermally driven refrigeration below the freezing point of water, the ammonia absorption system must be considered. However, these systems are normally applied in very large capacities and have seen limited use. For the lower temperature refrigeration, the driving temperature must be at or higher than approximately 120°C for a reasonable performance. Figure 18 illustrates how the geothermal absorption process works.

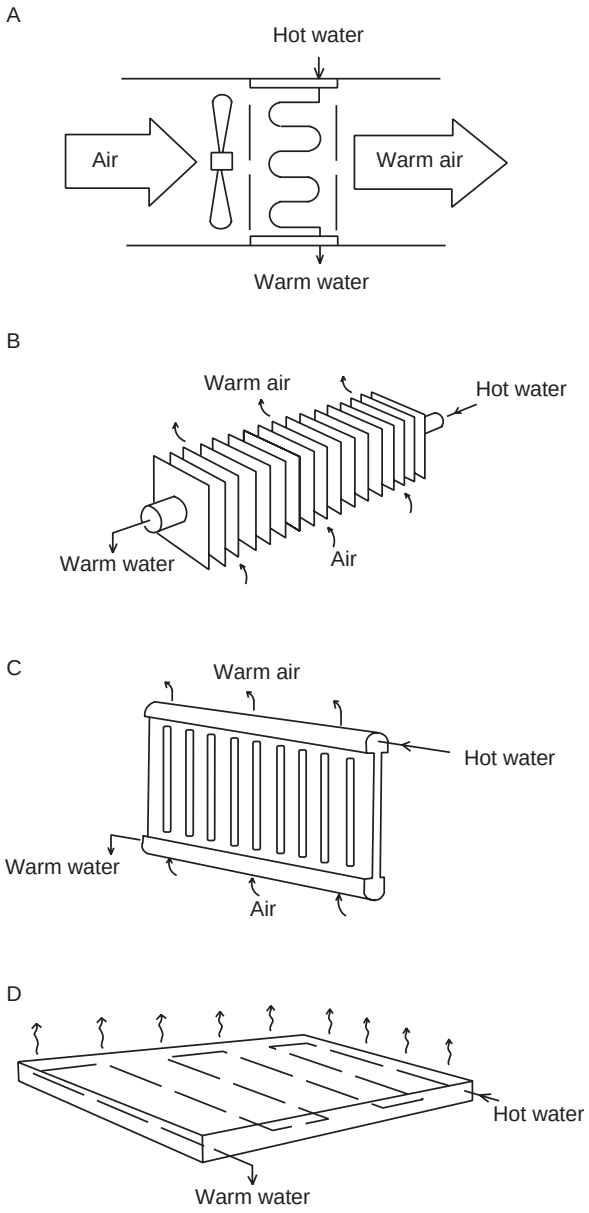

FIGURE 17 Convectors: (A) forced air; (B) material convection (finned tube); (C) natural convection (radiator); and (D) floor panel.

3. ECONOMIC CONSIDERATIONS

Geothermal projects require a relatively large initial capital investment, with small annual operating costs thereafter. Thus, a district heating project, including production wells, pipelines, heat exchangers, and injection wells, may cost several million dollars. In contrast, the initial investment in a fossil fuel system includes only the cost of a central boiler and distribution lines. The annual operation and

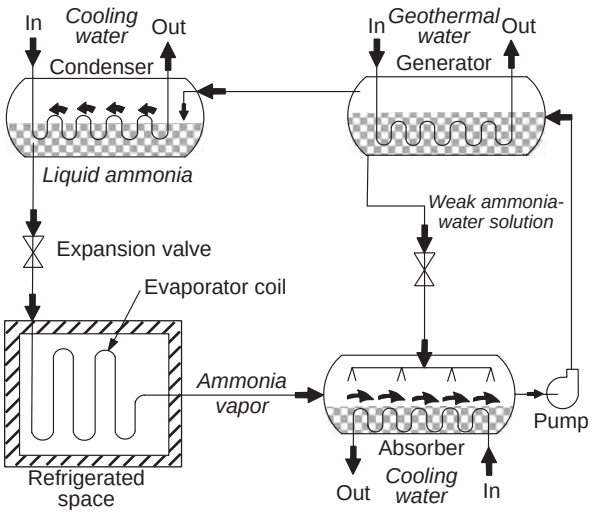

FIGURE 18 Geothermal absorption refrigeration cycle.

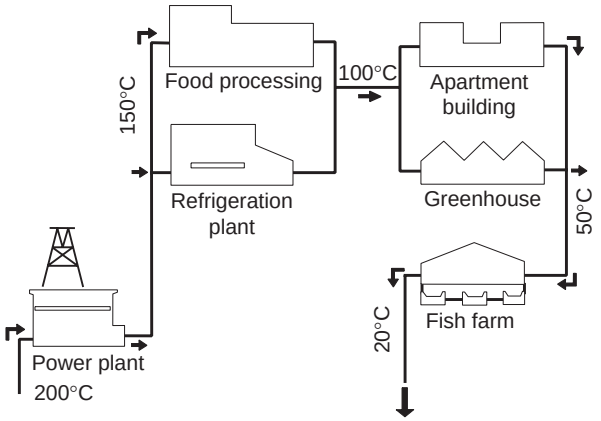

FIGURE 19 An example of cascading.

maintenance costs for the two systems are similar, except that the fossil fuel system may continue to pay for fuel at an ever-increasing rate, whereas the cost of the geothermal fuel is stable. The two systems, one with a high initial capital cost and the other with high annual costs, must be compared.

Geothermal resources fill many needs, including power generation, space heating, greenhouse heating, industrial processing, and bathing. Considered individually, however, some of the uses may not promise an attractive return on investment because of the high initial capital cost. Thus, one may have to consider using a geothermal fluid several times to maximize benefits. This multistage utilization, where increasingly lower water temperatures are used in successive steps, is called cascading or waste heat utilization. A simple form of cascading employs waste heat from a power plant for direct-use projects (Fig. 19).

Geothermal cascading has been proposed and successfully attempted on a limited scale throughout the world. In Rotorua, New Zealand, after geothermal water and steam heat a home the owner often uses the waste heat for a backyard swimming pool and steam cooker. At the Otake geothermal power plant in Japan, approximately 165 tonnes per hour of hot water flows to downstream communities for space heating, greenhouses, baths, and cooking. In Sapporo, Hokkaido, Japan, the waste water from the pavement snow-melting system is retained at 65°C and reused for bathing.

Current district heating costs are 0.23–0.42 ¢/1000 kcal (0.27–0.49 ¢/kWh) in Turkey compared to 3.4 ¢/kWh for natural gas and 11.2 ¢/kWh for electricity-based heating. The Klamath Falls district heating system charges 1.6–2.0 ¢/kWh. This is 50–80% of the natural gas cost, depending on the efficiency of the gas conversion, and the comparable cost for electricity in the city is 5.5 ¢/kWh. Construction costs for heating in Turkey are $850–1250/kW and the cost per residence is approximately $2000, an investment that is amortized over 5–10 years. Stefansson reported that an average consumer heating cost in 1995 for four European countries was 2.4 ¢/kWh.

Other estimates (1990 data) of the capital cost for various direct-use projects in the United States are as follows:

Space heating (individual): $463/kW of installed capacity
District heating: $386/kW of installed capacity
Greenhouses: $120/kW of installed capacity
Aquaculture: $26/kW of installed capacity

International data indicate a rate of $270/kW of installed capacity for all projects reported, with a range of $40–1880/kW. In the United States, the annual operation and maintenance cost is estimated to be 5% of the installed cost.

4. FUTURE DEVELOPMENTS

There appears to be a major potential for the development of low to moderate enthalpy geothermal direct use throughout the world, which is not being exploited due to financial constraints and the low price of competing energy sources. Given the right environment, and as gas and oil supplies dwindle, the use of geothermal energy will provide a competitive, viable, and economic alternative source of renewable energy.

Future development will most likely occur under the following conditions:

1. Co-located resource and uses (within 10 km).
2. Sites with high heat and cooling load density (>36 MWt/km^2).
3. Food and grain dehydration (especially in tropical countries, where spoilage is common).
4. Greenhouses in colder climates.
5. Aquaculture to optimize growth, even in warm climates.
6. Ground-coupled and groundwater heat pump installation (for both heating and cooling).

Glossary

Annubar A device (trade name) that measures steam flow rate in a pipe.
bleed A small flow through a side valve below the master valve to keep a well hot.
casing A steel pipe that forms a well.
casing head flange The first flange that is attached to a well casing above ground.
directional (deviated) drilling Drilling a well away from the vertical line.
drain pot A short pipe at the bottom of a steam pipe to collect condensate flowing in it.
drawdown Downhole pressure loss causing a well unable to sustain constant discharge.
exergy The maximum thermodynamic work that can be converted from heat.
feed zone The location where geothermal fluids enter a well.
Kuster gauge A device (trade name) that measures pressure and/or temperature in a well.
master valve The first shut-off valve above the casing head flange of a well.
nozzle A short pipe attached to a pressure vessel or pipe.
reinjection The process of putting spent or unused geothermal fluids back into the ground.
sinker bar A long metal bar that provides counterweight when an instrument is lowered into a flowing well.
spinner A device that measures fluid flow direction and/or velocity in a well.
stimulation The process of removing the cold column of water sitting in a well so that the well can self-discharge.
superficial steam velocity Steam velocity assuming that the steam phase of a two-phase fluid occupies the entire cross section of the pipe.
tracer A chemical injected into a well to detect the water flow path.
turbine nozzle A wheel of fixed blades to direct steam flow to a wheel of rotating turbine blades.
wellhead The area around the casing head flange.
wellhead pressure (WHP) Fluid pressure in a well just below the master valve.

Energy can be converted from one form to another. Geothermal power generation is the production of electrical energy from the heat (thermal) energy of the earth (geo). Electricity is a much more convenient, clean, and useful form of energy than is heat. Geothermal energy has been used directly for its heat and therapeutic effect for thousands of years by the Romans, Chinese, and Turks. Its indirect use was realized in 1904 when Prince Piero Ginori Conti of Italy successfully produced electricity in an experimental "indirect cycle" using pure steam produced from a heat exchanger. This led to the first 250-kWe geothermal power station in 1913 at Larderello in Tuscany, Italy. Nowadays, geothermal energy is used directly for many purposes, but it is the generation of electricity that provides humankind with the most benefits and challenges. Whereas Larderello is the first dry steamfield that was developed for power, Wairakei in New Zealand is the first geothermal power station that was developed from a wet field. Energy conversion is subjected to the laws of thermodynamics. Geothermal power generation is similar to the conventional fossil fuel-fired power generation using steam turbines. The main difference is the lack of a manmade boiler in a geothermal power station; hence, steam supply requires more careful scientific assessment. However, geothermal power generation has other advantages. It has environmental benefits due to its low carbon dioxide emissions; it is "renewable" if managed in a sustained manner; it has cultural, social, and economic benefits in terms of tourism and recreational values; and because it is indigenous, it lessens the dependence on

 © 2004 Elsevier Inc. All rights reserved.

imported oil. Developing countries such as The Philippines, El Salvador, and Kenya have much of their electricity generated by geothermal energy, saving these countries a great deal in terms of oil imports.

1. GEOTHERMAL RESOURCES

The earth is an enormous sphere with more than a 6000-km radius. A solid brittle outer shell approximately 100 km thick, consisting of the continental crust (5–50 km thick) and the outermost part of the mantle, floats on a dense liquid metal core. Between the solid shell and the liquid core is the plastic layer of the mantle. The innermost core is believed to be solid metal due to the enormous pressure there. The continental crust is not one piece; rather, it is made up of many pieces known as tectonic plates. The earth has a heat source that is mainly from within the core due to radioactive materials. Heat is also generated by friction in the continental crust and the outermost mantle as the various tectonic plates move relative to each other. The consequences of this are the often catastrophic earthquakes and volcanic eruptions.

The temperature on the earth's surface ranges from about -50°C at the poles to about 50°C in the deserts. The earth's innermost core is believed to be approximately 5000°C ($\pm 1000^{\circ}$C). However, the earth's temperature gradient is not linear from the surface to the center of the earth but rather increases very steeply with depth from the earth's surface to approximately 1000°C at 100 km. To put things in perspective, we are looking at roughly 10 km of the continental crust for geothermal resources.

Geothermal resources can be defined as all of the heat energy stored in the earth's crust that is accessible locally. The word "locally" is important because a 20°C resource is usable at a location with -20°C ambient temperature but not 20°C (unless a heat pump is used). This is because heat transfer requires a temperature difference between a heat source and a heat sink. Geothermal resources from which energy could be extracted economically in the near future (<100 years) are parts of the useful accessible resource base. Geothermal resources that can be extracted economically today are defined as geothermal reserves. These identified reserves are further divided into possible, probable, and proven reserves depending on how much scientific work (geological, geophysical, geochemical, and drilling) has been carried out on them.

Whether a geothermal resource is technically suitable for geothermal power generation depends very much on the type and quality of the geothermal system and on the available technology. Currently, the geothermal system that is suitable for power generation is the hydrothermal type. This consists of a reservoir that contains hot water under high pressure. When this water is accessed by a drillhole, it ascends and some flashes to steam as the pressure releases.

The thermal water is mainly meteoric, so geothermal energy can be considered "sustainable" if the quantity of water withdrawn does not exceed recharge and if the heat added to the replenished water is at least equal to that extracted. However, geothermal energy is technically not strictly "renewable" because it is heat in the rock that heats the water, and this is not renewable. Most geothermal systems have lifetimes of less than 1 million years. Also, in general, heat that is extracted with the water from wells is much higher than that replenished from the reservoir rock because the heat capacity of water is much greater than that of the rock.

Hydrothermal systems are commonly divided into vapor- or steam-dominated and liquid- or water-dominated systems. In a steam-dominated system, the fluid in the reservoir is such that steam is the continuous phase that controls the pressure. When this fluid reaches the surface, the steam produced is normally superheated. In a water-dominated system, water is the continuous pressure-controlling phase. When this fluid reaches the surface, less than 50% by weight is steam. Although much of the world geothermal power generation comes from vapor-dominated systems, they are rare. The most famous are Larderello in Italy and The Geysers in California. Most geothermal systems are water dominated and are one-tenth the size of The Geysers in electrical power capacity. Examples of famous water-dominated systems include Wairakei in New Zealand and Cerro Prieto in Mexico.

Geothermal resources are commonly classified according to the average fluid temperatures in their reservoirs. Unfortunately, the demarcation lines are not agreed on (Table I). Exergy is also used to classify geothermal resources according to their specific exergy index,

$$SE \times I = (h - 273s)/1192,$$

where h is the specific enthalpy in J/g and s is the specific entropy in J/gK. Geothermal resources with $SE \times I > 0.5$ are high exergy or quality, those with $SE \times I < 0.05$ are low quality, and those in between are medium resources (Fig. 1).

TABLE I

Classification of Geothermal Resources by Temperature (°C)

	(a)	(b)	(c)	(d)
Low enthalpy	<90	<125	<100	<150
Intermediate	90–150	125–225	100–200	
High enthalpy	>150	>225	>200	>150

Source. Dickson and Fanelli (1990).

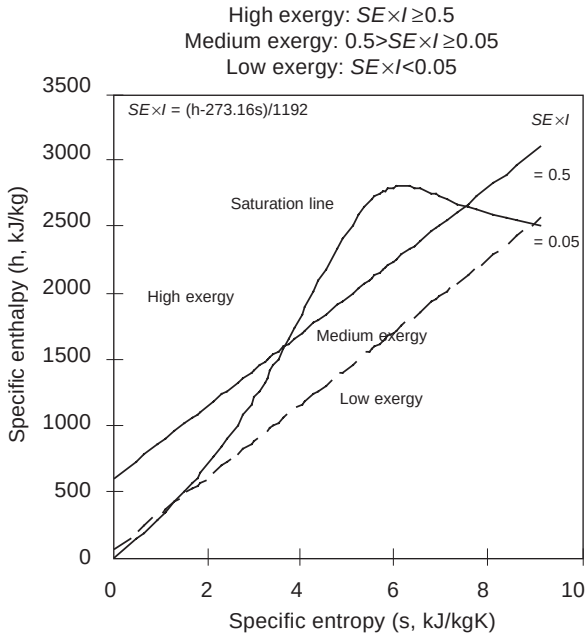

FIGURE 1 Classification of geothermal resources by exergy. Reproduced from Lee (2001).

The average earth's temperature gradient for the top 10 km from the surface is approximately 30°C/km. Places with gradient greater than 40°C/km are designated as thermal areas. Thermal fields are thermal areas with subsurface permeability that allows a fluid to convey deep-seated heat to the surface. Some thermal areas have 90°C/km gradient. The gradient can be higher in active volcanic areas.

Indicators of geothermal resources are surface thermal manifestations. However, a lack of surface manifestations does not imply a lack of geothermal resources (e.g., hot dry rock [HDR] system, geopressured system). Surface manifestations can be divided into active and inactive manifestations. Active manifestations are associated with heat and fluid discharges, whereas inactive ones are cold-altered ground and sinter deposits. Examples of active manifestations include hot springs, geysers, fumaroles, solfataras, mud pools, hot pools, warm ground, steaming ground, hydrothermal eruption craters, and volcanoes. Altered ground has rocks whose minerals have changed chemically due to interactions with thermal fluids. Sinter deposits are chemicals precipitated out of the thermal fluids and persist when the thermal fluids stop discharging.

An ideal geothermal system consists of a heat source and a reservoir of geothermal fluid in a confined space accessible by drilling. Heat is transferred from the heat source to the reservoir, which in turn transfers heat to the earth's surface. The heat source is normally a magmatic intrusion at shallow depths (5–10 km). The reservoir is a volume of hot rock that is permeable so that water can flow in and out of it. Because of the high pressure and temperature in the reservoir, the water tends to absorb gases such as carbon dioxide and hydrogen sulfide and to dissolve solid chemicals such as silica, calcite, and salts. When the geothermal fluid is withdrawn from the reservoir, pressure in the reservoir is likely to decrease, and this will cause more cold water to flow into the reservoir to be heated up again. This is the ideal renewable or sustainable geothermal system.

An HDR geothermal system contains a reservoir of hot rock that is not permeable. Research has been carried out to create permeability in the rock by hydrofracturing with water at very high pressure after drilling into the reservoir. Temperatures of 200°C have been measured in HDR at a depth of 3 km, and HDR systems of up to 10 km deep are being researched.

A geopressured geothermal system consists of a reservoir that is totally confined and contains water at very high pressure. There is no recharge of the reservoir water, which is usually saline. The presence of a geopressured system is most likely in a deep sedimentary basin. Pressures of 400 to 1000 bar abs and temperatures of 100 to 200°C at a depth of approximately 3 km are said to be typical.

A geothermal resource is normally "discovered" by geoscientific exploration. The exploration program normally follows the sequence of reconnaissance, prefeasibility, and feasibility studies. Geologists identify any geothermal surface manifestations and make geological and hydrological studies. These studies are important for all subsequent work, including siting of exploration and production wells. Geochemists study the chemistry of geothermal fluids on the surface to determine the type of geothermal system and estimate the reservoir fluid temperature. Geophysicists measure physical parameters such as heat flow, temperature, electrical conductivity, gravity, and

magnetism of the rocks. The information can be used to deduce the shape, size, depth, and capacity of the deep geothermal reservoir. Exploration wells are then drilled to confirm the power potential of the geothermal resource.

In a geothermal power project, the most important factor is the capacity and life of the resource. Unlike an oil reservoir that is exhausted when the oil is completely extracted, a geothermal reservoir can have its reservoir fluids replaced. This recharge of the geothermal reservoir fluids is an important process that controls the behavior of the reservoir. The study of recharge behavior is by means of geothermal reservoir engineering. Geological and well test data are normally analyzed using reservoir modeling computer software to estimate the capacity and life of the resource.

2. GEOTHERMAL POWER CYCLES

When a geothermal resource has been deemed suitable for power generation, a decision is required to select a suitable power cycle. A power cycle consists of a series of thermodynamic processes that converts heat energy to electricity. The most common geothermal power cycle is the Rankine cycle, consisting of two isothermal and two adiabatic processes. More than one power cycle can be used for a geothermal resource. Indeed, other direct uses can be combined with power generation.

Geothermal power cycles can be classified into five major types: steam Rankine cycle, organic Rankine cycle (ORC), total flow cycle, Kalina cycle system (KCS), and trilateral flash cycle (TFC). ORC, KCS, and TFC are binary cycles that use geothermal fluids as the primary heat source to vaporize a secondary fluid for power generation. Currently, nearly all geothermal power plants use steam or ORC or a combination of the two. There are several total flow machines, but they are not widely used. The first pilot Kalina geothermal power plant was commissioned in Iceland in 2000. TFC is still at the experimental stage.

The following subsections examine the various power cycles based on the types of geothermal resources.

2.1 Dry Steam (Vapor-Dominated) Systems

Dry steam systems are rare, but they have high power capacity and are currently producing approximately 50% of total world geothermal electrical power.

Conceptually, the power cycle for dry steam geothermal systems is the simplest: saturated or slightly superheated dry geothermal steam from wells is piped directly to condensing steam turbines (Fig. 2). The condensate is reinjected for environmental reasons. Other problems associated with solids and gases carried in the steam have to be addressed. Solids are removed using a trapping device before they reach the turbines, and gases are removed from the condensers by a gas extraction system. The gases are mainly carbon dioxide ($>90\%$) and some hydrogen sulfide. Depending on the environmental protection law, the hydrogen sulfide might need to be treated by a chemical process.

2.2 Two-Phase (Liquid-Dominated) Systems

Two-phase systems are liquid-dominated systems. In two-phase geothermal systems, the geothermal fluids contain both water and steam at roughly an equal weight ratio (i.e., dryness, $x \sim 0.5$) at the wellhead. The water phase needs to be removed by a separator, and the steam is piped to the steam turbines (Fig. 3). The separated water can be reinjected directly or, depending on the fluid pressure, can be flashed to produce a lower pressure steam for power generation before being reinjected (Fig. 4).

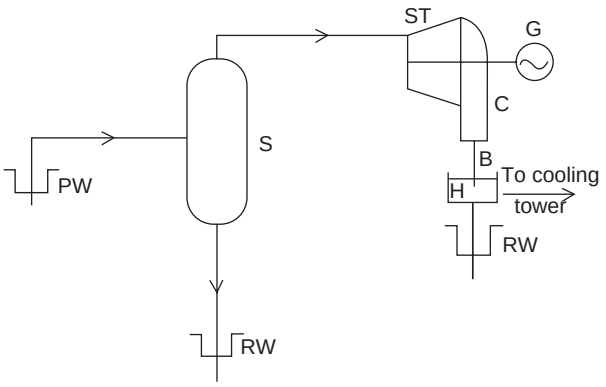

FIGURE 3 Power cycle for single-pressure hot water or two-phase geothermal systems. B, barometric leg; C, condenser; G, generator; H, hot well; PW, production well; RW, reinjection well; S, separator; ST, steam turbine.

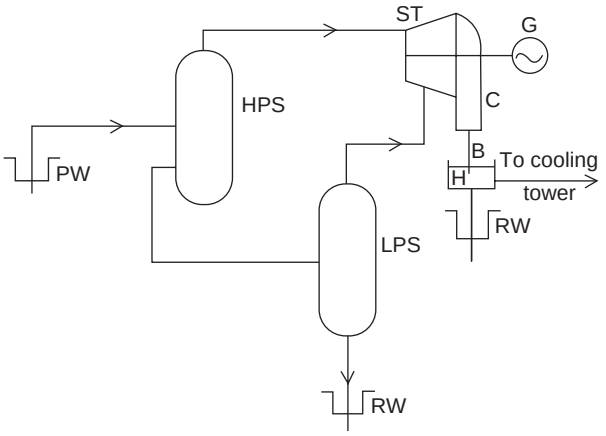

FIGURE 4 Power cycle for dual-pressure hot water or two-phase geothermal systems. B, barometric leg; C, condenser; G, generator; H, hot well; HPS, high-pressure separator; LPS, low-pressure separator; PW, production well; RW, reinjection well; ST, steam turbine.

2.3 Hot Water (Liquid-Dominated) Systems

Hot water systems are the most common geothermal systems suitable for power generation. In a hot water system, both the liquid and steam phases appear at the wellhead because the water flashes as it ascends the wells. The dryness fraction at the wellheads is normally less than 0.3. Depending on the wellhead pressures, the power cycle selected can be a single-pressure steam system (Fig. 3) or a dual-pressure one (Fig. 4). It is common to flash the water phase to produce more steam in a low-pressure flasher or separator. In practice, there is no real distinction between a flasher and a separator. Both are pressure

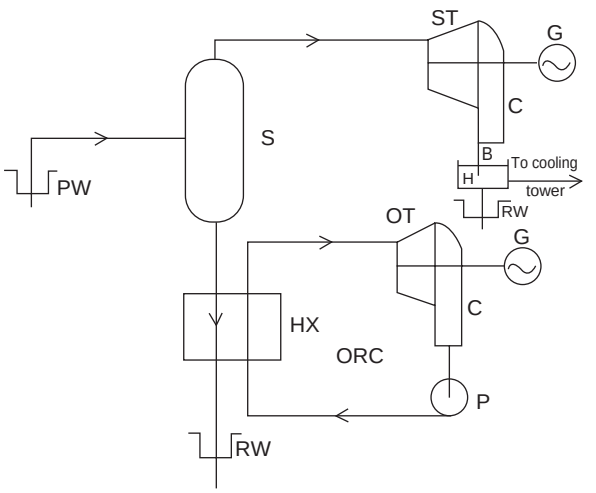

FIGURE 5 Power cycle for hot water or two-phase geothermal systems with binary ORC. B, barometric leg; C, condenser; G, generator; H, hot well; HX, heat exchanger; OT, organic vapor turbine; P, pump; PW, production well; RW, reinjection well; S, separator; ST, steam turbine.

vessels, and both have the function of separating the liquid from the steam phases. The flashing is normally done by a throttling orifice or valve installed upstream of the flash vessel. However, to maintain the large volume of low-pressure flashed steam, a flasher is normally larger than a high-pressure separator. Wairakei originally had a three-pressure steam system, but it was down-rated to a two-pressure system in 1983 because the steamfield drawdown could not sustain the high-pressure steam.

Nowadays, it is common to use the separated water for an ORC (Fig. 5). Exhaust steam from a back pressure turbine can also be used for a separate ORC (Fig. 6). For a hot water system that has a low dryness fraction, high gas content, or corrosive fluids, the steam Rankine cycle is unsuitable. A total flow or binary cycle (ORC, KCS, or TFC) may be used.

In a total flow cycle, the entire geothermal fluids from the wells are fed to a total flow machine that is robust enough to accept two-phase fluids (Fig. 7). The materials of construction can be selected to withstand the corrosive fluids. The helical screw expander is the first total flow machine to be developed and is now also used to generate electricity from waste heat in other industries. Other total flow machines are the biphase turbine and the Robertson engine.

In an ORC, the geothermal fluids are used to vaporize a low-boiling point (30–40°C) fluid, such as isopentane or isobutane, to very high pressure (15–20 bars), and this fluid is then used to provide the motive force for a vapor turbine. The advantage

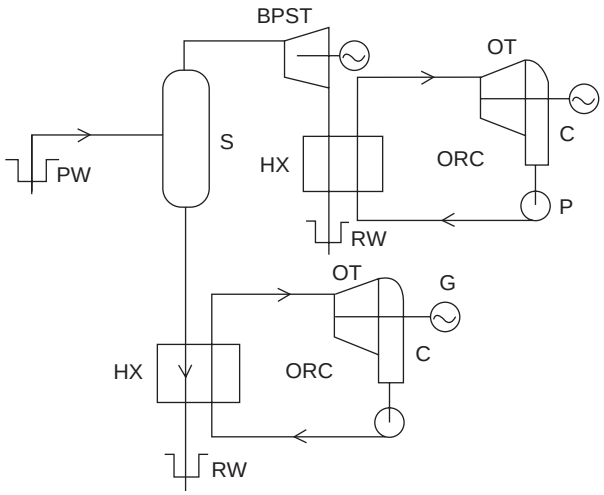

FIGURE 6 Power cycle for hot water systems with back pressure steam turbine (BPST) and binary ORC. See Fig. 5 caption for abbreviations.

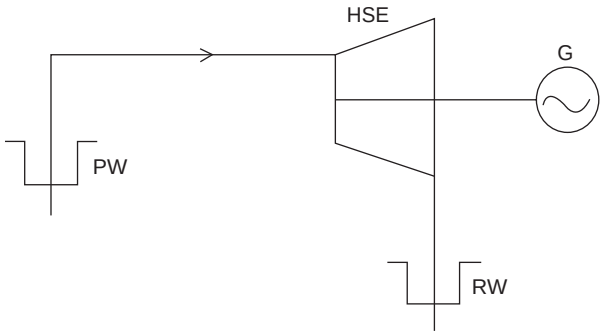

FIGURE 7 Total flow power cycle for hot water geothermal systems. G, generator; HSE, helical screw expander; PW, production well; RW, reinjection well.

of the binary ORC is that geothermal fluids with a temperature as low as 80°C can be used to generate electricity (Fig. 8).

A Kalina power cycle makes use of a mixture of two fluids in the secondary loop of the power cycle. It is considered a family of power cycle systems because not only can the ratio of the mixture of fluids vary with the temperature of the heat source, but different fluids also can be used for the mixture. An ammonia/water mixture appears to be the most suitable for geothermal applications. A pilot Kalina cycle geothermal power plant was commissioned in Iceland in 2000 and tested successfully using a geothermal fluid temperature of 121°C.

TFC, developed in 1993, is the latest binary power cycle. The concept of TFC is to improve the heat transfer process between the geothermal fluid and the secondary working fluid by keeping the working fluid

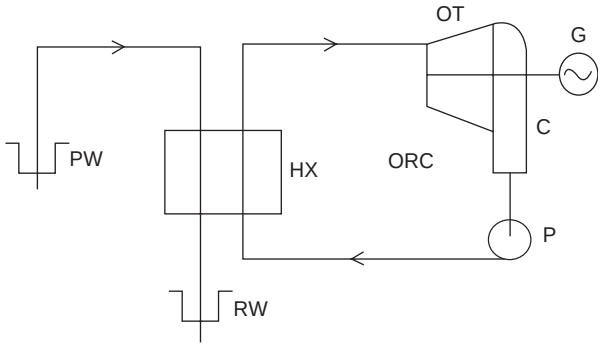

FIGURE 8 Binary ORC power cycle for hot water geothermal systems. See Fig. 5 caption for abbreviations.

as pressurized liquid, which is then used to power a helical screw expander. The best working fluid is still being researched, but low hydrocarbons appear to be most suitable.

2.4 Hot Dry Rock

HDR geothermal technology is still in the research stage. The concept is to drill two wells into hot rocks at a depth of 5 to 10 km, where the temperature gradient is high (70–90°C/km). Cold water is pumped into one well and pressurized to cause fractures in the hot rocks so that pressurized hot water flows up the other well. This is equivalent to an artificial liquid-dominated geothermal system. Power cycles suitable for natural hot water systems would be suitable for the HDR system.

2.5 Geopressured Geothermal System

A geopressured system of 1000 bar abs and 100°C is equivalent to an average hot water system in its ability to produce electricity. Because this is still at an early research stage, no power cycles have been proposed for a geopressured system, although the total flow power cycle using a helical screw expander appears to be most suitable.

3. GEOTHERMAL DRILLING

Geothermal drilling technology is adapted from the oil industry. Most of the geothermal wells are drilled with a rotary-type drilling rig. Because of the hard, abrasive, and high-temperature volcanic rocks of geothermal systems, the drilling bits require hard abrasive resistant teeth such as diamond or tungsten carbide. Hence, geothermal drilling is an expensive

activity in geothermal development. Most geothermal wells are drilled 1 to 2 km deep to intersect faults and fractures so as to increase the success rate of production from permeable zones. This is enhanced by directional or deviated wells as opposed to vertical wells of earlier development. Directional drilling also allows drilling of more than one well on a single well pad, especially in difficult terrains. A geothermal well typically costs U.S. $1 million and increases exponentially with depth. Geothermal drilling may be divided into three types: exploration, production, and reinjection.

Exploration drilling is carried out to assist earth scientists investigating a geothermal resource. Geologists will study the drill cuttings and drill cores of exploration wells that are normally drilled vertically and in small diameters (100–150 mm or 4–6 inches). It is not uncommon to make continuous drill cores from exploration wells so that the subsurface geology of the geothermal area can be confirmed. Exploration wells may be productive, and geothermal fluids discharged from the wells will confirm the chemistry of the fluids from earlier geochemistry studies.

Production wells are drilled after data from exploration wells have proven that a geothermal resource is economically viable in terms of its expected generating capacity and life. Geothermal fields of earlier development, such as Wairakei and Cerro Prieto, have vertical wells drilled to approximately 1 km deep. The fields have flat terrains, and wells are spaced as close as 20 m from each other. Nowadays, it is common to have several production wells drilled from a single well pad using directional drilling. Modern production wells are typically 2 km deep and may be deviated 1 km away from the well pad. Typical production wells have 250-mm ($9^5/_8$-inch) diameter production casing. Some large geothermal fields in The Philippines have large (500-mm or 20-inch) diameter production casing. (Note: As drilling is adapted from the oil industry dominated by the United States, the unit used is imperial.)

For environmental reasons, modern practices reinject most, if not all, geothermal fluids produced from the production wells back into the ground after the energy has been used. This is achieved by piping the spent geothermal fluids to reinjection wells. Reinjection wells are drilled similarly to the production wells. Good reinjection wells require as much permeability as do production wells to swallow the reinjected fluids. Hence, a good production well makes a good reinjection well. The reinjection may require pumping to achieve the required injection rate. However, reinjection of cooler geothermal fluids back into the ground may cool the hot fluids from production wells. Hence, reinjection wells are normally located either downstream of the flow direction of the geothermal fluids in the reservoir or at the edges of the production field so that reinjected fluids flow away from production zones.

A well is drilled by a rotating drilling bit (commonly a tricone bit with a tungsten carbide insert), with an additional load applied to it from the weight of a thick wall tube called the drill collar. The rotating motion comes from a rotating table with a square hole that transmits torque to a square tube known as the kelly. The kelly is connected to the drill collar by drill pipes to form the drill string. Drill pipes have a thinner wall than does the drill collar. The drill string is smaller in diameter than the hole being drilled, allowing a drilling fluid to be pumped down inside the drill string, clearing the cuttings around the drill bit, and carrying the cuttings up via the annulus between the hole and the drill string.

The drilling of a typical production well (Fig. 9) commences by drilling a large diameter hole (24–26 inches) up to approximately 50 m. A 20- to 22-inch outer diameter pipe (casing) is then cemented in the hole. The cementation is achieved by pumping a cement slurry down inside the casing and flowing up the annulus. The cement inside the casing is then displaced by water to just above the bottom of the casing (shoe). When the cement has set, a drilling wellhead with blowout preventer (BOP) is erected, controlling accidental discharge of geothermal fluid during drilling. Drilling continues with a smaller diameter hole (17.5 inches) for a $13^3/_8$-inch casing from the top of the cement near the casing shoe to the next casing depth. This sequence is repeated until three or four casings are cemented to a depth assessed to be the top of the desired production zone in the reservoir. The final casing is called the production casing, usually $9^5/_8$ inches in a $12^1/_4$-inch hole. In general, the shallow outer casings are required for drilling operations, whereas the inner casings are for production purposes. These casings not only control the geothermal fluids flowing inside the production casing but also prevent cold fluids outside from entering the well.

When the final section of the hole (8.5 inches) is completed in the production zone, a 7-inch casing with holes (slotted liner) is usually used to line the well. Unlike other casings, the liner is not cemented into place. It can be sitting at the bottom of the well or hanging from the production casing shoe. The liner prevents the production formation at the hole from collapsing and allows the geothermal fluids to

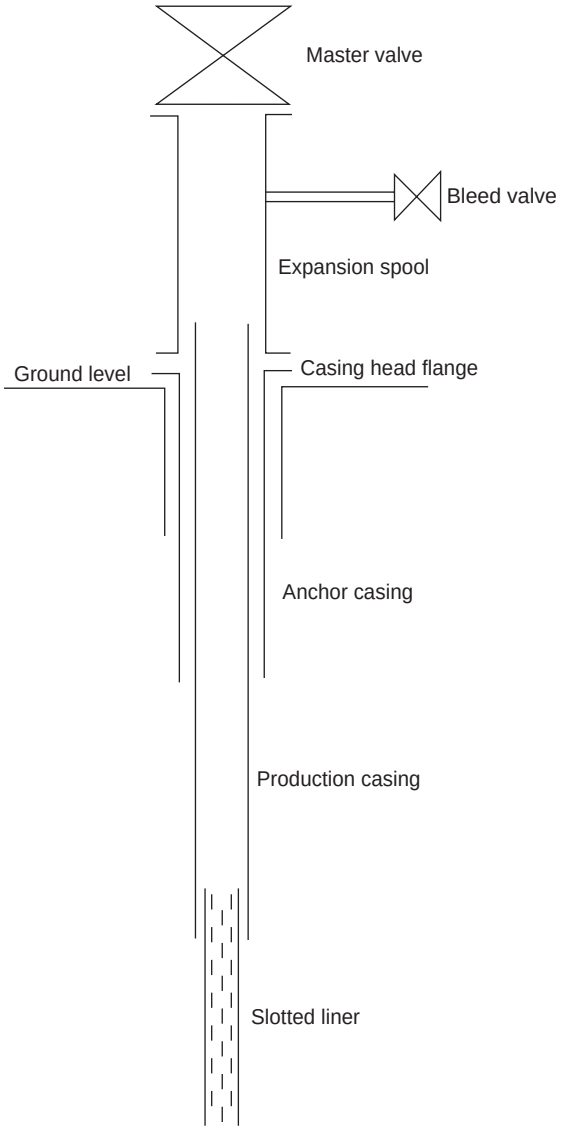

FIGURE 9 A typical well casing layout.

enter the well and flow up inside the production casing. A wellhead consisting of flanges, valves, and pipe spools is usually attached to the top of one of the intermediate cemented casings. The production casing is allowed to expand into a wellhead pipe spool during production of the hot fluids.

Because the safety of the drilling rig and the completed well can be at risk for an unstable well site, a complete geotechnical investigation might be necessary before site construction. Of particular concern is the possibility of a shallow blowout during drilling in areas with shallow permeable rock formation. To prevent this, consolidated grouting of the drilling site is carried out. This involves drilling and cementing slim holes to depths of 10 to 30 m around the drilling site. This will direct any accidental blowout discharge of geothermal fluids away from the drilling rig.

A reliable supply of water is essential for safe drilling operation. Water is required for the drilling fluid—usually mud, cementing, quenching, or controlling a well from discharging. Water is also used as the drilling fluid when total loss of circulation is encountered, especially in the production zone, to prevent sealing of the production zone by drilling mud. A typical production geothermal well requires a reliable water supply of 2 m^3/min.

An important factor in drilling a geothermal well is to prevent the well from discharging during drilling. This is achieved by having the column of drilling fluid create a pressure greater than the fluid pressure in the reservoir formation. To increase the density of the drilling fluid, bentonite is commonly added to the drilling fluid to form drilling mud. There are other advantages in drilling with mud. It can keep drill cuttings in suspension in the event of stoppage during the drilling operations such as connection of additional drill pipes. However, drilling with mud also has its drawback. When a production zone is hit, the drilling mud, having higher pressure than the formation, will flow into the production zone fractures, effectively sealing the production zone. Hence, alternative drilling fluids that will not seal the production zone should be used when drilling in the production zone. These can be aerated water, foam, or air. In such situations, the practice of balance drilling is best such that the drilling fluid pressure balances the formation pressure.

4. GEOTHERMAL STEAM PRODUCTION FIELDS

Geothermal wells need to undergo a test program before they are used. This is so that the baseline conditions of both the wells and the geothermal aquifers that they tap can be determined. This baseline data are critical because all future information is compared against them.

After drilling has been completed and before the initial discharge, the well downhole conditions are measured. The temperature and pressure are measured by using a clockwork Kuster gauge or electronic logging tools. Standard practice is to initially do an injection (or completion) test, that is, sometime at a series of flows, where the temperature, pressure, and possibly flows using a spinner tool are

measured at intervals down the open hole section of the well. The well is then shut in and allowed to fully heat up. This can take less than 1 day (e.g., for a steam well) to more than 6 months (e.g., for a deep well with poor permeability). The downhole conditions during heat-up are also measured at intervals. The well is shut in to minimize circulation so that conditions in the cased-off section can be measured and so that the gas column can depress the liquid in the well to the upper feed zone. The downhole measurements will reveal the production zones in a well because hot geothermal fluids circulating at the production zones will cause these areas to heat up faster. The pressure profile of a well can reveal the water level in the well. The water level can also be determined by lowering a float into the well.

Once the new well is fully heated, it needs to be discharged to rid it of drilling mud, fluid, and debris before the well can be put into service. The initial discharge is normally a vertical one due to the erosive nature of the materials. The well is then tested to determine its output characteristics, that is, mass flow rate and enthalpy as a function of wellhead pressure (Fig. 10). Chemical sampling is also done during this output test. These data are very important because they comprise the baseline information.

The well output can be measured by several methods. For a small well discharge, a simple calorimeter can be used. The well output is discharged into a large vessel containing a mass of cold water. A heat balance will determine the output.

A method unique to the geothermal well test is the James lip pressure method. This method makes use of discharging two-phase fluid at choked flow conditions through an open pipe. By measuring the static "lip" pressure at the open end of the pipe, the flow rate can be determined from a correlating equation. The equation now is in several forms. The original equation in imperial units is

$$G = 11400\ P^{0.96}/h^{1.102},$$

where G = flow in pounds/(s feet^2) of the lip pressure discharge pipe cross-section area, P = lip pressure in psia, and h = fluid enthalpy in Btu/pound.

In metric units, the equation is

$$G = 0.184\ P^{0.96}/h^{1.102},$$

where G = tonnes/(s cm^2), P = bar absolute, and h = kJ/kg.

The lip pressure method requires knowledge of the fluid enthalpy. However, the equation is relatively insensitive to enthalpy, so it can be estimated if not known. From experience, it is known that the discharge shape of the fluid at the lip pressure pipe will give some indication of the enthalpy. An estimate can also be made if the downhole conditions are known. If the fluid is known to be saturated water at a certain pressure during drilling, the enthalpy is also known. If the discharge is made into a silencer and the water flow rate is measured by a weir plate, the total mass flow can be determined. A quick estimate of the heat discharge or power potential of a well can be made by the lip pressure method during the first well vertical discharge. This number is useful for planning of the surface equipment for further tests.

A well output is most accurately measured by the separator method. The well is discharged into a separator. The steam phase is measured in a steam pipe using an orifice plate or Annubar, and the water is measured by a weir plate in a weir box at the silencer. The water flow rate needs to be corrected for that flashed in the silencer. However, this method is expensive. Production well surface equipment is normally designed to allow regular output tests with minimum disruption.

There are other well tests, such as downhole well pressure and temperature measurements, that are normally done with the well on bleed. Once a well has been initially discharged, it should not be completely shut off because a column of cold water may form in the well, preventing the well from discharging again without stimulation.

The discharge of a well may interfere with the flow of a nearby well. Interference tests can be done by either measuring the downhole pressures or measuring the discharge from a well while a nearby well is discharging at different flow rates.

After enough wells have been tested to confirm the geothermal field's capacity and suitability for the production of electricity, steamfield design needs to be carried out. It can be carried out in parallel with

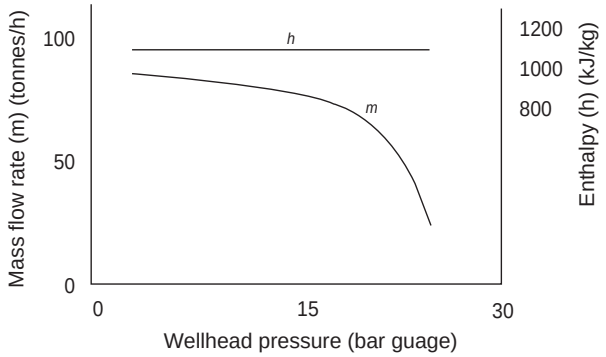

FIGURE 10 A typical geothermal well output characteristics.

further production well drilling. This is to determine the best method for collecting the geothermal fluids from the wells and processing them, especially when the geothermal fluids are two-phase ones. In general, a geothermal steamfield consists of the following major plants and equipment: the wells, the wellhead, the flasher/separator for a wet field, the silencer, fluid transmission pipelines, and a reinjection system.

4.1 The Wells

The use of a geothermal resource depends entirely on the output from the wells. A well's output can vary significantly from that of a typical well (Fig. 10). An example is the cycling wells that have fluctuating mass output with a cycle time as short as a few minutes. This type of well is not suitable for power production unless it can be balanced by stable output wells. Another type of problem well is one that continuously discharges solids with the well fluids. Sometimes this problem can be solved by throttling, but generally a dirty well is not used for production.

4.2 The Wellhead

A typical wellhead consists of several valves to provide service functions required (Fig. 11). The master valve is for completely shutting off the well. A small side valve is installed below the master valve to "bleed" the well when the main flow is shut off. It is not a good practice to completely shut in the well because the well may cool down and a column of cold water may sit in the well, preventing the well from discharging when the master valve is reopened. There may also be casing and cement damage from the thermal cycling. The well can flow again only when the column of water is removed by stimulation. Well stimulation is normally carried out by pumping air at the bottom of the well to airlift the flow. It can also be done by pumping steam or air into the well to depress the water column and then releasing the pressure quickly. Bleeding allows the well to stay hot.

It is difficult and costly to replace a master valve. A procedure must be in place to reduce damage during operation. A master valve is normally replaced by plugging the well below the master valve level, and this process normally requires a drilling rig. Some wells can be quenched by cold water injection through the bleed valves, allowing the valve to be changed. Because the master valve is so critical, it should be opened or shut only when there is no flow and should always be in either a completely shut or a fully open position. A sacrificial service valve is installed downstream of the master valve. The service valve can be used for throttling, but long-term throttling of a well is normally done using a throttling orifice.

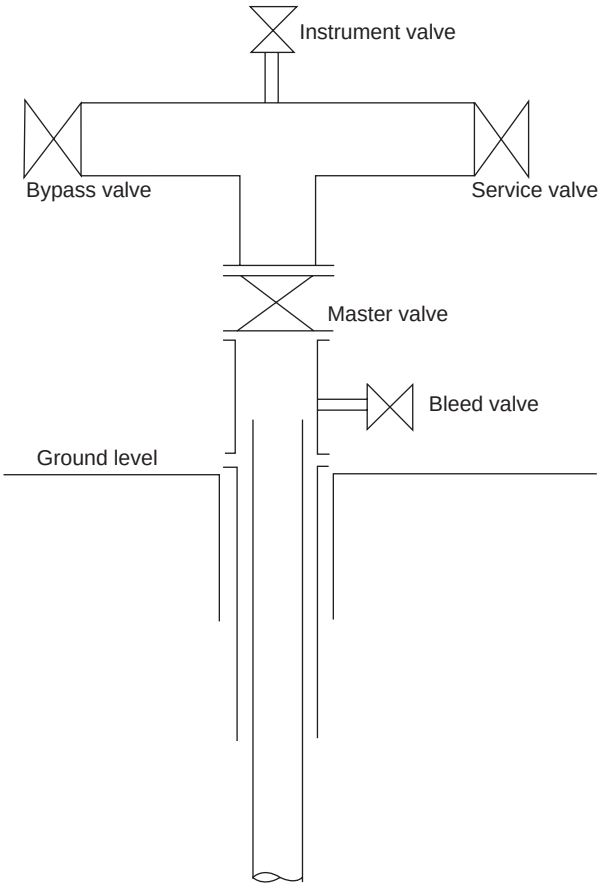

FIGURE 11 A typical wellhead and its valves' arrangement.

The service valve is commonly installed vertically above the master valve. It can be used to admit an instrument such as a Kuster gauge. The instrument is first lowered to sit above the shut master valve. The instrument is hung on a stainless steel wire that runs through a gland packing. The master valve is opened only after the gland packing is in place. The flanged spool with the gland system is called the recovery tube.

It is not common to make downhole measurements while a well is flowing. The instrument needs a long sinker bar to counter the buoyancy of the discharge. This means that a long recovery tube is needed. The flowing survey data are generally meaningful only if the well has a liquid feed zone of good permeability.

The bypass valve is required when the output of the well is not required for power generation for a short period, or for other reasons (e.g., tests, emergencies), and the well is not shut off due to possible interference. The flow is diverted through the bypass valve to a

silencer. For environmental reasons, discharge to waste via the silencer is not done unless necessary.

The arrangement of the wellhead valves normally results in the top service valve being several metros above the casing head flange. Earlier designs were to install the casing head flange in a deep cellar or at ground level, and a platform was built to access the service valve. Nowadays, a deep cellar is not preferred because hydrogen sulfide and carbon dioxide, being heavier than air, can accumulate in such a cellar, causing a lethal hazard. The preferred option is to install the casing head flange at ground level and have a tee piece just above the master valve and the service valve on the horizontal pipework. A small instrument valve or a blind flange is installed on the tee piece directly above the master valve.

4.3 The Flasher/Separator

Although sometimes a flasher is differentiated from a separator, the two are the same pressure vessel in practice. A flasher allows high-pressure geothermal water to flash at a lower pressure. In practice, the lower pressure is achieved by a throttling orifice or valve upstream of the flasher/separator. The vessel then separates the two phases by centrifugal and gravity effects.

The modern separators differ in many aspects from those first used at Wairakei during the 1950s. They differ in size, location, body arrangement, separated water vessel, two-phase inlet nozzle, water outlet nozzle, steam outlet nozzle, and efficiency. The original Wairakei separators were wellhead separators. Each wellhead has its own small separator handling the capacity of a single well. It can be as small as 750 mm diameter and 2 m high, handling about 20 tonnes/h of steam. A modern separator can be larger than 3 m in diameter and 15 m high, and it operates as a separation plant, accepting well output of several large wells. It can handle 600 tonnes/h of steam and is rated at more than 60 MWe.

The earliest separators at Wairakei were the Woods type, and some are still operating there today. A Woods separator has a U-bend-type separator operating in series with a top steam outlet cyclone separator that has a tangential two-phase inlet nozzle. The later design was the significantly cheaper Weber type with a bottom steam outlet (Fig. 12). A modern separator has a spiral inlet nozzle. This spiral inlet design increases the capacity of the separator by increasing the inlet superficial steam velocity from 20 to 40 m/s before the separation process breaks down. The water outlet nozzle is installed at the bottom of the body exiting from the side. This is to improve the efficiency of water discharge to the water vessel, minimize erosion if the water is laden with solids, and minimize the risk of debris entering or blocking the water outlet pipe. The Weber separator has an efficiency that produces steam dryness exceeding 99.9% at design flow rates.

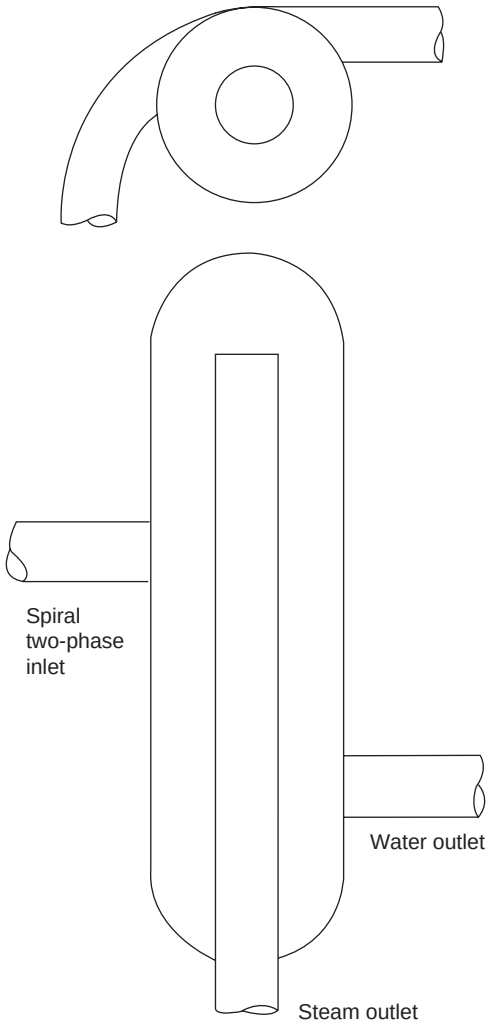

FIGURE 12 A common Weber-type geothermal separator.

A modern separator design is an integral design that does not have a separate water vessel. Some modern designs incorporate an integral horizontal water vessel to reduce the height. To reduce height and earthquake effect further, large horizontal separators can be used.

4.4 The Silencer

A geothermal silencer is like a separator operating at atmospheric pressure. It is normally connected directly to a well and a separation plant for bypass

or emergency discharge. The silencer reduces the high-frequency noise discharging from an open pipe to a low-frequency rumbling noise that is more bearable to human ears. The earlier Wairakei silencer design consisted of twin barrels, and the body was made of timber. The modern silencer design consists of a single barrel made of corrosion-resistant steel, sometimes internally lined with concrete (Fig. 13). Fiberglass barrels worked well for silencers not in constant use. Some new silencer designs have a cone fitted at the top of the barrel to increase the steam velocity so that it is dispersed farther away from the silencer area. The noise can be further attenuated with an annulus full of scoria rock in the silencer barrel.

For a dry steamfield, a silencer is commonly just a pit full of rocks. A bypass pipeline discharges the dry steam at the bottom of the pit.

4.5 Fluid Transmission Pipelines

Many kilometers of pipelines are required in a geothermal steamfield to transport geothermal fluids from the wells and ultimately to the power plant. The geothermal fluids can be a two-phase steam/water mixture, separated steam, or separated water. All of the pipelines together with the separators, valves, and other plants and equipment in a geothermal steamfield have been collectively known as the energy gathering system (EGS), steam gathering system (SGS), steam collection system (SCS), or fluid distribution and collection system (FDCS).

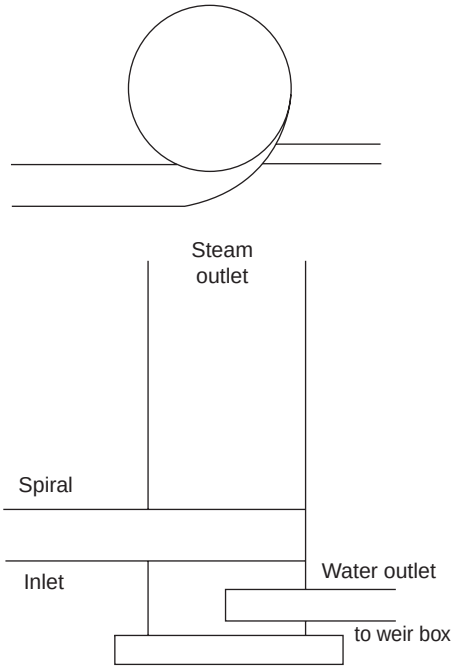

FIGURE 13 Modern single-barrel silencer.

When wet steamfields, such as Wairakei and Cerro Prieto, were first developed, geothermal two-phase flow was not well understood and two-phase pipelines were kept to a minimum. So, separators were installed at the wellheads, and separated water and steam were transported as single-phase fluids from the separators to the desired destinations. So, each wellhead had a complicated pipe network.

Nowadays, two-phase pipelines are used extensively to transport geothermal fluids from several wells to feed a separation plant. This design greatly simplifies the pipe network at each wellhead and the whole steamfield because it allows the use of fewer large diameter pipelines in the steamfield. Another more important advantage is that large diameter pipes cause less pressure loss of the fluid being transported, thereby conserving energy.

The location of a separation plant is important because it affects well outputs and the total pressure loss and, ultimately, the economics of the power project. Two other factors affect the location of the separation plant: steam quality and steam pressure control.

The efficiency of a separator can be 99.99%. For a large separation plant, there may be 500 kg/h of water carryover in the separated steam. This water carryover needs to be removed as much as possible before it reaches the steam turbines because the water carryover in droplets traveling at high velocity erodes the turbine blades or solids precipitated from the water deposit in the turbine nozzles, ultimately choking the turbine output. There are two ways in which to remove the water carryover. One is to install a demister or scrubber at the power station end. The other is to install drain pots along the steam pipelines. The drain pots do not work if the steam velocity is high and the water carryover travels as droplets with the steam. There is also a minimum number of drain pots spaced at a minimum distance apart for the drain pots to function properly. This means that there must be a minimum length of steam pipeline downstream of the separation plant to allow for the scrubbing of the steam phase.

The second factor is that a minimum pipe length, and hence volume, is also required for the pressure control system to function properly.

4.6 Reinjection System

A major problem with a liquid-dominated steamfield is the large quantity of separated water that requires

disposal. When Wairakei was developed roughly 50 years ago, environmental concerns were not an issue and the separated water system was designed to simply drain into the nearby Waikato River. Nowadays, the only acceptable method is reinjection (unless the field is situated near the sea). Either the water flows down the well by gravity or, more often, a pump is required to increase the injectivity of the well. A control system is generally required to stop flooding or steam carryover.

The location of a reinjection well is important. A reinjection well within a steamfield can replenish the geothermal fluid that has been withdrawn, but cooler reinjected fluid may break through to the production wells and cool the production fluids. Nowadays, the strategy is to reinject at the perimeter of the steamfield to minimize the risk of the cooling effect. A problem with this strategy is that the permeability on the margins is generally poor, so more wells are needed. The aquifer flow paths can also change under exploitation so that reinjection wells can have rapid returns to production areas where initial tracer tests showed no flow. In the steam-dominated field of The Geysers, waste sewage water is reinjected to replenish the drawdown of the field.

TABLE II

World Installed Geothermal Power Generating Capacity in 2000

Country	MWe
United States	2898.0
The Philippines	1909.0
Italy	785.0
Mexico	755.0
Indonesia	589.5
Japan	546.9
New Zealand	437.0
Iceland	170.0
El Salvador	161.0
Costa Rica	142.5
Nicaragua	70.0
Kenya	57.0
Guatemala	33.4
China	32.0
Russia	25.0
Turkey	20.4
Portugal (Azores)	16.0
Ethiopia	8.5
France (Guadeloupe)	4.2
Thailand	0.3
Australia	0.2
Total	**8661.0**

5. GEOTHERMAL POWER STATIONS

The total installed geothermal power generating capacity in the world is approximately 9000 MWe from 21 countries, with the United States leading at nearly 3000 MWe and The Philippines with nearly 2000 MWe (Table II). Other major countries are Italy, Mexico, Indonesia, Japan, and New Zealand, with between 400 and 800 MWe each.

Geothermal power stations have very high availability, load, and capacity factors ($>90\%$). They are most suitable as base load power stations. Liquid-dominated reservoirs are not suitable for peak load generation because two-phase flow and the separation process make their operations and control at changing flows difficult.

A geothermal power station that uses steam turbines to generate electricity is similar to a conventional fossil fuel-fired power station. The main differences are:

- Geothermal steam is usually saturated steam at less than 10 bar abs and 200°C (occasionally superheated up to $\sim$50 bar abs and 300°C), but in a fossil fuel-fired power station, the steam can be supercritical to as high as 300 bar abs and 600°C.
- Geothermal steam normally contains impurities of noncondensable gas (NCG) at up to a few percentage points by weight of steam (mainly carbon dioxide [$>90\%$] and a few percentage points of hydrogen sulfide) and dissolved solids (mainly silica or calcite) that precipitated from flashing of the liquid phase.
- A fossil fuel-fired power station has a boiler and the steam/water is in a closed loop, whereas a geothermal power station does not have a boiler and the steam/water is in an open loop.

Because of the low-pressure saturated steam, a geothermal steam turbine unit is limited to a maximum capacity of approximately 55-MWe condensing unit due to the maximum length of the last-stage turbine blades limited by the material metallurgy. Two of these turbines can be installed on a single shaft to a 110-MWe generator.

The NCG is allowed to pass through the steam turbines but must be removed from the condensers so

that the low subatmospheric pressure in the condensers can be maintained. A gas extraction system is used to remove the NCG from the condensers. A steam jet ejector is suitable for low gas contents of less than 1% weight of steam. A steam jet ejector has no moving parts, so it is easy to operate and has a low maintenance cost. However, the steam flow used to drive it is high (~five times the NCG flow rate). Hence, steam jet ejectors are suitable only for low NCG levels. The NCG removed from the condensers is normally exhausted to the atmosphere.

For economic reasons, a gas exhauster is required when the gas contents exceed 2%. This is normally a multistage centrifugal compressor with an intercooler. Recirculation valves between the stages are necessary for control. It is typical to drive the compressor by electric motor, but the compressor can be driven by the steam turbine.

A liquid ring pump can be used to replace the final-stage steam jet ejector to improve efficiency and economy. Liquid ring pump systems are used in fossil fuel-fired power stations to maintain condenser vacuum. They have a small capacity, so they are suitable only for low gas contents.

The condensers mentioned previously are direct-contact condensers. Shell and tube condensers can also be used to better control NCG emissions. However, shell and tube condensers are expensive and less efficient.

When a geothermal resource cannot produce a sufficient quantity of clean enough steam to drive steam turbines, other modes of power generations need to be used. If the steam contains too much NCG (>10% weight of steam), a condensing turbine unit becomes uneconomical. In such a case, a back pressure turbine that does not have an after-condenser can be used. The steam is exhausted directly to the atmosphere, but this mode of generation is unlikely to be acceptable nowadays for environmental reasons. Either total flow or binary mode of generation needs to be used.

Many geothermal ORC binary plants are in operation around the world. A heat exchanger (shell and tube type) is used to transfer heat from the geothermal fluids to a low-boiling point secondary fluid (isopentane or isobutane). The secondary fluid superheated vapor drives a vapor turbine that exhausts to an air-cooled shell and tube condenser. The secondary fluid is in a closed loop, and the spent geothermal fluids are reinjected.

Whereas an ORC binary plant usually uses an air-cooled condenser, a typical condensing steam turbine unit uses a direct-contact condenser. The resultant condensate/cooling water mixture is normally removed from the condenser via a barometric leg or a pump. This condensate mixture flows to a holding pond known as the hot well, and from there it is pumped to a cooling tower to be cooled for recirculation to the condensers. As the geothermal steam from the steamfield eventually becomes a part of the recirculating cooling water, the total volume of the recirculating water tends to increase, even though some is evaporated at the cooling tower. Hence, some of the condensate mixture is reinjected from the hot well. Because this condensate mixture is warm (~40°C) and oxygenated, it is quite corrosive to carbon steel. Stainless steel pumps, pipes, and well casing are required for condensate reinjection.

Two types of cooling towers are commonly used for a geothermal power station: natural draft and mechanical draft cooling towers. For economic reasons, a natural draft cooling tower is built for an approximately 100-MWe capacity geothermal power station. Natural draft cooling towers also function better in a cooler climate. For warm climates, mechanical draft cooling towers are more suitable. Because the fan of a mechanical draft cooling tower is limited by the length of the its blades due to the strength of the construction material, a mechanical draft cooling tower has a small capacity. So, mechanical draft cooling towers are normally built as rows of cells.

6. ENVIRONMENTAL IMPACTS AND OTHER TECHNICAL PROBLEMS

Geothermal power stations have their own unique developmental, operational, technical, and environmental problems. Many geothermal resources occur in or near national parks or remote uninhabitable locations because they are normally associated with volcanoes and have beautiful surface manifestations and so become public reserves and tourism hot spots. Most of these geothermal resources do not get developed for power generation. Examples include Yellowstone Park in the United States and Orakei Korako Geyserland in New Zealand. However, geothermal resources that exhibit little surface manifestation in national parks do get developed. Examples include Hatchobaru and Otake in Japan.

Volcanoes, and hence geothermal resources, are also associated with mythical power and beliefs. The development of these geothermal resources requires much consultation and negotiation with

the natives inhabited in the areas. The final development of these resources normally includes some forms of partnership and reparation for the natives. Examples include Mount Apo in The Philippines and Ohaaki in New Zealand.

The development of a geothermal power project will have environmental impacts on the physical surroundings as well as on the socioeconomics and health of the surrounding communities. The physical environment includes the land, water, air, flora, and fauna. Most countries have strict environmental legislation such as the National Environmental Policy Act (NEPA) in the United States and the Resource Management Act (RMA) in New Zealand. The most important requirement of the environmental laws is the environmental impact report (EIR). This report is also called the environmental assessment (EA), environmental impact assessment (EIA), environmental impact statement (EIS), and assessment of environmental effects (AEE). The acts mandate processes that must be followed for the assessment and suggestions for any preventive and mitigating measures. Any disagreement may be redressed in an environment court. The EIR normally follows a checklist of environmental impacts. The positive result of an EIR is an environmental permit or consent, approved and issued based on the technical, environmental, and social acceptability of the proposed project.

Every geothermal resource is unique; hence, the actual physical environmental impacts of a geothermal power project development and its subsequent operation vary from one project to another. Some examples of the common physical environmental impacts are described next.

The land may be unstable, so any development may trigger landslide or soil erosion that could be made worse in areas of heavy rainfall. This is particularly true for many geothermal systems in difficult terrain associated with volcanic environments. Examples of geothermal systems with difficult terrain include The Geysers in the United States and Leyte in The Philippines. The actual land area required for a geothermal power plant is relatively small compared with that needed for other types of power plants when the areas of the resources are taken into account. A 100-MWe geothermal power plant requires approximately 1 km^2 of land; a coal-fired power plant requires approximately 4 km^2, including the coal mining area; a hydropower station requires roughly 10 to 30 km^2; and a wind power station requires approximately 40 to 70 km^2. The land uses that are unique to a geothermal power plant are the pipeline corridors and geothermal well pads. Some geothermal areas are used for farming (e.g., Mokai and Rotokawa in New Zealand), but geothermal power plants and steamfields can coexist very well with other land uses such as farming and agriculture. Indeed, some development of geothermal systems provides aquaculture (e.g., prawn farm in Wairakei) and recreation (e.g., swimming pool at Svartsengi, Iceland).

Land subsidence is a common occurrence in geothermal development. Wairakei, after more than 40 years of operation, has a general subsidence of 10 to 30 mm/year over the whole steamfield. The maximum subsidence is approximately 250 mm/year, creating a small lake 18 m deep. Fortunately, the area of maximum subsidence is confined to a small area at the perimeter of the steamfield, causing minimal effects. Subsidence has also occurred at the Ohaaki after more than 20 years. It is difficult to predict land subsidence before the development of a geothermal steamfield. So, a monitoring program of the ground levels is required from the start of the development to ensure the safe operation of the steamfield as well as for environmental reasons. In general, the withdrawal of liquid from wet fields appears to cause greater subsidence than does withdrawal of steam only from dry fields.

The fluid production from a steamfield may also cause the surface manifestations to change, causing hydrothermal eruptions and creating new mud pools, fumaroles, and ground steam discharges. The changes to the "Craters of the Moon" near Wairakei are believed to be the result of fluid production at Wairakei. The withdrawal of geothermal fluids may also cause local micro earthquakes.

Gaseous discharge from the operation of a geothermal power plant is relatively small compared with that from the operation of a fossil fuel-fired power station. In general, the combustion of fossil fuels to generate electricity produces 3 to 20 times more carbon dioxide (kg/kWh) than that produced by a geothermal power plant. Although geothermal steam normally contains a small quantity of hydrogen sulfide that is not present in fossil fuels, the combustion of fossil fuels produces much more sulfur dioxide and nitrogen oxides that are not present in geothermal steam.

Water is required for the well drilling and construction phases. A circulating water system is required for the power plant during operation. Wet geothermal fields produce much separated geothermal water that requires disposal. The takings and discharges of water during the development,

construction, and operation stages all must be assessed for environmental impacts to the sources and sinks of water. All of these require water rights that are reviewed and monitored at regular periods.

Because the amount of land required for a geothermal power plant is relatively small, the effects on flora and fauna are also relatively small. However, being unique in nature, geothermal areas may also contain unique forms of flora and fauna. These flora (mostly fungi) and fauna (small organisms) may survive only in the warm areas of the geothermal activities. Their ecosystems might need to be protected and maintained.

Noise pollution of a geothermal power project will occur during the well drilling, construction, and operation phases. Because many geothermal areas are in remote areas where the background noise is very low ($\sim$40 dBA), any additional noise from geothermal activities will be heard by the local residents immediately. Impacts of noise on animals are reported to affect their behavior, physical size, and reproductive activities. Well drilling produces noise of 80 to 110 dBA, and a well discharging without a silencer produces 120 to 125 dBA of noise, which is at the threshold of pain for the human ear. The noise of a well discharging into a silencer is reduced to approximately 90 dBA.

Visual effects from a geothermal development include the tall drilling rig during drilling phases and the tall ($\sim$100-m) natural draft cooling tower if adopted. Wet mechanical draft cooling towers are much lower, but their plumes are much more visible. The plumes can be minimized with a wet and dry cooling tower. Visual impact of geothermal pipelines has been minimized by painting them the color of the background.

Socioeconomic impacts are of most interest to the federal and local governments and the surrounding communities. The costs, benefits, and impacts on the local and wider communities will ultimately determine the success or failure of a geothermal project. Since the 1992 Earth Summit of the UN Conference on Environment and Development (UNCED) in Rio de Janeiro, Brazil, the emphasis has been on sustainable development, defined by the World Commission on Environment as "development that meets the need of present generation without compromising the need of future generations to meet their needs."

A fundamental purpose of a socioeconomic impact study of a geothermal development is to identify the three key sectors that are affected by the project: investor, beneficiary, and victim. The final outcome of the project must have the equity of benefit and compensation to all affected sectors. The main aim of a socioeconomic study is to determine the changes in conditions within, adjacent to, and in proximity to the project area as well as the direct and indirect impacts of these changes. This requires past and current baseline data, usually going back 10 years. These data are gathered from records, surveys, and consultations with the local communities and other interest groups. Social acceptability of projects are normally obtained if no extreme changes result and the affected communities can adjust their lifestyles to the new benefits that are gained. These benefits may include employment, lower electricity prices, and funding for local charities.

The most difficult problem that a geothermal power plant faces is the reliability of the steam supply. Well characteristics can and do change with time after a period of production. Many geothermal power stations (e.g., Wairakei, The Geysers) have never been loaded to their full capacities due to the shortfall of well output. The initial logical solution to this problem was to drill more wells, but this practice tends to worsen the problem with rapid drawdown. This problem is due to the overestimation of the reservoir power potential. The solution to this problem is staged development. The expected drawdown was incorporated during the design stage at Ohaaki, but the drawdown was faster than predicted.

A major operational problem that a geothermal power plant faces is the solid deposition of silica or calcite in wells and equipment exposed to the geothermal fluids. Although the chemistry of the deposition can be predicted with reasonable accuracy, the solution to the deposition problem is not always clear-cut. The common solution is to inject a chemical inhibitor into the problem wells. Suitable calcite inhibitors include polyacrylate, polymaleic acid, and phosphonate, depending on the application temperature. Many acids or alkali are suitable silica inhibitors.

The inhibitor is injected just below the fluid flashing point where the solid precipitates out of the liquid phase during flashing (Fig. 14). The inhibitor injection is very effective if applied correctly, although it does not actually stop deposition altogether. Physical removal of the solid deposits is still required once every few years instead of a few times each year without inhibitor. Not only is there a loss of production due to well shutdown to remove the deposits, but the cleaning may require a drilling rig or expensive acids.

Another hazard associated with a geothermal power plant is earthquake and/or volcanic eruption.

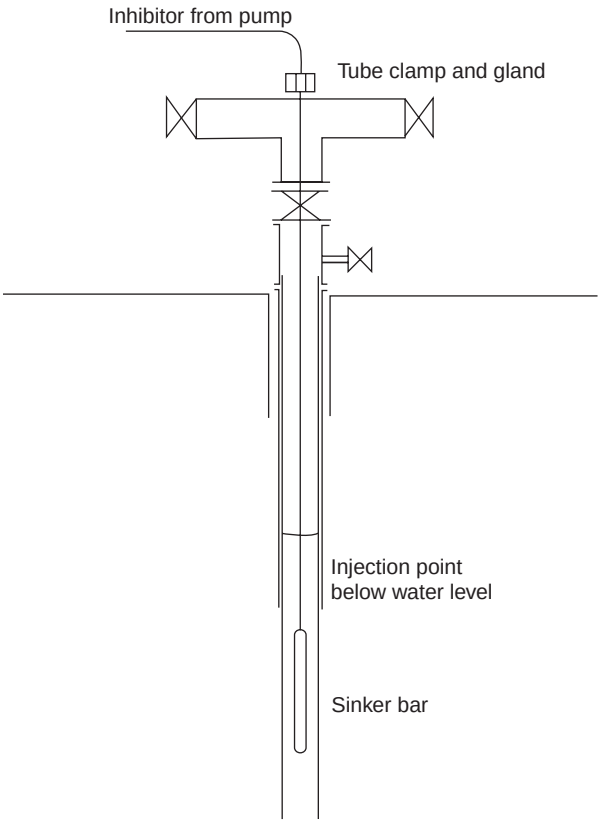

FIGURE 14 A typical inhibitor injection arrangement in a production well.

All plants and equipment can be easily designed to resist the expected seismic forces. Design for volcanic hazard is relatively easy if the discharge is slow-moving lava because it is simply a matter of locating the plant outside the lava flow path. It is much more difficult if the discharge is of the ash type.

7. COMMERCIAL DEVELOPMENT OF GEOTHERMAL POWER PROJECTS

In most countries, geothermal resources are classified as natural resources belonging to the government. Since the 1980s, there has been a worldwide trend to corporatize and/or privatize government commercial activities. Whereas the geothermal resources in the United States have been commercially developed by the private sector since the 1960s at The Geysers, other countries, notably The Philippines, Indonesia, and New Zealand, did not started private commercial geothermal projects until the 1980s. These private power developers are known as independent power producers (IPPs). There is a perception that the private sector is more efficient than the public sector. The efficiency arises from the increased flexibility of the private sector and its accessibility to commercial funding.

There are several types of contracts in the commercial development of geothermal power projects. In a BOT (build, operate, and transfer) contract, a private developer builds the whole power station (including the steamfield), operates the power station for an agreed period of time to recoup its investment, and then transfers the power station back to the host country. In a BOO (build, own, and operate) contract, the developer builds and operates the power station as its own business. In a BOOT (build, own, operate, and transfer) contract, the developer transfers the power station back to the host country after an agreed period.

Developing a geothermal resource carries higher commercial risks than does building and operating a power plant. From a private developer's viewpoint, it is more favorable to just have an energy conversion agreement (ECA) contract in which the private developer builds and operates a power plant, converting the geothermal steam supplied by the host country and producing electricity for the host country (Fig. 15). The host country develops the geothermal resource. An ECA contract will involve a steam sales agreement (SSA) and a power purchase agreement (PPA). In a more traditional EPC (engineer, procure, and construct) contract, an engineering consulting company designs and builds the power plant and/or steamfield for a fee.

When private developers first entered the commercial development of geothermal power projects, they developed the resources, operated the steamfields, and sold steam to power companies operated by government agencies. The classic IPP operation is for the private sector to develop both the geothermal resource and the power plant and to sell electricity to the host utility that deals with the electricity market. The latest trend is the ECA operation.

An IPP, like any other investor, looks for a good return on its investment. To minimize the investment risk, the IPP wants certainty in costs and revenues over the investment period. A geothermal power project is like a hydropower project—capital intensive but with a low running cost. A geothermal project is commercially viable only if it creates a positive net present value (NPV) over its economic life for the investors. This requires a guaranteed stream of revenue in the future from the power sales, and the risks in the steam supply from the

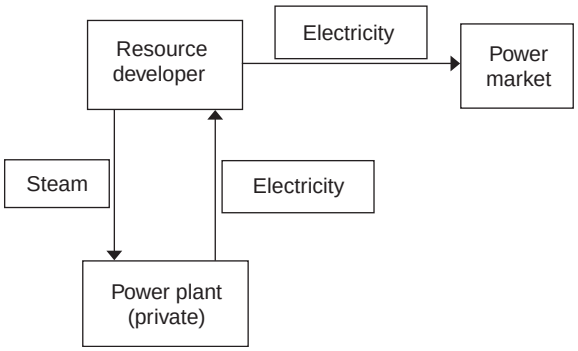

FIGURE 15 ECA project structure.

geothermal resource must be manageable. Therefore, the selection of the exploitation process, power cycle, and power plant is critical to minimize capital cost and maximize power output.

Risks are inherent in the resource and power plant development. Resource exploration risk is relatively high, with a corresponding higher return potentially at moderate investment. This type of risk is familiar to the mining and oil exploration companies. The steamfield and power plant development risk is low. Most IPPs and bankers are familiar with this risk. Risks are best managed by those who are best at controlling them. A developer is best responsible for the project implementation, and contractors are best at managing risks within their own areas of work. Some risks, such as resource and steamfield process risks, must remain with the owner. Risk allocation has driven the move toward EPC contracts.

There is an apparent conflict between the financial goal of maximizing return with a rapid development program and the risk mitigation strategy to minimize risk with a slow program. The solution to this apparent dilemma is to adopt a staged development.

The production drilling stage is a major expenditure phase, with each well costing U.S. $750,000 to $3 million. Well outputs are highly variable, from a dry well to one that may produce 40 MWe. Once production drilling starts, the aim is to produce electricity, and hence return on investment, as soon as possible. Cost controls are paramount during the production drilling stage.

A decision is required for the generating capacity of the power plant. For a staged development, the capacity of the first stage can be 25% of the estimated power potential. Because there are economies of scale in turbo-generator unit size, the tendency is to go for the largest single unit of approximately 55 MWe if possible. However, this requires optimization against operational flexibility and power demand. In general, the power plant costs approximately 50 to 55% of the total cost of a geothermal power project, the production drilling costs 25%, and the steamfield costs 15%, with the remaining 5 to 10% of costs due mainly to exploration drilling. Currently, a geothermal power project costs between U.S. $1000 and $2000/kWe, depending on the quality of the steam. An electricity unit cost of U.S. 5 to 8 cents/kWh is achievable. This is very competitive compared with conventional thermal and hydropower stations.

4. Energy

Glossary

container glass The largest glass sector; formed by a two-stage process of initial forming by pressing followed by blowing to obtain the finished hollow shape.
cullet Scrap or waste glass that is added to the batch materials.
float glass Flat glass that is made by floating molten glass on a pool of molten tin.
glass A material with a three-dimensional network of atoms that forms a solid lacking the long-range periodicity typical of crystalline materials.
optical fibers Very high-purity silica glass fibers used to transmit light for telecommunications.
oxy-fuel firing The replacement of the combustion air with oxygen in a glass furnace.
recuperator A continuous heat exchanger that preheats combustion air with the heat from the exhaust gases.
regenerator A stack of refractory material that absorbs the heat from exhaust gases. There are two regenerators in a regenerative furnace that are cycled over a specific time period.

Glass is a material that enjoys widespread use in many commercial applications, including buildings, beverage containers, automobiles, and telecommunications. However, the manufacture of glass is a very energy-intensive undertaking and the industry is constantly working to reduce its energy consumption. This article describes the use and flow of energy in commercial glass production. In order to understand the relationship between energy and glass manufacturing, this articles first defines what glass is and then describes how it is produced.

1. INTRODUCTION

The atomic or molecular structure of solid materials can generally be found in two states: ordered and disordered. If the atoms of a material are ordered in a repeated array throughout, the structure will be an ordered three-dimensional pattern. This is a crystalline material. Solid materials that lack long-range atomic order are noncrystalline or amorphous. When a material is cooled from a liquid state to a solid, its formation into a crystalline or amorphous solid depends on how easily the random atomic structures of the liquid can organize into an ordered state while cooling. Factors such as composition and cooling rate are important. Rapid cooling of a liquid enhances the formation of an amorphous structure since the material is given little time to reach an ordered state. This is a glass. Figure 1 shows a comparison of the ordered arrangement of crystalline silicon dioxide and the disordered arrangement of a silicon dioxide glass. A common definition of a glass was given by the physicist W. H. Zachariasen, who stated that glass is an extended, three-dimensional network of atoms that forms a solid lacking the long-range periodicity (or repeated, orderly arrangement) typical of crystalline materials.

Manufactured glass products are made by melting crystalline raw materials into a molten state. The melt is subsequently shaped into the desired product and cooled to make a rigid form. The composition of the glass depends on the desired properties of the glass, which in turn define which raw materials are needed. Conceptually, there are thousands of different combinations of raw materials that will produce a glass, but in practice there are a limited number of formulations that are used to make the common glass products that are used on a daily basis. These limitations are typically dictated by practical and economic considerations.

2. TYPES OF GLASS

Glasses can be found in the natural environment, mostly in areas of volcanism where erupted magma is quickly cooled before crystallization can occur. Perhaps the best known example is obsidian, a black glass that consists mainly of oxides of silicon, aluminum, calcium, and sodium and/or potassium.

Commercially produced glasses differ widely in chemical composition and in physical and optical properties. Various materials can form a glassy or vitreous structure, such as the oxides of silicon and boron. Most commercial glasses are based on silica (SiO_2), which is the most abundant material on the earth's crust and is an excellent glass former. There are some nonsilicate glasses, but they make up only a very small fraction of commercially produced glass.

Pure vitreous silica glass can be made by melting quartz sand and cooling it quickly. Although silica makes an excellent glass for many applications, its high melting temperature ($>2000^{\circ}C$) makes it too expensive for use in commodity glass products such as bottles and windows. The melting temperature can be reduced to a practical range by the addition of fluxes, the most common of which are alkali oxides (Li_2O, Na_2O, and K_2O). However, the addition of too much alkali can lead to the degradation of properties, such as the chemical durability of a glass (i.e., it will begin to dissolve when exposed to water). This can be compensated for by the addition of property modifiers, such as alkaline earth oxides (CaO and MgO) and aluminum oxide (Al_2O_3). The addition of these glass modifiers changes the glass structure, resulting in changes in the physical and chemical properties of the glass.

The composition used for a specific glass product depends on the desired final product performance, manufacturing characteristics (e.g., melting and forming), environmental considerations, and raw material/fuel costs. Although there are many different combinations of elements that will make a glass, there are some general compositional types that are widely used in commercial glass making. A glass made of silica, alkali, and alkaline earth elements is commonly called a soda-lime-silica glass and is the most common type. It has a relatively low melting temperature (begins melting at $\sim 800^{\circ}C$ and is usually processed up to $1400^{\circ}C$), has the proper viscosity characteristics for continuous production, and uses raw materials that are relatively inexpensive. It is the basis for making flat glass, containers, and consumer ware (e.g., drinking glasses).

Borosilicate glasses contain boron, which decreases thermal expansion, lowers viscosity, and allows faster fabrication speeds. Borosilicate glasses are used when resistance to thermal shock is desired, such as for cookware laboratory glass. Fiberglass products that are used for thermal insulation and structural reinforcement of composites contain boron.

Lead crystal and crystal glass are silicate glasses with added lead. The lead decreases viscosity and, hence, decreases the temperatures needed to work the glass and enhances the dissolution of refractory particles. Lead increases the refractive index of the glass, imparting a brilliance to the finished piece.

Specialty glasses include a variety of products, such as cathode ray tubes (CRTs), lighting glass (tubes and bulbs), laboratory and technical glassware, optical fibers, ceramic glasses (cookware), and glass for the electronics industry (e.g., LCD panels). Optical fibers are a specialty glass that is made of extremely high-purity silica. Optical fiber glasses cannot attain the needed purity levels produced by melting silica sand, so the glass is manufactured by precipitating chemically purified silica vapor.

3. INTRODUCTION TO COMMERCIAL GLASS MANUFACTURING

Glass manufacturing is essentially a commodity industry, with the majority of product sold to other industries, such as beverage, construction, and automobile manufacturers. In 1999, the U.S. glass manufacturing industry produced more than 18 million metric tons, worth approximately $17.6 billion. In the European Union, 1996 production was approximately 29 million metric tons (Table I).

3.1 Raw Materials

The overall goal of glass manufacturing is to convert crystalline raw materials into a homogeneous, flowing liquid that is free of visible defects that can be formed into a final product. This needs to be accomplished as quickly and as economically as possible and, at the same time, comply with all environmental regulations. Figure 2 shows a schematic diagram of the process of commercial glassmaking as described in this section. There are several methods of making and forming glass, but all begin with the mixing of raw materials or "batching." For most glasses, the most important glass former is silica. The raw material for this is quartz sand usually derived predominantly from sandstone deposits. Such deposits must contain few impurities, such as iron, which will affect the color of the glass. Glass property modifiers are introduced with a mix of limestone ($CaCO_3$) and dolomite ($CaMg[CO_3]_2$). The alkali flux is usually soda ash (Na_2CO_3), which comes from either a mined mineral ore called trona or the Solvay process of reacting sodium chloride with limestone. The soda and lime materials are carbonates so that upon heating the carbonate is driven off as volatile CO_2, leaving the metal oxide behind. Feldspar or nepheline syenite are aluminosilicate minerals that can be used in the batch to add alumina (Al_2O_3) and some alkali. Borosilicate glass batches can have 5–10% borate minerals, such a borax ($Na_2O \cdot 2B_2O_3 \cdot 5H_2O$) and colemanite ($Ca_2B_6O_{11} \cdot 5H_2O$) added to them. Mineral or rock wool is often made from slag that is a by-product from metal smelting.

Recycled glass, or cullet, is added to the batch to reuse waste glass from both within the plant and outside sources. Cullet also provides an early melting liquid phase that enhances reaction rates. The effect of cullet on energy use is discussed later. The main problem associated with cullet is the potential for contamination, particularly from pieces of metal, ceramic, or glass-ceramic. These contaminants can, at best, lead to rejected product and, at worst, damage the expensive refractory lining.

Minor additives include colorants, reducing agents, and fining agents. Colorants are added to control or add color and are usually oxides of transition metals or rare earth elements, such as cobalt, cerium, iron, and chrome. Fining agents are used to promote the removal of bubbles from the melt that, if not removed, will result in flaws in the final product. Common fining agents include sulfates,

TABLE I

Glass Sectors and Annual Production (Million Metric Tons)

Sector	European Union[a]	United States[b]
Flat glass	6.4	4.5

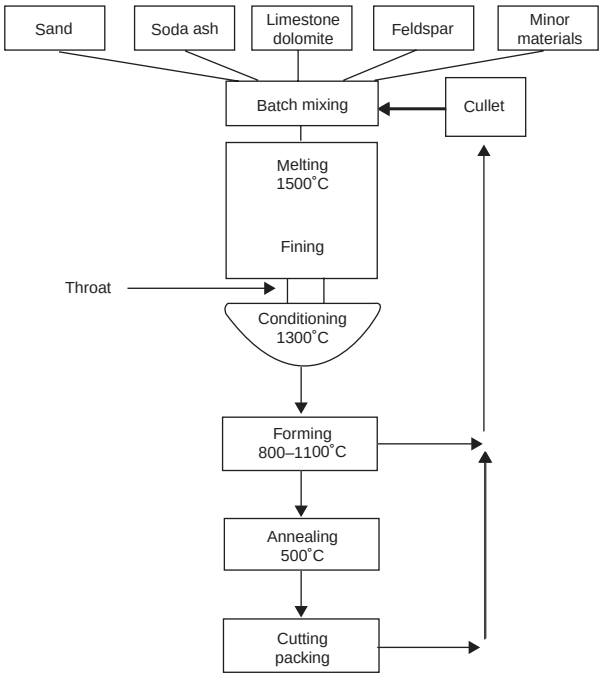

FIGURE 2 Schematic diagram of the process of commercial soda–lime–silica glassmaking showing raw materials, process sections, and approximate operating temperatures.

fluorides, nitrates, and oxides of arsenic or antimony. The most common combination for soda–lime–silica glasses is sodium sulfate and a reducing agent such as carbon.

The batching process consists of transferring raw materials directly from storage silos into a hopper and subsequently mixing the raw batch in a large-scale mixer. Cullet may be added after mixing. The mixed batch is placed in storage hoppers located directly adjacent to the "dog house," or the end of the glass furnace at which the batch is introduced and melting commences. The batch may be moistened with water or sometimes caustic soda to reduce particle segregation during transport to the furnace.

TABLE II

Advantages and Disadvantages of Different Furnace Types

Furnace type	Advantages	Disadvantages
Regenerative	Long furnace life	Higher NO_x levels
	Long-term experience	Higher capital cost
Direct fired (mostly oxygen/fuel)	Reduction in fuel	Refractory corrosion
	NO_x reduction	Short-term experience
	Lower capital cost	Cost of oxygen production
	Particulate reduction	
Electric	Efficient	High electricity cost
	No one-site pollution	Short furnace life

3.2 Glass Melting Furnaces

There are several types of melting furnaces used in the glass industry depending on the final product, raw materials, fuel choice, the size of operation, and economic factors. A melter can be either periodic or continuous. The latter is most widely used in large-scale operations. Continuous melters maintain a constant level by removing the glass melt as fast as raw material is added. Table II shows the three major types of furnaces and their advantages and disadvantages. The energy for melting comes from either the combustion of fossil fuels or electricity. The temperature necessary for melting ranges between 1300 and 1550°C. All furnaces are lined with high-temperature refractory materials to keep the corrosive melt from escaping and to insulate the melter.

Regenerative combustion furnaces recover heat from the exhaust stream to preheat the incoming combustion air by alternatively passing the exhaust and combustion air through large stacks of latticework refractory brick (regenerators or checkers). There are two sets of regenerators, so that as one is being preheated by the exhaust gases the other is transferring heat to the incoming combustion air (Fig. 3). The cycle is reversed approximately every

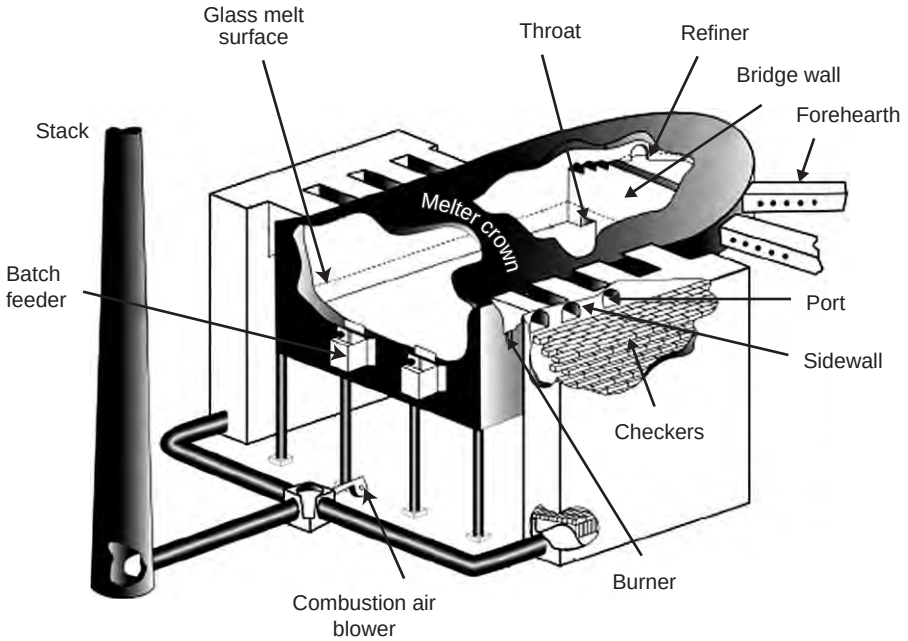

FIGURE 3 Diagram of a cross-fired regenerative furnace. This type is often used in large-volume production of container and flat glass. From U.S. Department of Energy (2002). "Energy and Environmental Profile of the U.S. Glass Industry."

20 min. Most glass-container plants have either end-fired (burners at each end) or cross-fired (burners on each side) regenerative furnaces, and all flat glass furnaces are cross-fired with five or six ports on each side with two burners for each port. Combustion air preheat temperatures of up to 1400°C may be attained, leading to very high thermal efficiencies. A variant of the regenerative furnace is the recuperator, in which incoming combustion air is preheated continuously by the exhaust gas through a heat exchanger. Recuperative furnaces can achieve 800°C preheated air temperatures. This system is more commonly used in smaller furnaces (25–100 tons per day). For large-capacity installations (>500 tons per day), cross-fired regenerative furnaces are almost always used. For medium-capacity installations (100–500 tons per day), regenerative end-port furnaces are most common.

A direct-fired furnace does not use any type of heat exchanger. Most direct-fired combustion furnaces use oxygen rather than air as the oxidizer. This is commonly called oxy-fuel melting. The main advantages of oxy-fuel melting are increased energy efficiency and reduced emission of nitrogen oxides (NO_x). By removing air, nitrogen is removed, which reduces the volume of the exhaust gases by approximately two-thirds and therefore reduces the energy needed to heat a gas not used in combustion. This also results in a dramatic decrease in the formation of thermal NO_x. However, furnaces designed for oxygen combustion cannot use heat-recovery systems to preheat the oxygen. Initially, furnaces that use 100% oxy-fuel were used primarily in smaller melters (<100 tons per day), but there is a movement toward using oxy-fuel in larger, float glass plants.

An electric furnace uses electrodes inserted into the furnace to melt the glass by resistive heating as the current passes through the molten glass. These furnaces are more efficient, are relatively easy to operate, have better on-site environmental performance, and have lower rebuild costs compared to the fossil-fueled furnaces. However, fossil fuels may be needed when the furnace is started up and are used to provide heat in the working end or forehearth. These furnaces are most common in smaller applications because at a certain size, the high cost of electricity negates the improved efficiency.

Some regenerative furnaces use oxygen enrichment or electric boost to optimize the melting process. Electric boosting adds extra heat to a glass furnace by using electrodes in the bottom of the tank. Traditionally, it is used to increase the throughput of a fossil fuel-fired furnace to meet periodic fluctuations in demand without incurring the costs of operating a larger furnace. It is also used to enhance the pull rate (the output at the forming end) of a furnace as it nears the end of its operating life.

3.3 The Melting Process

Regardless of the furnace type used, there are four basic steps to melting glass:

1. Conversion of the batch into a molten liquid free of undissolved crystalline material (called stones)
2. Removal of bubbles, or fining
3. Homogenizing the liquid so that it is chemically and thermally uniform
4. Conditioning the melt to bring it to a state in which it can be formed into the desired product

For a continuous furnace, these four steps occur simultaneously. The average residence time, from introduction of the batch to forming, is on the order of 24 h for container furnaces and up to 72 h for float glass furnaces. Glass melting tanks can contain 1500 tons or more of molten glass.

The melting of the batch consists of several steps from the moment it is introduced into the tank. Due to the low thermal conductivity of the batch materials, the initial melting process is quite slow. As the materials heat up, the moisture evaporates, some of the raw materials decompose, and the gases trapped in the raw materials escape. The first reaction is the decomposition of the carbonates at approximately 500°C, which releases CO_2. The fluxes begin to melt at approximately 750°C and begin to react with the silica. At 1200°C, the silica sand and other refractory materials dissolve into the molten flux. As the remaining silica dissolves into the melt, its viscosity increases rapidly.

Bubbles are generated by the decomposition of raw materials, from reactions between the melt and the glass tank, and from air trapped between batch particles. These are removed as they rise buoyantly through the melt to the surface or as gases dissolve into the melt. Removal of the last few bubbles is the most difficult. Fining agents enlarge these bubbles to assist in their removal. Fining occurs as the melt moves forward through the throat of the melter to the conditioner, where melt homogenization and cooling take place.

Without homogenizing the melt, linear defects called cords (regions of chemical heterogeneity) will be seen in the final product. Furnaces are designed to promote recirculating convective currents within the melt to homogenize the glass. Convective mixing can

be enhanced by physically stirring the melt with bubbles or mechanical stirring devices.

3.4 Forming Processes

After melting, fining, and homogenization, the melt passes through the throat of the furnace (Fig. 3) into a conditioning chamber, where it is cooled slowly to a working temperature between 900 and 1350°C. It is then ready to be delivered as a viscous mass through the forehearth to be formed into a specific product. The role of the forehearth is to remove temperature gradients and transfer the molten glass to forming operations. It consists of an insulated refractory channel equipped with gas-fired burners or electric heaters and an air cooling system.

Flat glass is most commonly formed by the float process, whereas patterned and wired glass are formed by rolling. Float glass and rolled glass are produced almost exclusively with cross-fired regenerative furnaces. The float process was developed by the Pilkington Brothers Glass Company of England in the 1950s, and it is the technique of pouring the melted glass onto a pool of molten tin. The glass floats on the tin and spreads out to form a uniform thickness. The glass is then mechanically stretched or constrained to attain the desired ribbon width and thickness. The tin bath is surrounded by a reducing atmosphere of nitrogen and hydrogen to keep the bath from oxidizing. The glass ribbon is pulled and modulated by water-cooled pulleys and exits the bath into the annealing lehr. Annealing is the process of heating and cooling the glass at a controlled rate to remove any residual stresses that could cause catastrophic failure while in use. After exiting the lehr, the glass is automatically cut into the desired sizes. The float method uses much less energy than preceding plate and sheet glass forming due to the use of more efficient furnaces and the elimination of the need for surface polishing and grinding. Rolled glass is formed by squeezing molten glass at approximately 1000°C between water-cooled steel rollers to produce a ribbon with a surface pattern or embedded wire.

Containers such as bottles and jars are made using a two-stage pressing and blowing process. This process is fully automated and begins with molten glass flowing from the furnace forehearth to a spout or set of spouts. The flow of glass is controlled by a mechanical plunger that produces a piece or gob of molten glass. The gob is then conveyed to the forming process, which produces a primary shape in a blank mold using compressed air or a metal plunger. The primary shape is placed into the finish mold and given its final shape by blowing compressed air into the container. During the forming process, the glass temperature is reduced by as much as 600°C to ensure that the containers are sufficiently rigid when placed on a conveyor. The cooling is achieved with high volumes of blown air against the molds. After forming, the containers are annealed by reheating to 550°C in a lehr and then cooled under controlled conditions. Larger operations can produce 500 bottles per minute.

Glass fibers can be found in nature where fountaining lavas are wind blown to produce long strands known as Pele's tears, after the Hawaiian goddess of fire. The manufacture of commercial glass fiber is similar, with some exceptions. Most fiber glass melts are produced with cross-fired recuperative furnaces, although there are several oxy-fuel fired furnaces in Europe. Short-strand glass wool is produced by spinning the melt in a crucible lined with holes. As the molten glass is ejected through the holes, high-velocity air blows the glass into fibers. For continuous glass fibers, the melt flows from the furnace through a series of refractory-lined channels to bushings. Bushings have several hundred calibrated holes or bushing tips that are electrically heated to precisely control the temperature and, thus, the viscosity and flow rate of the melt. The melt is drawn through the bushing tips by a high-speed drum to form continuous filaments. Once drawn from the bushing, the filaments are quickly cooled and then coated with a polymer binder.

4. ENERGY

Based on the previous description of glassmaking, it is evident that glass manufacturing is a very energy-intensive process. Energy accounts for 15–25% of the cost of glass products, depending on the sector and the country of manufacture. In 1999, the U.S. glass industry spent more than $1.3 billion on approximately 295 quadrillion joules (PJ) [280 trillion British thermal units (Btu)], including products from purchased glass. Taking into account electricity losses due to generation, transmission, and distribution, this figure increases to 417 PJ (395 trillion Btu) of total energy use.

By far the most energy-intensive components of glass manufacture are melting and refining, which together account for 70–80% of the total energy requirements. The remaining energy is used in the forehearths, tin bath (for float glass), forming/cutting processes, annealing, and other plant services. For

example, in container manufacturing, the furnace accounts for 79% of the total energy used. The other areas of energy use are the forehearth (6%), compressed air (4%), mold cooling (2%), lehr (2%), and others (7%).

4.1 Sources of Energy

The sources of energy used to produce glass are natural gas, electricity, and, to a lesser extent, fuel oil. Fuel oil has been historically important, but today natural gas is the dominant fossil fuel used in glassmaking. Natural gas has higher purity, is relatively easy to control, and does not require on-site storage facilities. The higher purity of natural gas results in a reduction of sulfur dioxide emissions relative to fuel oil. Natural gas accounts for approximately 80% of energy use and more than 98% of purchased fuels in the U.S. glass industry. Although natural gas is mainly used to melt the raw materials, it is also used in emission control either to reduce NO_x in the exhaust stream or to incinerate toxic emissions from glass fiber production. Electricity is used in smaller resistance melters, fiberglass bushings, tin bath heating, annealing, and for powering motors to produce compressed air and operate conveyers and blowers.

4.2 Theoretical vs Actual Energy Use in Melting

The theoretical minimum energy required to transform the crystalline raw materials to a molten liquid is approximately 2.68 GJ/metric ton for a soda–lime–silica glass formulation. The calculation assumes all available heat is fully utilized and has three components:

- The heat of fusion to form the melt from the raw materials
- The heat, or enthalpy, required to raise the temperature of the glass from 20 to 1500°C
- The heat content of the gases released during melting.

The actual amount of energy required can be from 2 to 15 times the theoretical minimum, although for the majority of large-scale melters it is generally less than 8 GJ/ton. The amount of energy per unit of product produced can be referred to as the specific energy or energy intensity. As a comparison to other materials, the values for glass are similar to those of cement (5.4 GJ/ton) and lower than those of steel and iron (25.4 GJ/ton) and pulp and paper products (32.8 GJ/ton).

In addition to the specific product, the type of furnace and the desired quality of the glass affect the specific or per unit energy use. For instance, because flat glass needs to be completely free of imperfections, it generally requires longer residence times in the furnace than does container glass and therefore uses more energy per ton of glass produced. Table III shows the range of specific energy values for several different fossil fuel furnaces and glass products. Efficiencies in large regenerative furnaces can be as high as 55% and electric furnaces are 70–90% efficient (not considering the 25–30% efficiency of off-site electricity generation). Electric melters are more efficient because there are no heat losses in the stack or regenerator. Table IV shows the range of efficiencies for several types of furnaces.

The large differences between the theoretical and the actual energy used can be attributed to heat losses and other inefficiencies. The majority of heat loss is

TABLE III

Energy Consumption for Melting and Refining

Furnace type	U.S. average specific energy (GJ/metric ton)	EU average specific energy (GJ/metric ton)[a]
Flat glass		
Regenerative side-port	8.4	6.3
Electric boost side-port	6.2	—
Container glass		
Large regenerative	7.5	4.2
Electric boost	5.3	—

from the furnace structure and through the removal of exhaust gases for fossil fuel melters. As described previously, modern melters that burn fuel employ a regenerator or recuperator to recover heat from the exhaust gases and preheat the incoming combustion air. This reduces the overall energy consumption by 50–70% compared to if it were direct-fired. The energy source, heating technique, and heat recovery method are central to the design of the furnace. The same choices also affect the environmental performance and energy efficiency of the melting operation.

4.3 Energy Reduction

The glass industry is constantly striving to close the gap between the theoretical and actual energy needed to melt raw materials into glass. Because melting and refining use the majority of energy in glass making, it is this part of the process that must be examined initially in any attempt to reduce per unit energy consumption. There are two general approaches toward reducing energy consumption: optimizing the existing system or completely replacing the current methods with and advanced melting system.

To reduce the amount of energy in conventional melting furnaces, the following may be addressed:

- Improvement of the combustion efficiency
- Reduction of the residence time in the tank
- Improvement of the insulation around the structure
- More effective use of the exhaust gas heat
- Oxy-fuel firing
- Increased cullet use

The melting technique chosen by a manufacturer is largely determined by economic considerations, and this can have a major effect on the energy efficiency. Although energy efficiency is an important aspect of the operating costs, these must be balanced by the other capital and operating costs, the desired production rate, and environmental performance (although energy efficiency and environmental performance are related).

Improvements in combustion efficiency have been driven by the need to reduce NO_x emissions. Reengineering of the burners and the control systems has also resulted in overall energy savings. Low NO_x burners reduce the volume of combustion air to close to stoichiometric levels, such that only the amount of air needed for combustion is introduced. Air that is introduced but not used in the combustion process would simply be heated and would carry that heat away in the exhaust.

The melt needs time (residence time) in the tank to produce a defect-free glass. However, the longer the melt remains in the tank, the more energy is expended in the process. Any reduction in the amount of time needed to melt, fine, or homogenize the melt will result in direct energy reductions. Residence times depend on the furnace temperature, composition of the batch, grain size of the batch ingredients, amount and grain size of cullet, and homogeneity of the batch. Improved batching techniques include ensuring optimal grain sizes and the addition of cullet. Because of the low viscosity of the initial melting fluxes, there may be a tendency for the batch to "unmix" and require excessive homogenizing times. Pelletizing or pre-reacting some of the batch components may reduce this effect. Furnace temperature can be increased to reduce melting and refining times, although this is done at the expense of the life of the refractory lining. Electric boost can be used in fossil fuel melters to increase the pull without changing the furnace size. In general, the electricity required to increase the pull rate by 1 ton is approximately 22–28 kW. The degree of homogeneity depends on the quality requirements, which vary considerably between and within glass sectors. Bubbling is a method of decreasing homogenization time in which air is injected through several nozzles installed at the bottom of the melting chamber, agitating the melt and promoting mixing.

As much as 30% of energy can be lost through the furnace structure. Structural heat losses are inversely proportional to the furnace size because of the change in melter surface area-to-volume ratio. Thus, larger furnaces have inherently lower heat losses. Regardless of the size of the melter, improvements in the insulation of the structure will increase energy efficiency. Most glass contact refractories that are used to line the furnace are dense, fusion cast materials that have high thermal conductivity and

need to be insulated. The application of insulation to a furnace depends on the area of the furnace and the operating conditions, and not all parts can be insulated. Insulation increases the operating temperature of the refractory lining, which tends to shorten its life span. Overheated refractory material can also degrade and shed material into the glass, creating defects. Therefore, more efficient insulation needs to be balanced with the quality of the glass and lifetime of the refractories.

Advances in refractory material engineering have allowed furnaces to operate longer between rebuilds at higher levels of insulation. For example, superduty, high-purity silica and alumina–zirconia–silica bricks have been developed for the crown to improve insulation. Sprayed fiber insulation can be applied to the regenerator structure, resulting in up to a 50% reduction in regenerator structural heat losses.

Up to 30% of the heat from melting is expelled through the exhaust gases. Furnaces equipped with regenerators or recuperators recover some of this heat, with end-fired regenerative furnaces generally more efficient than cross-fired regenerative furnaces. However, combustion control and furnace size are more limited for end-fired furnaces. The amount of energy recovered by regenerators may be increased by increasing the quantity of refractory bricks in the checkers using enlarged regenerator chambers or in separate but connected structures. However, as one approaches the physical maximum efficiency, there are limitations on the cost of the extra refractory bricks and the limitation of available space. Improved materials and designs such as corrugated cruciform bricks can improve heat transfer.

Gases exiting the regenerators or recuperators are 300–600°C, and there are other potential areas of use for the remaining waste heat, although too much heat loss in the exhaust stream will adversely affect the ability of the plant to vent the exhaust up the stack. One heat-recovery technique is to pass exhaust gases through a boiler to generate steam. The steam can be used for heating, on-site electricity generation, or to drive air compressors. Potential problems are fouling of the boiler tubes, high capital costs, and interconnection with the utilities (in the case of electricity generation).

Another potential use for the heat is preheating the batch or cullet, which is normally fed cold into the furnace. This can be accomplished by direct or indirect exposure of the batch to the exhaust gases. Direct preheating can be done by directing the hot exhaust gas opposite the batch as it falls from a feeder. This can raise the batch or cullet temperature up to 400°C. Indirect preheating systems use a plate heat exchanger and may consist of blocks of horizontal waste gas flow and vertical material funnels. This can lead to heating of the cullet or batch to 300°C. The exhaust gases exiting the preheaters will be cooled by approximately 270–300°C. Potential problems are increased particulate emissions and size sorting, although this is not as important in preheating cullet.

As mentioned previously, oxy-fuel firing can be more energy efficient than air-fuel furnaces. Most glass companies have incorporated some oxy-fuel firing into their operations, either as oxygen-enriched air or as 100% oxygen. A furnace that is equipped with oxygen-enriched air can produce the same amount of glass as with air combustion but at lower fuel input because of the reduced exhaust volume. However, when regenerative furnaces are converted to oxy-fuel firing, the heat-recovery checkers are eliminated. In addition, oxygen is expensive and to make oxy-fuel systems economical, a cost-effective and reliable source of oxygen is required. Several on-site systems can be used to fractionate oxygen from ambient air. Liquified oxygen can be used, but its use is limited by transportation costs. The energy required to use oxygen ranges from 250 to 800 kWh per ton of oxygen.

4.4 Cullet and Energy

Cullet has a lower melting energy requirement than the virgin raw materials because the heat of fusion of converting crystalline material to a liquid is not needed and its mass is 20% lower than that of the equivalent batch materials. General energy savings are 0.15–0.30% for each percent of cullet added to the batch. For example, a melter that uses 50% cullet will use 7.5–15% less energy than a batch with no cullet.

Most plants routinely recycle all internal cullet—that is, waste glass produced within the production process. For flat glass production, approximately 10–20% of the produced glass returns as internal cullet due to edge trimming, defects, product changes, and breakages. External sources of cullet (from consumer or external industrial sources) are also used, with the amount used depending on the product, specifications, availability, and price. The composition of external cullet can vary and the presence of impurities such as metal and ceramics may limit its use. Stringent final product quality requirements can restrict the amount of foreign cullet a manufacturer can use. Container glass manufacturing benefits from bottle recycling schemes and, depending on the

country, this sector can consistently use 80% cullet in the batch. It is more difficult for flat glass manufacturers to find external cullet, although they are able to obtain scrap from the industries that purchase their product, such as architectural and automotive window manufacturers. All manufacturers keep a store of cullet on site in the event that the raw material batching system is offline and they need to melt at 100% cullet.

4.5 Advanced Melters

The next generation of glass melters needs to be more energy efficient than current melters, but they also must operate as rapidly and economically to produce the highest quality product. Currently, the most efficient glass melters are the large regenerative furnaces, but they are also the most capital intensive, have high rebuild costs, and are very inflexible in terms of varying or reducing output.

There are potential technologies that can make melting more efficient by making heat transfer to the batch more efficient. Submerged combustion melting uses natural gas and an oxidizer injected directly into the melt, which improves heat transfer and promotes rapid mixing. Plasma, which is a partially ionized gas that conducts electricity, can be very efficient at transferring heat directly to batch materials, but it is difficult to apply on a large scale. Microwaves can heat without direct contact, but different components of the batch have different susceptibilities to heating by microwaves.

One obvious approach to reducing the energy needs of the commercial glass industry is to reduce the residence time of the melt in the furnace. Rapid glass melting systems would allow the raw materials to be melted and homogenized without the need for the relatively slow, convective mixing that is currently practiced. The industry would like the current average 24- to 48-h residence time of a melt reduced to 1 h.

Combined melting and mixing can be achieved using a variety of mechanisms. Higher temperatures reduce viscosity and decrease mixing times, but the reduced time must be balanced by the increased energy input. Higher temperatures also adversely affect the refractory lining and can increase emissions of NO_x and volatile components of the batch. Improved mechanical mixing will decrease homogenization times. Decreased fining times can be achieved by controlling the atmosphere surrounding the melt or applying a vacuum.

There are several conceptual designs of fully reengineered methods of melting glass. Many of these segment the furnace into distinct sections for melting, fining, and homogenization. One segmented melting concept takes advantage of the different melting requirements of virgin batch materials and cullet. Virgin batch is charged into an all-electric premelting furnace that converts 75% of the raw material into glass. The premelted batch then moves into an enlarged doghouse where cullet is added (cullet comprises at least 60% of the raw material). The batch/cullet mix then enters the second melting chamber that uses oxy-fuel burners. The potential benefits are up to 25% improved energy efficiency and lower emissions. Another concept under development, referred to as the advanced glass melter, injects all batch materials into the flame of a natural gas-fired furnace, heating them rapidly and discharging them into the melt chamber. Because of lower flame temperatures, this system has potential for low NO_x emissions.

Glossary

American Petroleum Institute (API) gravity A measure of specific gravity (in degrees) of crude oil or condensate. An arbitrary scale expressing the gravity or density of liquid petroleum products.

barrel A unit of volume equal to 42 U.S. gallons.

British thermal unit The quantity of heat required to raise the temperature of 1 lb of liquid water by 1°F at the temperature at which water has its greatest density (approximately 39°F).

fossil fuel An energy source formed in the earth's crust from decayed organic material. The common fossil fuels are petroleum, coal, and natural gas.

gas to liquids (GTL) A process that combines the carbon and hydrogen elements in natural gas molecules to make synthetic liquid petroleum products, such as diesel fuel.

generator capacity The maximum output, commonly expressed in megawatts, that generating equipment can supply to the system load, adjusted for ambient conditions.

liquefied natural gas (LNG) The liquefied product derived from natural gas (primarily methane) that has been reduced to a temperature of −260°F at atmospheric pressure.

megawatt One million watts of electricity.

oil resources The conventional oil resource base is defined by three categories: remaining reserves (oil that has been discovered but not produced); reserve growth (increases in reserves resulting mainly from technological factors that enhance a field's recovery rate); and undiscovered (oil that remains to be found through exploration).

pig iron The crude, high-carbon iron produced by reduction of iron ore in a blast furnace.

proved energy reserves The estimated quantities of energy sources that analysis of geologic and engineering data demonstrates with reasonable certainty are recoverable under existing economic and operating conditions. The location, quantity, and grade of the energy source are usually considered to be well established in such reserves.

tar sands The naturally occurring bitumen-impregnated sands that yield mixtures of liquid hydrocarbon and that require further processing other than mechanical blending before becoming finished petroleum products.

watt The unit of electrical power equal to 1 amp under a pressure of 1 V; 1 W is equal to 1/746 horsepower.

watt-hour The electrical energy unit of measure equal to 1 W of power supplied to, or taken from, an electric circuit steadily for 1 hr.

World energy use has increased steadily over the past several decades. Much of the growth in global energy consumption has been concentrated on the use of fossil fuels (oil, natural gas, and coal). This trend is expected to continue over the foreseeable future. Industrially mature nations will continue to rely on fossil fuels to meet their energy needs for all end uses, but the greatest rate of energy use is projected to occur in the emerging economies of the developing world. In these developing nations, fossil fuel use will be needed to feed growing industrial machinery, particularly the energy-intensive energy end uses that are needed to build industrial infrastructure, such as cement and steel-making, paper and pulp, and other energy-intensive processes. In this article, the trends of worldwide energy use by region are discussed. Also considered are the drivers of increased energy use, and the ramifications for future energy demand. These include the impact of increased energy demand on the environment and the role that advancing technologies may play on the world's future energy mix.

1. CURRENT ISSUES IN ENERGY DEMAND

Non-fossil-fuel energy sources (i.e., nuclear power and renewable energy sources) face difficulties in competing with fossil fuels. In the case of nuclear power generation, the industry has encountered political, economic, and social difficulties in many parts of the world, beginning with the nuclear accidents at Three Mile Island in the United States in 1979 and at Chernobyl in the Soviet Union in 1986. There is strong public sentiment against nuclear power in much of the industrialized world, based on concerns about plant safety, radioactive waste disposal, and the proliferation of nuclear weapons. Some growth in nuclear power may be expected among the developing countries of the world, particularly in developing Asia, where 17 of the 35 nuclear power reactors currently under construction worldwide may be found. However, the industrialized world is by and large expected to see a decline in nuclear power generation over the long term, as aging reactors are retired and are not replaced by new nuclear generators.

Renewable energy sources enjoy a great measure of popularity with the public—both because these sources of energy are cleaner burning compared to other energy sources and because they are not subject to resource depletion, perceived to be a problem for fossil fuels. However, renewable energy sources cannot yet compete economically with fossil fuel resources. With fossil fuel prices likely to remain moderate over the next quarter century, renewable energy sources will probably fail to gain market share relative to the fossil fuels in a business-as-usual scenario. In the absence of significant government policies aimed at reducing the impacts of carbon-emitting energy sources on the environment, it will be difficult to encourage a wide-scale expansion of renewable resources.

It should also be noted, however, that the renewable energy forecasts presented here deal only with commercial renewable energy sources, i.e., those projects connected to national electricity grids. The Paris-based International Energy Agency (IEA) has estimated that noncommercial, traditional biomass resources are the primary sources of heating and cooking for 2.4 billion people in the developing world. Unfortunately, sources of comprehensive data on the use of noncommercial fuels are not readily available on a consistent, worldwide basis, and so cannot be included in projections of global energy consumption. The IEA expects the developing populations of the world to begin to switch away from traditional fuels to commercial energy sources, but the reliance on the noncommercial fuels will clearly remain strong in the mid-term future given the high levels of current use.

Another trend that is expected to continue is a move toward improving energy intensity. As time goes by and energy technologies become more efficient and widespread, energy use becomes more and more productive. That is, by employing more efficient technologies, less energy is needed to produce the same amount of output. One part of the world where this is particularly obvious is among the nations of the former Soviet Union. Rich with fossil fuel resources and mired in dysfunctional political and economic systems, Russia and the Soviet satellite nations used energy very inefficiently for much of the past half century. With the fall of the Soviet Union in the early 1990s, these economies began to transition into a market-based economic system, and already the old, Soviet-era machinery and technologies are being replaced by more energy-efficient capital stock. This has meant an improvement in the region's energy intensity since the mid-1990s. As these trends continue, the transitional economies of Eastern Europe and the former Soviet Union will begin to see patterns of energy intensity that resemble those of the industrialized world.

The real growth in energy use is projected to occur in the developing economies of the world. Economic expansion is being accompanied by consumer demand for energy-consuming products. Growing demand for energy to fuel industrial end uses, as well as energy demand in the residential, commercial, and especially transportation and electric utility sectors, will have profound implications for the world's geopolitical relationships. There is tremendous opportunity for large increments of energy consumption in these economies, as nations strive to advance standards of living to match those of the industrialized world. In particular, many nations that are emerging economically will see consumer demand increasing for personal motor vehicles and a wide assortment of home appliances, including televisions and personal computers. National electrification has become an important goal of many of these nations, to improve both the productivity and the standards of living of their populations.

2. TODAY'S ENERGY USE

In the year 2001, 404 quadrillion British thermal units (Btu) of energy were consumed worldwide.

Petroleum products accounted for the largest share (39%) of the world's total energy consumption (Fig. 1). Oil products are particularly important for the transportation sector, and this will probably be true for the next several decades. The world's transportation infrastructure relies heavily on the combustion engine, which, in turn, largely relies on petroleum to operate. Currently, there are no truly commercially competitive alternatives to petroleum products in the transportation sector. Short of a substantial technological advance—such as hydrogen-fueled vehicles—that would offer competition to traditional petroleum-product-fueled automobiles, trucks, and airplanes, it will be difficult for any other fuel type to replace oil in this sector.

Although oil is predominant in the transportation sector, alternative fuels have displaced petroleum product use in other end-use sectors. In many parts of the world, for example, other fuels are increasingly used to fuel electricity generation and the importance of oil in this end-use sector has been decreasing over the past several decades. This trend is expected to continue into the future. Natural gas and nuclear power have been two energy sources that have taken market share away from oil in the electric utility sector, especially since the 1970s. Nuclear power generation advanced strongly in the 1970s. If it were not for the public concerns about the safety of nuclear power, because of accidents at Three Mile Island in 1979 (United States) and at the then-Soviet Chernobyl in 1986, nuclear generation may well have continued to experience significant growth and might have gained substantial market share among the electricity-generating energy sources.

Natural gas is now seen as the fuel of choice for new electricity generation worldwide. Combined cycle gas turbines have been demonstrated to be very efficient electricity generators. What is more, natural gas is widely regarded as a more cleanly burning fossil fuel compared to either coal or oil. In an age in which environmental concerns are increasingly important to the world's governments, natural gas is a desirable alternative to coal- or oil-fired power plants, and gas does not come with the negative aspects of nuclear power, such as concerns about safety and radioactive waste disposal. Where infrastructure and resources are available, natural gas has already gained significant share of the electricity sector. For instance, natural gas supplies more than half (54% in 2000) of the electricity generation in Russia, which, not coincidentally, possesses 31% of the world's total natural gas proved reserves.

Coal is the predominant source of electricity generation in many countries. In the United States, coal accounts for 52% of the country's total electricity-generating capacity. Although it is a relatively "dirty" form of energy (the combustion of coal emits more carbon dioxide than the same amount of natural gas and of most petroleum products), reserves of coal are also fairly widespread across the world and are plentiful. By some estimates, at current production levels, the world has enough coal to last for another 200 years or more. In two of the world's fastest growing developing economies, China and India, coal is an extremely important energy resource. These two countries alone are expected to account for more than 85% of the world increment in coal use over the next two and one-half decades (Fig. 2). Although incremental coal use over most of the world is expected to be for the generation of electricity, in China coal is also an important resource for

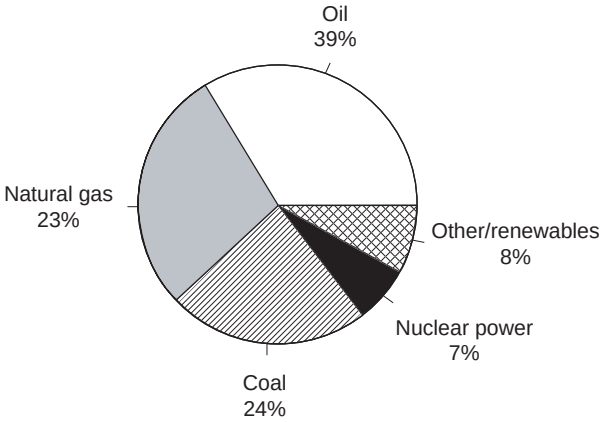

FIGURE 1 World energy use by fuel type, 2001. Data from Energy Information Administration (2003).

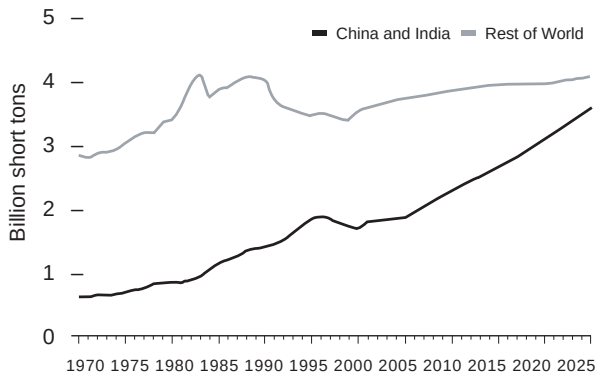

FIGURE 2 World coal use, 1970–2025. Data from Energy Information Administration (2003).

industrial purposes. China is the world's largest producer of both steel and pig iron. The country also uses coal for steam and direct heat for industrial applications, primarily in the chemical, cement, and paper and pulp industries. This heavy reliance on coal may lessen somewhat over the next two decades, but because coal is such a plentiful resource in China, it is difficult to envision a time when its importance will be eclipsed by any other currently available energy source.

As previously noted, nuclear generation showed great promise in the 1970s. Between 1970 and 1986, nuclear generation increased by an estimated 14% per year (Fig. 3). However, the nuclear accidents at Three Mile Island in 1979 and Chernobyl in 1986, in conjunction with the high capital costs associated with bringing nuclear generation into operation relative to coal- or natural-gas-fired generation, slowed the development of nuclear power. Despite problems associated with the disposal of highly radioactive waste, many analysts believed nuclear power would become an increasingly important source of the world's electric power mix. However, public wariness about the safety of nuclear power largely halted the growth of this sector in the 1990s, especially among the industrialized nations and the nations of Eastern Europe and the former Soviet Union. In fact, no orders for new nuclear generators have occurred in Austria, Hungary, Italy, Mexico, the Netherlands, Switzerland, or the United States since 1973. The only industrialized countries that still have plans to expand nuclear generation with new builds are Finland, France, and Japan.

Most of the growth in new nuclear generation is expected to occur in developing Asia (Fig. 3). Of the 35 reactors under construction in 2003, nearly half

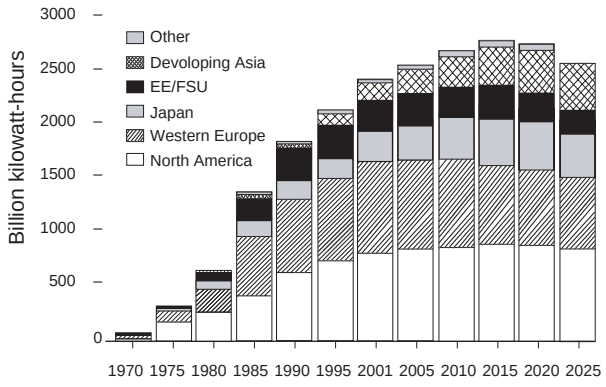

FIGURE 3 World nuclear power consumption by region, 1970–2025. EE/FSU, Eastern Europe/former Soviet Union. Data from Energy Information Administration (2003).

are located in the countries of developing Asia. This includes 8 reactors in India alone, 4 in China, 2 each in South Korea and Taiwan, and 1 in North Korea. These new reactors are expected to add some 12,000 MW of installed nuclear capacity to the existing 28,000 GW on-line in the region as of January 2003. Nuclear generation remains an attractive alternative to other forms of electricity in these countries, either because it will allow them to diversify their electricity-generating sources, such as in India and China, or because there are few indigenous resources that can be used to fuel electricity demand growth, such as in South Korea and Taiwan.

Many countries would like to expand the use of renewable energy resources. In the industrialized world, many governments view renewable energy resources (with the notable exception of large-scale hydroelectric power) as an attractive alternative to expanding electricity generation because of the lack of negative environmental impact, and renewable energy resources are often cited as a way for countries to reduce or limit emissions of carbon dioxide. In western Europe, many government incentive programs are in place to spur the growth of renewable resources, such as wind, solar, geothermal, and small hydroelectric generators, among others. Germany, Denmark, and Spain have made great strides in developing their wind generation capacity through government programs. That said, wind power and other nonhydroelectric forms of on-grid, commercial renewable energy resources remain fairly small portions of the electric generation mix of these nations.

As with any energy form, renewable energy does not come without its controversies. Sometimes populations faced with wind farms view them as eyesores, despoilers of the surrounding landscape, and there can be complaints about the noise that the whirring turbine blades can produce. Procuring site licenses has been particularly difficult in the United Kingdom. The Non Fossil Fuel Obligation—a program used in the United Kingdom to finance the development of renewable energy resources between 1989 and 2001, when it was replaced by the Renewable Obligation of the National Electricity Trading Arrangements program—approved power purchase contracts of wind capacity amounting to 2676 MW, but by the end of 2001 only 468 MW of wind capacity had been installed.

Hydroelectricity remains the largest and widest form of renewable energy worldwide. In the United States alone, hydroelectric power accounts for

between 8 and 10% of the nation's total electricity generation, depending on the amount of rainfall in any given year. Many developing nations rely quite heavily on hydro power for their electricity supplies. In South America, Brazil, Peru, and Chile use hydroelectricity for 80% or more for their electricity needs. Large-scale hydroelectric facilities are often controversial because of their impact on the environment and because it is often necessary to displace surrounding populations in order to create the reservoirs needed to supply the hydro turbines with enough water to generate needed electricity.

Because most of the hydroelectric capacity in industrialized countries has either already been exploited or is located far from the population centers that could use the hydro-generated electricity, much of the growth in hydroelectricity is expected to be in the form of large-scale hydro projects in the developing countries of the world, especially those in developing Asia. Although the average size of a thermal electricity generator (i.e., oil, coal, or natural gas) is about 300 MW, China is currently constructing an 18,200-MW hydroelectric project on the Yangtze River, the Three Gorges Dam project. In Malaysia, the government is pressing forward to construct a 2400-MW Bakun Dam project. These projects and others in Vietnam, India, and Laos, among others, have met with staunch opposition from the international community because of their potentially detrimental impact on wildlife, plant life, and the indigenous populations that will be disrupted by the dams' construction. Still, governments persist with the developments of large-scale hydro projects because of the strong growth in demand for electricity and in an effort to diversify electricity-generating energy sources.

Noncommercial biomass is often not discussed as part of the world's energy use. Although the burning of wood and other plant life to cook and heat water is considered an important component of energy use in many rural parts of the developing world, it is also difficult to quantify. The International Energy Agency has been attempting to measure the amount of biomass used worldwide since 1994. Their estimates indicate that some 2.4 billion people in the developing world still rely on traditional, noncommercial biomass to meet their heating and cooking needs. Even when people in the developing world have access to electricity to meet their lighting needs, they often still rely on biomass for other residential uses. The heavy reliance on surrounding flora is accompanied by many problems. Because developing countries typically have high population growth rates relative to the industrialized world, there is a tendency to need more and more plant life to satisfy the populace's energy needs. The result is that a locale's biomass is often overharvested, resulting in the danger of deforestation, which can degrade the environment and make sustaining life difficult, if not impossible. The Tata Energy Research Institute of India noted that many women in rural South Africa carry 20 kg of fuel wood an average of 5 km each day. The effort required to carry out this task accounts for a large share of the gatherer's daily caloric intake, and as deforestation requires the person to go farther and farther to achieve the requisite fuel wood, the task will eventually not be sustainable.

The use of biomass, particularly fuel wood, dung, and charcoal, can also negatively impact the health of the people utilizing these products. People dependent on biomass resources are consistently exposed to indoor particulate and carbon monoxide levels that are far in excess of those the World Health Organization has deemed safe. Traditional stoves that burn dung or charcoal often emit large amounts of carbon monoxide and other noxious gases, resulting with acute respiratory illnesses and a shortened life span. Although the International Energy Agency has noted that the use of biomass has been declining steadily since biomass surveys were initiated, the agency also believes that it will be 30 years or more before the world will see a substantial reduction in the reliance that developing nations' populations have on this energy source.

3. RESOURCES AND RESERVES

In the 1970s, in an environment of oil shortages caused by the oil embargo staged by the Organization of Petroleum Exporting Countries (OPEC) cartel members, many analysts were concerned with estimating the point at which oil supplies and, indeed, all fossil fuels would be depleted. Gas rationing and high world oil prices associated with this time period further fueled this concern. In fact, work done by the U.S. geologist M. King Hubbert suggested that world oil production would ramp up and peak over only a few short decades and then just as rapidly decline.

Technology has helped to increase the volume of proved oil reserves over the past few decades. Three-dimensional drilling and seismic imaging have been enormously helpful in improving the ability of the oil industry to produce heretofore unrecoverable oil. In part as a result of these enhancements, most

analysts today have a more measured view of the potential for world fossil fuel resources. In its most recent assessment of oil's long-term production potential, the U.S. Geological Survey identified at least 3 trillion barrels of ultimately recoverable conventional oil—that is, oil that can be recovered with current prices and technology—worldwide. Historically, it has been estimated that only about 25% of that oil that has been classified as "ultimately recoverable" has already been produced; rough calculations indicate that a likely peak in worldwide conventional oil production would occur at some point after 2020.

Analysts would agree that fossil fuels are a limited resource and, as such, are subject to depletion. Further, depletion would lead to scarcity and higher prices. There is, however, the matter of nonconventional resources. Nonconventional resources are defined as those resources that cannot be produced economically at current prices using current technology. This categorization shifts as the prices for these resources continue to rise, and the gap between conventional and nonconventional thus narrows. As a result, the combination of escalating prices and technological advancements will transform the nonconventional into the conventional. Much of the perceived pessimism regarding the finite quantities of resources has focused only on conventional resources as defined today. However, it was demonstrated in the 1990s that technological advances can help lower the costs of producing liquid fuels from several nonconventional sources, including heavy oils, tar sands, and natural gas.

Heavy oils generally have an American Petroleum Institute (API) gravity of less than 24° and will not flow on their own at standard reservoir temperatures. Tar sands are similar, but have more viscous oil that is located closer to the surface. More than 3.3 trillion barrels (oil in place) of heavy oil and tar sands are estimated to exist worldwide. The most significant deposits of these resources are found in Canada and Venezuela. There are two distinct ways to recover these resources. For deposits that are located close to the surface, mining can be used. For deposits located deeper under the surface, steam injection could be used to heat the oil and allow it to flow more easily, so that it behaves more like conventional resources. Although it is true that these heavy oils and tar sands will have to be cleaned and upgraded before they behave like conventional refinery feedstocks, higher prices for conventional sources would make the additional costs associated with the additional processes economical. A sustained world oil price of between $23 and $25 per barrel could make these nonconventional resources economical to develop and produce.

Significant portions of the world's natural gas resources are located in remote areas or in small deposits. Development of such sites is usually discouraged, because delivery by way of pipeline or in the form of liquefied natural gas (LNG) is not economical. However, natural gas molecules can be reconstituted as liquid synthetic petroleum products by employing an updated version of a technology that has been available since World War II, the so-called Fischer–Tropsch method. This gas-to-liquids (GTL) technology presents an attractive alternative for the small, remote deposits, because the infrastructure for petroleum products is already in place. GTL technology is also versatile enough to accommodate smaller gas deposits economically. By some estimates, GTL technology could be economically viable with sustained world oil prices of between $26 and $28 per barrel. It is possible to envision a scenario in which oil prices could climb even higher than those that would make nonconventional or GTL technologies economical. For instance, OPEC producers could adopt a conservative productive capacity strategy that might result in a doubling of prices, in real terms, over the next few decades. Sustained high world oil prices might further alter the supply side of the market even beyond those suggested by heavy oil, tar sands, and GTL. This might lead to the development of other nonconventional resources. Coal-to-liquids technologies and even shale oil could then economically be developed. Shale oil has enormous potential reserves that would dwarf those of conventional resources.

As with petroleum reserves, natural gas resources have in general increased in every year since the 1970s. As of January 1, 2003, proved natural gas reserves—that is, those quantities that can be recovered under present technologies and prices—were estimated by the *Oil & Gas Journal* at 5501 trillion cubic feet. Most of the increases in natural gas reserves in recent years have occurred in the developing world, and about 71% of the world's natural gas reserves are found in the Middle East and in the former Soviet Union (Fig. 4). The remaining reserves are spread fairly evenly among other regions of the world. Despite the high rates of increase in the use of natural gas worldwide, most regional reserves-to-production ratios have remained high. Worldwide, the reserves-to-production ratio is estimated at 62 years, but the former Soviet Union has a reserves-to-production ratio estimated at nearly 80 years; this

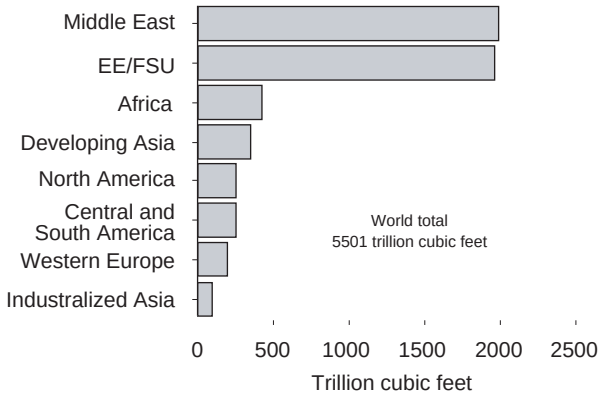

FIGURE 4 World natural gas reserves by region as of January 1, 2003. EE/FSU, Eastern Europe/former Soviet Union. Data from *Oil & Gas Journal*, Vol. 100, No. 52, December 23, 2002, pp. 114–115.

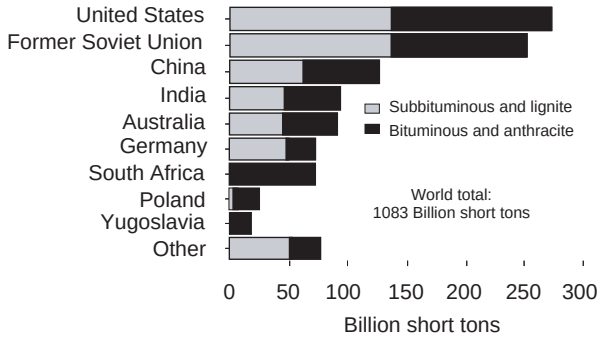

FIGURE 5 World recoverable coal reserves. Data from World Energy Council London, UK (2001) (for all countries except the United States; data for the United States provided by the Energy Information Administration); also based on unpublished data of the Coal Reserves Data Base (February 2002).

ratio in Africa and in the Middle East is about 90 years and over 100 years, respectively.

According to the U.S. Geological Survey's most recent assessment of world natural gas resources, there is a significant amount of natural gas that remains to be discovered. The mean estimate for worldwide undiscovered natural gas is 4839 trillion cubic feet. Of the natural gas resources that are expected to be added over the next 25 years, reserve growth accounts for 2347 trillion cubic feet. It is estimated that one-fourth of the undiscovered natural gas is located in undiscovered oil wells. Thus, it should come as no surprise that more than one-half of the mean undiscovered natural gas is expected to come from the Middle East, former Soviet Union, and North Africa. Although the United States has produced more than 40% of its total estimated natural gas endowment and carries less than 10% as remaining reserves, in the rest of the world reserves have been largely unexploited. Outside the United States, the world has so far produced less than 10% of its total estimated natural gas endowment and carries more than 30% as remaining reserves.

World coal reserves are also considered to be quite plentiful. Total recoverable reserves of coal are those quantities of coal that geological and engineering data indicate with reasonable certainty can be extracted in the future under existing economic and operating conditions; around the world, total recoverable reserves are estimated at 1083 billion short tons. At current consumption levels, there are still 210 years worth of sufficient coal reserves. Although coal deposits are widely distributed, 60% of the world's recoverable reserves is located in three regions; the United States holds an estimated 25% of world reserves, the former Soviet Union holds 23%, and China holds 12%. Another four countries, Australia, India, Germany, and South Africa, collectively account for another 29% (Fig. 5).

4. DRIVERS OF ENERGY DEMAND

There are several important drivers associated with the growth in energy demand. One driver, a nation's income, which can be measured by gross domestic product (GDP), can indicate how much energy a given nation will require to support the expanding economy. Potential growth in population will influence the demand for energy to support an expanding population. Another factor is the rate of efficiency gains a country makes in its energy consumption. Other factors, such as environmental policies, taxes, and subsidies, and other influences can also have an impact on the development of energy markets from country to country. An examination of these factors and how they are manifested in various parts of the world can help to explain the regional trends in energy consumption.

Although economic growth is certainly a key factor to determining the growth in energy demand, how energy is used relative to income can be equally important. Economic growth and energy demand are linked and the strength of that link varies among regions and their stages of economic development. In the industrialized world, history has shown the link to be a relatively weak one, with energy demand lagging behind economic growth. In developing countries, demand and economic growth have been

closely correlated in the past, with demand growth tending to track the rate of economic expansion.

The historical behavior of energy intensity in the former Soviet Union (FSU) is problematic. Since World War II, the levels of energy intensity in the Soviet Republic economies have been higher than they have been in either the industrialized or the developing nations (Fig. 6). In the FSU, however, energy consumption grew more quickly than GDP until 1990, when the collapse of the Soviet Union created a situation in which both income and energy use were declining, but GDP fell more quickly; as a result, energy intensity increased. As the nations of the FSU continue to recover from the economic and social problems of the 1990s, energy intensity should begin to decline once again, as new, more efficient capital stock replaces inefficient Soviet-era equipment and GDP continues to expand.

The stage of economic development and the standard of living of individuals in a given region strongly influence the link between economic growth and energy demand. Advanced economies with high standards of living have relatively high per capita energy use, but they also tend to be economies in which per capita energy use is stable or changes very slowly, and increases in energy use tend to correlate with employment and population growth. In the industrialized world, there is a high penetration rate of modern appliances and motorized personal transportation equipment. To the extent that spending is directed to energy-consuming goods, it involves more often than not purchases of new equipment to replace old capital stock. The new stock tends to be more efficient than the equipment it replaces, resulting in a weaker link between income and energy demand. In the developing world, standards of living, while rising, tend to be low relative to those in more industrially advanced economies.

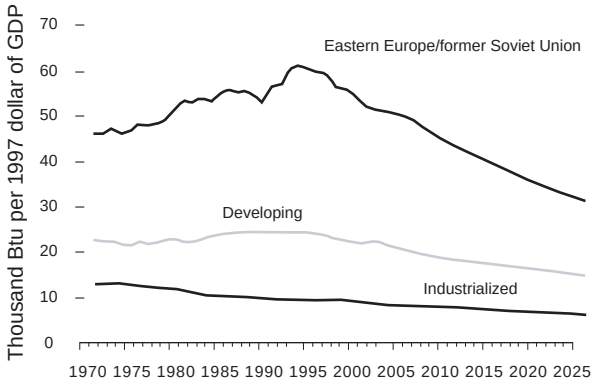

FIGURE 6 World energy intensity by region, 1970–2025. GDP, Gross domestic product. Data from Energy Information Administration (2003).

It is worth noting that, although economic growth and energy intensity impact the increases in energy demand, other factors may also influence the development of energy use. Individual countries may employ many devices to encourage consumer behavior. For instance, in the industrialized countries of western Europe, taxes are often levied in an effort to get consumers to use less energy. Motor gasoline and diesel fuel are heavily taxed in many western European countries. The government tries to use this disincentive to consume to lower congestion in urban areas and to lower the impact of motor vehicle emissions on the environment. In many industrialized countries, tax incentives, such as the wind production tax credit in the United States, are used to encourage consumers to use a more environmental, but not yet economically competitive, form of energy, in this case, wind. In the developing country, price subsidies are sometimes employed to make it possible for a population to increase the penetration of modern technologies. Many oil-producing countries, e.g., Indonesia and Nigeria, heavily subsidize their motor fuels to support fledgling motor vehicle ownership.

5. REGIONAL ENERGY USE

The current mix of the world's energy markets, the drivers associated with estimating increases in energy consumption, and the potential resources available to meet future demand have been considered; the regional trends in world energy use are now assessed.

At present, the industrialized world is responsible for the lion's share of the global energy use. The United States alone currently accounts for 25% of the total world energy use. In contrast, China, a country with a population of about four times that of the United States, presently consumes only 8% of the world's total energy production. Energy use among the industrialized countries is expected to grow, though more slowly in the future than it has over the past several decades. The industrialized countries will probably maintain the largest regional share of world energy consumption (Fig. 7). However, the growth in consumption is expected to be low relative to other parts of the world. Many industrialized nations—notably Japan and many of the countries of western Europe—are faced with slow population growth rates and thus energy markets will not need to accommodate a great deal of new populace. Further, most, if not all, of the energy end-use sectors

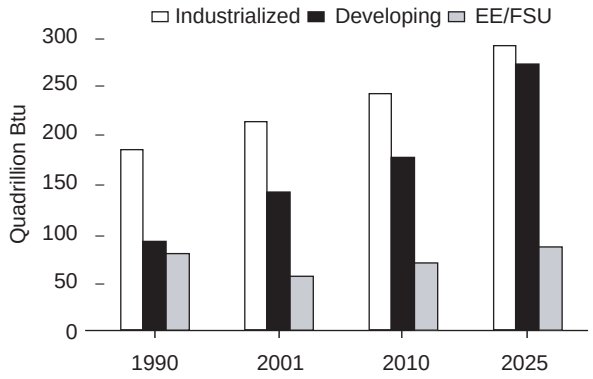

FIGURE 7 World energy consumption by region, 1990–2025. EE/FSU, Eastern Europe/former Soviet Union. Data from Energy Information Administration (2003).

TABLE I

Projected Growth in World Population by Region, 2001–2025[a]

Region	Average annual increase (%)
North America	0.9
Western Europe	−0.1
Industrialized Asia	0.2
Eastern Europe/former Soviet Union	−0.2
Developing Asia	1.1
Middle East	2.0
Africa	2.3
Central and South America	1.2
Total worldwide	**1.1**

[a]Data from United Nations (2001).

will not see large increments in energy demand. Residential and industrial consumers already possess well-established infrastructures, so most of the future energy demand will utilize more efficient equipment.

In comparison to the industrialized nations, there is enormous potential energy demand from burgeoning populations in the developing world. Africa, the Middle East, Central and South America, and developing Asia are all expected to experience average annual population increases of over 1.0% per year between 2001 and 2025 (Table I), with many individual countries among these regions seeing population growth in excess of 2% per year. A corresponding increment in energy consumption will be needed to ensure the prosperity of these economies. As these developing economies continue to emerge, there will be increasing consumer demand for electricity to run modern appliances such as refrigerators, stoves, ovens, washers, dryers, and even personal computers, to name a few, and also for personal motor vehicles. Motor vehicle ownership is considered to be among the first symbols of emerging prosperity in many developing countries, and as the industrial base expands, so too will the need to move goods and services to market.

The fastest growing energy markets will likely be centered in developing Asia. In the Energy Information Administration's *International Energy Outlook 2003*, economic growth in this region is projected to increase 5.1% per year between 2001 and 2025. This increment in the region's income will require a corresponding increase in energy use. The Energy Information Administration (EIA) expects developing Asian energy demand to grow by 3.0% per year over this time period. Many of the nations of this region have a relatively immature infrastructure. In China, for instance, there is great potential for the transportation sector to expand. In 1999, there were an estimated 12 motor vehicles per 1000 persons, compared to the 777 vehicles per 1000 persons recorded for the United States. Although a 2002 analysis by the EIA suggests that motorization levels in China might grow to as many as 52 vehicles per 1000 persons by 2020, China would still only have levels that are 6% that of the current U.S. motorization levels.

Growing transportation energy use could have a profound impact on the demand for world oil. With no economic alternatives to oil presently available, the pressures on world oil supplies will be great. In the case of China, should transportation energy use grow at a robust rate of, say, 5.0% per year between 2001 and 2025, an increment of 4.4 million barrels of oil per day would be required to fuel the Chinese transportation market. This is substantial, considering that total oil consumption in China is projected to grow by 5.9 million barrels per day over this time period. The geopolitical ramifications of such growth in demand could be significant. China became a net importer of oil in 1993, and in 2001 the country was importing 2.0 million barrels per day of oil, with 0.9 million barrels per day coming from the OPEC Persian Gulf. With the demand increases projected by the EIA, China's oil import dependence on the OPEC nations is apt to increase dramatically over the next two and one-half decades. In the EIA reference case, China will import 7.8 million barrels per day by 2025, most of which is expected to come from the Persian Gulf nations.

Energy demand could grow even more dramatically than analysts assume if developing markets

manage to reach the consuming patterns of the industrialized countries more quickly than conventional wisdom suggests. This is entirely possible. Consider the case of South Korea, where energy consumption grew rapidly over the past three decades, by nearly 12% per year. South Korea embraced a market-based economy and has made tremendous strides in becoming an industrialized nation. Standards of living have grown substantially. In 1970, South Korea had a per capita GDP of about $2000 per person (in real 1997 U.S. dollars), but by 2001 this had climbed to $11,908 per year. Per capita energy use correspondingly increased, from 21 million Btu per person in 1970 to 172 million Btu in 2001. In contrast, China's per capita energy use was 31 million Btu in 2001. Should China's per person energy use achieve the current South Korea per capita energy use levels by 2025, another 163 quadrillion Btu of energy (or 80% more than projected for China in 2025 according to the EIA reference case forecast) would be needed to meet the additional demand. A similar paradigm could be made for many other developing countries.

The potential for new energy demand is also fairly high in the transitional economies of the former Soviet Union. Although energy demand plummeted in the early 1990s after the dissolution of the Soviet regime, by the late 1990s and into the 21st century, the economies of these nations began to recover. The growth in energy use is not expected to be as dramatic as that in the developing world, mostly because the rate of population growth is set to decline or will remain slow in most of these nations, and because energy, in the past, has been used very inefficiently. As these economies transition from planned economies to more market-based economies and as foreign investment in the private sectors begins to take hold, energy will be used more efficiently and with new, less energy-intensive equipment.

6. SUMMARY

World energy use is poised to increase substantially over the next few decades. How energy markets develop and what kinds of political, economic, or social changes might influence these changes are impossible to determine with any degree of certainty. Current understanding of fossil fuel resources suggests that there will be ample supplies of fossil fuels available to meet the growing demand for the foreseeable future, at relatively low consumer costs. It is also true that government intervention to encourage conservation or to support the consumption of nonfossil alternatives may decrease the need to exploit all of these resources. Further, there is an opportunity for technological innovation that may advance the use of other energy forms in the future, but this cannot yet be predicted. After all, the share of world energy use of nuclear power generation grew from less than 0.5% in 1970 to almost 7% in 1999. A similar advancement, say in automobiles that could economically run on hydrogen, could profoundly change the world reliance on petroleum products, albeit the penetration of such an advancement might require more than only a few decades without some incentive to make such a dramatic change to the infrastructure.

1. Material Cycles
2. Geotectonic Cycle
3. Water Cycle
4. Carbon Cycle
5. Nitrogen Cycle
6. Sulfur Cycle

Glossary

carbon The sixth element of the periodical table and the key structural element of all living matter.
geotectonics The process of reforming the earth's surface that is driven primarily by creation and subduction of the ocean floor.
nitrogen The seventh element of the periodical table and an indispensable ingredient of proteins, the principal metabolic vehicles of life.
sulfur The 16th element of the periodical table whose presence in disulfide bonds makes the proteins three-dimensional.
water A triatomic molecule of hydrogen and oxygen with many unique physical and chemical properties that makes life possible.

The earth is a constant recipient of an enormous flux of solar radiation as well as considerable infall of the cosmic debris that also arrives periodically in huge, catastrophe-inducing encounters with other space bodies, particularly with massive comets and asteroids. Nothing else comes in, and the planet's relatively powerful gravity prevents anything substantial from leaving. Consequently, life on the earth is predicated on incessant cycling of water and materials that are needed to assemble living bodies as well as to provide suitable environmental conditions for their evolution. These cycles are energized by two distinct sources: Whereas the water cycle and the circulations of carbon, nitrogen, and sulfur, the three key life-building elements, are powered by solar radiation, the planet's grand tectonic cycle is driven by the earth's heat. For hundreds of thousands of years, our species had no discernible large-scale effect on these natural processes, but during the 20th century anthropogenic interferences in global biospheric cycles became a matter of scientific concern and an increasingly important, and controversial, topic of public policy debates.

1. MATERIAL CYCLES

Two massive material cycles would be taking place even on a lifeless Earth: (i) a slow formation and recycling of the planet's thin crust and (ii) evaporation, condensation, and runoff of water. As weathering breaks down exposed rocks, their constituent minerals are transported by wind in terrigenic dust and in flowing water as ionic solutions or suspended matter. Their journey eventually ends in the ocean, and the deposited materials are either drawn into the mantle to reemerge in new configurations 10^7–10^8 years later along the ocean ridges or in volcanic hot spots or they resurface as a result of tectonic movements as new mountain ranges. This grand sedimentary–tectonic sequence recycles not just all trace metals that are indispensable in small amounts for both auto- and heterotrophic metabolism but also phosphorus, one of the three essential plant macronutrients.

On human timescale (10^1 years), we can directly observe only a minuscule segment of the geotectonic weathering cycle and measure its rates mostly as one-way oceanward fluxes of water-borne compounds. Human actions are of no consequence as far as the

 © 2004 Elsevier Inc. All rights reserved.

geotectonic processes are concerned, but they have greatly accelerated the rate of weathering due to deforestation, overgrazing of pastures, and improper crop cultivation. Incredibly, the annual rate of this unintended earth movement, 50–80 billion metric tons (Gt), is now considerably higher than the aggregate rate of global weathering before the rise of agriculture (no more than 30 Gt/year).

In addition, we act as intentional geomorphic agents as we extract, displace, and process crustal minerals, mostly sand, stone, and fossil fuels. The aggregate mass moved annually by these activities is also larger than the natural preagricultural weathering rate. Our activities have also profoundly affected both the quantity and the quality of water cycled on local and regional scales, but they cannot directly change the global water flux driven predominantly by the evaporation from the ocean. However, a major consequence of a rapid anthropogenic global warming would be an eventual intensification of the water cycle.

In contrast to these two solely, or overwhelmingly, inanimate cycles, global circulations of carbon, nitrogen, and sulfur are to a large extent driven or mediated by living organisms, largely by bacteria, archaea, and plants. Another characteristic that these cycles have in common is their relatively modest claim on the planet's energy flows. Photosynthesis, carbon cycle's key terrestrial flux, requires only a tiny share of incident solar radiation, and the cycling of nitrogen and sulfur involves much smaller masses of materials and hence these two cycles need even less energy for their operation: Their indispensability for Earth's life is in renewing the availability of elements that impart specific qualities to living molecules rather than in moving large quantities of materials. Similarly, only a small fraction of the planet's geothermal heat is needed to power the processes of global geotectonics.

Although the basic energetics of all these cycles is fairly well-known, numerous particulars remain elusive, including not only specific details, whose elaboration would not change the fundamental understanding of how these cycles operate, but also major uncertainties regarding the extent and consequences of human interference in the flows of the three doubly mobile elements (carbon, nitrogen, and sulfur), whose compounds are transported while dissolved in water as well as relatively long-lived atmospheric gases. For millennia these interventions were discernible only on local and regional scales, but during the 20th century their impacts increased to such an extent that the effects of these interferences now present some historically unprecedented challenges even in global terms.

2. GEOTECTONIC CYCLE

The earth's surface is composed of rigid oceanic and continental plates. The former are relatively thin (mostly 5–7 km), short-lived [mostly less than 140 million years (Ma)], and highly mobile (up to 10–20 cm/year). The latter ones are thicker (only 35–40 km), long-lived (10^9 years), and some, most notably Asian and African plates, are virtually stationary. Plates ride on the nearly 3000-km-thick solid but flowing mantle, which is the source of hot magma whose outpourings create new seafloor along approximately 72,000 km of the earth-encircling ocean ridge system. Old seafloor is eventually recycled back into the mantle in subduction zones marked by deep ocean trenches (Fig. 1). There are substantial uncertainties concerning the actual movements of the subducted plates within the mantle: The principal debate is between the two-layer models and the whole-mantle flows.

Today's oceans and continents are thus transitory features produced by incessant geotectonic processes that are energized by three sources of the earth's heat: energy conducted through the lithosphere from the underlying hot mantle, radiogenic decay of heat-producing crustal elements, and convective transport by magmas and fluids during orogenic events. The relative importance of these heat sources remains in dispute, but the heat flow at the earth's surface can be measured with high accuracy. Its total is approximately 44 trillion watts (TW), prorating to approximately 85 mW/m^2 of the earth's surface. The average global heat flux of approximately 85 mW/m^2 is equal

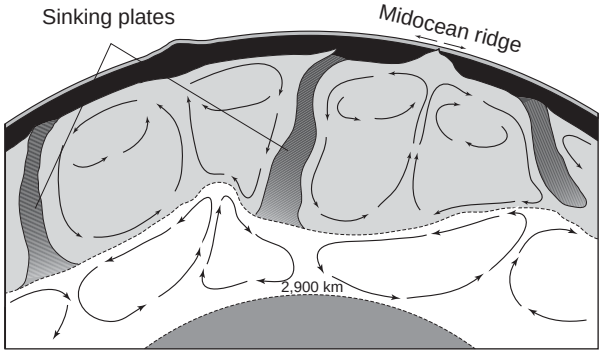

FIGURE 1 A cross section of the earth shows tectonic plates, an ocean ridge, a subduction trench, and, in this model, the circulation in mantle that is separated into two cells.

to a mere 0.05% of solar radiation absorbed by surfaces (168 W/m^2), but acting over huge areas and across long timespans, this flow is responsible not only for creating new ocean floor, reshaping continents, and building enormous mountain chains but also for energizing earthquakes and volcanic eruptions.

Mean oceanic heat flow is approximately 100 mW/m^2, whereas the continental flow is only approximately half as high. The ocean floor transmits approximately 70% of the earth's total geothermal flux and nearly one-third of the oceanic heat loss occurs in the South Pacific, where the spreading rates, particularly along the Nazca Ridge, are faster than anywhere else on Earth. By far the highest heat flows are along midocean ridges, where approximately 3–3.5 km^2 of new ocean floor is created by hot magma rising from the mantle. The total heat flux at the ridges, composed of the latent heat of crystallization of newly formed ocean crust and of the heat of cooling from magmatic temperatures (approximately 1200°C) to hydrothermal temperatures (approximately 350°C), is between 2 and 4 TW.

Divergent spreading of oceanic plates eventually ends at subduction zones, where the crust and the uppermost part of the mantle are recycled deep into the mantle to reappear through igneous process along the ridges. Every new cycle begins with the breakup of a supercontinent, a process that typically takes approximately 200 Ma, and is followed first by slab avalanches and then by rising mantle plumes that produce juvenile crust. After 200–440 Ma, the new supercontinent is broken up by mantle upwelling beneath it.

During the past billion years (Ga), the earth has experienced the formation and breakup of three supercontinents: Rodinia (formed 1.32–1.0 Ga ago and broken up between 700 and 530 Ma ago), Gondwana (formed between 650 and 550 Ma ago), and Pangea (formed 450–250 Ma ago and began to break up approximately 160 Ma ago). Pangea spanned the planet latitudinally, from today's high Arctic to Antarctica; its eastern flank was notched by a V-shaped Tethys Sea centered approximately on the equator. Unmistakable signs of continental rifting can be seen today underneath the Red Sea and along the Great Rift Valley of East Africa: The process of continental breakup is still very much under way.

Inevitably, these grand geotectonic cycles had an enormous impact on the evolution of life. They made it possible to keep a significant share of the earth's surface above the sea during the past 3 Ga, allowing for the evolution of all complex terrestrial forms of life. Changing locations and distributions of continents and oceans create different patterns of global oceanic and atmospheric circulation, the two key determinants of climate. Emergence and diversification of land plants and terrestrial fauna during the past 500 Ma years have been much influenced by changing locations and sizes of the continents. The surface we inhabit today has been, to a large extent, fashioned by the still continuing breakup of Pangea. Two of the earth's massive land features that have determined the climate for nearly half of humanity—the Himalayas, the world's tallest mountain chain, and the high Tibetan Plateau—are its direct consequences. So is the northward flow of warm Atlantic waters carried by the Gulf Stream that helps to create the mild climate in Western Europe. Volcanic eruptions have been the most important natural source of CO_2 and, hence, a key variable in the long-term balance of the biospheric carbon. Intermittently, they are an enormous source of aerosols, whose high atmospheric concentrations have major global climatic impacts.

3. WATER CYCLE

Most of the living biomass is water, and this unique triatomic compound is also indispensable for all metabolic processes. The water molecule is too heavy to escape the earth's gravity, and juvenile water, originating in deeper layers of the crust, adds only a negligible amount to the compound's biospheric cycle. Additions due to human activities—mainly withdrawals from ancient aquifers, some chemical syntheses, and combustion of fossil fuels—are also negligible. Both the total volume of Earth's water and its division among the major reservoirs can thus be considered constant on a timescale of 10^3 years. On longer timescales, glacial–interglacial oscillations shift enormous volumes of water among oceans and glaciers and permanent snow.

The global water cycle is energized primarily by evaporation from the ocean (Fig. 2). The ocean covers 70% of the earth, it stores 96.5% of the earth's water, and it is the source of approximately 86% of all evaporation. Water has many extraordinary properties. A very high specific heat and heat capacity make it particularly suitable to be the medium of global temperature regulation. High heat of vaporization (approximately 2.45 kJ/g) makes it an ideal transporter of latent heat and helps to retain plant and soil moisture in hot environments. Vaporization of 1 mm/day requires 28 or 29 W/m^2, and with average daily evaporation of approximately

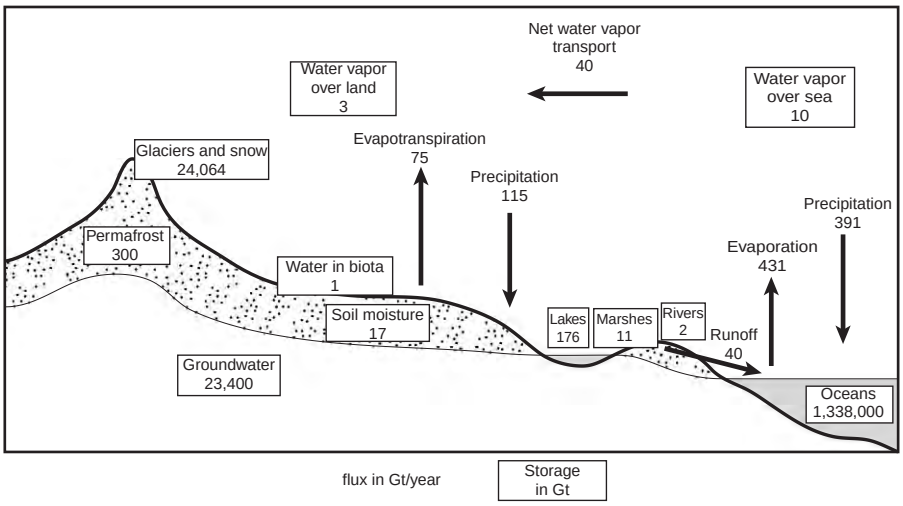

FIGURE 2 Annual flows of the earth's global water cycle. The totals are all in billion of metric tons.

3 mm, or an annual total of 1.1 m, the global latent heat flux averages approximately 90 W/m^2. This means that approximately 45 quadrillion watts (PW), or slightly more than one-third of the solar energy absorbed by the earth's surface and the planet's atmosphere (but 4000 times the amount of annual commercial energy uses), is needed to drive the global water cycle.

The global pattern of evaporation is determined not only by the intensity of insolation but also by the ocean's overturning circulation as cold, dense water sinks near the poles and is replaced by the flow from low latitudes. There are two nearly independent overturning cells—one connects the Atlantic Ocean to other basins through the Southern Ocean, and the other links the Indian and Pacific basins through the Indonesian archipelago. Measurements taken as a part of the World Ocean Circulation Experiment show that 1.3 PW of heat flows between the subtropical (latitude of southern Florida) and the North Atlantic, virtually the same flux as that observed between the Pacific and Indian Oceans through the Indonesian straits.

Poleward heat transfer of latent heat also includes some of the most violent low-pressure cells (cyclones), American hurricanes, and Asian typhoons. Oceanic evaporation (heating of equatorial waters) is also responsible for the Asian monsoon, the planet's most spectacular way of shifting the heat absorbed by warm tropical oceans to continents. The Asian monsoon (influencing marginally also parts of Africa) affects approximately half of the world's population, and it precipitates approximately 90% of water evaporated from the ocean back onto the sea. Evaporation exceeds precipitation in the Atlantic and Indian Oceans, the reverse is true in the Arctic Ocean, and the Pacific Ocean flows are nearly balanced.

Because of irregular patterns of oceanic evaporation (maxima up to 3 m/year) and precipitation (maxima up to 5 m/year), large compensating flows are needed to maintain sea level. The North Pacific is the largest surplus region (and hence its water is less salty), whereas evaporation dominates in the Atlantic. In the long term, oceanic evaporation is determined by the mean sea level. During the last glacial maximum 18,000 years ago, the level was 85–130 m lower than it is now, and satellite measurements indicate a recent global mean sea level rise of approximately 4 mm per year.

The difference between precipitation of evapotranspiration has a clear equatorial peak that is associated with convective cloud systems, whereas the secondary maxima (near 50°N and °S) are the result of extratropical cyclones and midlatitude convection. Regarding the rain on land, approximately one-third of it comes from ocean-derived water vapor, with the rest originating from evaporation from nonvegetated surfaces and from evapotranspiration (evaporation through stomata of leaves). Approximately 60% of all land precipitation is evaporated, 10% goes back to the ocean as surface runoff, and approximately 30% is carried by rivers (Fig. 2). Because the mean continental elevation is approximately 850 m, this riverborne flux implies an annual conversion of approximately 370×10^{18} J of potential energy to kinetic energy of flowing water, the principal agent of geomorphic denudation shaping the earth's surfaces. No more than approximately

15% of the flowing water's aggregate potential energy is convertible to hydroelectricity.

The closing arm of the global water cycle works rather rapidly because average residence times of freshwater range from just 2 weeks in river channels to weeks to months in soils. However, widespread construction of dams means that in some river basins water that reaches the sea is more than 1 year old. In contrast to the normally rapid surface runoff, water may spend many thousands of years in deep aquifers. Perhaps as much as two-thirds of all freshwater on Earth is contained in underground reservoirs, and they annually cycle the equivalent of approximately 30% of the total runoff to maintain stable river flows. Submarine groundwater discharge, the direct flow of water into the sea through porous rocks and sediments, appears to be a much larger flux of the global water cycle than previously estimated.

4. CARBON CYCLE

The key structural element of life keeps cycling on several spatial and temporal scales, ranging from virtually instantaneous returns to circulations that take 10^8 years to complete. At one extreme are very rapid assimilation–respiration flows between the plants and the atmosphere and less rapid but still fast assimilation–decomposition–assimilation circuits that move the element from the atmosphere to plant tissue of various ecosystems and return it to the atmosphere after carbon's temporary stores in dead organic matter (in surface litter and soils) are mineralized by decomposers (Fig. 3). The other extreme involves slow weathering of terrestrial carbonates, their dissolution, riverborne transport, and eventual sedimentation in the ocean, and the element's return to land by geotectonic processes. Human interest in the cycle is due not only to the fact that carbon's assimilation through photosynthesis is the foundation of all but a tiny fraction of the earth's life but also to the cycle's sensitivity to anthropogenic perturbations.

Photosynthesis, the dominant biospheric conversion of inorganic carbon from the atmospheric carbon dioxide (CO_2) to a huge array of complex organic molecules in plants, proceeds with very low efficiency. On average, only approximately 0.3% of the electromagnetic energy of solar radiation that reaches the earth's ice-free surfaces is converted to chemical energy of new phytomass. Short-term maxima in the most productive crop fields can be close to 5%, whereas even the tropical rain forests, the planet's most productive natural ecosystems, do not average more than 1%. Plant (autotrophic) respiration consumes approximately half of the gross photosynthesis, and it reduces the global net primary productivity [i.e., the new phytomass available every year for consumption by heterotrophs (from bacteria to humans)] to approximately 60 Gt of carbon on land and approximately 50 Gt of carbon in the ocean.

Virtually all this fixed carbon is eventually returned to the atmosphere through heterotrophic respiration, and only a tiny fraction that accumulates in terrestrial sediments forms the bridge between the element's rapid and slow cycles. After 10^6–10^8 years of exposure to high pressures and temperatures, these sediments are converted to fossil fuels. The most likely global total of biomass carbon that was transformed into the crustal resources of coals and hydrocarbons is in excess of 5 Tt of oil equivalent, or 2.1×10^{23} J. However, some hydrocarbons, particularly natural gas, may be of abiotic origin. Much more of the ancient organic carbon is sequestered in kerogens, which are transformed remains of buried biomass found mostly in calcareous and oil shales.

Intermediate and deep waters contain approximately 98% of the ocean's huge carbon stores, and they have a relatively large capacity to sequester more CO_2 from the atmosphere. The exchange of CO_2 between the atmosphere and the ocean's topmost (mixed) layer helps to keep these two carbon reservoirs stable. This equilibrium can be disrupted by massive CO_2-rich volcanic eruptions or abrupt climate changes. However, the rate of CO_2 exchange between the atmosphere and the ocean is limited because of the slow interchange between the relatively warm mixed layer ($>25^\circ$C in the tropics) and cold (2–4°C) deep waters. As is the case on land, only a small fraction of organic carbon is not respired and goes into ocean sediments (Fig. 3).

Analysis of air bubbles from polar ice cores shows that the atmospheric concentration of CO_2 has remained between 180 and 300 parts per million (ppm) during the past 420,000 years and 250–290 ppm since the rise of the first high civilizations during the 5000 years preceding the mid-19th century. Humans began changing this relatively stable state of affairs first by clearing natural vegetation for fields and settlements, but until the 19th century these releases of CO_2 did not make any marked difference. These conversions became much more extensive after 1850, coinciding with the emergence of fossil-fueled civilization.

Land use changes dominated the anthropogenic mobilization of carbon until the beginning of the 20th

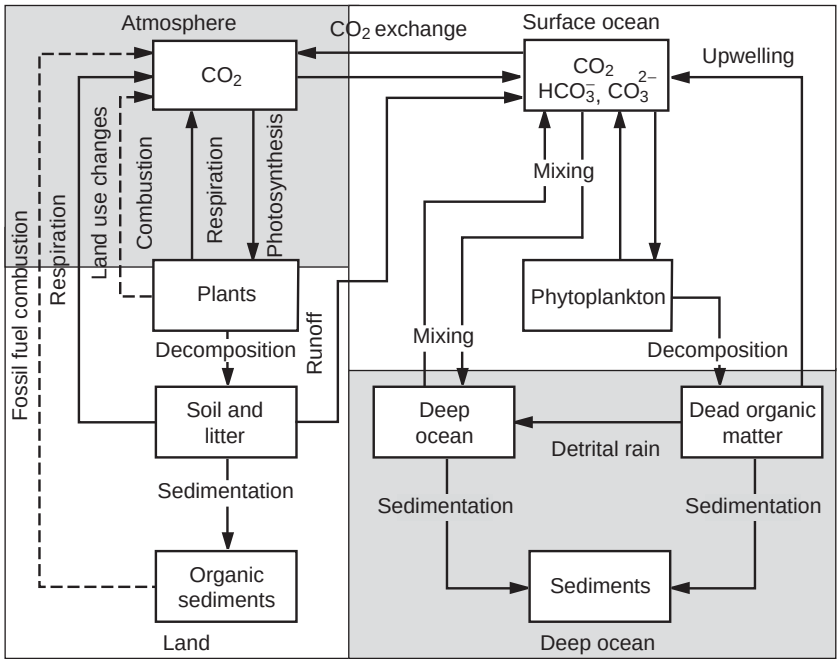

FIGURE 3 Principal reservoirs and flows of the biospheric carbon cycle.

century and they are now the source of 1.5–2 Gt of carbon per year to the atmosphere. Fossil fuel combustion had accelerated from an annual conversion of 22 EJ and emissions of less than 0.5 Gt of carbon in 1900 to more than 300 EJ and releases of more than 6 Gt of carbon by 2000. Every year, on average, approximately half of this anthropogenic flux of approximately 8 Gt of carbon stays in the atmosphere. As a result, atmospheric CO_2 levels that have been constantly monitored at Hawaii's Mauna Loa observatory since 1958 increased from 320 ppm during the first year of measurement to 370 ppm in 2000.

A nearly 40% increase in 150 years is of concern because CO_2 is a major greenhouse gas whose main absorption band of the outgoing radiation coincides with Earth's peak thermal emission. A greenhouse effect is necessary to maintain the average surface temperature approximately 33°C above the level that would result from an unimpeded reradiation of the absorbed insolation, and energy reradiated by the atmosphere is currently approximately 325 W/m^2. During the past 150 years, anthropogenic CO_2 has increased this flux by 1.5 W/m^2 and other greenhouse gases have added approximately 1 W/m^2.

The expected temperature increase caused by this forcing has been partially counteracted by the presence of anthropogenic sulfur compounds in the atmosphere, but another century of massive fossil fuel combustion could double the current CO_2 levels and result in rapid global warming. Its effects would be more pronounced in higher latitudes, and they would include intensification of the global water cycle that would be accompanied by unevenly distributed changes in precipitation patterns and by thermal expansion of seawater leading to a gradual rise in sea level.

5. NITROGEN CYCLE

Although carbon is the most important constituent of all living matter (making up, on average, approximately 45% of dry mass), cellulose and lignin, the two dominant molecules of terrestrial life, contain no nitrogen. Only plant seeds and lean animal tissues have high protein content (mostly between 10 and 25%; soybeans up to 40%), and although nitrogen is an indispensable ingredient of all enzymes, its total reservoir in living matter is less than 2% of carbon's huge stores. Unlike the cycles of water or carbon that include large flows entirely or largely unconnected to biota, every major link in nitrogen's biospheric cycle is mediated by bacteria.

Nitrogen fixation—a severing of the element's highly stable and chemically inert molecule (N_2) that makes up 78% of the atmosphere and its incorporation into reactive ammonia—launches this great cascade of biogenic transformations. Only a very

limited number of organisms that possess nitrogenase, the enzyme able to cleave N_2 at ambient temperature and at normal pressure, can perform this conversion. Several genera of rhizobial bacteria live symbiotically with leguminous plants and are by far the most important fixers of nitrogen on land, whereas cyanobacteria dominate the process in freshwaters as well as in the ocean.

There are also endophytic symbionts (bacteria living inside stems and leaves) and free-living bacterial fixers in soils. The current annual rate of biofixation in terrestrial ecosystems is no less than 160 million metric tons (Mt) of nitrogen, and at least 30 Mt of nitrogen is fixed in crop fields. Biofixation is a relatively energy-intensive process, with 6–12 g of carbon (delivered by the plant to bacteria as sugar) needed for every gram of fixed nitrogen. This means that the terrestrial biofixation of approximately 200 Mt of nitrogen requires at least 1.2 Gt of carbon per year, but this is still no more than 2% of the net terrestrial primary productivity.

Subsequently, there are four key links in the nitrogen cycle (Fig. 4). After nitrogen fixation is nitrification, the conversion of ammonia to more water-soluble nitrates, which is performed by a small number of bacterial species living in both soils and water. Assimilation is the incorporation of reactive nitrogen, be it as ammonia (NH_3) or as nitrate (NO^{-3}), by autotrophic organisms into amino acids that are then used to synthesize proteins. Ammonification is enzymatic decomposition of organic matter performed by many prokaryotes that produces ammonia for nitrification. Finally, denitrification is the closing arm of the cycle in which bacteria convert nitrates into nitrites and then into N_2.

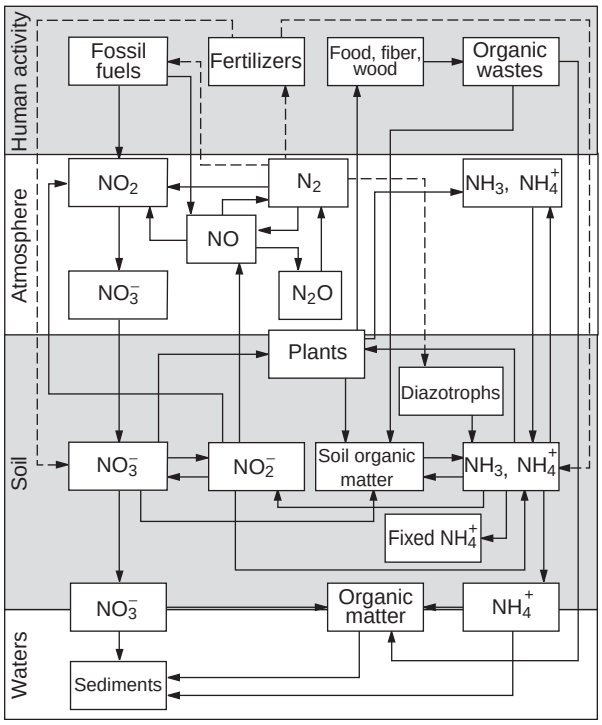

FIGURE 4 Biogeochemical nitrogen cycle centered on plants.

Human interference in the nitrogen cycle is largely due to the fact that heterotrophs, including people, cannot synthesize their own amino acids and hence must digest preformed proteins. Because nitrogen is the most common yield-limiting nutrient in crop cultivation, all traditional agricultures had to resort to widespread planting of leguminous crops and to diligent recycling of nitrogen-rich organic wastes. However, the extent of these practices is clearly limited by the need to grow higher yielding cereals and by the availability of crop residues and human and animal wastes. Only the invention of ammonia synthesis from its elements by Fritz Haber in 1909 and an unusually rapid commercialization of this process by the BASF company under the leadership of Carl Bosch (by 1913) removed the nitrogen limit on crop production and allowed for the expansion of the human population supplied by adequate nutrition (both chemists were later awarded Nobel Prizes for their work). Currently, malnutrition is a matter of distribution and access to food, not of its shortage.

These advances have a considerable energy cost. Despite impressive efficiency gains, particularly since the early 1960s, NH_3 synthesis requires, on average, more than 40 GJ/t, and the conversion of the compound to urea, the dominant nitrogen fertilizer, raises the energy cost to approximately 60 GJ/t of nitrogen. In 2000, Haber-Bosch synthesis produced approximately 130 Mt of NH_3 (or 110 Mt of nitrogen). With production and transportation losses of approximately 10%, and with 15% destined for industrial uses, approximately 82 Mt of nitrogen was used as fertilizer at an aggregate embodied cost of approximately 5 EJ, or roughly 1.5% of the world's commercial supply of primary energy.

The third most important human interference in the global nitrogen cycle (besides NH_3 synthesis and planting of legumes) is the high-temperature combustion of fossil fuels, which released more than 30 Mt of nitrogen, mostly as nitrogen oxides (NO_x), in 2000. Conversion of these oxides to nitrates, leaching of nitrates, and volatilization of ammonia from fertilized fields (only approximately half of the nutrient is actually assimilated by crops) and from animal wastes are the principal sources of nitrogen leakage into ecosystems. Excess nitrogen

causes eutrophication of fresh and coastal waters, and it raises concerns about the long-term effects on biodiversity and productivity of grasslands and forests. NO_x are key precursors of photochemical smog, and rain-deposited nitrates contribute to acidification of waters and soils. Nitrous oxide, a potent greenhouse gas, released during imperfect denitrification is another long-term environmental concern.

6. SULFUR CYCLE

Sulfur is an even rarer component of living molecules than is nitrogen. Only 2 of the 20 amino acids that make up proteins (methionine and cysteine) have the element as part of their molecules, but every protein needs disulfide bridges to make long three-dimensional polypeptide chains whose complex folds allow proteins to be engaged in countless biochemical reactions. The largest natural flux of the element is also the most ephemeral: Sea spray annually carries 140–180 Mt of sulfur into the atmosphere, but 90% of this mass is promptly redeposited in the ocean. Some volcanic eruptions are very large sources of SO_2, whereas others have sulfur-poor veils; a long-term average works out to approximately 20 Mt of sulfur per year, and dust, mainly desert gypsum, may contribute the same amount (Fig. 5).

Biogenic sulfur flows may be as low as 15 Mt and as high as 40 Mt of sulfur per year, and they are produced on land by both sulfur-oxidizing and sulfate-reducing bacteria present in water, mud, and hot springs. Emitted gases are dominated by hydrogen sulfide, dimethyl sulfide (DMS), propyl sulfide, and methyl mercaptan. DMS is also generated in relatively large amounts by the decomposition of algal methionine in the ocean, and these emissions have been suggested to act as homeostatic controllers of the earth's climate. Higher concentrations of DMS would increase albedo by providing more condensation nuclei for increased cloudiness, the resulting reduced insulation would lower planktonic photosynthesis, and diminished DMS emissions would provide fewer condensation nuclei and let in more solar radiation. Later studies showed that not just the magnitude but also the very direction of this feedback are questionable.

Human intensification of the sulfur cycle is due largely to the combustion of coals (containing typically approximately 2% sulfur) and crude oils (sweet crudes have less than 0.5% and sour ones more than 2% sulfur). Some natural gases are high in sulfur, containing it mainly as hydrogen sulfide (H_2S), but it is easily removed before they enter pipelines. Fossil fuel combustion accounts for more than 90% of all anthropogenic sulfur emissions, whose global total increased from 5 Mt in 1900 to approximately 80 Mt in 2000. The remainder is emitted largely during the smelting of color metals (mainly Cu, Zn, and Pb), and a small share originates in chemical syntheses.

Our interest in the sulfur cycle is mainly due to the fact that sulfur dioxide (SO_2) emitted from fossil fuel combustion and nonferrous metallurgy is rapidly oxidized to sulfates, whose deposition is the leading source of acid deposition, both in dry and in wet forms. Before their deposition, sulfur compounds remain up to 3 or 4 days in the lowermost troposphere (average, <40 h), which means that they can travel several hundred to more than 1000 km and bring acid deposition to distant ecosystems. Indeed, the phenomenon was first discovered when SO_2 emissions from central Europe began to affect lake biota in southern Scandinavia. Because of the limits on long-distance transport (atmospheric residence times of DMS and H_2S are also short-lived), sulfur does not have a true global cycle as does carbon (via CO_2) or nitrogen (via denitrification), and the effects of significant acid deposition are limited to large regions or to semicontinental areas.

Deposited sulfates (and nitrates) have the greatest impact on aquatic ecosystems, especially on lakes with low or no buffering capacity, leading to the decline and then the demise of sensitive fish, amphibians, and invertebrates and eventually to profound changes in a lake's biodiversity. Leaching of alkaline elements and mobilization of toxic aluminum from forest soils is another widespread problem in acidified areas, but acid deposition is not the sole, or the principal, cause of reduced forest productivity. Since the early 1980s, concerns about the potential long-term effects of acidification have led to highly successful efforts to reduce anthropogenic SO_2 emissions throughout Europe and in eastern North America.

Reductions of sulfur emissions have been achieved by switching to low-sulfur fuels and by desulfurizing fuels and flue gases. Desulfurization of oils, although routine, is costly, and removing organic sulfur from coal is very difficult (pyritic sulfur is much easier to remove). Consequently, the best control strategy for coal sulfur is flue gas desulfurization (FGD) carried out by reacting SO_2 with wet or dry basic compounds (CaO and $CaCO_3$). FGD is effective,

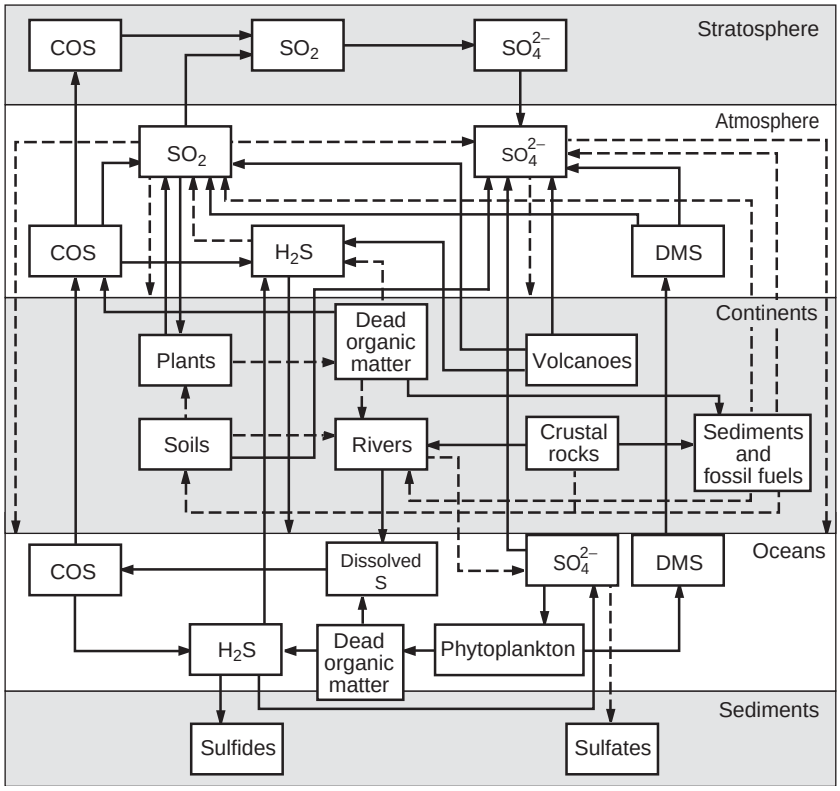

FIGURE 5 Sulfur's biogeochemical cycle extends from the stratosphere to marine sediments.

removing 70–90% of all sulfur, but the average U.S. cost of $125/kW adds at least 10–15% to the original capital expense, and operating the units increases the cost of electricity production by a similar amount. Moreover, FGD generates large volumes of wastes for disposal (mostly $CaSO_4$).

Airborne sulfates also play a relatively major role in the radiation balance of the earth because they partially counteract the effect of greenhouse gases by cooling the troposphere: The global average of the aggregate forcing by all sulfur emissions is approximately $-0.6\,W/m^2$. The effect is unevenly distributed, with pronounced peaks in eastern North America, Europe, and East Asia, the three regions with the highest sulfate levels.

A 16-fold increase in the world's commercial energy consumption that took place during the 20th century resulted in the unprecedented level of human interference in global biogeochemical cycles. Thus, we must seriously consider the novel and a very sobering possibility that the future limits on human acquisition and conversion of energy may arise from the necessity to keep these cycles compatible with the long-term habitability of the biosphere rather than from any shortages of available energy resources.

Glossary

embodied energy The energy consumed "upstream" to facilitate a flow of goods or services (units = energy).
energy cost of living The energy required to facilitate a household's consumption of goods and services (units = energy/year).
energy intensity (ε) The energy required to facilitate a flow of one unit of a specified good or service (units = energy/gloof).
gloof Generic term to cover the range of goods and services; for example, a pound of fertilizer, the dollar value of an airline ticket, or a liter of water.
indirect effect Necessary costs not considered "direct." For example, auto fuel is usually considered direct energy, whereas energy to build roads is considered indirect. It depends on the definition and system boundary.
input–output (I–O) analysis A subdiscipline of economics that explicitly determines indirect effects.
net energy analysis A comparison of the energy costs and the energy produced by an energy technology such as a coal mine or photovoltaic panel.
power Energy per unit time (units = energy/time).
system boundary The limit up to which costs, benefits, impacts, and consequences are considered; can refer to spatial, temporal, or conceptual issues.
trophic position (TP) An indicator of dependence of an organism or group of organisms on solar-driven photosynthesis in an ecosystem. If the system has a linear food chain, it is called trophic level (dimensionless).
vertical analysis (also known as process analysis) A method to determine energy cost by tracing back through the production process.

Energy analysis determines the total energy required to produce a good or service, including the indirect effects through the chain of production and delivery. This energy is commonly called energy cost, although it does not mean the monetary cost of energy. Once the energy cost is known, the energy requirements of different patterns of production/consumption of goods and services can be analyzed. In this article, the imprecise term energy is used, although the preferred, thermodynamically correct term is free energy.

1. INTRODUCTION

Most of us know intellectually that energy—solar and fossil—supports all of our life-support systems, from agriculture to transportation, commerce, and medicine. Some of us know this more viscerally as well; ecologists and farmers see every day that "all flesh is grass." Readers may remember the U.S. east coast blackout of 1965, the oil crisis of 1973 (long waiting lines at gas stations), or even the California electricity shortages during the summer of 2001. I first "got it" while sitting in traffic in 1971 in Oak Ridge, Tennessee. Ahead of me was a car towing a trailer on which there was an aluminum pleasure boat. Because there was increasing controversy in the Tennessee Valley regarding electricity powered by strip-mined coal and nuclear reactors and also from dams, energy was on my mind. I knew that aluminum is an energy-intensive metal, and I realized that I was looking at "embodied" energy, and hence embodied environmental damage and controversy.

On that day, I started 30 years of work in energy analysis. When I see bread, autos, baby carriages, lawn sprinklers, hospitals, playgrounds, orchestral concerts, haircuts, blue jeans, orthodontic braces, street artists, aircraft carriers, or banjoes, I see energy. The question was and is the following: How much embodied energy? In this article, I present methods used to quantify energy cost and illustrate how it is used in several applications.

 © 2004 Elsevier Inc. All rights reserved.

Energy cost is an example of an indirect effect. Once we realize that a good or service "embodies" an input that is not evident, we are free to calculate the energy cost of an orange, the orange cost of energy, the water cost of hamburger, or how much pollution is released when a Sierra Club book (or this encyclopedia) is published. However, then we are vexed with how far to go in the calculation. For example, how much energy is required to allow a car to travel 1 mile? Here are possible answers to the question:

1. The fuel burned
2. Plus the energy to extract, refine, and transport the fuel
3. Plus the energy to manufacture the car (prorated to 1 mile's use)
4. Plus the energy to produce tires, replacement parts, etc.
5. Plus the energy to build and maintain roads.
6. Plus the energy to maintain auto repair shops, government regulation and registration services, etc.
7. Plus the energy to produce and maintain that portion of the health system used to care for accident victims and sufferers of auto-related health problems.
8. Plus …

Where to stop depends on how we bound the issue, and in the end this decision should be made by the users of the result.

Also, there are additional steps. A similar expanding wave of concern and impact ripples out from, for example, the energy to make the car, which could include

1. The energy consumed at the assembly plant
2. Plus the energy used to make the steel, glass, rubber, etc.
3. Plus the energy used at the iron mine, sand pit, and sulfur mine
4. Plus …

even including the cars used by the iron mine so that the process runs in circles, although successive steps become smaller.

2. METHODS TO DETERMINE ENERGY COST

2.1 Vertical Analysis

The previous process is called vertical analysis or process analysis; I call it following your nose. Fig. 1 indicates the stepwise process of producing a product such as a car. The auto factory is the box on the far left. To produce an auto, the factory receives inputs from three other sectors—for example, steel, glass, and rubber. Each of these receives inputs from other sectors, and so on. Vertical analysis traces this web of inputs backward. At each node, it evaluates the amount of the desired input (e.g., energy) at that point and prorates it on the basis of that sector's output. Given the complexity of a modern economy, vertical analysis is labor-intensive and data-demanding.

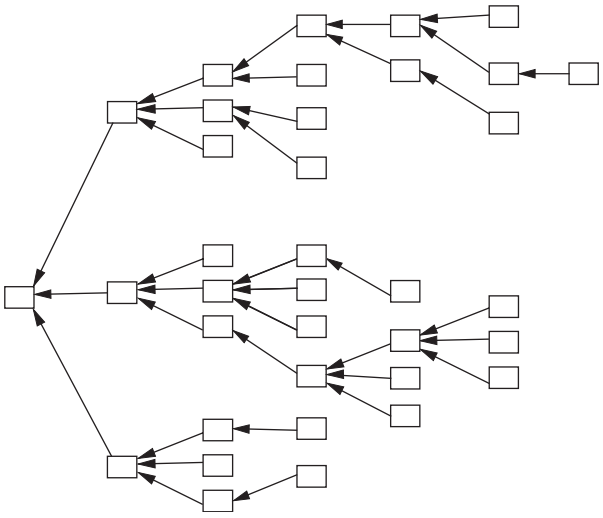

FIGURE 1 Schematic representation of vertical analysis (also called process analysis) to determine energy cost.

2.2 Input–Output Analysis

Economic input–output (I–O) analysis is a well-established method to trace indirect effects in monetary terms. The U.S. Department of Commerce prepares detailed information on the dollar transactions among 350–500 sectors covering the U.S. economy. Many other nations have similar programs. Using several assumptions, one can use the analytical machinery of I–O to combine these data with supplementary information on energy use to determine energy cost.

We start with an economy with N sectors, each with an output flow measured in units of gloof/time. Gloof can be almost anything: tons of steel, pounds of butter, hours in a dentist's chair, dollars worth of day care, etc. It can even vary from compartment to compartment (as in the following example). The assumptions are as follows:

1. Every flow in the system that we wish to count (units = gloof/time) has an associated energy

intensity according to its source compartment (units = energy/gloof).

2. Embodied energy flows everywhere there are flows that we consider important, and the magnitude of the embodied energy flow (units = energy/time) is the product of the energy intensity (units = energy/gloof) times the original flow (units = gloof/time). This assumes that the flow variable is a good surrogate for embodied energy, which is a judgment call by the user.

3. Embodied energy is conserved in each compartment—that is, the amount "in" equals the amount "out."

Assumption 3 is stated by Eq. (1) and illustrated in Fig. 2.

$$\sum_{i=1}^{N} \varepsilon_i X_{ij} + E_j = \varepsilon_j X_j, \tag{1}$$

where X_{ij} is the actual gloof flow from compartment i to compartment j (units = gloof$_i$/time), X_j is the sum of all output flows from compartment j (units = gloof$_j$/time), E_j is the actual energy input flow to compartment j from outside the system (units = energy/time), and ε_j is the energy intensity of output of compartment j (units = energy/gloof$_j$). Equation (1) is assumed to hold for each of the N compartments, yielding N equations in N unknowns. We know the X_{ij}'s and E_j's, so we can solve for the ε_j's. Equation (1) formalizes the allocation of indirect effects in a self-consistent manner and can be used to allocate indirect anything, not just energy.

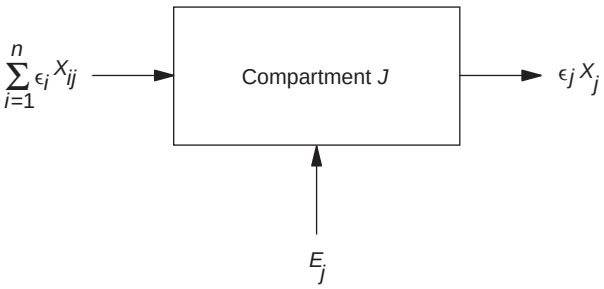

FIGURE 2 Input–output approach to determine energy cost. It is assumed that the embodied energy in = embodied energy out. E_j is the energy flow into sector j (units = energy/time), X_{ij} is the flow of product i to sector j (units = gloof/time), X_j is the total output of sector j (units = gloof/time), and ε_j is the energy intensity of product j (units = energy/gloof).

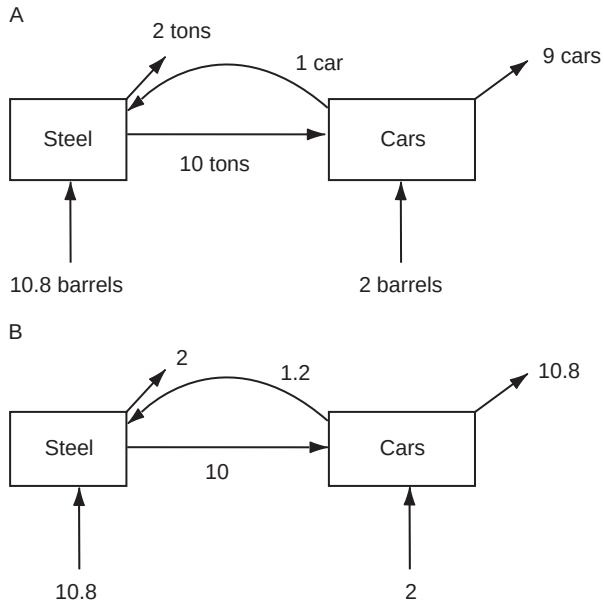

FIGURE 3 A two-sector economy illustrating the calculation of energy cost. (A) Original flows per unit time. Diagonal arrows represent shipments to final consumption. Energy inputs are in barrels of oil. (B) Embodied energy flows (units = barrels/unit time). All flows are assumed steady over time.

2.3 An Example of the Calculation of Energy Cost

Figure 3A shows a two-sector economy burning oil to produce steel and cars. We use Eq. (1) to determine the energy intensities:

$$\text{Steel sector: } 10.8 + 1\varepsilon_{\text{car}} = 12\varepsilon_{\text{steel}}$$
$$\text{Car sector: } 10\varepsilon_{\text{steel}} + 2 = 10\varepsilon_{\text{car}}$$

Solving these two equations gives $\varepsilon_{\text{steel}} = 1$ barrel oil/ton steel and $\varepsilon_{\text{car}} = 1.2$ barrel oil/car. The embodied energy flows are obtained by multiplying the flows in Fig. 3A by the intensities, giving the result shown in Fig. 3B. Each sector is in embodied energy balance, as we assumed in Eq. (1). In addition, the whole system is in balance: 12.8 barrels of oil enters and is burned, and 12.8 barrels of embodied oil is contained in the shipments of steel and cars to final consumption. Furthermore, only 2/12 of the energy to produce a car is used directly (i.e., burned in the auto factory).

This is the I–O approach for two sectors. Calculation for systems with more sectors is operationally the same but tediously complicated—a job easily handled by computers. Typical results are shown in Table I. In addition, one may show that a vertical analysis of Fig. 3A yields the same results as the I–O approach. Because of the feedback of cars to steel, the analysis has an infinite number

TABLE I

Energy Intensities for Personal Consumption Categories, 1972–1973[a]

Consumption category	Energy intensity (103 Btu/$1972)	Consumption category	Energy intensity (103 Btu/$1972)
Food at home	54	Auto insurance	19
Food away from home	44	Auto registration and fees	0[a]
Alcoholic beverage	51	Local bus and train, commuting	56
Tobacco	30	Local bus and train, school	56
Rented dwelling	14	Local bus and train, other	56
Owned dwelling	12	Transportation to school away from home	132
Other shelter, lodgings	21	Plane, trip outside commuting area	167
Fuel oil and kerosene	890	Train and bus, trip outside commuting area	68
Coal and wood	795	Ship, trip outside commuting area	129
Other fuels	795	Limousine and taxi, trip outside	56
Gas main	915	commuting area	
Gas in bottles and tanks	999	Car rental	38
Electricity	616	Health insurance	19
Water, sewage, trash	26	Health care	47
Telephone, telegraph, cable	24	Personal care	48
Domestic service	0[a]	Owned vacation home	12
Household textiles	59	Other transportation costs on vacation	91
Furniture	45	All-expense tours, summer camps	31
Floor coverings	71	Other vacation expenses	33
Major appliances	66	Boats, aircraft, motorcycles	65
Small appliances	65	Television	48
Housewares	57	Other recreation	41
Miscellaneous house furnishings	48	Reading	43
Dry cleaning, laundry	44	Private education	35
Clothing	44	Public education	37
Vehicle purchase	68	Miscellaneous consumption expenditure	41
Vehicle purchase finance charges	27	Personal insurance and pensions	20
Gasoline and oil	443	Gifts and contributions	41
Tires and lubrication	69	Increase in savings	47
Batteries	59	Housing purchase and improvement	40
Auto repair and service	37	Increase in investment	47

[a] Labor and government services are assumed to have zero energy intensity relative to the consumer. For labor, this is done to avoid double counting. For government, the energy requirement is not lost but rather charged against government expenditures.

of steps, but a computational trick makes this manageable.

For typical energy studies, the following assumptions have usually been made: Energy inputs are coal, petroleum, natural gas, and a "fossil equivalent" of hydro, wind, photovoltaic, and nuclear electricity. Solar energy input to silviculture and agriculture is usually considered a free input and not counted for economic systems. However, solar energy is usually counted in energy analysis of ecosystems.

3. ILLUSTRATIONS/APPLICATIONS OF ENERGY COST

3.1 Auto Manufacture and Use

Energy analysis showed that approximately 12% of the energy to produce and market a U.S. automobile was consumed in the automobile sector vs. 37% in the primary metals sectors. In addition, the fuel in the tank was only approximately 60% of the energy to provide auto transport; the other 40% was car

TABLE II

Energy Cost of Corn Production in Illinois, 1996

Type of agiculture:	Conventional
Crop:	Yellow corn
Field size:	76 acres
Yield:	168 bushels/acre
Calorific energy of crop	5.13×10^9 Btu (402×10^3 Btu/bushel)
Crop energy/input energy:	8.4

	$1996 Cost or Btu	Energy intensity (10^3 Btu/$1996 or Btu/Btu)	Energy (10^6 Btu)	% of total
Seed	$2284	26.2	59.8	9.8
Fertilizer	$4725	769.7	363.7	59.6
Herbicide	$2179	26.2	57.0	9.3
Pesticide	0	26.2	0	0.0
Machines	$2017	10.7	43.0	7.0
Farm fuel	52×10^6 Btu	1.20[a]	62.3	10.2
Custom application	$2129	11.6	24.7	4.0
Total			610.4	100.0

[a] Twenty percent extra energy is consumed in extracting, refining, and transporting fuel to point of use. This is an experimental plot; in commercial practice, typically some pesticides would be applied.

manufacture (8%), energy cost of energy (9%), tires, maintenance, road construction, parking, insurance, etc. This is an old result from the 1970s, but it is still compelling.

3.2 Grain Production

The ecologist Howard T. Odum said we eat "potatoes made of oil," a reflection of the energy demands of modern mechanized agriculture. Table II shows typical energy requirements for a corn crop. In the rich soil and favorable climate of Illinois, the fossil energy inputs sum to only one-eighth of the crop's calorific value (the sun is not counted). Note that fertilizer and herbicides account for 2/3 of total energy input, while farm fuel is only 10%. It is debatable whether fossil fuel inputs should be compared with the calorific content of food. More compelling are studies that show that the fossil energy input per unit of food output has increased during the past several centuries. Likewise, if we move to the right on any of these spectra—good→marginal soil and climate, grain→flesh, low→high processing and packaging, near→distant—the energy inputs typically increase. For the average food as delivered to American mouths, the fossil energy input is 5–10 times the calories delivered.

3.3 Household Energy (Energy Cost of Living)

Once obtained, energy intensities can be used to link everyday personal consumption patterns with their impact in resource use, as indicated in Eq. (2):

$$\text{Energy} = \sum_{i=1}^{N} (\text{energy intensity of consumer good } i) \times (\text{consumption of consumer good } i). \quad (2)$$

As with much energy analysis, effort peaked in the 1970s and 1980s, but here I present an update.

3.3.1 Energy Intensities

Very few vertical analyses have been performed on specific products, such as automobiles and agricultural chemicals. The remaining energy intensities have been calculated for approximately 350 sectors covering the full range of economic expenditures in the U.S. I–O economic tables. One assumes that dollars are a satisfactory numeraire for allocating embodied energy. Energy data compatible with I–O data are provided by the U.S. Department of Energy, Energy Information Administration. These are used with a version of Eq. 1.

One immediate question is whether the energy intensities do vary among sectors. If not, the energy

TABLE III

Energy Intensities of Consumer Expenditures, Updated (by Approximations) to 1999

Expenditure category	Energy intensity (Btu/$1999)
Food	9095
Alcohol and tobacco	5457
Housing	5457
Residential energy	105000
Gasoline and motor oil	115000
Auto purchase, maintenance	10914
Public transportation	20000
Apparel	8025
Health, personal care	8560
Entertainment and communication	5457
Education and reading	7276
Miscellaneous	7490
Contributions	7490
Insurance, pension	3638
Asset change	8560

consequences of spending a dollar for any good or service would be the same, and the details of expenditures would be irrelevant. We already know that the primary metals industry is energy intensive compared with a service industry, but we are interested in consumption options open to individuals and households, which generally covers finished products. Even so, there is a significant variation, as shown in Table I. For example, the energy intensity of gasoline was 443,000 Btu/$ 1972, whereas that of private education was 35,000 Btu/$ 1972, a variation of a factor of 13. Among nonenergy, nontransportation categories, there was a variation of a factor of 5, from rental dwellings (14,000 Btu/$ 1972) to floor coverings (71,000 Btu/$ 1972). In Table III, the consumption categories have been aggregated to 15 and updated to 1999.

3.3.2 Household Consumption Data

The U.S. Bureau of Labor Statistics (BLS) periodically performs detailed surveys of consumption "market baskets" of U.S. households. A total of 19,000+ households were surveyed in 1972 and 1973, with expenditures broken down into 61 categories as given in Table I. In the updated analysis here, I use results of a smaller BLS survey for 1999. The system boundary thus is defined by what the household purchases.

Combining expenditures and intensities using Eq. (2) yields Fig. 4, which shows the energy cost taken back to the mine mouth or wellhead, of the market basket of average households in lowest and highest expenditure quintiles and for the overall average household. Of the 15 consumption categories, 2 are direct energy expenditures (residential fuel and electricity and auto fuel). For the average households, these amount to 5% of monetary expenditures (Fig. 4A) but 44% of the household's total energy cost (Fig. 4B). Figure 4B also shows that for the lowest quintile, the direct energy requirement is approximately 57% of the total, and for the top quintile it is approximately 33%. There seems to be an upper limit on how much auto fuel a household can use but not on football tickets, clothing, furniture, plane tickets, second homes, etc. For the average expenditure level and above, one would miss more than half of the energy cost of living by examining only direct energy.

Under certain assumptions, the energy cost of living can be used for two more speculative purposes: to predict the economic effects of energy price increases on different households (this has been done), and in the analysis of sprawl issues (because more auto use and larger residences are associated with living further from urban centers).

3.4 Appliances: Energy to Operate vs Energy to Produce/Maintain/Dispose

What fraction of the energy use for a refrigerator or a toaster is used to manufacture, market, maintain, and mash it, and what fraction is used to operate it? The answer is useful in evaluating different strategies to reduce energy use, such as increasing operational efficiency, decreasing energy use in manufacture, or increasing the device's lifetime. This is an example of life cycle cost in energy terms. Consider all the energy associated with an appliance:

$$E_{\text{life}} = \text{manufacturing energy} + \text{maintenance energy} + \text{disposal energy} + \text{operational energy}.$$

The average total power is the lifetime energy divided by the lifetime, T:

$$p_{\text{tot}} = \frac{E_{\text{life}}}{T} = \left(\frac{\text{manufacturing} + \text{maintenance} + \text{disposal}}{E_{\text{life}}} + 1\right) \times p_{\text{operation}}. \quad (3)$$

For electric appliances, energy is measured in kilowatt-hours, and power is measured in kilowatts.

Table IV summarizes energy use for selected household appliances. Most appliances tend to have

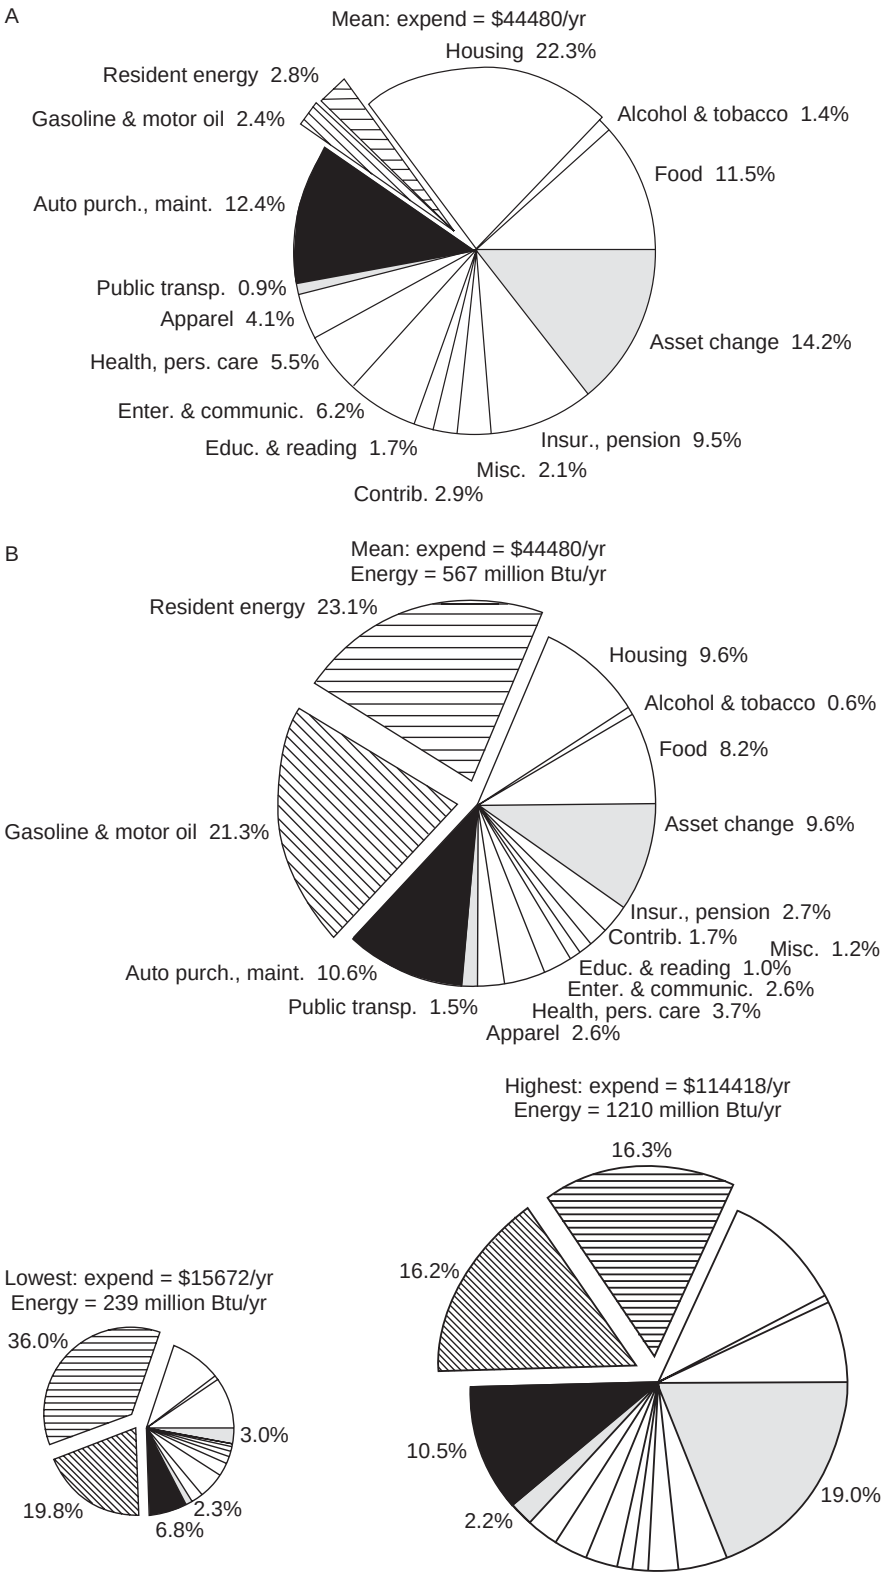

FIGURE 4 Energy cost of living, 1999. (A) Annual expenditures for average U.S. household. (B) Energy costs of expenditures in Fig. 4A and for lowest and highest expenditure quintiles as well. Figure 4B is obtained from Fig. 4A by multiplying energy intensities by expenditures (Eq. 2). In Fig. 4B, the area of the circle is proportional to the total household energy impact.

TABLE IV

Comparison of Operating and (Manufacuring + Maintenance + Disposal) Energy for Selected Appliances

Electric appliance	$p_{operation}$ (kWh/year)	T(year)	Indirect fraction (manufacturing–maintenance + disposal) as fraction of life energy	Classification ($p_{operation}$/indirect fraction)[b]
Blender	17	14	0.34	Low/high
Mixer	14	14	0.35	Low/high
Refrigerator	750	14	0.13	High/low
Water heater	4700	8	0.01	High/low
75-W incandescent bulb[b]	657	0.1	0.02	High/low
17-W compact fluorescent bulb[b]	146	1.14	0.08	High/low
Coffee maker	83	8	0.07	Low/low
Toaster	43	8	0.19	Low/low
Personal computer (at work)[c]	160	7	0.5	High/high

[a]Classification: $p_{operation}$: <100 kWh/year = low; ≥ 100 kWh/year = high. Indirect fraction: <0.25 = low; ≥ 0.25 = high.
[b] Assumes bulbs are on continuously. These two bulbs provide approximately equal light levels.
[c] Assumes the computer is used 8 h/day, 200 days/year.

high operation power and a low indirect energy fraction [i.e., (manufacturing + maintenance + disposal)/$E_{life} < 1$] or vice versa. For the appliances usually considered large energy users, such as refrigerators, freezers, water heaters, and light bulbs, the fraction is ≤ 0.25. For smaller appliances, it is ≥ 0.25. This implies, but does not prove, that to save energy one should concentrate on operational energy efficiency for the first group, whereas for the second there is likely potential in both operational and manufacturing efficiency.

The personal computer, if used 8 h a day, 5 days a week, has a high operation power (160 kWh/year) and a high indirect fraction (≈ 0.5).

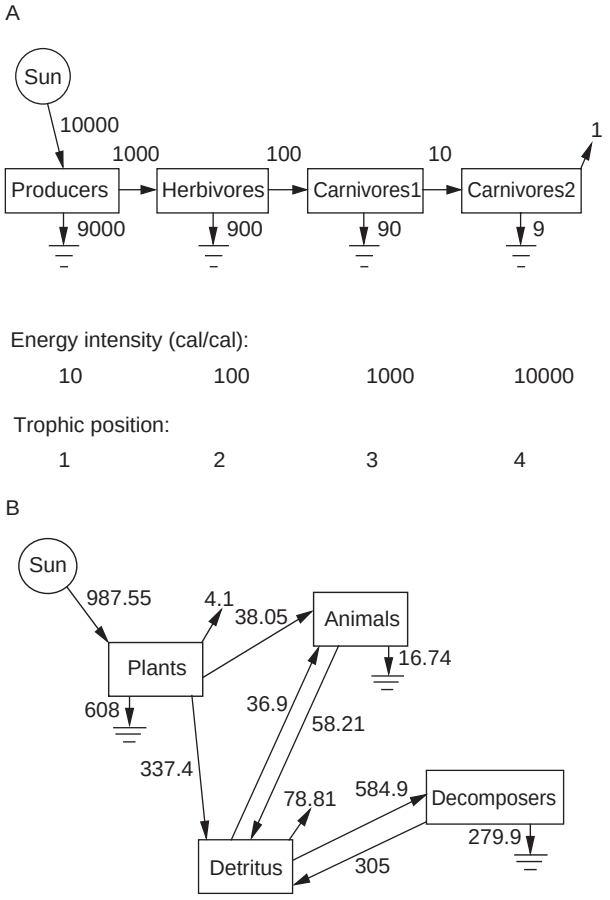
3.5 Energy Cost in Ecosystems

There are several indicator quantities that summarize indirect energy effects in ecosystems. Two that are especially appropriate for quantifying the solar dependence of all life (with the negligible exceptions of deep-sea vent communities, which are based on geochemical energy) are energy intensity and trophic position. Trophic structure refers to the number of energy "transactions" separating the sun (which is assigned trophic position 0) from the compartment in question. Originally, energy flow in ecosystems was visualized in terms of straight food chains, for which trophic positions (called trophic levels in this case) are successive integers (Fig. 5A). However, most ecosystems have web-like energy flows (Fig. 5B). Equation (1) applies to webs, so calculating energy intensities requires no new technique. On the other hand, trophic position needs to be defined. The trophic position of a compartment, TP, is the energy-weighted sum of TPs of inputs $+1$. Using the language we used for calculating energy intensities, for each compartment,

$$\mathrm{TP}_j = \sum_{i=1}^{N} \left(\frac{X_{ij}}{\sum_{i=1}^{N} X_{ij}} \right) \mathrm{TP}_i + 1. \qquad (4)$$

Equation (4) is similar to Eq. (1), but it has two important differences. First, the flows X_{ij} must be in terms of biomass energy because trophic ecology is by definition concerned with energy flow. Second, the factors in the bracket sum to 1 because they are normalized with respect to the input flows, whereas in Eq. (1) normalization is with respect to total output and the factors X_{ij}/X_j need not sum to 1. Equation (4) represents N equations in N unknowns.

For the (idealized) food chain in Fig. 5A, the weighting factors are all 1, and Eq. (4) gives the trophic positions 1–4. For the (real) food web in Fig. 5B, TPs are 1, 3.43, 3.90, and 4.90. Because plants receive input only from the sun, $\mathrm{TP}_{plants} = 1$. Because decomposers gets all their input from detritus, $\mathrm{TP}_{decomposers} = \mathrm{TP}_{detritus} + 1$. Animals and detritus have more than one input, and their TPs are mixtures. In this accounting, decomposers (e.g., bacteria) are on top of the energy pyramid and the food web.



Compartment	Energy intensity (cal/cal)	Trophic position
Plants	2.60	1.00
Animals	9.56	3.43
Detritus	12.40	3.90
Decomposers	23.80	4.90

FIGURE 5 Energy intensities and trophic positions for food chain and web. (A) Idealized food chain. (B) Boreal bog ecosystem food web. Units for both = g fixed carbon m^{-2} $year^{-1}$. Flows to ground symbols are metabolic losses. Detritus is dead material the origin of which is not visually identifiable. Decomposers include bacteria.

4. CONCLUSIONS

Energy is important, and the idea of energy cost makes intuitive sense. The details of obtaining and using energy cost complicate its usefulness, but when done transparently, it can provide insight and help in decision making. To do it transparently, we require at the least a procedure, a system boundary, and many assumptions. For brevity, I have not discussed most of the assumptions, and I have included only a few applications of energy cost. Others include comparing energy embodied in imported and exported goods and services (energy balance of trade), comparing embodied energy and labor costs to determine the employment effects of energy policy, determining equity effects of energy taxes, and comparing the energy cost with the energy output of an energy source technology such as a power dam. The latter, called net energy analysis, is presented in a separate article in this encyclopedia.

Glossary

capital maintenance Keeping produced and natural capital intact as a principle of sustainability of economic activity, applied in environmental accounting.

dematerialization Reduction of material inputs into, and residual outflows from, the production and consumption of goods and services as a means of diminishing environmental pressure from economic activity.

energy accounts Accounts and balances, which measure energy inputs, transformations and uses; sometimes extended to include material flows in embodied energy values.

energy theory of value Rationale for the quantitative evaluation of natural resources and goods and services in terms of energy expended in their production.

environmental accounting (1) National accounting: short for integrated environmental and economic accounting, as advanced by the System of Environmental and Economic Accounts (SEEA). (2) Corporate accounting: usually refers to environmental auditing but also includes environmental costing and life-cycle (cradle-to-grave) assessments of products.

environmental valuation Different techniques of estimating a monetary value for natural assets or asset changes in environmental accounting, including market valuation of natural resources, maintenance costing of environmental impacts, and damage valuation of environmental effects.

environmentally adjusted (net) capital formation (ECF) Environmental accounting indicator that deducts the cost of natural capital consumption from net capital formation.

environmentally adjusted (net) domestic product (EDP) Environmental accounting aggregate, obtained by deducting the cost of natural capital consumption from net domestic product.

green accounting Popular term for environmental accounting, including material flow accounts.

material flow accounts Physical accounts and balances, which present inputs of materials into the economy, their accumulation, and their outflow to the natural environment and other economies; usually measured in mass (weight) units.

natural capital Natural assets in their role of natural resource supply and provision of environmental services (notably of waste/residual disposal) for economic production and consumption.

System of Environmental and Economic Accounts (SEEA) Extended national accounts system, advanced by the United Nations and other international organizations; incorporates natural assets and asset uses to measure the interactions between environment and economy in physical and monetary units.

total material requirement (TMR) Key indicator of material flow accounts that measures the total material base of the economy; includes besides direct material inputs, "hidden" movements of materials associated with imports and extraction of natural resources.

Green accounting is a popular term for environmental accounting or, more precisely, integrated environmental and economic accounting at national and corporate levels. At both levels, the purpose is to capture the elusive notion of long-term sustainability of economic performance, hampered by environmental impacts of production and consumption. Long lists of environmental and sustainable development indicators failed to assess sustainable economic growth and development in a comprehensive and transparent manner. The more systematic greening of the national accounts succeeds in defining and measuring the environmental sustainability of economic activity. This article describes the concepts and methods of environmental accounting at the national level and addresses specifically the role of energy in accounting and sustainability analysis.

1. ACCOUNTING FOR SUSTAINABILITY

1.1 Concepts and Indicators of Sustainable Development

Conspicuous pollution incidents in the 1960s and the energy crises of 1973 and 1974 brought about environmental gloom. Well-known titles like Carson's "silent spring" or Loraine's "death of tomorrow" alerted to risks for human survival. The Club of Rome presented in 1972 a computerized and hence seemingly objective world model, which predicted the collapse of the industrial system and Malthusian population decline within this century. Nonrenewable resource depletion was the main reason for this business-as-usual scenario.

William Kapp can be credited with alerting mainstream economists to the social costs of environmental concerns. Neoclassical economics had largely ignored environmental phenomena as external to economic planning and budgeting. In Kapp's view the staggering social costs of environmental damage had reached a magnitude beyond the capacities of welfare analysis, national income accounting, and compartmentalized social and natural sciences. Based on a similar assessment of compartmentalized institutions, the World Commission on Environment and Development (WCED) advanced in 1987 the notion of sustainable development. The commission's report on "Our Common Future" described the new development paradigm as an integrative approach to tackling the interlocking environmental and developmental crises. Two Earth Summits, convened by the United Nations in 1992 in Rio de Janeiro and 2002 in Johannesburg, confirmed sustainable development as a global paradigm of equal importance for industrialized and developing countries.

The WCED also offered the popular definition of sustainable development as "development that meets the needs of the present without compromising the ability of future generations to meet their own needs." The definition is vague: it does not specify the categories of human needs, does not give a clear time frame for analysis and does not indicate particular roles for the environment or social concerns in long-term development. The paradigm needs to be operationalized, and indeed numerous indicators for and of sustainable development have since been advanced.

Indicators *for* sustainable development typically include long lists of measures of environmental, social, economic, and institutional aspects of development. Relatively loose frameworks generate some useful categorization but do not in general link or aggregate these indicators. The main drawback of indicator lists is the difficulty of comparing and evaluating data expressed in different units of measurement. Such indicators may support the management of particular areas of environmental, social, or economic concern but are less useful for the overall planning and implementation of sustainable development.

Proposals of indicators, or indices rather, *of* sustainable development has been the response to the comparability and aggregation problem. The approach is to average or otherwise combine selected indicators, or to correct conventional economic aggregates of wealth, income, and consumption. Compound measures of sustainable or human development or social progress deserve our attention since they all try to take the environment "into account." Well-known examples are the following:

- Human Development Index (HDI), developed by the United Nations Development Programme. The index is an average of per capita income, life expectancy, and education, intended to provide a more complete (than GDP) assessment of human achievements.
- Environmental Sustainability Index (ESI), initiated by the World Economic Forum. An average high performance of 20 indicators, made up of 68 variables, defines environmental sustainability.
- Genuine Progress Indicator (GPI) for the United States, later applied and modified in other countries. The GPI subtracts defensive expenditures (of environmental protection, defense, and other welfare maintaining—rather than increasing—expenses) and adds or subtracts positive and negative environmental and other social costs and benefits.
- World Bank's National Wealth aggregate of produced assets, natural capital, and human resources.

All these indices suffer from a more or less arbitrary selection of partially correlated indicators, a questionable mix of weighting and valuation techniques, or inconsistency with standard accounting concepts and conventions. The idea seems to be to demonstrate the nonsustainability of economic growth, rather than to support policy making. For instance, the authors of the GPI present their

indicator explicitly as a means to discredit GDP as a measure of social progress.

1.2 Green Accounting: Assessing the Environmental Sustainability of Economic Growth

The elusive notion of sustainability needs to be operationalized in a more transparent and systematic manner. To this end, natural science offers basic principles for the nature-economy interface, and economics provides the tool of accounting for this interface. Thermodynamic laws of matter and energy conservation and dissipation govern the use of natural resources. Formal double-entry accounting can then be applied to assess the use (input) and dispersion (output) of these resources from/to the natural environment.

Figure 1 illustrates the "throughput" of materials (including energy carriers) through the economy. The figure also shows the two basic functions of the environment: (1) resource supply of raw materials, space, and energy to the economy (source function) and (2) waste assimilation (sink function). The latter represent an important ecological service. Other ecosystem services such as habitat for species, soil protection, or local climate control are sometimes categorized as indirect benefits for humans; they are probably better assessed by regionalized environmental and ecological statistics.

The fortunate coincidence of physical laws that ensure the equality of inputs and outputs of energy and materials, and input-output based economic accounting points to an obvious approach of applying the latter to the former. The result is green accounting—that is, the extension of conventional economic accounts into the physical world of the use and abuse of nature by economic activity.

The application of accounting tools requires aggregation of physical environmental data by means of a common measuring rod. Environmentalists and economists—to make a crude distinction between ecological and economic views of the human environment—disagree on whether to use physical measures, or prices and costs, for weighting the importance of environmental impacts. Environmental economists seek to "internalize" the costs of environmental impacts (environmental "externalities") into the decisions of households and enterprises. Environmentalists, on the other hand, refute such commodification of an indivisible (public) good on whose value markets should not have a say.

Two operational sustainability concepts can thus be distinguished according to the economic and ecological outlook:

- Economic sustainability makes use of the established requisite for economic growth, capital maintenance, and extends the (produced) capital concept to include nonproduced natural capital.
- Ecological sustainability considers material throughput through the economy as a pressure on the carrying capacities of natural systems, and aims to reduce this pressure to tolerable levels by dematerializing the economy.

Two accounting systems attempt respectively to capture these notions of sustainability. Material flow accounts (MFA) and related physical input-output tables (PIOT) measure material flows in physical—weight—units. The United Nations System for integrated Environmental and Economic Accounting (SEEA) embraces both physical and monetary accounts, seeking compatibility with the worldwide adopted System of National Accounts (the SNA). Considering the integrative power of the SEEA, the

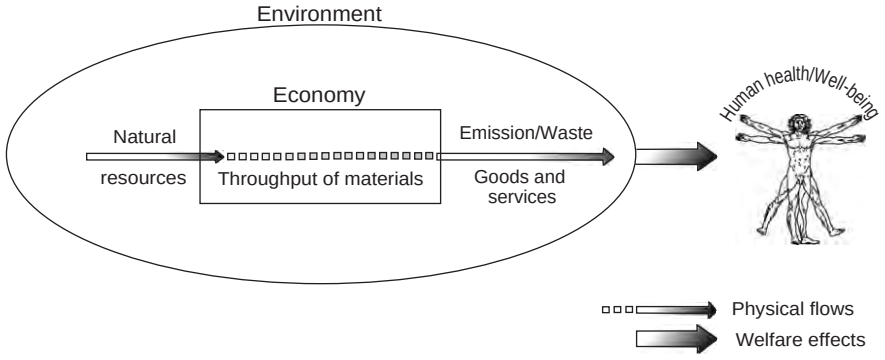

FIGURE 1 Environment-economy interaction and effects. Flows of material throughput from the environment into the economy and out of the economy into the environment. Outputs from the economy and the environment affect human welfare. From Bartelmus (2001) Fig. 1, p.1723, with permission from EOLSS publishers.

1992 Earth Summit called for its application by all member States of the United Nations in its Agenda 21. An international group of experts and accountants has now revised the SEEA, which the United Nations and other international organizations will issue as "Integrated Environmental and Economic Accounting 2003."

The narrow focus on environmental (at the expense of social and other concerns) sustainability of economic activity by both types of accounts does not do justice to the much broader paradigm of sustainable development. Development itself encompasses, besides economic objectives, social, ecological, cultural, and political ones. A corresponding broad sustainability notion would therefore have to incorporate all these objectives. Measurability is the main problem in accounting for these concerns, even when more narrowly focusing on the costs of human, social, and institutional capital formation and use in economic growth.

1.3 Energy: The Ultimate Limit?

Several energy analysts and ecological economists have deplored the neglect of energy in mainstream economic analysis. In their view, energy can be seen as the ultimate source of life and at the same time as its ultimate limit. The reasons for this neglect include a relatively low share of energy costs in production due to incomplete energy accounting and the underpricing of energy resources. Prices that ignore the social costs of energy depletion and pollution from energy production and use create a delusion of abundance and might undermine the sustainability of economic activity. Subsidies, notably of labor-intensive fossil fuel production, may increase employment but aggravate underpricing and environmental impacts. Addressing the pressures on and scarcities of natural resources, the WCED seems to concur that the ultimate limits to global development might indeed be determined by the impacts of energy use.

The significance of energy production and consumption for the overall sustainability of economic development can, however, only be assessed in a broader context of accounting, comprehensively and comparably, for economic benefits, natural resource use, and waste generation by different economic sectors. Section 2 describes the general concepts and methods of such accounting.

Section 3 then indicates how environmental accounting applies to energy production and consumption and related environmental impacts. It does not elaborate on the different techniques of narrowly defined energy balances and analyses. Rather, the section shows how energy fits into the environmental accounting frame and how such accounting may contribute to assessing the sustainability of economic performance and growth.

2. THE CONCEPTS AND METHODS OF INTEGRATED ENVIRONMENTAL AND ECONOMIC ACCOUNTING

2.1 Material Flow Accounts: Assessing the Physical Metabolism of the Economy

Figure 2 can be viewed as the accounting interpretation of the generic environment-economy interface of Fig. 1. It represents the material flow accounts (MFA), which Robert Ayres and others have characterized as picturing the physical metabolism of society. The MFA show material inputs from abroad and the natural environment, their accumulation as stock in infrastructures and other durable goods, and their output of wastes and residuals into the environment and (as exports) to other countries. The MFA were developed in Austria and Germany and mostly applied in industrialized countries. The statistical office of the European Union, Eurostat, prepared guidelines on economy-wide MFA for improving the international comparability of the accounts.

Adding up the material flows (in tons) obtains various indicators at different stages of throughput as shown in acronyms in Fig. 2. Table I elaborates on the definition and contents of these indicators. Perhaps best known is the total material requirement (TMR). The indicator is defined as the sum of primary material inputs, including their ecological rucksacks. These rucksacks are hidden flows, which do not become a physical part of any product but are associated with its production, use, and disposal (e.g., soil erosion from agriculture or forestry, or gangue from mining).

Scholars of the German Wuppertal Institute, who focused their work on compiling and analyzing material flow accounts, have argued that their indicators measure actual and potential, and possibly still unknown, environmental impacts. A downward trend of the TMR, together with the usual upward trend of economic output (GDP), would thus indicate a decoupling of environmental pressure from economic growth. This can be seen as a process of dematerialization of the economy, and hence of ecological sustainability, as defined previously.

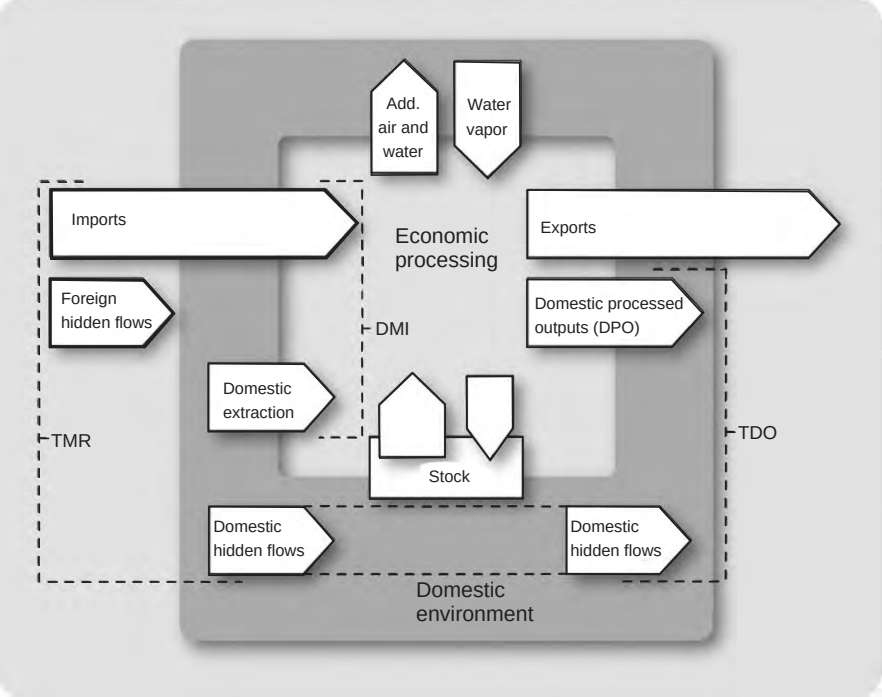

FIGURE 2 Material flow accounts and indicators. Adding up material flows at various stages of throughput through the economy obtains different indicators of material input, accumulation, and output. From Matthews *et al.* (2000), "The Weight of Nations: Material Outflows from Industrial Economies," Fig. 1, p. 5, World Resources Institute, Washington, DC, with permission.

The question is, how much dematerialization makes economic growth sustainable? Since physical material flows are not expressed in monetary units and are therefore not directly comparable to economic output or income, we can answer this question only by setting standards or targets for desirable rates of economic growth and necessary throughput reduction. The former president of the Wuppertal Institute, Ernst von Weizsäcker advanced the "Factor 4" standard of halving material input into the economy while doubling wealth over a period of 3 to 5 decades. Factor 4 and other standards of even a higher order can be interpreted as dematerialization targets for global sustainable development.

Overall indicators like the TMR are relatively crude measures of environmental impact since they use the weight of material inputs for weighting the significance of potential environmental effects. Table I shows therefore also various output indicators of wastes and emissions. They do weigh impacts by weight but are closer to specific environmental pressures and impacts. Their decline is indicative of the detoxification of the economy as they address the sink/pollution concern of sustainability.

2.2 Linking Physical and Monetary Accounts

The MFA were not developed in full consistency with economic concepts and measures. Their purpose was, at least initially, to provide an alternative to misleading—with regard to the human quality of life—accounting aggregates such as GDP. As a result, the MFA differ from standard and extended (see Section 2.3) economic concepts and indicators, notably with regard to the following:

- The narrow focus on material flows, excluding stocks and stock changes of produced and natural assets
- A corresponding inability to assess permanent losses (depletion and degradation beyond regeneration) of natural assets by flow indicators such as the TMR—an essential concern of sustainability
- A focus on different categories of materials by the MFA, rather than on the economic sectors responsible for the consumption of natural resources and the emission of residuals
- The assumption that material inputs reflect actual and potential environmental impacts, as opposed

TABLE I

Material Flow Balance and Derived Indicators[a]

Inputs (origin)	Outputs (destination)
Domestic extraction	Emissions and wastes
• Fossil fuels (coal, oil, etc.)	• Emissions to air
• Minerals (ores, gravel, etc.)	• Waste landfilled
• Biomass (timber, cereals, etc.)	• Emissions to water
	Dissipative use of products
Imports	• (Fertilizer, manure, compost, seeds, etc.)
Direct material inputs (DMI)	Domestic processed output (DPO) to nature
Unused domestic extraction	Disposal of unused domestic extraction
• From mining/quarrying	• From mining/quarrying
• From biomass harvest	• From biomass harvest
• Soil excavation	• Soil excavation
Total material input (TMI)	Total domestic output (TDO) to nature
	Exports
	Total material output (TMO)
Upstream flows associated with imports	
Total material requirement (TMR)	Net additions to stock (NAS)
	• Infrastructures and buildings
	• Other (machinery, durable goods, etc.)
	Upstream flows associated with exports

to the (cost value of) actual impacts recorded for a specific accounting period

- The use of physical (mass) units of measurement rather than the monetary (price and cost) values of economic accounts.

Facing mounting criticism of the conventional accounts and pressure to modify (to "green") these accounts for environmental impacts, national accountants took first steps toward incorporating readily available environmental statistics into their accounting frameworks. To this end, they made use of—physical, Leontief-type—input-output tables whose monetary counterparts are already a part of the national accounts system. The result is a relatively weak integration of environmental data either into a purely physical input-output table (PIOT) or as an add-on of physical indicators into the conventional accounts. The latter generates a hybrid physical-monetary National Accounting Matrix including Environmental Accounts (NAMEA).

German statisticians compiled a comprehensive PIOT for 1990 and updated the tabulations for 1995 (but did not publish them so far). The German PIOT is basically a sectoralization of the compound MFA: it specifies the material and substance flows as inputs and outputs in a detailed sectoral breakdown. Stock/asset accounts of produced capital goods and natural resources are omitted, as are difficult-to-assess-and-allocate ecological rucksacks. Supplementary subtables present energy balances in calorific values (terajoules) and in terms of inputs, outputs and transformations of energy carriers.

The Dutch NAMEA goes further by linking physical with monetary data. It stops short of any monetary valuation of environmental impacts by juxtaposing environmental statistics and indicators next to the economic activities responsible for environmental impacts. Like the PIOT, the NAMEA incorporates impacts on the source and sink functions of the environment in its supply (output) and use (input) accounts, as shown in Table II. In addition, the NAMEA presents some further weighting (beyond the use of tons) and aggregation for national environmental themes. The themes include energy (in calorific values), acidification, eutrophication, greenhouse effect, ozone layer depletion, and loss of natural resources (of gas and oil).

Table II is a simplified structure of a hybrid accounting system, based on the NAMEA approach. It presents the conventional economic accounts of production, consumption, capital accumulation, income generation, and international trade. Below and to the right of these accounts (separated by dashed lines), material and substance flow accounts are added to the economic transaction rows and columns of the economic accounts. The NAMEA can thus be seen as a PIOT linked to a monetary input-output table with some further supplementary indicators for selected environmental policy themes.

2.3 SEEA: Integrating Physical and Monetary Accounts

Physical accounts do not have the integrative power of the monetary national accounts. Weighting

TABLE II

Simplified Structure of a NAMEA

	Monetary accounts				Physical accounts	
Use / Supply	Industries 1, 2, . . .	Households (public and private)	Capital	Rest of the world (ROW)	Material flows (residuals, natural resources)	Policy themes, loss of natural resources
Products	Intermediate consumption	Household consumption	Gross capital formation	Exports	Emissions from industries	
Consumption of households					Emissions from households	
Capital	Capital consumption			Capital transfer from ROW	Other volume changes (discoveries etc.)	
Income generation	Value added, NDP					
Rest of the world (ROW)	Imports		Capital transfer to ROW	Balances	Transboundary pollutants to ROW	
Material flows (residuals, natural resources)	Natural resource inputs		Contributions to policy themes, loss of natural resources	Transboundary pollutants to ROW		Contributions to policy themes, loss of natural resources

environmental impacts by weight of substance and resource flows may alert us to trends of overall environmental pressures and serve the management of particular natural resources; physical accounts cannot, however, compare the significance of environmental problems with the environmental and economic costs and benefits, as perceived by economic agents. Calculating ratios of resource productivity (GDP/TMR) or ecoefficiency (environmental impacts per GDP) is the most one can do to relate physical impacts to economic output. Monetary valuation appears to be the only possibility of fully integrating environmental concerns into the economic accounting system while ensuring consistency and comparability of "greened" with conventional economic indicators.

Pricing "priceless" environmental source and sink functions that are not traded in markets has its own problems. National accountants, especially from industrialized countries, have therefore been quite recalcitrant to implementing environmental accounts in monetary terms. They seem to believe that they might lose some of their longstanding goodwill if they let in new controversial concepts and valuations even through supplementary, so-called satellite accounts. While some accountants now favor the incorporation of the cost of depletion of economic natural resources (like timber, oil, or fish; see the appendix to this article) into the conventional accounts, many still consider the costing of environmental externalities a matter of modeling.

Nonetheless, the relatively new system for integrated environmental and economic accounting (SEEA), advanced by the author and his colleagues at the United Nations Statistics Division, did tackle the valuation problem. The objective was to incorporate environmental concerns into a comprehensive, integrated national accounts system. The basic methods of market valuation, maintenance costing, and contingent (damage) valuations are briefly described in the appendix. Their objective is to overcome major flaws of the conventional (monetary) accounts, in particular the following:

- Neglect of new scarcities of natural resources, which are a threat to sustained productivity of the economy
- Exclusion of environmental degradation as an externality of economic activity
- Accounting for environmental protection expenditures as national income and product when such outlays could be considered as a maintenance cost of society.

Figure 3 shows how environmental functions can be consistently integrated in the national accounts by doing the following:

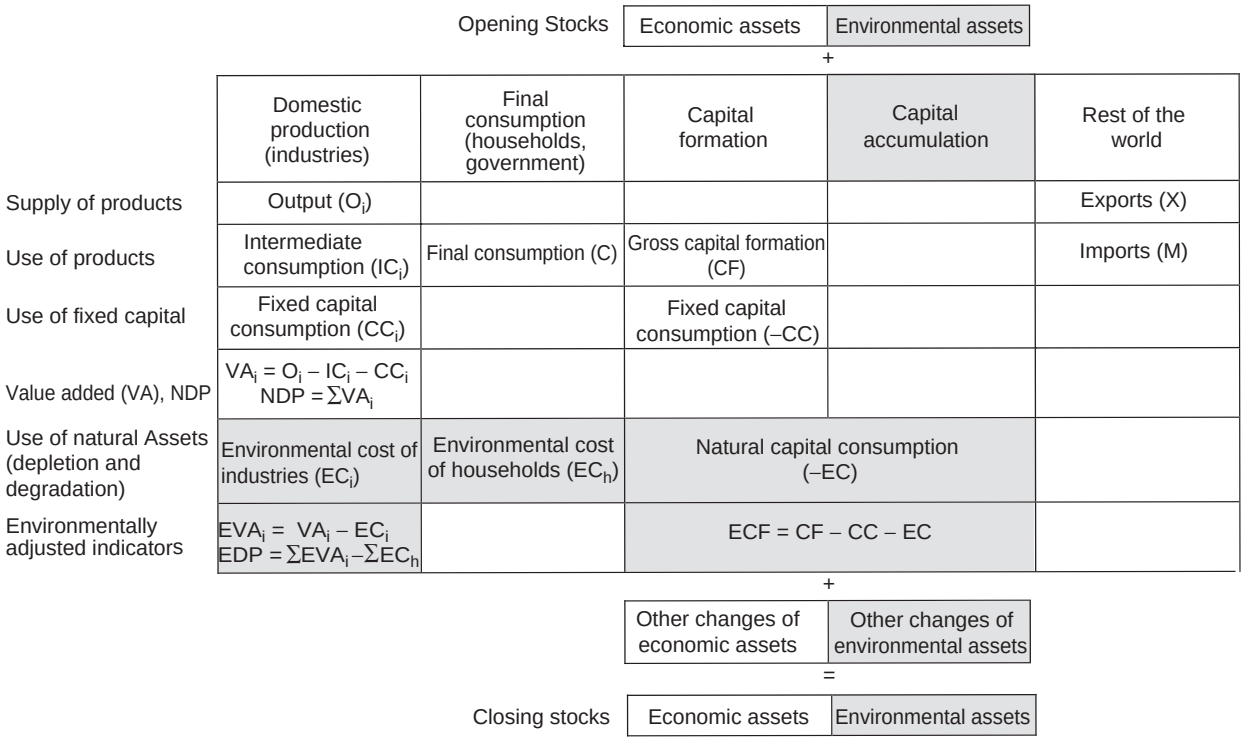

FIGURE 3 SEEA: structure and main indicators. The integrated accounting system incorporates environmental and natural – economic assets into the conventional flow and stock accounts and defines new environmentally adjusted ("green") economic indicators. From Bartelmus (1999), "Greening the National Accounts, Approach and Policy Use," DESA Discussion Paper No. 3, Fig. 3, p.7. United Nations, New York.

- Incorporating environmental assets as natural capital—in addition to produced (fixed) economic capital—into the asset accounts of the SNA
- Costing natural capital consumption (EC) in addition to and in consistency with fixed capital consumption (CC) in both the asset, and supply and use accounts
- Maintaining the accounting identities for the definition and calculation of the key economic (value added, VA, net domestic product, NDP, capital formation, CF), and environmentally adjusted (EVA, EDP, and ECF) indicators.

Environmental protection expenditures could be shown explicitly as "thereof" items of the supply and use of products in Fig. 3. The SEEA identifies these expenditures in appropriate classifications but does not suggest their deduction from GDP as a defense against welfare losses.

Accounting for natural capital consumption and maintenance (through reinvestment) extends the sustainability notion, as already built into the conventional net indicators of value added and capital formation, into the field of environmental services for the economy. In analogy to the wear and tear (i.e., the ultimate destruction) of capital goods in the production process, natural capital loss is defined as the permanent loss of natural resource stocks and waste absorption capacities. This definition clarifies the content of physical depletion and degradation—beyond natural regeneration and replenishment: the regeneration of nature can be seen as a cost-free natural repair process rather than as a capital loss.

Moreover, the costing of capital maintenance avoids controversial damage (to health and ecosystems) valuation (see the appendix). It can be argued, from an economic, utility maximizing optimality point of view, that such welfare effects are the correct values for environmental cost internalization into the budgets of households and enterprises. However, the purpose of national accounting is not welfare analysis or modeling of optimal behavior but the ex-post assessment of economic performance.

The revised SEEA takes a different, somewhat ambiguous view on welfare and other valuations. On the one hand, the monetization of the use of environmental assets is deemed to be a case of modeling a so-called green GDP; on the other hand,

damage valuation, as applied in cost-benefit analyses, is extensively discussed. As a consequence, the revised SEEA trades much of its original systemic character for flexibility in a modular, issue-oriented approach.

3. ACCOUNTING FOR ENERGY AND RELATED IMPACTS

Energy resource scarcities and environmental impacts from energy production and use are sometimes presented as the principal environmental problem; however, they do not tell the whole sustainability story. The previously described, accounting systems tell a more comprehensive story. This section illustrates, therefore, how the part of energy can be assessed within the full network of economic-environmental interactions. A detailed technical description of energy statistics and balances is thus beyond this article and would also be more relevant for the management of selected energy categories than for overall environment and sustainability policies.

3.1 Physical Energy Accounts

Physical energy balances are an established tool of energy statistics. They present the origin and destination of energy flows in calorific values or other energy equivalents. In accounting terms, such balances are "supply and use accounts," which can be made compatible with the national accounts. Typically they ignore, however, a number of environmental concerns, including the following:

- Important new and renewable energy sources, as well as nutritional energy flows, needed for getting the full picture of what Helmut Haberl calls "society's energetic metabolism"
- Environmental and social impacts of energy production and use such as resource depletion, emissions, land use changes, resettlement for hydropower development, and accidents.

To some extent, the previously described physical accounts incorporate the depletion of energy sources and the environmental impacts of energy production and use by appropriate coverage and classifications of energy carriers and substance flows. Perhaps best suited for detailed energy accounting in this regard are the physical input-output tables (PIOT). Table III illustrates the approach taken in supplementary energy tables of the PIOT. The table can also be interpreted as an elaboration of the physical part of the hybrid NAMEA (Table II) with regard to energy inputs and outputs, measured in calorific values. However, the PIOT do not relate emissions to energy supply and use but list them separately for the standard economic sectors. As in the NAMEA, the flows of residual substances could of course be added as outputs of energy production and consumption and as inputs into nature and the rest of the world.

The flow accounts of the PIOT do not show stocks of produced or natural capital, but stock changes only, as accumulation. As a consequence, periodic inputs and outputs balance only in the nonaccumulative flows for industries and households. The last row of Table III indicates an imbalance for produced and nonproduced natural assets and foreign trade (i.e., a net accumulation in the inventories of energy products and cultivated natural assets) and for nonproduced energy raw materials. The trade balance is negative, reflecting a net import of goods and services.

Physical flow accounts do not measure the ultimate objective of energy use, namely the production of energy services like heating, transportation or work. As a proxy, the energy PIOT includes various categories of final, or useful, energy. Most energy accounts exclude, however, the nutritional energy supply to humans and animals, needed for work and drive power, as well as hidden energy flows generated outside the boundary of the particular energy system. Inclusion of these flows would permit a comprehensive assessment of the energetic metabolism of societies as a complement to the industrial metabolism measured by material flow accounts.

3.2 Integrated Physical and Monetary Energy Accounts

Section 2.3 and Fig. 3 described the integration of physical and monetary accounts in the SEEA. The revised SEEA focuses largely on the physical side, at least as far as (noneconomic) environmental assets (see the appendix) are concerned. Its flow accounts thus cover energy supply and use in a similar fashion as PIOT and NAMEA. Both systems play in fact a dominant part in the revised SEEA. Considering, however, that the main reasons for greening the (monetary) national accounts have been environment-related deficiencies of the established accounts, the following brief discussion of energy stocks and flows is based on the more integrative original SEEA and its operational handbook.

TABLE III

PIOT for Energy Balances[a]

Supply	Industries 1, 2 etc.	Accumulation		Household consumption	Rest of the world (ROW)
		Produced assets	Nonproduced natural assets		
Inputs					
Raw materials[b]	x[c]				
Products[d]	x	x[e]		x	x
Waste for incineration	x				
Useful energy to nature[f]			x		
Energy losses to nature			x		
Outputs					
Raw materials[b]			x		
Products[d]	x	x[g]			x
Waste for incineration					
Useful energy [f]	x			x	
Energy losses	x			x	
Inputs minus outputs		x(+)	x(+)		x(−)

Source. Based on a case study for Germany (Stahmer, Kuhn, and Braun, 1998, Tables 4 and 5).
[a] Unit of measurement: calorific value, for example, joule or ton of oil equivalent (toe).
[b] Energy carriers and hydropower.
[c] Energy production (electricity, mining).
[d] Fuelwood, electricity, gas, coal, oil, natural gas, chemical and petroleum products, etc.
[e] Change in stocks.
[f] Light, heat.
[g] Cultivated natural assets (forestry, fishery).

The main advantages of such accounting over physical energy balances are the following:

- Coverage, definition, and valuation of energy stocks (oil deposits, standing fuel wood, etc.)
- Clear definition and costing of changes in stocks, notably the depletion of renewable (biotic and aquatic) and nonrenewable (fossil) energy resources as capital consumption
- Comparability of energy stocks and flows (stock changes)
- Comparability of conventional economic indicators of the energy sector (capital formation, value added, cost, income, etc.) with environmentally (cost-)adjusted indicators.

Assessing the current and future availability of energy resources, and hence of energy stocks and consumption, is a key concern of any sustainability analysis from the "capital maintenance" point of view (see Section 1.2). A number of categories and definitions used in the SEEA cater to this concern and are particularly relevant to energy carriers. For mineral and energy (subsoil) resources, the so-called McKelvey box categorizes physical stocks according to the probability of their existence and the economic feasibility of their extraction. The national—economic—accounts include proven reserves only (as opposed to probable, possible, or speculative resources), which are deemed profitable to exploit. The SEEA adopts the same definition of proven reserves to ensure consistency in (depletion) cost accounting and corresponding net indicators. Separate tables could of course present asset stocks weighted by probability (of existence) factors.

Subsoil energy carriers are nonrenewable resources. Any extraction reduces by definition the total availability of the resource, regardless of any potential discoveries of new deposits, and hence depletes the resource. The U.S. Bureau of Economic Analysis (in a one-time case study) disagreed, however, and treated discoveries as production (development) of a capital good. This approach offsets largely the extraction of the nonrenewable resource, turning it statistically into a renewable one. As a result, the total value of stocks of mineral

reserves has not changed much in the United States since 1958 (in constant prices). Further noteworthy issues, related to the accounting for nonrenewables and dealt with in the forthcoming revised SEEA, are the treatment of decommissioning costs (e.g., of nuclear power plants) as anticipated ("leveled-off") capital consumption, and of subsidized assets (with negative rents) as noneconomic, zero-value stocks.

The assessment of the depletion of renewable (energy) resources is more complex, since processes of natural regrowth of biotic (fuel wood) and replenishment of cyclical (water) resources, as well as capital formation (afforestation) need to be accounted for. The idea is to obtain the net amount of the permanent loss of the resource—beyond its sustainable yield—which should be costed as nonsustainable capital consumption. The determination of sustainable yield requires complex modeling for specific yield uses such as fuel wood from timber production, or water use for hydropower or as a coolant. In practice, the overall change in the physical amount and value of a resource between opening and closing stocks is frequently taken as a proxy for its depletion in physical and monetary terms. For example, the sustainable cut of forests is usually measured as the net increase in forest biomass, accounting for felling, natural losses from disease or fire, natural regrowth, and reforestation. This simplification neglects, however, changes in the composition and age structure of the forest that may affect future yields and economic returns.

Similarly, changes in the assimilative capacity of environmental media, owing to natural and human-made restoration, should be taken into account when estimating the net emissions—from energy production and use—that cannot be safely absorbed by natural systems. Only these emissions overload nature's existing assimilative capacities and should be costed as (nonsustainable) environmental externalities (see the appendix).

As discussed earlier, the physical and monetary environmental accounts consider only the permanent loss of natural capital as capital consumption. Most new and renewable energy sources like wind, sun, or ocean, have not experienced such loss, and their *(in situ)* economic value can be assumed to be zero. Of course, this does not mean that there are no investment and operating cost for harnessing these energy sources. However, these are conventional expenses (capital formation, capital consumption, and operating cost) that are covered by the established national accounts. The SEEA, and notably its revised version, identifies these environmental activities as natural resource management and exploitation by means of additional regrouping and classification. These environmental expenditures are important for the management of the different resources but do not assess the core environmental concerns of depletion and degradation.

The purpose of monetary estimates of economic (private) and environmental (social) costs is to assess the environmental sustainability of economic activity. However, some energy analysts and ecological economists appear to share Malcolm Slesser's view that monetary valuation is "after all nothing more than a highly sophisticated value judgement." Instead, they suggest the use of energy values or potentials for measuring the natural or absolute value of goods and services—independent of volatile market preferences. Different valuation principles for material and energy flow accounting include the following:

- Embodied energy, the direct and indirect energy required to produce goods and services
- Exergy, the potential work content of materials, energy carriers, and residuals
- E*m*ergy, the energy memory of the total amount of energy of one kind, required directly and indirectly to make a product or service (advanced in the writings of the late Howard Odum)

The main critique of these energy valuations has been, in turn, on the neglect of individual value judgements or preferences of economic agents. Additional, more practical problems are the data and knowledge requirements for a myriad of different production and transformation processes that use energy and generate emissions and discharges. Energy value accounting does therefore not seem to be capable of capturing the overall interaction of environment and economy. Such accounting could provide useful supplementary information for energy policies and management; it is less likely, though, to become a tool of overall assessments of economic or ecological sustainability.

4. OUTLOOK: POLICY USE OF ACCOUNTING INDICATORS

Rapther than reviewing the wide range of uses of a multipurpose accounting system, this section leads us back to the initial main concern of green accounting—the assessment of sustainability.

Table IV provides a framework for sustainability accounting and analysis with regard to the two key operational, economic and ecological, sustainability concepts. The table sets out from the rationale and strategies of reducing material throughput through dematerialization and of sustaining economic growth through capital maintenance. The corresponding physical and monetary accounting tools and indicators measure relatively strong and weak sustainability, respectively. Compliance with minimum standards for the preservation of critical (irreplaceable) capital is to attain strong sustainability. On the other hand, monetary accounts and their adjusted economic indicators imply the substitutability of different capital categories and production factors. They aim to assess the—weak—sustainability concept of overall capital maintenance.

Reducing material flows into the economy, as expressed in particular by their sum total, TMR, aims at decoupling economic growth from the generation of environmental impacts. A collaborative study, published by the World Resources Institute, shows that TMR per capita has been leveling off for selected industrialized countries (Germany, Netherlands, the United States) at about 80 tons per annum, except for Japan at 45 tons (because of its low per capita energy use). Given that GDP per capita has been rising in the high-TMR countries, there is some—relative—delinkage from growth, albeit far from the sustainability targets of Factor 4 (see Section 2.1). At least in these countries, ecological sustainability has not been in sight during the accounting periods (1975–1993).

Unfortunately, there does not seem to be an automatic solution to delinking environmental impacts or pressures from economic growth as suggested by the Environmental Kuznets Curve hypothesis. The corresponding inverted U-curve correlates low environmental impacts with low levels of economic development (per capita income), increasing impacts with industrialization and decreasing impacts with affluence. The possible transition to a dematerialized service economy might explain the automaticity, but empirical confirmation (except for a few pollutants) is elusive. Environmental regulation, possibly supported by fiscal incentives (subsidies for resource-saving technologies and disincentives such as material consumption taxes) will therefore need to be applied to ensure the preservation of critical capital.

Costing produced and natural capital consumption is a means to reserve funds for reinvestment and hence capital maintenance. At the macroeconomic level, the deduction of these costs from GDP obtains EDP, a net indicator whose decrease would indicate nonsustainable economic growth. Case studies of the SEEA, as presented, for instance, by Kimio Uno and Peter Bartelmus, did not show a reversal of (upward) GDP trends by EDP. However, this does not necessarily confirm sustainability because of the relatively short time series available.

A more pertinent way of looking into the sustainability of economic performance would be

TABLE IV

Concepts, Indicators, and Policies of Environmental Sustainability

	Ecological sustainability: Dematerialization/detoxification	Economic sustainability: Produced and natural capital maintenance
Rationale	Reducing throughput below carrying capacities	Sustaining economic growth
Strategy	Decoupling economic growth from environmental pressure	Maximizing economic growth while keeping produced and natural capital intact
Accounting tools	Material flow accounts (MFA), physical input-output table (PIOT), national accounting matrix including environmental accounts (NAMEA)	System for integrated environmental and economic accounting (SEEA)
Key indicators	TMR, TDO, DMI, TMC, resource productivity: GDP/TMR	"Green" economic aggregates: EDP, EVA, ECF, total wealth
Strength of sustainability	Strong: reduction of material and substance flows to meet sustainability standards (Factor X targets), maintenance of critical capital	Weak: overall capital maintenance, allowing substitution between produced and natural capital and other production factors
Policy instruments	Regulation and standard setting (Factor X, emission standards), fiscal (dis)incentives for material-saving innovation	Use of green indicators and variables in economic analysis and policy; market instruments of environmental cost internalization

Source. Adapted from Bartelmus, P. (2003), abridged version of Table 1, p.68, with permission.

to measure a nation's ability to generate new capital after taking produced and natural capital consumption into account. The Environmentally adjusted Net Capital Formation (ECF) indicator showed a significant difference between some developing and industrialized countries. For example, Indonesia, Ghana, and Mexico at times exhibited nonsustainability by using up more capital than generating new one (i.e., they showed an overall disinvestment in produced and natural assets). Industrialized countries, on the other hand, did increase their capital build-up and met thus one necessary condition for sustaining their economies.

Past overall capital maintenance or increase hide, however, the fact that in the long run complementarities of natural capital might make it impossible to maintain production and consumption patterns and growth rates. The empirical testing of this assumption should be an important field of sustainability research.

At the microeconomic level, one important use of environmental (social) cost accounting is to determine the level at which market instruments of cost internalization such as eco-taxes should be initially set for different economic agents according to polluter/user-pays-principles. The ultimate effects of environmental cost internalization on production and consumption patterns and overall economic growth and employment need, of course, be modeled with the usual restrictions and assumptions. The results of such modeling might point to the need of resetting the original levels of market instruments according to their predicted efficacy.

Greened national accounts and PIOTs are a particularly useful tool for integrative environmental-economic modeling since they generate a high degree of transparency with regard to the underlying data and indicators. This applies also to the manifold energy scenarios (and related climate change models), which have predicted or denied reaching the limits of energy supply and, possibly, economic growth. They have also generated a wide range of policy options according to differing coverage, modeling techniques, and policy targets. The International Institute for Applied Systems Analysis (IIASA) and the World Energy Council have presented concise overviews of energy scenarios on their Web sites.

As already mentioned, greened national accounts can only capture the immediate interaction between environment and economy. A broader assessment of sustainability would have to take account of social, institutional, and political aspects of sustainable development. In the field of energy, the disparities in the distribution of and access to scarce nonrenewable resources have triggered aggressive policies of securing affordable energy supply. Assessing natural resource availability, ownership, and trends of consumption in different regions and nations could alert us to looming resource scarcities and to possible international conflicts in resource use. It might also be the first step toward more rational policies of ensuring energy security, and perhaps security, for all.

APPENDIX: MONETARY VALUATION IN THE SEEA

Market valuation uses prices for natural assets, which are observed in the market. It is usually applied to economic assets of natural resources. The SNA defines economic assets as "entities (a) over which ownership rights are enforced … and (b) from which economic benefits may be derived by their owners." Figure 3 displays therefore part of natural capital consumption under the column of economic assets.

Where market prices for natural resource stocks, such as oil deposits or fish in the ocean are not available, the economic value of these assets can be derived from estimates of the—discounted—sum of life-long net returns, obtained from their potential use in production. It is at this value that a natural asset would be traded if a market existed for the asset. Market valuation techniques are also applied to changes in asset values, caused in particular by depletion (i.e., their nonsustainable use). These value changes represent losses in the income-spinning capacity of an economic asset. Depletion cost allowances reflect thus a weak sustainability concept, calling for the reinvestment of environmental cost in any income-generating activity.

Maintenance valuation permits the costing of the degradation of noneconomic—environmental—assets, in particular from emissions. Typically these externalities are not traded in markets. The SEEA defines maintenance cost as those that "would have been incurred if the environment had been used in such a way as not to have affected its future use." Maintenance costs refer to best-available technologies or production processes with which to avoid, mitigate, or reduce environmental impacts. They are used to weight actual environmental impacts, generated during the accounting period by different

economic agents. As with depreciation allowances for the wear and tear of produced capital, such costing can be seen as the funds required for reinvesting in capital maintenance.

The SEEA also discusses contingent and related damage valuations. These valuations are applied in cost-benefit analyses of particular projects and programs but are hardly applicable at the national level. They refer to the ultimate welfare effects (damages) of environmental impacts, which are incompatible with the market price and cost conventions of the national accounts. The original SEEA considered damage valuation in environmental accounting as experimental, and its operational handbook discourages its application.

Glossary

autonomous energy efficiency index (AEEI) The rate at which the economy becomes more or less energy intensive, with the price of energy remaining constant relative to the prices of other inputs. Indicates productivity improvements in energy use that are not caused by increases in energy prices.

bottom-up analysis (model) An analysis (or model) that focuses on the financial costs of technologies that, if widely adopted to meet the energy service needs of firms and households, would lead to reductions in greenhouse gas emissions. Tends to estimate low costs of greenhouse gas abatement.

computable general equilibrium (CGE) model A top-down model of the economy that includes all of its major components (consumers, producers, government, external agents) and markets (capital, labor, materials, energy, interindustry trade, final goods and services, government revenues and expenditures, international trade) and the relationships between them. Such a model can compute the new general equilibrium that results after a perturbation to one component or market, as would be caused by a greenhouse gas tax that affected the price of energy and perhaps other goods and services.

consumers' surplus A premium that consumers are willing to pay for a good or service above what they actually pay for it (its market price).

economies of learning The reductions in financial costs (capital and operating) of technologies (especially newer technologies) as manufacturers and operators gain experience with them with greater production. The rate of learning, and thus cost decline, is sometimes referred to as an "experience curve."

economies of scale The reductions in financial costs (capital and operating) of technologies as larger units are built or a greater number of units are manufactured on a regular basis. Can occur with old and new technologies.

elasticities of substitution (ESUB) Changes in the relative use of inputs (capital, labor, energy, materials) in response to changes in their relative costs. A high elasticity implies an easy ability to switch away from an input, such as energy, as its relative price increases, and a low elasticity implies the opposite.

financial costs The monetary costs that are used by engineers and financial planners to estimate the initial and ongoing capital outlay required by an investment. Unless preceded by a term such as "expected," financial cost estimates exclude consideration of financial risks, or intangible costs and benefits (e.g., consumers' surplus).

hybrid analysis (model) An analysis (or model) that combines the technological explicitness of the bottom-up approach with estimation of consumer and firm behavior of the top-down approach.

option value The increase in expected net benefits resulting from the decision to delay an irreversible investment under uncertainty. While this definition is predominant in energy efficiency literature, there are alternative definitions for this term.

top-down analysis (model) An analysis (or model) that focuses on aggregate relationships between inputs and outputs of the economy, and the interplay of these through price feedback mechanisms. The relative costs and uses of inputs (capital, labor, energy, and materials) are portrayed in production functions for firms and in consumption or utility functions for households. A "computable general equilibrium model" (CGE) is a type of top-down model. Top-down models tend to estimate high costs of greenhouse gas abatement, although this depends on the values of their elasticities of substitution and autonomous energy efficiency index parameters.

In deciding how and by how much to reduce greenhouse gas emissions, policy makers need to know the potential cost. But there are alternative definitions of cost, the evolution of technologies and preferences is a complex and highly uncertain process that can profoundly influence estimates of long-run cost. For these and other reasons, independent researchers and interest groups have produced widely divergent estimates of costs, and policy makers do not know whom to believe. The different analytical and modeling approaches are discussed here in order to explain their relative contribution to the differences in greenhouse gas reduction cost estimates. Each contrasting cost definition and contrasting assumption of technical and preference evolution informs the estimates. The focus is on energy-related technologies, because these produce the greatest anthropogenic contribution to rising atmospheric concentrations of greenhouse gases, but the issues are equally relevant to all technologies and management practices that reduce greenhouse gas emissions, whether involving forestry, agriculture, treatment of municipal solid waste, or capture and storage of CO_2.

1. INTRODUCTION

In 1991, M. Grubb referred to "the missing models" in arguing for the development of a new generation of models that would better inform policy makers of the critical issues in estimating greenhouse gas (GHG) reduction costs. To be useful to policy makers, models for costing GHG reduction need to explain the key factors behind divergent cost estimates. But over a decade later, cost estimates still diverge widely, in part because of different assumptions about technology and preference evolution (which is perhaps inevitable) but also because of how costs are defined and depicted in GHG costing models. "Bottom-up" models tend to ignore or underrepresent important constraints to the adoption of new equipment, whereas "top-down" models incorporate these constraints but inadequately represent the potential for technological innovation and preference changes that can reduce costs in the long run. Newer "hybrid" models attempt to incorporate key strengths of both top-down and bottom-up approaches in order to be more useful to policy makers who face critical decisions about the magnitude and timing of GHG reduction targets.

2. ALTERNATIVE DEFINITIONS OF COST

An action to reduce GHG emissions is defined as a change in equipment choice, equipment use rate, lifestyle, or resource management practice that changes GHG emissions from what they otherwise would be. Examples are: choosing more efficient light bulbs, turning off unused lights, telecommuting some days of the week, and practicing forestry or agriculture differently. The cost of an action is the difference in costs between the business-as-usual scenario and a world in which the action is undertaken. Unfortunately, analysts apply alternative definitions of these costs.

2.1 Bottom-Up Cost Definition and Critique

Bottom-up analysis, applied frequently by engineers, physicists and environmental advocates, estimates how changes in energy efficiency; fuel type; emission controls on equipment, buildings, and infrastructure; and even land-use practices might lead to different levels of GHG emissions. Technologies (furnaces, light bulbs, electric motors, vehicles) that provide the same energy service (space heating, lighting, industrial motive force, personal mobility) are generally assumed to be perfect substitutes except for differences in their financial costs and their emissions of GHGs and other pollutants. When their financial costs (capital and operating) in different time periods are converted into present value using a social discount rate, many current and emerging technologies available for reducing GHG emissions appear to be profitable or just slightly more expensive relative to existing equipment. Bottom-up analyses often show, therefore, that substantial GHG emission reduction can be profitable or low cost if the low-emission technologies were to increase from their small market share to achieve market dominance.

Although they are all characterized by a focus on technologies and by cost definitions that are restricted to financial costs, bottom-up models can vary in terms of how they depict the interconnections between different decisions in the economy. A simple bottom-up analysis would assess each energy service individually (home heating, commercial lighting) and conduct a financial analysis to determine the least-cost technology for each. A fully integrated, optimizing bottom-up model would determine the least-cost technology for all services simultaneously. This

integrated approach may indicate a very different outcome if the model shows, for example, that dramatic reductions in GHG emissions from the electricity sector are inexpensive. If these are pursued, then a drop in the GHG content of electricity will reduce the GHG cost-effectiveness of electricity conservation actions in the end-use sectors. A well-known, integrated bottom-up linear programming model used in North America, Europe, and increasingly elsewhere is the MARKAL (market allocation) optimization model.

An indication of the bottom-up approach is provided by researchers assessing the costs to the United States of achieving the target it negotiated (but has not ratified) under the Kyoto Protocol of 1997. The U.S. government agreed to reduce its GHG emissions to 7% below their 1990 level by 2010. According to forecasts at the time, this represented a reduction of almost 30% from expected emission levels for 2010. Brown and coauthors at five major energy research laboratories funded by the U.S. government found that the United States could reduce to its 1990 level of emissions with no net cost to the U.S. economy, and thus virtually no impact on gross domestic product (GDP). This could be achieved with a host of policies, including a GHG tax of no more than $25/ton of carbon ($25/t C). All of the reductions would be attained domestically, even though the United States has the capability under the Kyoto agreement to purchase reduction credits from other countries.

Many economists, however, criticize the bottom-up approach in general, and this study in particular, for the assumption that a single, *ex ante* (anticipated) estimate of financial cost differences indicates the full social cost of switching technologies. Economists such as A. Jaffe and R. Stavins argue that technologies may differ to consumers and businesses in ways that are not represented by this single financial value. The mundane example of purchasing a light bulb illustrates these differences.

- New technologies usually have a higher chance of premature failure than do conventional technologies and therefore pose greater financial risk. There is some probability that *ex poste* (realized) financial costs will exceed *ex ante* financial costs for new technologies. New compact fluorescent light bulbs have exhibited higher rates of premature failure compared to conventional incandescent light bulbs, requiring a higher than expected financial outlay because of early replacement in some cases.
- Technologies with longer payback periods (relatively high capital costs) are riskier if the cumulative probability of failure or accident, or undesired economic conditions, increases over time. Because of the higher purchase cost of compact fluorescent light bulbs, the chance of accidental breakage prior to paying back the initial investment is higher than for an incandescent light bulb.
- Two technologies may appear to provide the same service to an engineer but not to the consumer. Many people find compact fluorescent light bulbs to be less than perfect substitutes for incandescent light bulbs in terms of attractiveness of the bulb, compatibility with fixtures, quality of light, and timing to reach full intensity, and would pay more to maintain high levels of these nonfinancial attributes.
- Not all firms and households face identical financial costs: acquisition, installation, and operating costs can vary by location and type of facility. Compact fluorescents may be more expensive to acquire in nonmetropolitan areas where the market is smaller. This heterogeneity means that a comparison of single-point estimates of financial costs may exaggerate the benefits of market domination by a low-GHG technology.

The first two differences relate to "option value," which is the expected gain from delaying or avoiding an irreversible investment while waiting for new information that might lead to a better decision. The third difference refers to what economists call "consumers' surplus," or the extra value that consumers realize above the financial cost of a particular technology. The fourth difference simply acknowledges "market heterogeneity," i.e., that a technology may be cheaper than its competitor in one circumstance but more expensive in another.

When consumers and businesses are asked, induced, or forced to switch away from a technology they would otherwise have chosen, economists say that the social cost of this switch is the difference in financial costs plus or minus any intangible costs related to option value, consumers' surplus, and market heterogeneity. By ignoring these values, bottom-up analysts may overestimate the willingness of firms and households to take actions that reduce GHG emissions, and thus underestimate the social cost. Politicians, in contrast, seem to be instinctively aware of these other values, and tend to question claims that GHG emissions can be reduced at little or no cost. In providing only part of the cost picture, the bottom-up approach is less helpful to policy makers than it could be.

Another challenge with the bottom-up approach is that its technology-specific focus hinders the ability to assess broader macroeconomic effects, notably the trade and structural repercussions resulting from changes in energy prices and costs in the economy. In this sense, bottom-up models usually provide only a "partial equilibrium analysis" of the response to GHG reduction policies. If, however, the cost of GHG reduction is as low as this approach often concludes, or if governments are unwilling to pursue rapid and costly decreases in GHG emissions, then macroeconomic feedbacks may be small enough that this partial equilibrium assessment is sufficient. But even if energy-focused GHG policies are too modest to elicit a significant macroeconomic change, they may cause unintended responses in energy markets that are outside the purview of a conventional bottom-up model. For example, subsidized or voluntary decisions to acquire more energy-efficient equipment (cars, lights, appliances, industrial machinery) reduce energy service operating costs, and may thus encourage greater consumption of energy services. The magnitude of this "rebound effect" is disputed, but certainly all sides agree that at some point lower operating costs foster higher use. Returning to the lightbulb example, the installation of outdoor decorative and security lighting, often using high-efficiency lightbulbs, is increasing in North America. Most bottom-up models do not, however, link the demand for energy services to the cost of the service, and thus would not simulate a rebound effect.

2.2 Top-Down Cost Definition and Critique

The alternative, top-down analysis of economists usually relies on historical and cross-sectional market data to estimate aggregate relationships between the relative costs and the relative market shares of energy and other inputs to the economy, and links these to sectoral and total economic output in a broader, equilibrium framework. Elasticities of substitution (ESUB) indicate the substitutability between any two pairs of aggregate inputs (capital, labor, energy, materials) and between energy forms (coal, oil, gas, renewables) within the energy aggregate. Another key parameter in such models, the autonomous energy efficiency index (AEEI), indicates the rate at which price-independent technological evolution improves energy productivity. Relatively high parameter values for AEEI and for energy-related ESUB (a large degree of substitutability between energy and capital, and between GHG-intensive and non-GHG-intensive forms of energy) equate to a relatively low cost of GHG emission reduction. Because these parameters are estimated from real market behavior, as energy prices and energy consumption have changed historically, they are said to reveal the actual preferences of consumers and businesses—and therefore implicitly incorporate losses or gains in option value and consumers' surplus, as well as reflect the market heterogeneity of real-world financial cost conditions.

With these key response parameters estimated, economists simulate the economy's reaction to an economic signal (a GHG tax, tradable GHG permits, technology subsidies, or some combination of these) that increases the relative cost of GHG-intensive technologies and behavior. The magnitude of the economic signal necessary to achieve a given GHG reduction target provides the implicit marginal cost of that target. Because top-down models usually integrate energy supply and demand within a total economy model, this marginal cost includes the feedback between energy supply and demand, on the one hand, and between these components and the economy as a whole, on the other. Top-down approaches are, therefore, more often associated with a "general equilibrium analysis" of policy effects; models designed expressly to close all key economic feedback loops are referred to as computable general equilibrium models (CGE models). Because movement away from current technologies includes all intangible value losses, top-down analysis usually generates substantially higher estimates of GHG reduction costs.

The top-down parameters, ESUB and AEEI, are usually estimated from historical data. Historical data generate relatively low values for the economy's willingness to substitute (ESUB) away from GHG-intensive technologies and activities, in part because full long-run price responses are difficult to detect in an ever-changing world. Experts can, however, judgmentally change the AEEI or ESUB parameter values to generate low-cost estimates, simply by portraying consumers and businesses as more prone to switch technologies in response to changes in financial costs—in effect, reducing the estimated option value losses, consumers' surplus losses, and market heterogeneity that otherwise explain technological inertia. But setting these parameters judgmentally undermines to some extent the very argument in favor of the top-down approach, by forgoing its real-world empirical basis. The future value of AEEI, being highly uncertain, is hotly disputed.

Top-down models are relatively easy to construct, and this may explain why there are so many variants in contrast to the dominance that MARKAL has attained among integrated bottom-up modelers. Some of the top-down models in the United States are G-Cubed, MERGE, SGM, and MIT-EPPA; all of these are computable general equilibrium models. Top-down models have also been applied to estimating the costs to the United States of achieving its Kyoto target, and these provide a contrast with the bottom-up estimate. Weyant and Hill summarized the results of a multimodel evaluation of the Kyoto protocol by several top-down models, especially the CGE type. Of the 11 participating models, 8 models found that the United States would require a carbon tax of at least $150/t C, and of these, 4 models required a tax higher than $250/t C (one higher than $400/t C). GDP impacts ranged from modest levels to the loss of over 3% of economic growth.

Like the bottom-up approach, however, the top-down approach is also vulnerable to the criticism of being unhelpful to policy makers. Substantial reduction of GHG emissions, in order eventually to stabilize atmospheric concentrations, is a long-run objective that requires dramatic technological change over a lengthy period in which consumer preferences are also likely to evolve. Policy makers need to know if and how their policies can influence long-run technological change, and thus the *ex ante* and *ex poste* financial costs of technologies, as well as the long-run evolution of consumer preferences, in ways that reduce these intangible losses from switching to less GHG-intensive technologies.

Even if the confidence intervals of the estimated ESUB and AEEI parameters are narrow, meaning that they are relatively robust at explaining past changes in energy demand, there is no guarantee that parameter values derived from past experience will remain valid into the future. Financial costs and consumer preferences change over time, and the magnitude and direction of this change may be influenced by policy. For example, until recently, there was no incentive to design and commercialize low-GHG technologies. Now, such technologies are under development worldwide. Azar and Dowlatabadi note that as research, development, and production expand, aided by government policy, "economies of scale" and "economies of learning" reduce financial costs and can reduce option values, perhaps dramatically. The market penetration of these new technologies and their falling costs imply higher future values for ESUB and AEEI, reflecting the economy's increasing ability to reduce GHG emissions at lower costs.

A similar logic applies to historical estimates of consumers' surplus losses. A typical pattern in new technology commercialization is an initial phase of slow market penetration, limited to acquisition by early adopters, followed by a market transformation phase in which expanding consumer awareness and acceptance precipitate a feedback loop of product improvement, intensified marketing effort, and accelerating dissemination. This shift in consumer preferences means lower consumers' surplus losses from technology switching, implying that the long-run social costs of GHG reduction may be partially influenced by policy. Again, this would cause higher long-run values for the all-encompassing ESUB and AEEI parameters of top-down models, and thus lower costs of GHG reduction. Returning to the light bulb example, the growing cumulative production of compact fluorescent light bulbs has reduced their production cost and market price over the past decade, which in turn has shortened investment paybacks and decreased the financial risks from premature breakage. Manufacturers have also improved the reliability and attractiveness of compact fluorescents (appearance, size, hue) so that they are now closer substitutes for incandescent light bulbs. Does this mean that the household market for light bulbs is on the verge of a market transformation in which compact fluorescent light bulbs overtake and marginalize incandescent light bulbs? It might. But an important caution is that low-GHG technologies are not guaranteed lower financial costs and growing consumer acceptance. Experienced marketers of new products are well aware of the difficulty of predicting financial cost reductions and future consumer preferences; the experience of every new technology is different. If the general trend of technological evolution, however, is for new technologies to increase the ability and willingness of consumers and businesses to opt for low-GHG choices, as is likely, then AEEI and ESUB values will increase and the long-run costs of GHG emission reduction will fall.

The importance of technological change for estimating future costs raises another challenge for the top-down approach in terms of its usefulness to policy makers. Because conventional top-down analysis conceives of technological change as an abstract, aggregate phenomenon, characterized by ESUB and AEEI parameter values, it only helps policy makers assess top-level policy instruments, such as taxes and tradable permits. But policy makers often prefer technology- and building-specific policies in the form of tax credits, subsidies, and regulations because these policies avoid the dramatic

(and unpopular) increases in energy prices that would otherwise be required to cause the degree of technological transformation for substantial GHG emission reductions. A model is thus more useful to policy makers if it can assess the combined effect of these focused policies with perhaps relatively modest economy-wide applications of taxes and tradable permits, but conventional, aggregated top-down models are unable to do this.

2.3 Compromise Hybrid Costing Approaches

In summary, the top-down and bottom-up approaches offer competing cost definitions, both of which have their failings in terms of usefulness to policy makers. The bottom-up approach ignores option values and consumer preferences. The top-down approach incorporates these cost factors, at an aggregate level, but ignores the potential for long-run changes to them as technology-specific and economy-wide policies stimulate technical change and perhaps shifting consumer preferences.

Researchers have tried to address these different strengths and weaknesses of top-down and bottom-up analysis by designing policy costing models that are both technologically explicit and behaviorally realistic—simulating the economy's long-run building and equipment stock turnover as a function of policies that target technological innovation and business and consumer preferences, while incorporating feedbacks between energy supply and demand, and between the energy system and the structure and output of the economy. Bohringer and others refer to this as a "hybrid modeling" approach, because it attempts to bridge the top-down/bottom-up schism. An example of a so-called hybrid model is the National Energy Modeling System (NEMS) of the U.S. government. Like a bottom-up model, NEMS is highly disaggregated, having substantial technological detail in its representation of energy supply and of the individual energy demand sectors (transportation, residential, commercial/institutional, and industry). But, unlike a typical bottom-up model, technology choices within these sectors are simulated based on behavioral parameters that are mostly estimated from real-world empirical data. Alternative vehicle choice in the NEMS transportation module, for example, is based on parameters estimated from surveys that asked consumers about vehicle options. Also, the model is close to general equilibrium in that a policy simulation equilibrates energy supply and demand, on the one hand, and this supply–demand composite with the macroeconomy as a whole, on the other hand.

With the hybrid modeling approach, the policy analyst can help the policy maker sort out the importance of differing definitions of cost for the estimates of GHG reduction costs. A hybrid model can first be applied in bottom-up mode, focusing just on financial costs and treating these in a deterministic manner, ignoring risk factors and intangible costs such as consumers' surplus losses. Then, its parameters can be adjusted to incorporate the estimated effects of these other factors. The policy maker has the opportunity to see the importance of these different cost definitions for the different policy cost estimates, and to test the cost assumptions that seem most plausible. For example, the U.S. Energy Information Administration applied NEMS in 1998 to estimate the costs of U.S. compliance with the Kyoto Protocol. It estimated that a carbon tax of $294/t C was required to reach the target with domestic actions alone and that this would cause a 3% loss in GDP growth. These results are within the range of top-down models in the multimodel evaluation, but distant from the bottom-up study of the U.S. national research laboratories. This is not surprising given that the 12-year period between 1998 and the Kyoto deadline year of 2010 provides insufficient time for policies to influence the evolution of new technology costs or consumer preferences. Because hybrid models and top-down models have the same definition of cost, they are likely to show similar costs of GHG reduction over a short-period simulation. Over a 20- or 30-year time frame, however, the cost estimates from a hybrid model could diverge significantly from those of a typical top-down model, if the hybrid included dynamic influences on technology costs and consumer preferences, as is explained in the following section.

3. UNCERTAINTIES AND ASSUMPTIONS ABOUT TECHNOLOGY AND PREFERENCE CHANGE

Even if the definition of costs were not in dispute, the challenge of GHG emission reduction presents enormous uncertainties that can result in widely divergent cost estimates. For a given country, three broad categories of uncertainty stand out.

- Uncertainty about external factors creates profound uncertainty for the GHG reduction costs of a given country. Will other countries make and keep

emission reduction targets, and if so at what cost and with what implication for competitive trade conditions? To what extent will a given country be allowed to utilize international permits and international actions to meet its commitment? What international emission permit trading mechanism will exist and what will be the price of permits?

- Uncertainty about technological innovation and its implications for future financial costs increases as the time horizon is extended. Over a 20- to 30-year time frame, dramatic technological change may occur with equally dramatic implications for the financial cost of GHG reduction policies. For example, innovations that reduce the cost of converting fossil fuels into hydrogen, while sequestering safely underground the CO_2 by-product, raise the prospect of accelerated commercialization of GHG-free, hydrogen-based technologies such as fuel cells. The financial costs of such technologies are not independent of public policy, although the relationship is highly uncertain.
- Uncertainty about consumer and business preferences increases as the time horizon is extended. How might these preferences change as environmental awareness, income, available technologies, and policy alter over that same 20- to 30-year time frame? Thus, policies that mandate the development and commercialization of hydrogen-based fuel cell vehicles are likely to influence the marketing efforts of vehicle manufacturers, with a possible effect on the preferences of consumers. Again, the magnitude of this effect is highly uncertain.

The importance of external uncertainty is usually assessed by constructing and simulating scenarios that show contrasted but plausible future values for uncertain factors, such as the price of internationally traded GHG emission permits or crude oil. If, however, a country has a significant influence on the market of internationally traded energy commodities or GHG permits, as is the case for the United States, it should also model the relationship between its domestic policies and these international prices. The NEMS model of the U.S. government has modules that link developments in the U.S. market to international energy prices and could link to a module of internationally traded GHG permits. Top-down models, being more aggregated, have dominated the exploration of this uncertainty so far, although there have been significant advances in recent years in linking together the MARKAL bottom-up models from several countries for this type of analysis.

Given the long-run nature of an environmental challenge such as climate change risk, and the profound technological change that is required to achieve substantial GHG emission reductions, the uncertainties associated with technological innovation and consumer and business preferences are of great significance for the estimation of costs. For addressing these uncertainties, bottom-up, top-down, and hybrid approaches offer different capabilities.

3.1 Top-Down Approaches to Long-Run Uncertainty, and Critique

Although top-down models have not traditionally been applied to extremely long-run periods in which the technological context is likely to change, some economists have used them for 50- and even 100-year simulations of the policy response to climate change risk. But as the time frame extends further into the future, the character of technical change plays an increasingly important role in determining the costs of GHG reduction, yet technical change in top-down models is simply portrayed via the ESUB and AEEI parameters. These parameters are typically estimated from past technological and preference changes associated with price changes for energy and other inputs.

How confident can the modeler, and the policy maker, be in the stability of these parameter values in future time periods? For example, how does the top-down modeler translate new information about the cost of renewable electricity generation or high-efficiency light bulbs into their parameter estimates for AEEI and ESUB? How does the modeler show the policy maker the relationship between technology-focused research and development policies and these same parameters? To be useful to policy makers, models need to indicate the direction, probability, and impact of technological changes that influence both the financial costs and consumers' surplus costs of GHG emission reduction—and the extent to which these changes might be influenced by policy. Parameters estimated from historical conditions may have little ability to anticipate the future technology and preference dynamics in response to policies seeking to induce long-run, profound technological change.

3.2 Bottom-Up Approaches to Long-Run Uncertainty, and Critique

In recognition of this challenge, bottom-up modelers have focused on applying lessons from past technological innovations to new technologies, linking cumulative manufacture and expanded application

of a technology to reductions in its financial costs—the "economies of learning" or "experience curves" discussed earlier. For example, as global production of windmills has grown over the past 20 years, the cost of windmill-generated electricity fell quickly at first and today continues gradually down toward an asymptote, possibly in the range of (U.S.) $0.04/kWh or even lower. Researchers suggest that zero-emission, hydrogen-fueled vehicles could exhibit a similar declining cost pattern over the next 20–30 years.

In this bottom-up framework, the analyst can make projections about the declining financial costs of emerging technologies as they penetrate the market, assume a rate of diffusion, and then calculate the resulting GHG reductions and financial costs. Bottom-up modelers can also link the future financial costs of these new technologies to policy initiatives, such as research and development subsidies, in what Grubler, Nakicenovic, and Victor, among others, refer to as "endogenous modeling of induced technical change." But the very criticisms of bottom-up modeling that motivated the development of hybrid modeling approaches apply equally to the exploration of long-run technical change. Uncertainty about emerging technologies concerns not just the diversity of views on their future *ex ante* financial costs (the slope of their experience curves), but also uncertainty about the willingness of consumers and businesses to embrace any particular technology as its financial costs fall and awareness of it increases.

An example is the choice of technology for providing personal mobility in the urban areas of industrialized countries. Emerging substitutes for the conventional vehicle driven by a gasoline-fueled internal combustion engine include replacing gasoline with ethanol, adopting battery–gasoline vehicles, adopting hydrogen-fuel-cell vehicles, and switching to public transit. Bottom-up modeling of induced technical change could show a substantial decrease in the *ex ante* financial cost of public transit relative to the alternatives, but this would mislead policy makers if it had dramatically underestimated the reluctance of urbanites in wealthy countries to switch away from personal vehicles. A similar concern applies to many of the new technologies that are now being applied to estimate the long-run costs of GHG reduction.

3.3 Hybrid Efforts to Address Long-Run Uncertainty

Uncertainty internal to the system being modeled, therefore, is related both to the long-run dynamic between technology commercialization and financial costs, on the one hand, and between technology commercialization and preferences, on the other. To be useful to policy makers, simulations of policies to induce long-run technical change should provide an indication of how reductions in the *ex ante* financial costs of technology options might translate into rates of market penetration, the critical issue overlooked by most bottom-up modeling.

To address this uncertainty, researchers of technological change policy, such as Train, increasingly apply "discrete-choice models" to relate past preferences to certain technology attributes in what is called "revealed preference research." Estimated confidence intervals provide an indication of uncertainty. But for new technologies there is no past market behavior, so discrete-choice researchers must instead ask consumers and businesses to make choices between new or even hypothetical technologies with different bundles of attributes, what is called "stated preference research." An example is to ask consumers to make a choice from among a set of vehicles that vary in terms of acceleration, refueling time, fuel type, emissions, and range. Confidence intervals from this research indicate uncertainty, but may be biased or imprecise given that the choices are hypothetical.

Hybrid models are well suited for incorporating the estimates from discrete-choice modeling into their behavioral parameters. First, discrete-choice research is focused at the technology level, the same level of resolution at which bottom-up and hybrid models operate. Second, hybrid models have behavioral parameters at the level of detail required for simulating technology choices—decision-specific discount rates, and technology-specific costs that can be adjusted to reflect consumers' surplus differences. Research in this direction is still at an early stage, but recent advances are showing a good deal of promise. The transportation module of the NEMS hybrid model, for example, already contains in its behavioral parameters the results of revealed and stated preference research on alternative vehicle choices. Other approaches to addressing technical uncertainty involve subjective adjustment of top-down model parameters (ESUB and AEEI) to incorporate lessons from technology-focused research, and the introduction of behavioral elements into the technology-choice algorithms of bottom-up models.

4. ASSESSMENT

Bottom-up models can be useful to policy makers by showing the technological possibilities for advancing

toward an environmental target, such as reducing GHG emissions. However, these models can also be misleading in that their definition of cost is restricted to a single *ex ante* estimate of financial costs that ignores possible losses of option value and consumers' surplus by businesses and consumers. Most bottom-up models are also not able to estimate the overall effect of energy-impacting policies on the macroeconomy. Top-down models, in contrast, can be useful to policy makers because they incorporate the preferences of businesses and consumers—in that their parameters are usually estimated from real-world behavior—and connect the energy system to the macroeconomy. Bottom-up models tend to estimate low costs of GHG reduction relative to top-down models. Different types of comparative analysis, some of it using hybrid models that combine technological explicitness with behavioral realism, can help policy makers understand the role of these different definitions of cost on the divergence in cost estimates between the two approaches.

A second key challenge for GHG reduction cost estimation is due to uncertainties, and hence different assumptions, about technology and preference changes over very long periods. Recent research with bottom-up models attempts to explore how financial costs may decrease as new technologies experience the benefits of learning and perhaps mass production. However, these models lack the behavioral component that is critical in assessing the extent to which the decreasing cost of a new technology will drive its adoption by consumers or firms. Models with hybrid characteristics of technological explicitness and behavioral realism offer some hope to improve the usefulness of models for decision makers and thus address Grubb's challenge of more than a decade ago to develop "the missing models."

Glossary

E3 models Energy–economy–environment models.
final energy The form of energy that is bought and sold in the market to consumers.
greenhouse gas (GHG) A gas that can trap heat in the atmosphere by absorbing the longwave radiation emanating from Earth's surface.
Kyoto Protocol An agreement between industrialized countries (the so-called Annex B countries), obliging them, individually or jointly, to ensure that their average annual carbon dioxide equivalent emissions of six greenhouse gases (CO_2, CH_4, N_2O, SF_6, CF_4, and halocarbons) will be 5% below 1990 levels in the commitment period 2008 to 2012.
primary energy Naturally occurring form of energy.
reference energy system (RES) A schematic and aggregated representation of all energy conversion technologies and the flows between them. A RES is not uniquely defined, but rather depends on the level of aggregation considered in a particular analysis.
scenario A qualitative and/or quantitative description of (the development) of a system, based on a set of internally consistent assumptions concerning the main driving forces.
stochastic models Representations that include uncertainty by replacing certainty (of parameters and functional relations) with probability distributions.
storyline In connection with a scenario, a storyline is a qualitative, textual description of how the future might evolve.

This article reports on global carbon emissions projected with long-term energy–economy–environment (E3) scenarios. Many of the prominent emission scenarios have been published under the auspices of the Intergovernmental Panel on Climate Change (IPCC). After briefly discussing methodological aspects of scenario building—in particular its driving forces and other inputs—the article proceeds to systematically discuss scenario results for three groups of scenarios, that is, high-impact, CO_2 mitigation, and sustainable development scenarios. For these groups, ranges are given for the most important inputs and outputs. For mitigation scenarios, typical mitigation costs are reported.

1. GREENHOUSE GAS EMISSIONS SCENARIOS

In the context of this article, the term "scenario" means the qualitative and/or quantitative descriptions of (the development of) a system, based on a set of internally consistent assumptions concerning the

 © 2004 Elsevier Inc. All rights reserved.

main driving forces. A scenario of greenhouse gas (GHG) emissions then depicts the development of GHG emissions over time for a given geographical region. As the greenhouse gas problem is a global problem, the focus here is describing global scenarios.

In addition to including a geographical specification, the system used to describe GHG emissions usually also includes so-called driving forces. These driving forces comprise socioeconomic, demographic, and technology variables that determine the evolution of the energy, agricultural, and other systems, the major sources of anthropogenic GHG emissions. GHG emission scenarios include one or more greenhouse gases, but in most cases, one of the greenhouse gases included is carbon dioxide (CO_2). For most GHG emission scenarios, the six gases included in the Kyoto Protocol are the maximum number of gases considered. Analogous to the glass roofs of actual greenhouses, greenhouse gases are restricted in the narrow sense to mean gases that trap the heat that emanates from Earth's surface, but other gases and aerosols (such as SO_x, water vapor, black carbon, and others) influence the heat balance of Earth (for instance, but not always, by shading, which has a cooling effect). The so-called precursor gases are yet another important factor for the dynamic heat balance of the atmosphere. They are not greenhouse gases, but they are involved in atmospheric chemical reactions that produce or absorb greenhouse gases.

The most important use of greenhouse gas emission scenarios is to serve as inputs for models that calculate the climate impact of given global emission pathways. Conceptually, the climate impact of GHG emissions is described by the chain: emissions, atmospheric concentrations, radiative forcing (a measure of the amount of heat trapped per unit area, e.g., per square meter), temperature change, and specific impacts (e.g. land losses due to sea level rise). Consecutive links of this chain are connected through a complex system that is not yet completely understood. Any evaluation of the causal chain between GHG emissions and impact is therefore surrounded by considerable uncertainty. To give an example, according to recent estimates from the Intergovernmental Panel on Climate Change (IPCC), the temperature increase that is expected to result from a doubling of atmospheric GHG concentrations (relative to preindustrial levels) may range between 1.7 and 4.2 K.

2. THE DIFFERENCE BETWEEN SCENARIOS, PROJECTIONS, AND FORECASTS

It is important to distinguish a scenario from forecasts and, even more so, from predictions, the most important difference being that forecasts and (to an even higher degree) predictions are meant to portray particularly likely future developments. In contrast, scenarios may very well include elements that may not be considered the most likely development. For example, the task of perhaps the most prominent efforts to generate GHG emission scenarios, the IPCC Special Report on Emission Scenarios (SRES), edited by Nakićenović and Swart in 2000, was to portray the entire range of plausible greenhouse gas emissions during the 21st century. Another example of scenarios that are not constructed for the purpose of portraying particularly likely developments are those scenarios that describe a consistent set of circumstances that lead to a desired outcome. If models are used to generate such a scenario, the model is often run "backward." Scenarios designed to generate a particular outcome are called "normative." In contrast, scenarios that describe the consequence of assuming alternative future states of the world, which usually are meant to be particularly likely, are called "descriptive." This distinction is conceptual, and borderline cases exist that could be classified either way.

3. SCENARIOS, UNCERTAINTY, AND PROBABILITY

A common way of treating uncertainty is to define probability distributions, according to which an uncertain event is distributed. Many probability distributions are well understood, and the interpretation of medians, percentiles, variances, and other indicators is a common practice in research. Perhaps less common is the insight that probabilities such as those describing uncertainties about the evolvement of the climate system are subjective and that they therefore cannot be uniquely determined. As a practical definition of probability (in contrast to a strictly formal mathematical definition), de Finetti (1974) proposed "degree of belief." Of course, belief is always in the eyes of the beholder, and it is therefore consistent with this definition to postulate that all probabilities are subjective and that probability theory is the science of analyzing and

processing given (subjective) probability distributions.

This way of looking at probabilities is far from commonplace, and the perception and interpretation of probabilistic statements by the interested public are therefore unpredictable. Moreover, it can easily happen that two scientists attach different degrees of belief to one and the same scenario, even when they have produced that scenario jointly. Publishing different probabilities for the same scenario would then almost certainly cause confusion. This was the reason that Nakićenović and Swart, and the other authors of the IPCC SRES report, refrained from estimating probabilities or the relative likelihood of each of the 40 GHG emission scenarios that they generated and published. Of course, there are scientific disciplines in which subjective probabilities of most scientists match or in which it is acceptable to work with probability distributions such as Gaussian (normal) distributions, the parameters of which have been estimated from empirical data. In such cases, the use of probability distributions and, possibly, of stochastic models is well established, and the interpretation of the results is straightforward, at least conceptually. This is not the case for GHG emission scenarios, for which subjective probabilities of different scientists and policymakers alike may vary quite substantially. Instead of hiding these differences and then wondering how it is possible that different conclusions are drawn from identical scenarios, it would appear worth trying to be more specific about differences of subjective probabilities, particularly of the catastrophic consequences of climate change. Doing so could be a way of transferring disagreement on the mitigation measures to disagreement on probabilities, which could lead to agreement on how to manage uncertainty surrounding many aspects of climate change.

4. ENERGY–ECONOMY–ENVIRONMENT SCENARIOS

Many scenarios of greenhouse gas emissions belong to the family of energy–economy–environment (E3) scenarios. There is a close relationship between the three systems. E3 scenarios usually focus on the energy system, including the economy as a driving force and the environment to map the environmental impact of energy production, conversion, and end use. Although global E3 scenarios now usually include the climate issue as one of the most important global environmental problems, the global climate need not be the main theme of such scenarios. More and more scenario builders address the issue of sustainable development, which is a more general concept that includes the issue of climate change.

5. WHY BUILD SCENARIOS OF GREENHOUSE GAS EMISSIONS?

Generally speaking, GHG emission scenarios are built to analyze the consequences of policy action (or non-action) on the development of greenhouse gas emissions, the costs of their abatement, and the impact on the economy. National scenarios can serve the purpose of designing national policies to fulfill a GHG emission reduction commitment such as the targets set by the Kyoto Protocol. Global scenarios can serve as inputs to climate models. In this way, many GHG emission scenarios can collectively describe the range of plausible emissions, with climate models describing the range of possible consequences on climate. It is still too early for climate models to calculate numerical estimates of climate impacts within reasonably narrow bounds. Should this be possible at some future date, GHG emission scenarios can be the first step of an analysis that compares abatement costs with avoided damage. Until that date, damage scenarios will have to serve as placeholders for accurate quantitative estimates.

6. HOW ARE SCENARIOS OF GREENHOUSE GAS EMISSIONS BUILT?

The process of scenario building depends on the subject of the scenarios and the issues to be analyzed with them. An illustration of a typical and widespread method to build long-term GHG emission scenarios is the method that was used to build the scenarios described in the IPCC Special Report on Emission Scenarios (SRES).

As already mentioned, the purpose of the SRES was to gauge the range of plausible global GHG emissions in the 21st century. This required thinking of limiting cases on the high and low ends of the plausible range. The first step in defining the limiting cases—and, in fact, defining any case—was to think of general circumstances that would be consistent with and lead to the targeted outcome in terms of

GHG emissions. High levels of emissions, for example, could be the consequence of high rates of population growth and economic growth, high carbon-intensity of gross domestic product (GDP), poor technological progress, and other factors. Such qualitative assumptions are then formulated in the "storyline." A storyline is a qualitative, textual description of how the future might evolve. It gives the rationale and narrative behind a specific combination of driving forces aiming at directing the development path of aggregate variables of a scenario (for instance, relative to their past trends). For example, "high economic growth rate" means that assumptions of economic growth in a scenario should be on the high side of past trends. Such qualitative characterizations included in storylines are later quantified and transformed into model input numbers.

7. DRIVING VARIABLES OF SCENARIOS

The most important of the "driving variables" of energy demand, which in turn is a major determinant of carbon emissions, are GDP and energy intensity of GDP. Disaggregating one step further, GDP can be thought of as the composite of population and GDP per capita. Energy intensity, together with the carbon intensity of energy supply, can be aggregated to the carbon intensity of GDP. Looking only at the logic of the variables and the problem, the carbon intensity of GDP might seem to be the most obvious driving variable to determine carbon emissions of an economy. However, the point of disaggregating, creating even more variables, is eventually to arrive at those variables that can be most plausibly projected into the future. This criterion depends on the expertise of the scenario builders, and different groups therefore use different driving variables for the projection of carbon emissions.

8. SCENARIOS AND E3 MODELS

The route from storylines, via driving forces, to scenarios is through formal (mathematical) models. Although this discussion is not on modeling, it appears appropriate to give a description of some relevant modeling terms here.

There are several criteria to classify models. One way is to classify them by the overall purpose of model usage, into normative and descriptive. This distinction is particularly important for models that project carbon emissions. For instance, scenarios projecting low-level carbon emissions are often built for the purpose of specifying a set of conditions under which certain environmental goals can be reached. In contrast, descriptive models typically describe the development of a system as the consequence of few assumptions, which are often meant to be particularly likely. An important class of descriptive scenarios is the group of "business-as-usual" scenarios, which aim at projecting past trends in a straightforward way into the future. Sometimes, such scenarios are also referred to as "dynamics-as-usual" scenarios if the point is to be made that systematic changes of trends have been incorporated in them and that incorporating them leads to distinctly different results, compared to mere trend extrapolations.

The core of energy models aiming at projections of greenhouse gases usually incorporates an abstract image of energy flows from primary-energy to final consumption. This image is usually called a reference energy system (RES). Conceptually, the RES has primary energy carriers on its input end and energy demands (and by-products such as pollutants) on the output end. The two ends are connected by a set of technologies that extract, convert, transport, and distribute various forms of energy. One important characterization of an energy model is the degree of detail with which its RES is described in the model. Another way of characterizing models is by its so-called system boundaries. For energy models, one important issue with respect to the system boundary of the model is whether energy demand is substitutable by other factors of production, such as capital and labor, and whether it is price responsive. This issue concerns the degree of detail in which the overall economy is described in the energy model.

9. MODEL INPUTS AND OUTPUTS

As previously stated, the driving forces determine model output such as greenhouse gas emissions. A most important qualifier to this general statement is the amendment "within the given constraints." Using the concept of the reference energy system, such constraints concern primary-energy recoverability, the availability and performance of technologies, and energy demand. Of these groups, energy demand is the one that is shaped the most by the driving forces discussed thus far, because it reflects GDP,

population, GDP per capita, and energy intensity. Energy intensity is also related to the conversion efficiencies of the technologies included in the reference energy system. So is the carbon intensity, which, in addition to being related to the performance of non-carbon-emitting technologies, is also related to the model assumptions on the recoverability of hydrocarbon energy resources.

Generally speaking, technological progress can therefore be considered as another driving force of greenhouse gas emissions. It overlaps with other driving forces, but in many studies, the role of technological development is central. In comparison to the other driving forces, this may well be regarded by policymakers as one of the driving forces that can be steered particularly effectively (for instance, by supporting research and development of energy technologies). As it will be substantiated later, during the discussion of the policy relevance of long-term GHG emission scenarios, it can be argued that such a policy would be aiming at influencing the driving forces in a much more sustainable way, compared to energy taxes or "command-and-control" measures. This, of course, is not meant to say anything against the latter, just to emphasize the importance of technology policy as an important additional way of driving greenhouse gas emissions in the right direction. In fact, the mitigation of greenhouse gases to volumes that would lead to a "stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system," as postulated by the United Nations Framework Convention on Climate Change, would suggest combining all available policies and measures for the given purpose.

10. PUBLISHED SCENARIOS

One recent comprehensive effort to explore alternative GHG emission paths projected for the 21st century led to the publication of the IPCC Special Report on Emission Scenarios (SRES). The SRES scenarios were developed to represent the range of driving forces and emissions in the scenario literature so as to reflect current understanding and knowledge about underlying uncertainties. Hence, plausibility, size, and location of the emissions range were defined by emission scenarios that had been published by the time the SRES work began. Note that the SRES scenarios do not include additional climate initiatives, which means that no scenarios are included that explicitly assume the implementation of climate policies, such as the United Nations Framework for Climate Change (UNFCC) or the emissions targets of the Kyoto Protocol.

The first step of SRES work thus consisted of compiling what has become also known as the SRES database, produced by Morita and Lee in 1998. This database includes the results of some 400 E3 scenarios, which are described in terms of the most important variables characterizing the long-term development of the E3 system either globally or for major world regions. The variables include population, economic growth, energy demand, carbon emissions, and others. Although not all scenarios in the database report on all variables, the scenarios included can be regarded as representative of the range of possibilities still regarded as plausible by the global modeling community 5 years after they were collected in the SRES database.

One way of interpreting the ranges of the projected carbon emissions and their driving forces would be to see them as quantifications of the uncertainty surrounding the evolvement of the variables during the course of the present century. To what extent the ranges and frequency distributions quantify the uncertainty in any reliable way (i.e., to what extent they can be interpreted as probabilities) is open for speculation and individual judgment. In the overview of scenario results given in the following section, such an interpretation of frequencies as probabilities is withheld, and the focus is instead on the description of statistical indicators, such as medians, variances, the minimum, and the maximum.

11. OVERALL RANGES OF GREENHOUSE GAS EMISSIONS AND THEIR DRIVING FORCES

For the summary presentation of ranges of greenhouse gas emissions and their driving forces, a common way of graphically presenting values and ranges of a number of variables is to use a regular polygon and (zero-based) axes between the center and each vertex. A heptagon representation with seven variables is chosen to summarize the global scenarios of the SRES database; five variables describe the values of scenario variables in the year 2100, one describes a cumulative figure up to that year, and one describes a growth rate. The five variables with values for 2100 are (1) CO_2 emissions, expressed in billions of tons (Gt, gigatons; 10^9 tons)

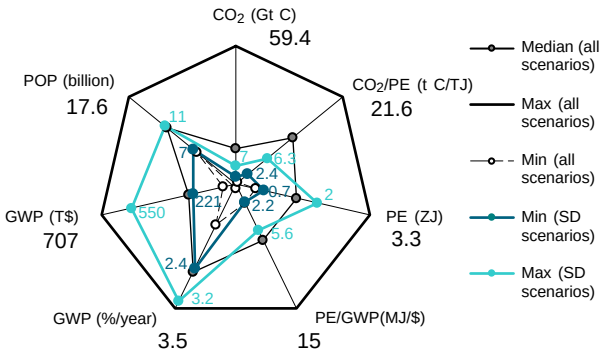

FIGURE 1 Global carbon emissions and their main driving forces. The minimum and maximum of the values for the Special Report on Emissions Scenarios database, as well as for the sustainable-development (SD) scenarios only, are shown on seven axes of the heptagon, and they are connected. The seven axes show ranges for indicators across the scenarios in 2100 (see text for discussion). PE, Primary energy; GWP, gross world product; T$ trillions of dollars; POP, population. IIASA, International Institute for Applied Systems Analysis.

of carbon, (2) specific carbon emissions per unit of primary energy (PE), expressed in tons of carbon per terajoule, (3) total primary energy demand up to the year 2100, expressed in zetajoules (10^{21} joules), (4) specific primary energy consumption of economic output, expressed as gross world product (GWP) in megajoules per U.S. dollar (1990 purchasing power), and (5) gross world product, expressed in trillions (10^{12}) of U.S. dollars (1990 purchasing power); (6) population, expressed in billions (10^{9}) of people; and (7) growth of gross world product, expressed as the average annual growth rate of the GWP between 1990 and 2100. The resulting heptagon is presented in Fig. 1.

The outer, symmetric heptagon in Fig. 1 represents the maximum values for the group of all SRES database scenarios for each of the seven variables. The smallest irregular heptagon inside this envelope represents the respective minimum values for all SRES database scenarios. Another irregular heptagon shows the respective seven median values for all SRES database scenarios. Preempting the later discussion of sustainable development (SD) scenarios, the figure also shows, for comparison, two heptagons that connect the seven minimum and maximum values for the group of SD scenarios for each of the seven variables.

In interpreting the heptagons, it should be remembered that any one of them is unlikely to connect points that belong to the same scenario. For instance, it would not appear logical if either a minimum or a maximum heptagon connected values for the same scenario. Take economic growth and primary-energy intensity, for example. One common assumption in E3 scenarios is that with higher economic growth, technological progress can occur faster. As a consequence, the maximum primary energy intensity should not coincide with maximum economic growth. Figure 1 also illustrates that CO_2 emissions in the year 2100 cover a range between zero, i.e., no net carbon emissions, to almost 60 billion tons (gigatons) of carbon (Gt C), with the median at approximately 18 Gt C, significantly below halfway. In contrast, world GDP growth and population both have a "bias" toward the maximum. For economic output, this means that the SRES database does not include scenarios with zero or low economic growth during the 21st century.

12. THREE GROUPS OF SCENARIOS

The overall ranges of global GHG emissions and their driving forces provide a first overview of possibilities that have been considered by modelers. To better understand the sometimes considerable differences between GHG emissions (and between other variables) projected in different scenarios, three separate groups of scenarios are now described: high-impact, CO_2 mitigation, and sustainable-development scenarios. The description of these three groups also includes scenarios that have contributed to neither SRES scenarios nor the SRES database. The reason is that the mandate for the authors of the SRES was to survey carbon emissions in scenarios that did not include explicit climate policies. Although scenarios that included more general environmentally benign strategies, such as sustainable development, were included, explicit climate mitigation scenarios were not included in the SRES process. Rather, they were included in another IPCC publication, the Third Assessment Report, compiled by Metz *et al.* in 2001.

Another preface is required before we can meaningfully describe SD scenarios. We follow a definition of SD E3 scenarios as proposed by the Environmentally Compatible Energy Strategies (ECS) Project at IIASA. According to this definition, all scenarios that satisfy the following four criteria will be referred to as sustainable-development scenarios:

1. Economic growth (in terms of GDP per capita) is sustained throughout the whole time horizon of the scenario.
2. Socioeconomic inequity among regions, expressed as the world-regional differences of gross domestic product per capita, is reduced significantly

over the 21st century, in the sense that by 2100, the per capita income ratios between all world regions are reduced to ratios close to those prevailing between Organization for Economic Cooperation and Development (OECD) countries today.

3. Long-term environmental stress is mitigated significantly. In particular, carbon emissions at the end of the century are approximately at or below today's emissions. Other GHG emissions may increase, but total radiative forcing, which determines global warming, is on a path to long-term stabilization. Other long-term environmental stress to be mitigated includes impacts to land use (e.g., desertification). Short- to medium-term environmental stress (e.g., acidification) may not exceed critical loads that threaten long-term habitat well being.

4. The reserves-to-production (R/P) ratios of exhaustible primary-energy carriers do not decrease substantially from today's levels.

The proponents of this definition argue that it has been inspired by and is consistent with the "Brundtland spirit," which is quantitative enough to serve the purpose of classifying long-term energy–economic scenarios, and that it comes close to the definition of weak economic sustainability, complemented with some environmental and social constraints.

The quantitative characterizations of the three groups of E3 scenarios in this section are based on 34 scenarios that were developed and published by the IIASA's ECS Project since 1998. These include scenarios developed with the World Energy Council (WEC) in 1998, scenarios developed for the IPCC Special Report on Emissions Scenarios, as well as scenarios developed for the impact assessment for the Working Group III of the IPCC Third Assessment Report. As to the ranges of carbon emissions and driving forces, the 34 IIASA ECS scenarios are representative of the scenarios in the SRES database.

12.1 High-Impact Scenarios

Most scenarios of the SRES database include a high-level environmental impact in at least one respect. For the quantitative summary in this subsection, the eight IIASA ECS scenarios that are representative of these high-impact scenarios have been selected. One class of scenarios in this group consists of the business-as-usual scenarios. In particular, the SRES-B2 scenario, which was designed in such a way that its driving variables stay in close proximity to the medians of the SRES database, is classified as high impact. Another important function of high-impact scenarios is to serve as a reference, relative to which mitigation and other policies can be quantified. One example is the SRES-A1C scenario ("C" stands for coal), in which atmospheric CO_2 concentrations in the year 2100 reach 950 parts per million by volume (ppmv), more than three times the preindustrial level. SRES-A1C is also characterized by a high rate of economic growth. The projected global GDP in 2100 is 550 trillion (10^{12}) U.S. dollars (in 1990 prices). Relative to global GDP in 1990, 20.9 trillion, this corresponds to an average annual growth rate of just below 3%. The lowest economic growth rate in this group of eight scenarios is projected in the IIASA WEC B scenario, one of the business-as-usual scenarios. There the projected average annual growth rate is 2%.

Global population does not show characteristic features in the high-impact scenarios. Projections range from 7.1 billion (after an earlier peak) to 15.1 billion in the year 2100. Global primary-energy consumption in the high-impact scenarios ranges from 1500 to 2700 exajoules (EJ) in 2100. Relative to the global consumption in 1990, 350 EJ, this range implies annual growth rates between 1.3 and 1.9%.

12.2 CO_2 Mitigation Scenarios

Mitigation scenarios explore cases in which the global atmospheric CO_2 concentration is stabilized at different levels. The following description is based on 19 IIASA ECS scenarios. These scenarios were constrained to stabilize atmospheric CO_2 concentrations at levels of 450, 550, 650, and 750 ppmv in 2100, and they used high-impact scenarios as references. The criterion that classifies scenarios in this group raises the question as to whether constraining atmospheric CO_2 concentrations in this way leads to sustainable-development scenarios. The answer is "not necessarily." Of the 19 scenarios included in this group, only 8 would also qualify as SD scenarios. Although this observation is based on a sample that might be considered small, it suggests that sustainable development is a more general strategic goal compared to climate mitigation.

Making a reference-mitigation pair of scenarios comparable suggests leaving crucial assumptions on general technological development and resource availabilities the same in both scenarios. At the same time, it could be argued that it would appear implausible to assume exactly the same kind of technological progress as in the reference and stringent emission mitigation, and at the same time. There is no clear-cut solution to this issue, but to

keep rules simple, the same set of technology data and the same set of resource availabilities as for the corresponding baseline scenarios were assumed for the mitigation cases. To respond to the "technological response" argument, sustainable-development scenarios were built (these are described in the following subsection).

The main mechanisms to reduce emissions relative to the reference cases can therefore be summarized as supply shifts toward primary-energy carriers, with less carbon content and price responsiveness of final energy demand. As a general characterization of the carbon emission trajectories in the mitigation cases, it can be said that they are similar to those derived by other modelers for the same concentration limits, in particular the popular "WRE" trajectories described by Wigley, Richels, and Edmonds in 1996. Very often, the first question about mitigation concerns costs. Choosing typical examples of mitigation aiming at atmospheric CO_2 concentrations of 550 ppmv (corresponding to roughly twice the preindustrial level), and quantifying the difference in global GDP in 2100 between the mitigation scenarios and the corresponding reference cases, obtains reductions of 7 trillion U.S. dollars for the SRES-A2 scenario (236 instead of 243) and 8 trillion for the SRES-A1C scenario (542 instead of 550). These correspond to relative reductions by 3 and 1.5%, respectively. At the average annual growth rates of economic output assumed in the two scenarios, this would mean delaying the achievement of the given output by 1.5 and 0.5 years for the A2 and A1C scenarios, respectively. In comparison with the reductions of global economic output in the mitigation cases, the difference in primary-energy consumption is relatively higher. In A2-550, primary-energy consumption in 2100 is 18% lower than that of the reference A2 scenario. In A1C, this difference is lower (6%).

The comparison of these two pairs of scenarios clearly shows that the relative economic impact of mitigation is higher where lower growth had been projected in the corresponding reference case. Nonetheless, reaching the mitigation goal of 550 ppmv in the higher growth scenario A1C reduces atmospheric CO_2 concentrations in the year 2100 by a larger amount (from 950 ppmv), compared to the lower growth scenario A2 (from 780 ppmv).

12.3 Sustainable-Development Scenarios

By the definition used here and in comparison to most other scenarios, sustainable-development scenarios project low levels of GHG emissions. The following description is based on seven IIASA ECS scenarios. Three distinct general qualitative strategic ideas are reflected in this group of scenarios. One idea can be dubbed "small is beautiful," and it leads to the scenarios of the SRES-B1 family. These scenarios are characterized by low energy intensity of GDP, which is dominated by the service sector. Energy supply is highly decentralized and relies to a high degree on renewable energy. In contrast, the SRES-A1T scenario describes a high-technology interconnected world in which technological progress (in particular, in the field of carbon-free sources, which include nuclear energy) is key to creating an environmentally compatible global energy system.

Built some years earlier than the SRES scenarios, the two sustainable-development scenarios of the IIASA WEC set (IIASA-WEC C1 and IIASA-WEC C2) describe a "global family" in which the industrialized countries transfer substantial amounts of resources to the developing countries and regions, to aid development in a way that preserves the global environment. Even without involving the assumption of massive international transfers of wealth, all scenarios in this group assume a fully cooperative world with efficient markets and without constraints such as trade barriers, monopolies, and the like. This assumption can be regarded mostly normative in the sense of the distinction between normative and descriptive, and substantial amounts of goodwill would be required to implement any of the sustainable-development scenarios.

Comparing projected GDP of sustainable-development scenarios with the projections of all scenarios in the SRES database (Fig. 2) shows that projected GDP in SD scenarios tends to cover the higher part of all GDP projections. The crosshatched area in Fig. 2 includes average annual GDP growth rates between 2 and 3%. This suggests that sustainable development tends to require wealth rather than to prevent it. According to the definition of sustainable-development scenarios, projected global carbon emissions in this group in 2100 are below today's emissions. Accordingly, atmospheric CO_2 concentrations in the year 2100 are between 445 and 560 ppmv. Figure 3 illustrates the carbon emission reductions projected in sustainable-development scenarios, comparing the carbon intensity of primary energy in SD scenarios with that of all scenarios in the SRES database. Figure 3 shows that the highest projected average decarbonization rates in the database are near 3.3% per year between 1990 and 2100.

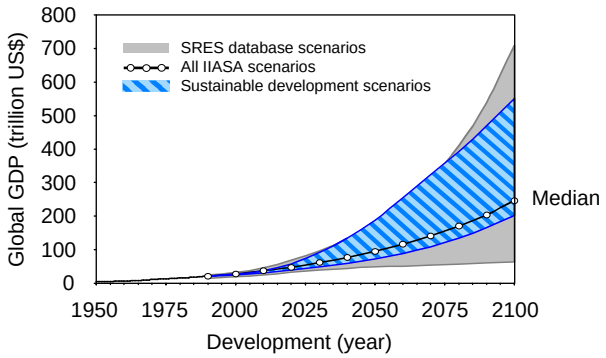

FIGURE 2 Global economic product (GDP) in trillions of 1990 U.S. dollars; development from 1950 to 1990 and in the scenarios [193 of which are from the Special Report on Emission Scenarios (SRES) database] from 1990 to 2100. Historical data are from two United Nation studies published in 1993; the database is from Morita and Lee (1998). IIASA, International Institute for Applied Systems Analysis.

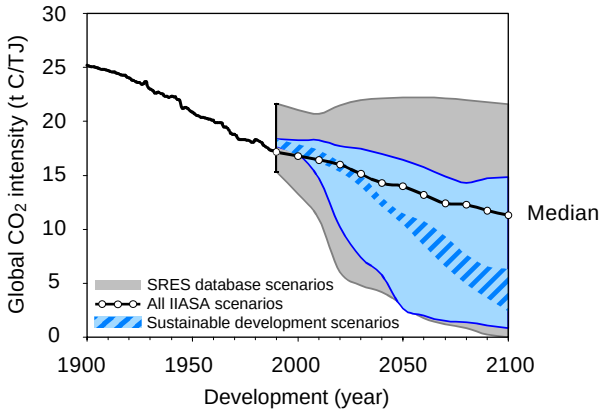

FIGURE 3 Global carbon intensity of primary energy; actual development from 1900 to 1990 and in the scenarios [140 of which are from the Special Report on Emission Scenarios (SRES) database] from 1990 to 2100. Historical data are from Nakićenović (1996); the database is from Morita and Lee (1998). Note that net carbon emissions are used to calculate the carbon intensities (i.e., bioenergy is excluded). The differences in the carbon intensities for the base year are due to different accounting conventions and data problems in general. IIASA, International Institute for Applied Systems Analysis.

This means a reduction of energy-related carbon emissions per unit of primary energy by a factor of 40 during this time horizon, which, in turn, leads to an energy system with almost no carbon emissions. Decarbonization in the sustainable-development scenarios leads to projected carbon intensities for the year 2100 between 2.4 and 6.3 C/TJ, both down from 18 C/TJ in 1990.

13. INTEGRATED ASSESSMENT OF CLIMATE CHANGE

Analyses of emission reduction, explicitly or implicitly, mainly address the cost component of climate abatement. For a more complete view of the problem, however, it is necessary also to get an estimate of the benefits of emission mitigation in terms of avoided damage. This is the task addressed by models for the integrated assessment of climate change. In view of the substantial uncertainties surrounding the impacts of climate change, estimates of avoided damage vary within wide ranges, even for given emissions. Still, a range of estimates can be better than no estimate, and any damage estimate is good enough to analyze the cost-effectiveness of policies and measures (that is, the cost of a unit of emission reduction). This aspect of cost-effectiveness was one motivation for the ongoing efforts to study more greenhouse gases than CO_2 only, although CO_2 is the most important anthropogenic greenhouse gas and therefore has been studied most intensively. The most obvious non-CO_2 greenhouse gases to analyze in addition to CO_2 are those included in the Kyoto Protocol of the UNFCC (CH_4, N_2O, SF_6, CF_4, and halocarbons). The six "Kyoto gases" and their abatement are the subject of the Stanford-based Energy Modeling Forum study (EMF-21), which involves modelers from North America, Europe, and Asia. The study is still ongoing in 2003, but the first preliminary results show that considering GHGs other than CO_2 leads to significantly reduced mitigation costs.

14. SCENARIOS AND POLICYMAKING

Mitigation scenarios incur mitigation costs in terms of GDP lost, but such costs for sustainable-development scenarios have not been reported here. The reason is that the mitigation scenarios discussed herein were defined relative to reference cases, whereas SD scenarios were defined in absolute terms. This may seem just like a curious coincidence, but it is not, and it appears worth emphasizing the policy implications of this difference, which is not just a methodological peculiarity, but by deliberate design. This difference means to express the idea that a strategy aiming directly at sustainable development could be more effective than conceptually constraining the evolvement of a system that is implicitly

assumed to be preferable, if not for the risk of catastrophic consequences of climate change. This has been recognized in the past for strategies to mitigate local pollution in cases in which the issue is to limit pollution either by so-called end-of-pipe technologies or by avoiding it from the beginning. It has been argued, for instance, that given enough notice (time), progress in automobile technology could have achieved the same emission reduction as catalytic converters, by improving the internal combustion engine instead of treating the exhaust gases. It is the idea of sufficient notice that may provide for an analogy to GHG emissions. If it holds, this analogy suggests that aiming for sustainable development might be more promising than imposing carbon constraints, given that sufficient time is available for action. In turn, this means that action should be initiated sooner rather than later.

The projections of GHG emissions and their driving forces reported here vary over wide ranges. Carrying the analysis further, to atmospheric GHG concentrations, radiative forcing, temperature change, and impacts, in a sense increases the size of these ranges, as a consequence of the uncertainties surrounding the evolvement of the global climate, which is not understood well enough to predict the consequences of given GHG emissions within narrow limits. Whatever the overall strategy to avoid catastrophic consequences of climate change, this uncertainty will play a major role in policymaking. What will be called for is uncertainty management at unprecedented scales, and flexibility of strategies will be an obvious plus.

Glossary

Central European Electricity Interconnection (CENTREL) Regional group of four transmission system operator companies of the Czech Republic, Hungary, Poland, and Slovak Republic.

energy chain All stages associated with energy supply by means of specific energy carriers including mining, processing, and conversion of an energy carrier, as well as the treatment and disposal of the produced waste.

mixed oxides fuel (MOX) Oxides of plutonium and uranium.

Organization for the Nordic Electric Cooperation (NORDEL) Includes Denmark, Finland, Norway, Sweden, and Island.

Union for the Coordination of Transmission of Electricity (UCTE) Members in year 2002 are Austria, Belgium, Bosnia-Herzegovina, Czech Republic, Croatia, Denmark (associated member), France, Germany, Greece, Hungary, Italy, Luxembourg, Macedonia, the Netherlands, Poland, Portugal, Slovak Republic, Slovenia, Spain, Switzerland, and Serbia and Montenegro. The CENTREL countries Czech Republic, Hungary, Poland, and Slovak Republic have officially joined UCTE in 2001.

According to the Intergovernmental Panel on Climate Change, the earth's climate system has changed, globally and regionally, with some of these changes being attributable to human activities resulting in emissions of greenhouse gases. Energy supply and the fossil systems in particular are the dominant contributors to the emissions of these gases. This article provides an overview and comparison of greenhouse gas emissions associated with fossil, nuclear, and renewable energy systems. In this context, both the direct technology-specific emissions as well as the contributions from full energy chains within the life cycle assessment framework are considered. This discussion also provides examples illustrating the differences between industrialized and developing countries and explores the impact of technological advancements.

1. INTRODUCTION

1.1 Global Greenhouse Gas Emissions from Energy Systems and Other Sources

According to the Intergovernmental Panel on Climate Change (IPCC), the anthropogenic greenhouse gas (GHG) emissions contributing most clearly to global warming in terms of relative radiative forcing are CO_2, CH_4, halocarbons, and N_2O. Radiative forcing is the change in the net vertical irradiance (expressed in watts per square meter: Wm^{-2}) at the boundary between the troposphere and the stratosphere. Compared to the preindustrial era 250 years ago, additional radiative forcing due to increases of the well-mixed greenhouse gases is estimated to be $2.43\,Wm^{-2}$. CO_2 contributes most ($1.46\,Wm^{-2}$), followed by methane ($0.48\,Wm^{-2}$), halocarbons ($0.34\,Wm^{-2}$), and N_2O ($0.15\,Wm^{-2}$).

Other possible factors influencing the global climate are less well understood and thus quantitatively

 © 2004 Elsevier Inc. All rights reserved.

more uncertain. Among them are stratospheric ozone (cooling), tropospheric ozone (warming), sulphate (cooling), black carbon and organic carbon (warming or cooling), biomass burning (cooling), mineral dust (warming or cooling), aerosol indirect effects (cooling), land use (change of albedo, i.e., share of reflected sun light), and solar variation.

Table I shows the global emissions of the major greenhouse gases and the contribution of anthropogenic sources for the late 1990s. CO_2 emissions originate mainly from combustion of fossil fuels (i.e., from energy systems). These CO_2 emissions are quite well known. For CH_4 and N_2O, the total emission rates are much more uncertain and it is difficult to assess global emissions from single sources. Halocarbons are molecules containing carbon and either chlorine, fluorine, bromine, or iodine. Among the halocarbons are several refrigerants that are used as working fluids for cooling or heating (i.e., for transport of thermal energy). Many refrigerants interesting for energy uses (in refrigerators, heat pumps, air conditioners, etc.) have very high global warming potentials (GWP) on a per kg emitted basis. Energy scenarios for reduction of CO_2 emissions often include increased use of heat pumps substituting for fossil fuel heating systems. It has to be kept in mind that refrigerant emissions due to leakages counteract to a certain extent in the total GHG balance. Halocarbon emissions are almost completely made by humans. The table does not include refrigerants like CFC-11 or CFC-12, which have been banned because of their high ozone-depleting potential; they show low emission rates but are still abundant in the atmosphere due to emissions in the past.

TABLE I

Annual Emissions of Important Greenhouse Gases in the Late 1990s

	Annual emissions (Mt/year)	**Lifetime (years)**	**GWP 100-year**	**CO_2-equiv. 100-year (Mt/year)**
II. CO_2	29,000		1	29,000
Fossil fuels	*22,400*			*22,400*
Cement production	*700*			*700*
Land use, etc.	*6000(3000–9000)*			*6000*
III. CH_4	600	8.4–12	23	13,800

1.2 Methodological Basis and Scope of Comparisons

The most straight-forward accounting of GHG emissions can be based on emission factors associated with combustion of the various fossil fuels. This approach can be used for the establishment of the overall national emission inventories but is not practical when the goal is to account fully for emissions associated with the use of specific technologies. While uses of nuclear and renewable energy sources exhibit practically negligible emission levels for GHGs at the stage of power generation, the same is not necessarily true for other stages of the corresponding energy chains. In addition, emissions may arise when manufacturing the components for the plants, transporting fuels and other materials, or in the decommissioning stage.

Life cycle assessment (LCA), an approach utilizing process chain analysis specific to the types of fuels used in each process, allows for the full accounting of all such emissions, also when they take place outside of the national boundaries. Thus, LCA considers not only emissions from power plant construction, operation, and decommissioning but also the environmental burdens associated with the entire lifetime of all relevant upstream and downstream processes within the energy chain. This includes exploration, extraction, processing, and transport of the energy carrier, as well as waste treatment and disposal. The direct emissions include releases from the operation of power plants, mines, processing factories, and transport systems. In addition, indirect emissions originating from manufacturing and transport of materials, from energy inputs to all steps of the chain, and from infrastructure are covered.

An alternative, not process-oriented approach, is the input/output (I/O) method; it divides an entire economy into distinct sectors and based on the inputs and outputs between the sectors generates the energy flows and the associated emissions. A hybrid approach is also frequently employed, combining LCA and I/O methods; the I/O method is then used exclusively for assessing processes of secondary importance.

This article provides comparisons of GHG emissions, based on several approaches mentioned earlier. The largest part of the data cited here has been derived using a full scope LCA implementation. Due to consistency and other practical reasons it is not feasible to account for results from all major published studies addressing the GHG emissions. As the main reference work, the most recent results of the comprehensive Swiss study addressing LCA-based environmental inventories in Europe has been used. This is supplemented by some results from studies carried out by researchers in and for other countries. More details on the methodological aspects of LCA as applied in the Swiss study will be provided in Section 3.

2. FUEL-SPECIFIC GREENHOUSE GAS EMISSION FACTORS

For national accounting of direct CO_2 emissions from fuel combustion, the International Energy Agency (IEA) within OECD uses the IPCC methodology. Neither GHGs other than CO_2 nor non-energy emission sources are included in the IEA statistics. Table II summarizes the fuel-specific emission factors.

The direct emissions based on the factors provided in Table II can be combined with appropriate contributions from the production chain of fuels. Table III shows the emission factors per unit of mass from the upstream chain of selected fuels in the Swiss LCA study. The large variations for coal products depend on the differences between the producing regions (mainly the energy needed for mining and the coalbed methane emissions) and between supply mixes (transport energy). The variations for coke and coke by-products depend on the lower average efficiency assumed for the world average production versus coke making in Central Europe.

A Japanese LCA study addressed burdens from fossil fuel extraction, processing, and transportation, associated with uses of the fuels in Japan. The supplying countries were addressed separately. In Table IV, only the average emission factors are shown. In the Japanese study, CO_2 and CH_4 emissions are given separately; here they are summed using for methane the GWP according to IPCC. The average values for coal are in the lower end of those estimated by the Swiss study, partly because of the different distribution of the origin of the coal and the transport distances, partly due to the different assumptions on the energy uses at mine and methane emissions. The Japanese study did not address the refinery step, which explains the differences for oil. The results for CO_2 emissions for a single supplying country may change by a factor of four for coke, three for steam coal, two for crude oil and LPG, but only by about 20% for LNG.

TABLE II

Carbon Conversion Factors for Fuels[a]

	Fuel	Carbon emission factor (tC/TJ)	Carbon emission factor (tCO_2/TJ)
Liquid fossil	Primary fuels		
	Crude oil	20	73
	Orimulsion	22	81
	Natural gas liquids	17.2	63
	Secondary fuels/products		
	Gasoline	18.9	69
	Jet kerosene	19.5	72
	Other kerosene	19.6	72
	Shale oil	20	73
	Gas/diesel oil	20.2	74
	Residual fuel oil	21.1	77
	LPG (liquid petroleum gas)	17.2	63
	Ethane	16.8	62
	Naphta	20	73
	Bitumen	22	81
	Lubricants	20	73
	Petroleum coke	27.5	101
	Refinery feedstocks	20	73
	Refinery gas	18.2	67
	Other oil	20	73
Solid fossil	Primary fuels		
	Anthracite	26.8	98
	Coking coal	25.8	95
	Other bituminous coal	25.8	95
	Subbituminous coal	26.2	96
	Lignite	27.6	101
	Oil shale	29.1	107
	Peat	28.9	106
	Secondary fuels/products		
	Patent fuel and brown coal/peat briquettes (BKB)	25.8	95
	Coke oven/gas coke	29.5	108
	Coke oven gas	13	48
	Blast furnace gas	66	242
Gaseous fossil	Natural gas (dry)	15.3	56
Biomass	Solid biomass	29.9	110
	Liquid biomass	20	73
	Gas biomass	30.6	112

3. ENERGY CHAIN-SPECIFIC GREENHOUSE GAS EMISSIONS

This section provides chain-specific results obtained in the Swiss LCA study for Switzerland and Europe, supplemented by representative result examples from a number of published analyses by researchers in other countries. Some additional basic features of the LCA methodology as applied in the Swiss applications are summarized here; most of these principles also apply to other state-of-the-art studies, which, however, may differ in terms of scope, level of detail, specific assumptions, and methodology applied (some results are based on hybrid approaches). The most important features are as follows:

- Energy systems, transport systems, material manufacturing, production of chemicals, waste treatment and disposal, as well as agricultural products, have been assessed using detailed process analysis developed under consistently defined common rules.
- Electricity inputs were modeled using production technology or supply mix as close as feasible to the actual situation. In case of lack of specification, the UCTE mix was used as an approximation.
- Allocation criteria were developed for multipurpose processes.

The results provided here focus on electricity supply, but selected results are also given for heat generation and for cogeneration systems.

3.1 Fossil Energy Chains

3.1.1 Coal

3.1.1.1 Hard Coal In the Swiss study European country-specific average power plants operating around year 2000 were analyzed. For the estimation

of the infrastructure of the plants, two power levels of 100 and 500 MW were considered; a mix with a share of 10 and 90%, respectively, was defined for the reference plant. The reference unit was assumed to be used for middle load with 4000 hours of operation per year at full capacity, and operate 150,000 hours during its lifetime. Emissions of CO_2 were estimated on the basis of the coal characteristics (e.g., lower heating values in the range of 22.1 to 26.6 MJ/kg), and the average net efficiencies of single units operating in Europe (29 to 40%), while emissions of CH_4, N_2O, and CO are averages taken from the literature.

Average coal from eight supplying regions was considered: West and East Europe, North and South America, Australia, Russia, South Africa, and Far East Asia. Specific average data were used for coal characteristics (e.g., upper heating values in the range of 20 MJ/kg to 28 MJ/kg), share of open pit and underground mines, methane emissions, land use, and energy uses for each of these regions. Import mixes in year 2000 for all European countries with coal plants have been defined.

The average methane emissions from coal mining in the eight modelled regions range between 0.16 g CH_4/kg (typical emission from open pit coal mines in the United States) and 13.6 g CH_4/kg product coal (West Europe).

The results for GHG GWP 100a from the chains associated with the average hard coal in European countries is between 949 g CO_2-equiv./kWh for the NORDEL countries and 1280 g CO_2-equiv./kWh for the Czech Republic (including several cogenerating plants, where the emission is entirely allocated to the electricity generation). The average for UCTE countries (excluding CENTREL) in year 2000 is 1070 g CO_2-equiv./kWh. Methane contributes nearly 7%, and N_2O 0.8% to the total GHG emissions for the UCTE average hard coal chain; CO_2 emissions practically cover the rest.

The upstream chain contributes between 8% (Portugal) to 12.5% (Germany) to total GHG. The total GHG associated with production regions varies between 0.04 kg CO_2-equiv./kg coal at production in South America up to 0.288 kg CO_2-equiv./kg coal at production in Russia.

Figure 1 provides a comparison between the range of average estimates of normalized GHG emissions for UCTE-countries, the average for Japan and United States, the range obtained for the coal chain in the Province Shandong in China, and the range according to a worldwide survey carried out in 1997. The Japanese and U.S. results are on the lower side of the ranges for UCTE countries and in the 1997 survey; the same applies to the lower range of the estimates from the study for China. The higher range from the China study reflects the low efficiencies characteristic in particular for small units in China as well as large contributions from mining; the potentially substantial but difficult to estimate additional GHG emissions from uncontrolled coal fires have not been included.

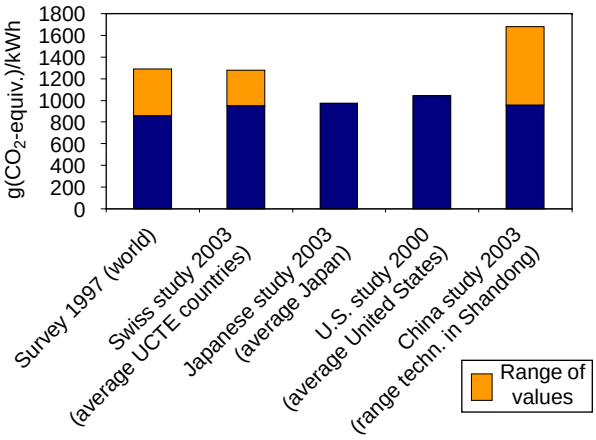

FIGURE 1 Greenhouse gas emissions from coal power plants. The figure shows ranges of greenhouse gas emissions in CO_2-equivalents per kWh electricity from coal power plants and associated fuel cycles according to different studies. From Survey (1997), Van de Vate, J. F., *Energy Policy* 25, pp. 1–6; Swiss study (2003), Dones *et al.*; Japanese study (2003), Hondo (2003); U.S. study (1999), Spath *et al.* (1999); China study (2003), Dones *et al.* (2003).

3.1.1.2 Lignite The reference plant used for lignite in the Swiss LCA study has similar characteristics as for hard coal but a larger share of plants with low rated power was used. The reference unit is assumed to be used for base load with 6000 hours of operation per year at full capacity, and work 200,000 hours during its lifetime. Emissions of CO_2 are estimated on the basis of the characteristics of the average lignite (e.g., lower heating values in the range of 5.2 to 16.6 MJ/kg) and the average efficiencies of single units operating in Europe (range for country-average is between 23 and 40%), while emissions of CH_4, N_2O, and CO are UCTE averages taken from the literature.

Considering that lignite plants are mine-mouth, only an average European open-pit mine has been modeled on the basis of information limited to only few mines. Only 0.23 g CH_4/kg lignite are assumed to be emitted during mining operations.

The results for GHG GWP 100a from the chains associated with the average lignite power plants in

European countries is between 1060 g CO_2-equiv./kWh for Austria and 1690 g CO_2-equiv./kWh for the Slovak Republic. The average for UCTE countries (excluding CENTREL) in year 2000 is calculated as 1230 g CO_2-equiv./kWh. Methane contributes about 0.6%, and N_2O 0.5% to total GHG emission for the UCTE average lignite chain; CO_2 emissions practically cover the rest. Mining contributes marginally between 0.9% (France) to 2.6% (Greece) to total GHG.

3.1.2 Oil

Since the role of oil in electricity generation is decreasing, only few key facts are provided from the Swiss study. The European country averages for GHG emissions of oil chains range from 519 to 1200 g CO_2-equiv./kWh 100-year. The UCTE average around the year 2000 was about 880 g CO_2-equiv./kWh 100-year, of which about 88% or 775 g/kWh are the direct emissions during power plant operation.

For the fuel oil supply, emissions occur during crude oil exploration, long-distance transport (e.g., in transoceanic tankers), oil processing in refineries, and local distribution. For an average oil power plant in Europe, the highest contributions to the upstream GHG emissions occur in the oil exploration phase and in the heavy oil processing in refineries.

3.1.3 Gas

3.1.3.1 Natural Gas Chain For natural gas, like for the other fossil fuel fired electricity or heating systems, the dominant contributor to GHG emissions are the CO_2 emissions from the power plant or boiler. Natural gas is transported in pipelines over long distances. Since natural gas consists mainly of methane (i.e., natural gas itself is a greenhouse gas), leakages in the pipelines can contribute significantly to the total GHG emissions. For European countries, the methane emissions can make up to about 10% of the total GHG emissions in the full chain depending on the location of the natural gas power plant or the boiler. Together with CO_2 and other GHG emissions in the upstream chain, the emissions other than directly from the power plant can constitute more than 10% of the total GHG emissions for European natural gas power plants (about 17% for the UCTE average in year 2000).

The country averages of the full chain GHG emissions of natural gas power plants in Europe range from 485 to 991 g CO_2-equiv./kWh 100-year. The UCTE average around the year 2000 was about 640 g CO_2-equiv./kWh 100-year. Therein are about 530 g direct CO_2-equiv./kWh emissions during operation of the power plants.

For the modeling of the best technology combined-cycle gas power plant, data from the new 400 MW power plant Mainz-Wiesbaden (Germany) were used. According to the operators, this is the natural gas power plant with the highest net electric efficiency (58.4%) worldwide (year 2001). Because the efficiency depends also on the local conditions (the Mainz-Wiesbaden plant is located directly at the river Rhine, which yields good cooling conditions), it was assumed that a comparable plant at an average location in Europe would have a net efficiency of about 57.5%. The full chain GHG emissions of the best combined-cycle power plant (about 420 g/kWh) are much lower than those of an average gas power plant.

Figure 2 compares the range of average estimates of normalized GHG emissions from the gas chain for UCTE-countries, with the average for LNG in Japan, results for combined cycle plants in Europe, Japan and the United States, and the range according to the worldwide survey carried out in 1997. The upper range in the survey probably represents a plant using a gas mix rather than pure natural gas.

3.1.3.2 Industrial Gas Industrial gas covers blast furnace gas from steel production and coke oven gas.

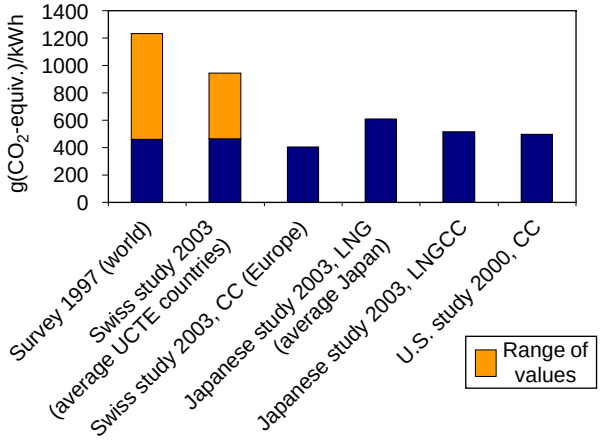

FIGURE 2 Greenhouse gas emissions from gas power plants. The figure shows ranges of greenhouse gas emissions in CO_2 equivalents per kWh electricity from gas power plants according to different studies. From Survey (1997), Van de Vate, J. F., *Energy Policy* **25**, pp. 1–6; Swiss study (2003) Dones *et al.*; Japanese study (2003), Hondo (2003); U.S. study (2000), Spath, P. L., and Mann., M. K., "Life Cycle Assessment of a Natural Gas Combined-Cycle Power Generation System," National Renewable Energy Laboratory, Golden, CO.

The results cited here are based on the mix of blast furnace gas and coke oven gas used for electricity production in UCTE around year 2000. Due to its high CO_2 content, blast furnace gas has high CO_2 emission factors of 90 to 260 g/MJ burned gas. Emission factors of coke oven gas range between 40 and 90 g/MJ gas burned. This leads to exceptionally high total GHG emissions, exceeding 1700 g CO_2-equiv./kWh for the European average industrial gas mix. The methane contribution comes mainly from the coke oven gas production chain.

3.1.4 Heating and Cogeneration

3.1.4.1 Heating Two hard coal heating systems were modeled in the Swiss LCA study: an industrial furnace with capacity in the range 1 to 10 MW, and a stove of about 5 to 15 kW. The thermal efficiency of the furnace is 80%, the one of the stove 70%. The industrial furnace is assumed to be fuelled with the average Western European hard coal supply mix, the stove either with coke or with briquettes.

Assuming that all CO is oxidized into CO_2, CO contributes about 10% to the total GHG emissions associated with the stove. Direct CH_4 emissions from burning briquettes are 20 times higher than from burning coke in the stove. In case of the briquette, direct methane emissions from the stove are about 50% of the total methane emissions calculated for the chain. Due to a lower carbon content per unit of energy, burning briquettes has lower direct CO_2 emissions than burning coke.

Condensing gas and oil boilers use the heat from combustion and the heat from condensation of the water in the flue gas. Modern condensing natural gas boilers can reach annual net efficiencies of about 102%, modern oil boilers about 98%. (The ratio refers to the lower heating value of the fuel therefore efficiencies of more than 100% are possible for condensing boilers.) High efficiency reduces the CO_2 emissions. Direct CO_2 emissions of a modern condensing natural gas boiler <100 kW are about 56 g/MJ, the GHG emissions of the full chain for a condensing natural gas boiler in Central Europe in year 2000 add up to about 71 g/MJ CO_2-equiv. 100-year. For a 10 kW condensing nonmodulating oil boiler with direct CO_2 emissions of about 74 g/MJ, the full chain GHG emissions for location Central Europe are about 89 g/MJ CO_2-equiv. 100-year.

Figure 3 shows a comparison of GHG emissions for the energy chains based on various heating technologies of different capacity, utilizing hard coal, natural gas, and oil. The lowest emissions are for the natural gas systems, followed by oil systems.

3.1.4.2 Cogeneration Figure 4 shows a comparison of CO_2 emissions per kWh_e from modern small cogeneration plants of different capacity and technology, located in Switzerland. Allocation of emissions to the products is in this case based on exergy. The higher the capacity, the higher the electric efficiency and the lower the CO_2 emissions for electricity. The total efficiency is approximately constant for the different plants shown. The CO_2 emissions per MJ fuel burned are the same for all natural gas plants but higher for the diesel plant because of the higher emission factor of diesel oil.

3.2 Nuclear Energy Chain

The amount of GHG emissions from the nuclear chain associated with light water reactors (LWRs) is controlled by few parameters: the nuclear cycle considered, the average enrichment and burnup at discharge of the fuel, the lifetime of the plants, especially of the power plant, and, most important, the enrichment process used and the electricity supply to the enrichment diffusion plant (if its services are used).

The Swiss LCA study on energy systems addresses the Swiss, French, German, and average UCTE nuclear chains, separately modeling boiling water reactor (BWR) and pressurized water reactor (PWR) power plant technologies with reference to the two 1000 MW class units installed in Switzerland.

The chain was decomposed into several steps: uranium mining (open pit and underground), milling, conversion, enrichment (diffusion and centrifuge), fuel fabrication, power plant (light water reactors), reprocessing, conditioning (encapsulating spent fuel), interim storage of radioactive waste, and final repositories (geological for high and intermediate level waste).

The study assumes partial or total reprocessing of the fuel, according to the conditions in West European countries. In particular, 40% of the total spent fuel produced at Swiss and German plants during their lifetime was assumed to be reprocessed, whereas for France this is most likely the fate of 100% of the fuel; for UCTE a weighted average of 80% of total spent nuclear fuel was assumed to undergo reprocessing. Mixed oxides fuel (MOX) was modeled in the study as MOX is

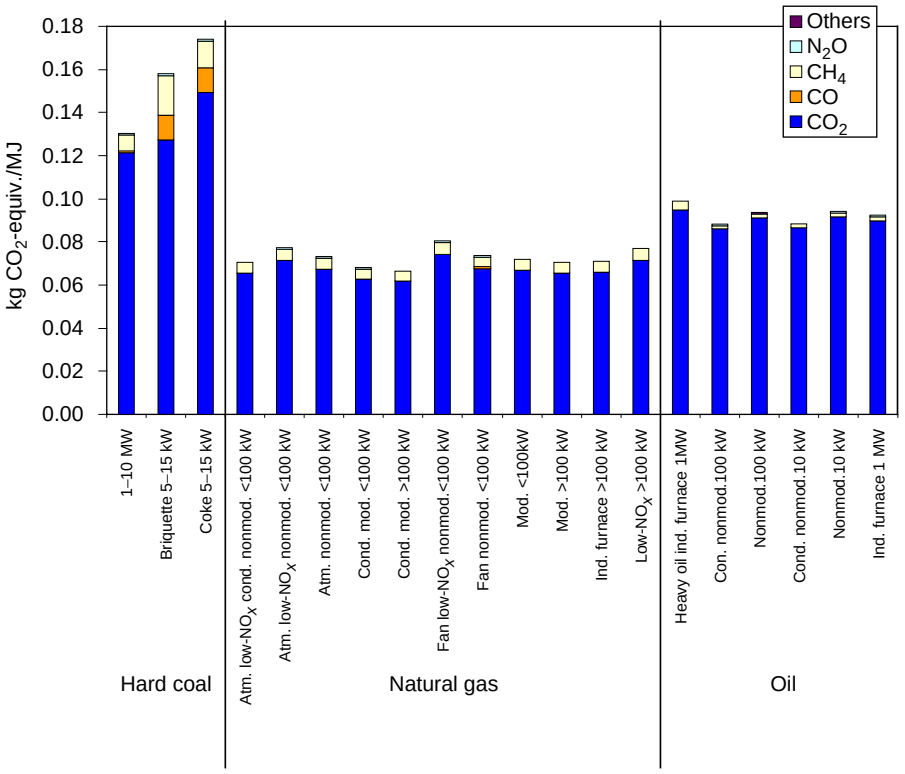

FIGURE 3 Greenhouse gas emissions from fossil fuel heating systems. CO_2-equivalent emissions per MJ heat are shown for different fuels and different technologies. Atm., atmospheric boiler; Fan, fan burner; Mod., modulating boiler; Cond., condensing boiler; Ind. furnace, industrial furnace. Low-NO_x refers to boilers built in early 1990s. All emission factors estimated for boilers operating around year 2000 in Central Europe; modulating boilers refer to the most modern technology on the market. From Dones *et al.* (2003).

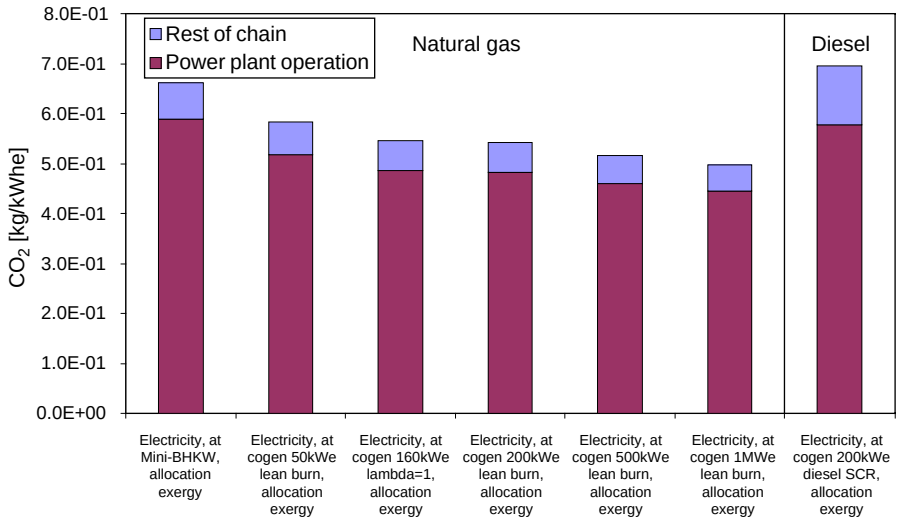

FIGURE 4 CO_2 emissions per kWhe from modern small cogeneration plants of different capacity and technology. Lambda = 1: cogeneration unit with three-way catalyst. Mini-BHKW is a small device comparable to a boiler for a small house with about 2 kWe. SCR, selective catalytic reduction. The allocation to electricity is based on the exergy of electricity and heat assuming an upper temperature of about 80°C for heat. From Dones *et al.* (2003).

widely used in Western Europe, for which recycled plutonium is mixed with depleted uranium from enrichment.

Lifetime of 40 years was assumed for the power plants. Average U-235 enrichment ranges between 3.8% for French PWR and Swiss BWR and 4.2% for Swiss PWR. The corresponding average burnup of spent fuel ranges between nearly 43 MW_{th} day/kgU for the French plants and 52 MW_{th} day/kgU for the Swiss PWR. The study includes a description of enrichment supplies and relevant electricity input, based on a literature search and assumptions on the worldwide enrichment market and country-specific enrichment services.

The total emissions of GHG for the modeled nuclear chains are calculated between approximately 6 and 11 g CO_2-equiv./kWh, where the minimum is estimated for the French nuclear chain, assuming 10% MOX, and 100% use of enrichment at the diffusion Eurodif plant in Tricastin (supplied by nuclear plants and using no CFCs as refrigerants but water). The maximum was calculated for Germany, under the assumption of about 13% MOX and a mix of enrichment services including 10% of the USEC diffusion plant which is assumed to be supplied by coal power plants; nearly 70% of the enrichment services are assumed to be supplied by URENCO facilities (one is based in the north of Germany), based on centrifugal technology, which is about 65 times less energy intensive than the USEC plant.

Calculated total GHG is prevalently from CO_2 emissions, between 90 and 93%. Methane contributes between 3 and 6%, whereas N_2O is between approximately 1 and 3%. The hydrofluoro- and hydrochlorocarbon emissions from the enrichment stage are below 5%.

The GHG associated with the power plant ranges between approximately 1 and 1.3 g CO_2-equiv./kWh, and the waste management (back-end or downstream) between approximately 0.6 and 1 g CO_2-equiv./kWh. The upstream chain makes the rest, which may substantially change according to the main assumptions for the cycle.

For comparison, the total GHG emissions for the Chinese reference chain were estimated at 9 g CO_2-equiv./kWh using centrifuge technology for all enrichment services. Conversely, taking the extreme assumption of only diffusion enrichment powered by coal plants, the highest GHG emission was calculated at nearly 80 g CO_2-equiv./kWh. When electricity mixes with mixed fuels (also including gas and nuclear) are used, this amount could be halved to about 45 g CO_2-equiv./kWh.

3.3 Renewable Energy Chains

3.3.1 Biomass

For biomass burning boilers and cogeneration systems modeled in the Swiss LCA study, only untreated wood was considered (i.e., no waste wood combustion was accounted for). The emission of direct, biogenic CO_2 from combustion was calculated with a carbon content in dry wood of 0.494% for all types of wood fuels. All carbon absorbed by the trees and contained in the wood that is eventually burned was assumed to be emitted during the combustion, either as CO_2 or as CO. Furthermore, all CO is assumed to be fully oxidized to CO_2 in the atmosphere and as such accounted in the total GHG.

Infrastructure and emission data are corresponding to average operation of modern wood boilers, available on the central European market around year 2000. The wood fuel supply chain represents average central European conditions.

Several classes of heating technologies were modeled, namely 6, 30, and 100 kW for wood log furnace, and 50, 300, and 1000 kW for wood chips furnace, using wood directly from forest or residual wood from industrial processes. Boiler operation was modeled for hardwood (mainly beech), softwood (mainly spruce), and the Swiss commercial residual wood mix (72% softwood, 28% hardwood). Wood pellet furnaces of 15 and 50 kW were also modeled.

For the industrial wood chips, practically all burdens of the processes have been allocated to commercial wood products on the basis of an economic evaluation, rather than to the residues eventually burned in furnaces. This zero-allocation assumption might not be applicable if wood chips would become more important for heat production.

Figure 5 shows the comparison of the results of the Swiss study with an Austrian LCA study, the latter analyzing wood heating systems in Central Europe. Only the systems with high efficiency modeled in the Austrian study are used here, as these have comparable efficiencies as assumed in the Swiss study.

The capacities of the logs and chips boilers used for this comparison are between 6 and 1000 kW for the Swiss study and 10 to 50 kW for the Austrian study. The pellet boilers have similar capacities in the Swiss and Austrian studies. The electric power rates of the CHP plants are between 335 and 400 kWe for the Swiss study and 210 kWe to 36 MWe for the Austrian one.

The total efficiencies of log/chips and pellet boilers are between 68 and 85%. The electric efficiencies of

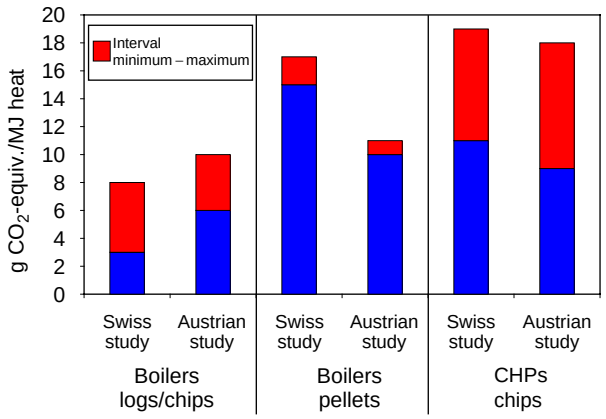

FIGURE 5 Greenhouse gas emissions for wood heating systems. The figure shows the comparison of results of two studies, Swiss and Austrian, analyzing wood heating systems in Central Europe, using LCA. From Swiss study, Dones *et al.* (2003); Austrian study, Jungmeier *et al.* (1999), Treibhausgasbilanz der Bioenergie. Vergleich der Treibhausgasemissionen aus Bioenergie-Systemen und fossilen Energiesystemen. Joanneum Research, Institut für Energieforschung, Graz. Bericht Nr.: IEF-B-06/99.

the cogeneration (CHP) plants in the Swiss study are between 0.9 and 2.3%, thermal efficiencies are between 76 and 78%. The Austrian study reports electric efficiencies of the CHP plants between 8 and 39%, and thermal efficiencies between 51 and 80%.

All values for net GHG emissions of the compared systems are within a relatively small range between 3 g CO_2-equiv./MJ and 19 g CO_2-equiv./MJ. There is no obvious correlation between system capacity and net GHG emissions. Direct CH_4 and N_2O emissions are usually lower at a higher capacity, but the indirect GHG emissions may be higher.

In general, the net GHG emissions from wood chips and wood logs heating systems are not significantly different. Due to incomplete combustion, burning wood logs in automatically controlled furnaces produces more CO and CH_4 than burning chips. Compared to all other heating systems, the (modern) 6 kW fireplaces are emitting relatively high amounts of CO and CH_4.

Compared to other wood boilers, pellet furnaces have higher net GHG emissions, between 15 and 17 g CO_2-equiv./MJ. More than 90% are CO_2 emissions of fossil origin. About 65% of these are due to material and energy uses in the fuel supply chain, and 22% are due to material and energy uses in fuel transport. The main reason is that energy requirements for the pellet production are higher than for chips and logs. Additionally, the transport distances of the pellets to the boilers are usually higher than for chips and logs.

Two wood cogeneration systems of 6400 and 1400 kW_{th} installed in Switzerland and burning industrial chips have been assessed in the Swiss LCA study, each of them with two alternative modes, with multicyclone filter and with enhanced emission control (electric filter + selective noncatalytic reduction (SNCR), assumed to operate with urea). Both systems are mainly designed for heat production (thermal efficiency of nearly 77%); the electricity (efficiency between 1 and 3%) is mostly used for self-consumption.

Allocating all emissions to heat production, 11 g CO_2-equiv./MJ are calculated for the technology with multicyclone-filter and 19 g CO_2-equiv./MJ for the technology with emission control. The reason for the higher GHG emissions of the second technology is that the urea in the SNCR is partially transformed to N_2O. However, the emission factor of this N_2O emission is quite uncertain, and only little information is available in the literature. The interval of N_2O emissions is between 4 and 41 mg/MJ wood input.

3.3.2 Hydro

3.3.2.1 Swiss and European Hydro Power Plants To reflect the situation in Switzerland and Europe, two main types of hydropower plants (storage and run-of-river) and additionally pumped storage plants were analyzed in the Swiss LCA study. A representative sample of four run-of-river power plants in Switzerland and one in Austria was used. Lifetime was assumed to be 80 years for the fixed structures and 40 years for other parts. Net average efficiency is 82% (best efficiency can be 88%).

A representative sample of 52 Swiss concrete dams with a height of more than 30 m was considered for calculating the average. Lifetime was assumed to be 150 years for the dam, 40 years for turbines and pipes, and 80 years for the rest of materials. Net average efficiency, including pipe losses, is 78% (best efficiency can be 84%). The data refer to plant construction of a mix of dam types built between 1945 and 1970; therefore they might not be fully representative for more modern construction, or for a specific dam type, or for an individual unit. The data have been extrapolated to preliminary describe dam mixes in other alpine countries (Austria, Italy, and France) and nonalpine European countries.

No studies seem to exist for CH_4 and N_2O emissions from hydroelectric storage plants in the Alpine region. Hence, the methane emission has been roughly extrapolated from data for natural Swiss lakes, which has been estimated as $4 \cdot 10^{-3}$ kg m^{-2} a^{-1}. Applying

this value as first guess to all Swiss reservoirs, the emission factor would be calculated at 0.014 g CH_4/kWh or 0.32 g CO_2-equiv./kWh. Measurements for N_2O releases from a natural lake in Switzerland have been used for a rough estimation of this emissions from reservoirs, given at $7.7 \cdot 10^{-5}$ g N_2O/kWh or 0.023 g CO_2-equiv./kWh. CO_2 emissions were not accounted for, due to the lack of information on the net balance (see below) for alpine regions.

The Swiss LCA study used available figures for direct GHG emissions from Norwegian and Swedish reservoirs, averaging around 6 g CO_2-equiv./kWh, also for all non-Alpine regions except Finish reservoirs, for which 30 g CO_2-equiv./kWh were assumed.

The results for GHG GWP 100a show that for alpine regions the construction of the dams contributes the most to the total emission of 4 to 5 g CO_2-equiv./kWh. The material (mostly concrete) contributes about 70% to total. With the above assumptions on direct CH_4 emissions, other European reservoirs may exhibit average emissions of 10 g CO_2-equiv./kWh and Finland around 34 g CO_2-equiv./kWh. By increasing GHG fluxes, the emissions associated with the construction of the dam decrease in importance. In case of run-of-river, results are of the order of 3 g CO_2-equiv./kWh.

A survey of several LCA studies performed in 1997 concluded that the indirect contributions approximately range 1 to 10 g CO_2-equiv./kWh for reservoir as well as for run-of-river plants, the difference depending on the plant and site characteristics (type of dam, height/width of dam, capacity of reservoir, location, installed electric capacity, load factor, dedicated transmission lines). However, small hydro may have somewhat higher GHG emission factors.

Pumped storage environmental burdens are a function of the input electricity source and the total efficiency, assumed to be 70%. Hence, results for GHG are strongly depending on the assumption for the input electricity mix. Results of the Swiss LCA study span from the lowest value for Norway (0.027 kg CO_2-equiv./kWh—mix based prevalently on hydro) to 1.62 kg CO_2-equiv./kWh for Poland (mix based mostly on coal). However, these results should be compared only with other systems providing the same service as pumped storage (i.e., peak load).

3.3.2.2 Issues Related to Direct GHG Emissions from Hydroelectric Reservoirs Direct GHG emitted during the operation of a reservoir due to the decomposition of organic matter should be counted for additionally to indirect emissions related to the construction, maintenance, and decommissioning of the plant, in order to compare hydropower with other electricity systems.

Since the late 1980s, research has been invested in the assessment of direct GHG emissions from the air-water interface of reservoirs. Key parameters mentioned for the GHG emission factors are climate (in tropical reservoirs the biodegradation is faster); amount of flooded biomass; nature of the flooded soils; depth of reservoir, which controls methane oxidization; and the ratio energy production to surface.

The state-of-the-art in 2003 for the estimation of GHG emissions from reservoirs comprises the consideration of the emissions from flooded land area only, with contributions from CO_2 diffusive emissions for the initial 10-year period after first filling, CH_4 bubbling and diffusive emissions, N_2O diffusive emissions, and degassing emissions for all previously mentioned species. Ongoing research is aiming at modeling the net emissions, including the entire catchment area and the various phases in the life of the reservoirs in the boreal, temperate, and tropical regions, including pre-impoundment natural GHG emissions, which may be substantial.

Diffusive flow is generally leading to greater GHG emissions than bubbling flow. It is reported that about 99% of CO_2 is released through diffusion, whereas for CH_4 this mechanism releases from 14 to 90% of the total flow. Canadian researchers report that diffusive CO_2 accounts for 80% of total emissions in boreal and temperate sites, whereas methane bubbling makes 60% of total emissions in shallow tropical sites but less than 10% in deep reservoir. In general, N_2O contributes only a few percentage points.

Canadian researchers estimated total GHG emissions (using IPCC 1996 GWP) of 265 g CO_2-equiv. $m^{-2} a^{-1}$ (± 150) from boreal and temperate reservoirs on the basis of measurements of diffusive emission fluxes at the water-air interface of 15 different hydroelectric developments. Data for six tropical reservoirs were summarized giving 4300 g CO_2-equiv. $m^{-2} a^{-1}$ (± 2300) for reservoirs with large shallow water areas (average depth below 10 m) and 1700 g CO_2-equiv. $m^{-2} a^{-1}$ (± 400) for deeper reservoirs (average depth >25 m). The Canadian researchers concluded that reservoirs in tropical regions emit between 5 and 20 times more GHG than in boreal and temperate regions.

Brazilian researchers reported the results of two surveys of measurements in several Brazilian

reservoirs located in different parts of the country. By extrapolating these two surveys to 1-year emissions, they obtained for total CO_2 plus CH_4 the approximate range 1050 to 3930 g CO_2-equiv. $m^{-2} a^{-1}$ (using IPCC 1996 GWP). Methane contributed 7 to 86% of the total GHG emissions. Using the average capacity factor for Brazilian hydroelectric plants of approximately 50%, an interval of 12 to 2077 g CO_2 equiv./kWh from direct emissions in the year of the measurements can be derived for different reservoirs. The average GHG emission factor for direct CO_2 and CH_4 emissions from seven plants, weighted by the energy generation, would be around 340 g CO_2 equiv./kWh. However, it would be inappropriate to use such estimation for the lifetime of the plants, because variations of the fluxes may occur.

On the basis of measurements by several teams of direct emissions in boreal and tropical reservoirs of direct emissions, and of the expected electricity production assuming a load factor of 0.6 and a lifetime of 100 years, Canadian researchers have estimated ranges of GHG emission factors. Boreal and temperate reservoirs would have average GHG emission factors between 0.01 and 0.06 kg CO_2 equiv./kWh, whereas emissions from tropical reservoirs would range between 0.2 and 3 kg CO_2 equiv./kWh. The highest specific emissions were found in shallow (average depth between 4 and 10 m) tropical hydroelectric developments where the ratio of energy production to flooded area is low. A 1997 survey reported for the La Grande Complex in Canada a direct GHG emission of 34 g CO_2-equiv./kWh, based on measurements; this would reduce to 15 g CO_2-equiv./kWh including all sources, assuming gradual return to zero net emissions after 50 years of operation.

Besides decomposition of organic matter, there is evidence of the strong influence of the flooded peat soil for methane emissions in Finn reservoirs, especially if they are shallow. Finnish sources based on direct measurements reported an average range of 65 to 72 g CO_2-equiv./kWh for such reservoirs.

The issue of the net GHG emissions deserves further research in various regions of the world considering the potential developments of hydropower.

3.3.3 Wind

The production of electricity by wind turbines generates no direct GHG emissions. Indirect emissions are following the construction and assembling of the wind power plant, the production and assembling of its materials, transports of materials, and waste disposal processes.

The Swiss LCA study analyzed several wind turbines for Swiss-specific and European average conditions. Plants with 30 kW, 150 kW, 600 kW, and 800 kW were modeled for onshore, and a unit of 2 MW for offshore (based on data from the wind park Middelgrunden, near to Copenhagen). Actual capacity factors in Switzerland range from 8 to 14%. The average for Europe was assumed 20% for onshore and 30% for offshore. The wind mix in Switzerland is mostly composed of 600 and 800 kW turbine, making 57 and 40% of wind electricity in 2002, respectively.

The GHG emissions are decreasing with increasing installed capacity of the turbine. For Swiss conditions, one 800 kW unit emits 20 g CO_2-equiv./kWh, while for average European conditions it decreases to 14 g CO_2-equiv./kWh, for both onshore and offshore. Other studies estimated a typical release of GHG associated to wind turbines in areas with optimal wind speed on the order of 10 g CO_2-equiv./kWh.

For the 800 kW plant, about 72% of GHG emissions stems from the production of materials; about 15% are caused by material processing, 8% by waste disposal, and the rest by transports, final assembling, and installation. The fixed parts (foundation and tower) cause 23% of the CO_2 emissions, the moving parts the rest. For the 2 MW offshore plant, about 81% of the emissions originate from the production of materials. The fixed parts make 44% of the total CO_2 emissions.

3.3.4 Solar

Mono- (mc-Si) and polycrystalline (pc-Si) silicon cell technologies utilized in photovoltaic (PV) panels were analyzed in the Swiss LCA study for Swiss conditions (yield of 885 kWh $kW_{peak}^{-1} a^{-1}$). The plants considered were grid-connected 3 kW_{peak} units installed on buildings in two configurations (i.e., integrated and nonintegrated slanted-roof); also façade and flat-roof were considered. The production chain has been decomposed into detailed steps. The efficiency of the PV cells was assumed to be 16.5% for mc-Si and 14.8% for pc-Si.

Use of electronic-grade silicon from the European electronic industry was assumed as input to the PV industry. The production of metallurgical grade silicon is assumed to occur in Norway (hydro-based electricity mix) and the purification in Germany, with use of a mix of hydropower and a highly efficient combined heat and power plant. To reflect market

conditions, besides electronic grade also a 50% share of off-grade silicon has been considered for the production of the wafers. Energy uses for purification were allocated on the basis of economic value of these two coproducts plus silicon tetrachloride. Changing these assumptions may lead to substantial change of the calculated emissions. In the future, solar grade silicon will probably be used, with associated reduced energy inputs for purification. This production was also modeled in the Swiss study, assuming an increase of cell efficiencies to 17.5% for the mc-Si and 15.7% for the pc-Si systems. Thirty years lifetime was considered for all conditions.

These assumptions lead to a decrease of total GHG emissions compared to previous analyses. Nonintegrated slanted-roof mc-Si panels exhibit about 73 g CO_2-equiv./kWh, whereas for pc-Si technology this value is 59 g CO_2-equiv./kWh. Integrated types have slightly lower LCA emissions. For future conditions, the emissions may decrease to 46 g CO_2-equiv./kWh and 39 g CO_2-equiv./kWh for the mc-Si and pc-Si technologies, respectively.

3.3.5 Heat Pumps

An attractive alternative to fossil fuel fired boilers is the use of heat pumps. Heat pumps can gain heat either from the ambient air, from the ground, or from groundwater. The seasonal performance factor (SPF) of an electric heat pump is the ratio between the annual heat energy output and the annual electric energy input. The SPF depends on the efficiency of the heat pump (coefficient of performance, COP), but also on the local climatic conditions and on the integration of the heat pump into the building (e.g., low- or high-temperature hydronic heat distribution system). Field measurements showed that the average SPF in Switzerland in the year 1998 was about 3.2. Air/water heat pumps using the ambient air had an average SPF of 2.8, brine/water heat pumps using ground heat had an average SPF of 3.9.

The total GHG balance of an electric heat pump depends strongly on the SPF of the heat pump and on the electricity mix used for operation. A heat pump is almost CO_2-free if an almost CO_2-free source of electricity (renewables or nuclear) can be used. But heat pumps can also improve the GHG balance of heating when electricity from fossil fuels is used. A combination of a heat pump with a seasonal performance factor of 3.5 and a cogeneration plant with an electric efficiency of 35%, a total efficiency of about 90%, and electric transmission losses of 2.5% yields about 174% heat relative to the fossil fuel input. The most modern natural gas combined-cycle power plants in Europe can reach a net electric efficiency of 57 to 58%. A combination of a 57.5% CC power plant with an SPF 3.5 heat pump yields a heat efficiency of about 200%.

On the negative side, there are the emissions of refrigerants from heat pumps (besides the indirect emissions from material production and maintenance valid also for other systems). The HFC refrigerant emissions from heat pumps over the lifetime are roughly 2 to 5 mg/MJ. For a heat pump with refrigerant R134a (HFC-134a), which has a 100-years global warming potential of 1300, this corresponds to GHG emissions of about 3–6 g/MJ CO_2-equiv. 100-year. Compared to the CO_2 emissions of a natural gas boiler in the order of 60 g/MJ, heat pumps still can provide a GHG reduction potential if the electricity supply is favorable from the GHG point of view.

Assuming a market penetration of 30% in the building sector using presently available technology, the IEA Heat Pump Centre estimated the CO_2 reduction potential of heat pumps being about 6% of the total global CO_2 emissions from fossil fuels in 1997. This does not include a full LCA analysis and insofar has to be viewed as a rough estimate.

4. COMPARISON OF GREENHOUSE GAS EMISSIONS

The energy sector plays a dominant role with regard to worldwide emissions of GHGs, in particular CO_2. About 77% of yearly CO_2 emissions worldwide originate from fossil fuels combustion. The contribution of the energy sector to the emission of other most important GHGs (i.e., CH_4 and N_2O) is much smaller in relative terms but still important. Based on the total GWP of all GHGs emitted yearly worldwide, the overall share of the energy sector in emissions relevant for global warming is of the order of 50%.

4.1 Current Technologies

The results presented in Section 3 for the individual electricity systems are summarized here. This focuses on the results of the Swiss LCA study for Switzerland and Europe, which cover a broad spectrum of options in a consistent manner. Some conclusions are provided. For a number of detailed comparisons of results for specific chains with other studies and for special issues, refer to Section 3.

Figure 6 shows the overall results with contribution of the various GHGs. In Figure 7 the same overall results are provided but with differentiation between contributions from power plant and rest of the chain. Figures 6 and 7 are complemented by the ranges of GHG emissions from European country-specific energy systems provided in Table V.

1. *Electricity systems ranking based on GHG emissions.* GHG emissions per unit of generated electricity are typically highest for industrial gas, followed by lignite, hard coal, oil, and natural gas. Hydro exhibits very low GHG emissions in boreal and temperate regions, in most cases two orders of magnitude lower than coal. However, hydroelectric developments in tropical regions may emit during

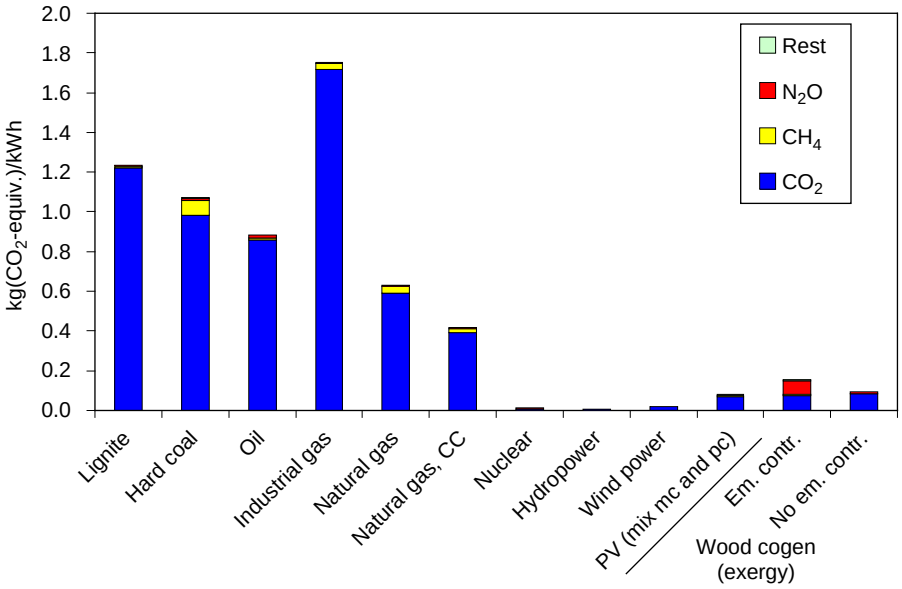

FIGURE 6 Overview of full chain greenhouse gas emissions for different electricity generation systems. The figure shows the contributions of the different greenhouse gases in kg CO_2-equivalents (100 years) per kWh_e. Lignite, hard coal, oil, industrial gas, natural gas, and nuclear refer to energy systems associated with average UCTE power plants around year 2000. Natural gas CC: Combined-cycle power plant of currently best technology, gas supplied by the European high-pressure grid. The renewables (hydropower, wind power, photovoltaic, wood) refer to location Switzerland. From Dones *et al.* (2003).

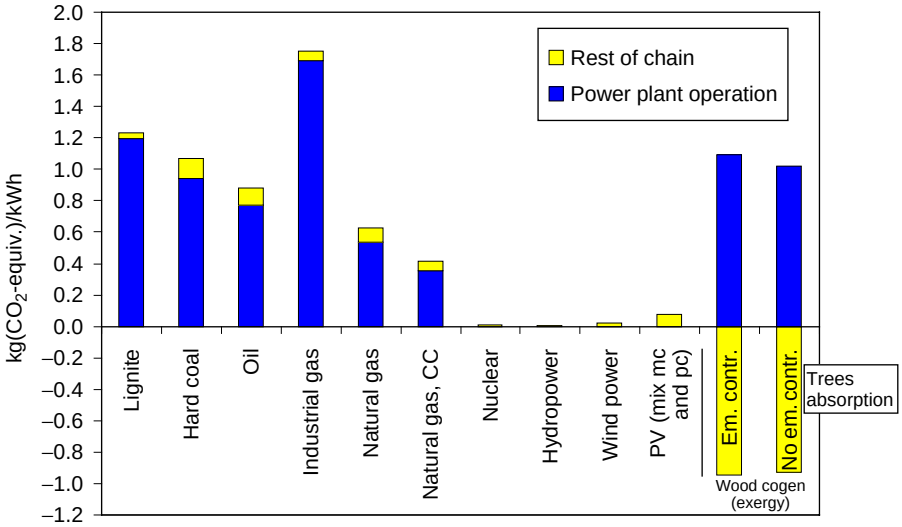

FIGURE 7 Greenhouse gas emissions from power plant operation and from the rest of chain for different electricity generation systems. For explanations see Fig. 6 and text.

TABLE V

Ranges of GHG Emissions per kWh Electricity from European Country-Specific Energy Sources, using GWP 100 years

	Minimum (kg CO_2-equiv./kWh)	Maximum (kg CO_2-equiv./kWh)
Lignite	1.060	1.690
Hard coal	0.949	1.280
Oil	0.519	1.190
Industrial gas	0.865	2.410
Natural gas	0.485	0.991
Nuclear power	0.008	0.011
Hydropower[a]	0.003	0.027
Wind power[b]	0.014	0.021
PV (mix mc and pc)[c]	0.079	—
Wood cogeneration[d]	0.092	0.156

[a] Mix of reservoirs and run-of-river plants.

[b] Calculated for average conditions of Switzerland (maximum) and Western Europe (minimum).

[c] Calculated for average Swiss conditions.

Source. Dones *et al*. (2003).

operation between 5 and 20 times more GHGs, which at the higher range is comparable to emissions from fossil sources. Taking into account full energy chain contributions including also the grey ones, GHG emissions from nuclear and wind energy (under favorable wind conditions) are in the same low range as typical for hydro. The corresponding net emissions for biomass are in the middle range (i.e., one order of magnitude lower than coal and one order of magnitude higher than nuclear and wind). The same applies to older solar photovoltaic systems in countries with climate conditions such as in central Europe, while current photovoltaic technologies exhibit even smaller differences compared to nuclear and wind; still better performance can be achieved in southern countries.

2. *Differences between industrialized and developing countries*. Based on quite limited comparative material for fossil systems, a pattern can be distinguished, namely the GHG emissions are significantly higher in the developing countries. This is due to use of technologies characterized by lower efficiency as well as distinct features of fuel cycles (relatively large methane emissions from mines and from gas pipelines; coalfield fires in China).

3. *Dominant GHGs*. CO_2 dominates GHG emissions from energy systems. In the case of hard coal and natural gas, the methane contribution in terms of CO_2-equivalents may reach the level of 10% due to high leakage rates from coal mines and gas pipelines. N_2O may be of high relative importance for wood cogeneration, if pollutant emission controls employing catalysts generating N_2O are applied.

4. *Role of GHG emissions other than from power plant*. For fossil systems power plant GHG emissions are clearly dominant. It can be noted that in the case of major pollutants, the situation may be quite different—that is, emissions from power plants are higher than the other contributions, but the latter may be very substantial. For European conditions the upstream part of the chain typically contributes about 10% of the total GHG emissions for the hard coal chain, slightly more than 10% for oil chain, and can approach 20% for conventional natural gas systems. For nuclear, wind and solar photovoltaic, the GHG emissions other than from power plant are totally dominant in relative terms. The same applies to typical hydro plants, with the exception of dams operating under special conditions resulting in very large direct emissions from reservoirs.

For comparisons of heating and cogeneration systems, refer to Figs. 3, 4, and 5. Gas boilers are as expected better performers than oil boilers when modern systems are compared. Biomass exhibits best GHG performance along with heat pumps, provided that electricity input to the latter comes from zero or low carbon sources. Cogeneration based on biomass is clearly favorable in terms of GHG emissions compared to the corresponding gas and oil systems. Evaluation of cogeneration is subject to variability, depending on which allocation scheme is employed.

4.2 Electricity Mixes

Calculating and presenting GHG emission data for single technologies is important for comparisons and decision making. However, it is also essential to generate the total burdens associated with the electricity mixes. These can then be used in LCA studies of products.

Two approaches are used to generate the relevant mixes (i.e., marginal and average mix approach). The marginal approach suggests to use the last available technology or mix of technologies (e.g., the cheapest available for base load, or the technology[ies], which will most probably cover an increase in demand, or the specific energy technology which will be chosen for a process/industry), whereas with the average

approach only average mixes supplying the grid are considered.

The Swiss LCA study addressed national production mixes for all European countries and the three major associations of electric transmission operators UCTE, CENTREL, and NORDEL in year 2000. GHG results for these electricity mixes are summarized in Table VI.

Depending on the shares of technologies, the total GHG emissions can vary by several orders of magnitude from the hydro-based Norwegian mix to the coal-based Polish mix. Additionally, the study addressed the issue of the supply mix. This was modeled by merging all imports to the domestic production mix and thus recalculating the share of technologies to be used both for the domestic supply mix as well as for the export mix. This model may somewhat overestimate the effective import shares and may not describe seasonal exchanges properly. The results for Switzerland, a country with intense exchanges of electricity with neighboring countries due to its central position in Europe, are illustrated in Table VII.

The GHG-free production mix based on hydro and nuclear (58 and 38%, respectively, in year 2000) changes to a supply mix with quite significant fossil components due to imports from Germany. Another issue concerns the influence of the grids (losses and material use) to the GHG associated to the electricity services. The analysis performed for the Swiss conditions leads to increases of GHG by 2.5, 5, and 18% with respect to the supply mix at the busbar of plants in the case of high, medium, and low voltage levels, respectively. With equal network losses, the increases may be lower in percent in case of country supply mixes with higher fossil share.

A Japanese study covered the electricity production mixes for 10 Japanese electric companies. Besides direct emissions from fossil plants, the authors included the emissions from the upstream chains, but excluded construction and decommissioning of the various facilities and transport systems. Only CO_2 and CH_4 were considered. Using GWP from IPCC 2001, the results are in the range of 296 to 795 g CO_2-equiv./kWh for nine companies, whose average is calculated at 468 and 1079 g CO_2-equiv./kWh for Okinawa. Remarkably, the UCTE (2000) and the Japanese production mixes have practically the same GHG intensity.

TABLE VI

LCA-Based GHG Emissions for European Electric Associations and Countries

Electricity mix	kg CO_2-equiv./kWh
Production mix (at busbar)	
UCTE	0.470
CENTREL	0.932
NORDEL	0.132
Country-specific production mix[a]	0.007–1.13
Country-specific supply mix[a,b]	0.010–1.11

[a] Minimum: Norway; maximum: Poland.

[b] The used model adds all electricity imports to the domestic production, recalculates the shares of technologies on this basis, and applies this portfolio to domestic supply and exports.

4.3 Advanced Technologies and Sequestration

4.3.1 Advanced Technologies

The LCA methodology has been originally developed and primarily applied for operating systems. Consequently, the input is normally based on the actual experience. Furthermore, the standard approach is static and its application to future systems requires extensions, extrapolations, and a number of additional assumptions on technological advancements and structural changes.

Few studies have implemented extensions of LCA applications to future systems, based on literature as well as direct information from the industry and on expert judgment. The result-driving parameters in the LCA study are emissions, efficiencies, material intensities (for construction and operation), and transportation requirements. The relative importance of these parameters varies significantly between energy chains.

The most important expected changes towards improvements of ecological performance identified in

TABLE VII

LCA-Based GHG Emissions for Swiss Electricity Mixes

Electricity mix	kg CO_2-equiv./kWh
Production mix (at busbar)	0.018
Supply mix (with import/export)[a]	0.120
High voltage	0.123
Medium voltage	0.126
Low voltage	0.142

Source. Dones *et al*. (2003).

the 1996 Swiss study on evolutionary future electricity generating technologies were as follows:

- *Gas systems*. Reduction of gas leakage, improvements of power plant burner performance characteristics and of overall power plant efficiency.
- *Hard coal systems*. Increased methane recovery in underground mining, improvements in power plant abatement technology, and of overall power plant efficiency.
- *Nuclear systems*. Reductions of electricity consumption in enrichment by replacement of diffusion by centrifuges or laser technologies, power plant improvements (particularly extended life time and increased burn-up).
- *Hydro systems*. Overall power plant efficiency improvements (turbine).
- *PV systems*. Improvements in the manufacturing of mono-crystalline-silicon (m-Si) and amorphous-silicon (a-Si) solar cells (yield, electricity consumption), and in cell efficiencies.

Some of the improvements mentioned have already been implemented in the best technologies available around year 2000, which are not yet widely disseminated.

For electricity inputs needed for the LCA modules external to Switzerland, a European mix for year 2010 was defined, based on a forecast by the International Energy Agency. The mix reflects the expansion of gas, reduction of oil shares, and a relatively small but significantly increased contribution of renewables other than hydro. Coal, hydro, and nuclear remain at about the same level percent. Since the new systems generally show better performance and lower emissions than the old ones, assumptions needed to be made with respect to the market penetration of the new ones. This was done individually for each energy source, taking into account their specificity and the expected developments reflected by the assumed overall contribution of each energy carrier to the mix.

Future electricity generation systems based on fossil chains have the potential to reduce GHG emissions by 20 to 40% in comparison with the corresponding present average European fossil systems. However, they remain the largest GHG producers: two orders of magnitude higher than hydro in Alpine regions, wind and nuclear, and one to two orders higher than photovoltaic.

4.3.2 Sequestration

Since CO_2 emissions into the atmosphere should be reduced, storage of CO_2 in geological reservoirs or in the ocean is a possible option under discussion. The sequestration procedure includes capture of CO_2 from the fuel combustion device, dehydration, compression, transport, and injection into the final reservoir.

The fate of CO_2 in ocean is not yet fully understood. Storage in geological reservoirs seems to be a more promising method, but also in this case there are open issues to be investigated like the permanency of the storage. Possible environmental risks of storage in saline aquifers include leakages, catastrophic releases (although considered unlikely), changes in geochemistry, water quality, and ecosystem health caused by pH shifts due to carbonic acid, or contamination of potable water due to displacement of brine.

Table VIII shows estimates of the storage capacities of possible geological reservoirs. Depleted gas and oil fields could store only about 40% of the CO_2 emissions expected between year 2000 and year 2050 (though this does not include fields that are not yet operating). The actual storage capacity of saline aquifers under reasonable economic conditions is highly uncertain.

The main techniques for CO_2 capture are postcombustion capture, precombustion capture, and oxy-fuel combustion. Postcombustion capture of CO_2 from the flue gas usually involves chemical solvents like monothanolamine (MEA). In precombustion capture, the fuel is converted into CO_2 and hydrogen; the hydrogen is then combusted. Oxy-fuel combustion means an increase of CO_2 concentration in the flue gas by using concentrated oxygen (which is, e.g., produced by cryogenic air separation) for combustion.

CO_2 capture reduces the net efficiency of a power plant and thus increases the fuel consumption per kWh delivered to grid. Using current technology, the

TABLE VIII

Global CO_2 Storage Capacities of Geological Reservoirs

CO_2 emissions and storage capacities	Gt CO_2
Emissions 2000–2050 (IPCC business as usual scenario)	2000
Theoretical storage capacities of geological reservoirs	
Depleted gas fields	690
Depleted oil fields	120
Deep saline aquifers	400–10,000
Unminable coal seams	40

Source. Gale (2002). (Storage capacities based on injection costs of up to 20 US $/ton CO_2; gas and oil fields exclude fields that are not yet producing.)

changes would be significant. For a natural gas combined cycle power plant, the fuel consumption is expected to increase by 16 to 28% due to CO_2 capture. The respective figures for coal power plants have been estimated to be 22 to 38% for pulverized coal and 16 to 21% for integrated gasification combined cycle (IGCC). Capital costs would increase by 300 to 800 US$/kW, or about 30 to 50% for IGCC, about 70 to 80% for pulverized coal, and about 80 to 100% for natural gas CC.

Glossary

Air Conditioning and Refrigeration Institute (ARI) The nonprofit organization that sets the standards for testing and comparisons for the heating, air-conditioning, and refrigeration industries.
aquifer A water-bearing geological formation; a large body of underground water.
coefficient of performance (COP) The ratio of heat energy delivered or extracted to work to operate the equipment.
compressor The device that, through compression, increases the pressure and temperature of entering refrigerant, and discharges a hot dense gas.
condenser A heat-exchange coil within a mechanical refrigeration system; used to reject heat from the system.
energy efficiency ratio (EER) The ratio of the rated cooling capacity (in British thermal units per hour) divided by the amount of electrical power used (in watts) for any given set of conditions.
entering water temperature (EWT) The temperature of the heat transfer fluid leaving the ground heat exchanger.
evaporator A heat-exchange coil within a mechanical refrigeration system; used to absorb heat into the system.
ground heat exchanger (GHE) A device that exchanges ground heat; thermal energy is extracted from (or rejected into, depending on mode of operation) the ground.
heat exchanger A device used to transfer heat from a fluid (liquid or gas) to another fluid; the two fluids are physically separated (usually by metal tubing).
heating seasonal performance factor (HSPF) The ratio of the total amount of heat energy supplied to the space for the heating season with respect to the total electrical energy required by the heating system for the same season.
heat pump A device that uses a refrigerant cycle to take low-quality heat, concentrate it to a higher quality heat, and move that heat to another location in the cycle.
heat sink The area or media where heat is deposited (inside a building, etc.).
heat source The area or media from which heat is removed (water, air, etc.).
heat transfer fluid A fluid (water, or a mixture of water and antifreeze) that is circulated through the ground heat exchanger via a circulating pump.
refrigerant A fluid (liquid or gas) that picks up heat by evaporating at a low temperature and pressure.
reversing valve A valve that changes the direction of refrigerant flow in a heat pump.
seasonal energy efficiency ratio (SEER) The average energy efficiency ratio over the entire cooling season.

Ground-source heat pumps (GSHPs), also known as geothermal heat pumps (GHPs), use electricity to move heat, not to generate it, and are recognized to be outstanding heating, cooling, and water-heating systems. The primary benefit of GSHPs compared to other systems is the increase in operating efficiency, which translates to reduced heating and cooling costs, but there are additional advantages. One notable benefit is that GSHPs are classified as renewable energy technology, although they are electrically driven. According to the U.S. Environmental Protection Agency (EPA), well-designed and properly installed high-efficiency GSHP systems produce less environmental harm as compared to any other alternative space-conditioning technology currently available. On a full fuel cycle basis, these systems are the most efficient technology available, with the lowest CO_2 emissions for minimum greenhouse warming impact.

1. GROUND-SOURCE HEAT PUMPS

Ground-source heat pumps are not a new idea. Patents on the technology date back to 1912, in Switzerland. One of the oldest GSHP systems in the United States, in the United Illuminating headquarters building in New Haven, Connecticut, has been operating since the 1930s.

There are two main types of GSHP systems: ground-coupled (vertical or horizontal) closed loop and water-source (groundwater) open loop, as shown in Figs. 1 and 2, respectively. Ground-coupled heat pumps (GCHPs) are known by a variety of names. These include ground-source heat pumps, earth-coupled heat pumps (ECHPs), earth energy heat pumping systems, earth energy systems, ground-source systems, geothermal heat pumps, closed-loop heat pumps, solar energy heat pumps, geoexchange systems, geosource heat pumps, and a few other variations. In marketing ground-source heat pumps, to cope with the diverse terminology, sales personnel may wish to connect GCHPs to renewable energy sources (solar, geothermal), to connect them to environmental awareness (earth energy), and to dissociate them from air heat pumps (ground-source systems). However, two terms are commonly used to describe the technology in general: geothermal heat pumps and ground-source heat pumps. The former term is typically used by individuals in marketing and government, and the latter is used by engineering and technical types. In addition, ground-coupled, groundwater, and surface water heat pumps are referred to as subsets of ground-source heat pumps. The systems will be referred to as ground-source heat pumps throughout this text.

The closed-loop systems use a buried earth coil as the ground heat exchanger (GHE) through which a heat transfer fluid, typically an antifreeze solution, is circulated. The GHE, installed either vertically in borings or horizontally in trenches, exchanges heat with the ground (Fig. 1). In open-loop systems, the groundwater is pumped into the heat pump unit, where heat is extracted from (or rejected into, depending on mode of operation) the water; the water is then disposed of in an appropriate manner. If possible, releasing the water into a stream, river, lake, pond, ditch, or drainage tile, known as open discharge, is the easiest and least expensive disposal method. A second means of water discharge is using a return well that returns the water to the ground aquifer (Fig. 2).

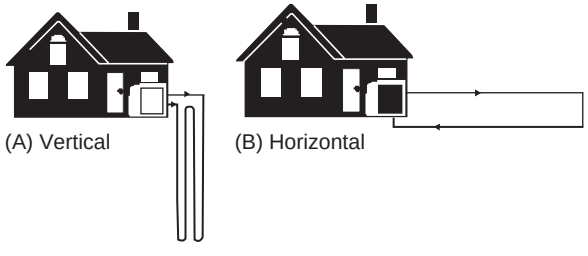

FIGURE 1 Ground-coupled (closed-loop) systems. Reproduced by permission from the Geo-Heat Center, Oregon Institute of Technology.

2. WORLDWIDE GROUND-SOURCE HEAT PUMP INSTALLATIONS

Among the worldwide applications of geothermal energy for direct utilization, GSHPs have had the largest rate of growth since 1995, almost 59%, representing 9.7% annually. Most of this growth has occurred in the United States and Europe, though interest is developing in other countries, such as Japan and Turkey. The installed capacity is 6875 thermal-derived megawatts (MW_t), and the annual energy use is 23,287 terajoules (TJ)/year, or 6453 gigawatt-hours (GWh)/year, at the beginning of 2000 in 27 countries, as shown in Table I. It is estimated that the actual number of installed units is around 500,000, and the equivalent number of 12-kW units installed is slightly over 570,000. It is estimated that 450,000 units are presently installed in the United States; thus, this rate of installation would add an additional 1.1 million units for a total of about 1.5 million units by 2010.

The world's largest GSHP installation is the Galt House East Hotel and Waterfront Office Buildings in Louisville, Kentucky. A 4700-ton GSHP system is used to meet the heating and cooling needs of the complex. The 70,000 m^2 (750,000 ft^2) Galt House East Hotel was completed in 1984 and uses a

[a] Thermally derived megawatts.

1700-ton GSHP system. The installation cost was $1500 per ton. In comparison, a conventional system would have cost between $2000 and $3000 per ton. The hotel complex energy use is approximately 53% of a similar non-GSHP system in an adjust unit, and the system saves about $25,000 monthly in reduced energy costs. The Waterfront Office Buildings, built in 1994, add about 89,000 m^2 (960,000 ft^2) of office space and almost 3000 tons of GSHP capacity to the project, making this the world's largest commercial GSHP project. It is reported that Galt House East has been operating for 15 years with no system problems and that the GSHP system has performed even better than expected.

One of the largest commercial GSHP systems running today is at Stockton College in Pomona, New Jersey, where 63 GSHPs with a total capacity of 1655 tons (5825 kW) are connected to a GHE, which consists of 400 wells, each 129 m (425 ft) deep.

3. MAIN COMPONENTS OF A GROUND-SOURCE HEAT PUMP SYSTEM

GSHPs use the relatively constant temperatures, typically 7° to 21°C (45° to 70°F), of the soil and water beneath the frost line to provide efficient heating and cooling all year long. The efficiencies achieved by these systems are impressive and allow commercial users to save up to 50% over conventional heating and cooling systems, plus they reduce

maintenance costs. GSHPs use the stable temperature of the ground as a heat source to warm buildings in winter and as a heat sink to cool them in summer.

A GSHP system for space heating and cooling of houses consists of three distinct subsystems (see Fig. 3):

1. Earth connection or ground heat exchanger. Many types of GHE designs are possible, but for GSHP systems, only two basic design concepts have been implemented so far. They are direct-expansion GHEs, which consist of a buried copper piping network through which refrigerant is circulated, and secondary fluid circulating GHEs, through which a water or a water–antifreeze solution is circulated. The GHE is buried in the ground near the building to be conditioned. Heat transfer fluid is circulated through the GHE via a circulating pump (stage 1, in Fig. 3).

2. Heat pump unit. This device is composed of five primary components (Fig. 3): a compressor (stage 2), a refrigerant–air (or water) heat exchanger (stage 3), an expansion valve (stage 4), and a heat exchanger between the refrigerant and GHE fluid (stage 5); there is also a reversing valve (stage 6). In the heating mode, heat is extracted from the ground by the GHE. This heat is transferred to the refrigerant in the refrigerant–fluid heat exchanger, is upgraded in the heat pump cycle, and is supplied to the house by the refrigerant–air heat exchanger, which acts as the condenser. In the cooling mode, the process is reversed to extract heat from the house and reject it to the ground. The most widely used type of unit is a water-to-air heat pump, which circulates a water or water–antifreeze solution through a liquid-to-refrigerant coil and a GHE. Air to be heated or cooled is circulated through a conventional finned-tube air-to-refrigerant coil and duct system. Water-to-water heat pumps are also used by replacing the forced air system with a hydronic loop. Systems using water-to-air and water-to-water heat pumps are often referred to as GCHPs with secondary solution loops, to distinguish them from direct-expansion GCHPs.

3. Heat distribution. There are two basic ways to distribute the energy extracted from the earth and water, namely, forced-air systems and hydronic systems. The simplest way to cool a building is to circulate air by using fans to blow the air through coils. This kind of system is not suitable for heating, however, unless the earth or water source is usually warm. In addition to space conditioning, GSHPs can be used to provide domestic hot water when the system is operating.

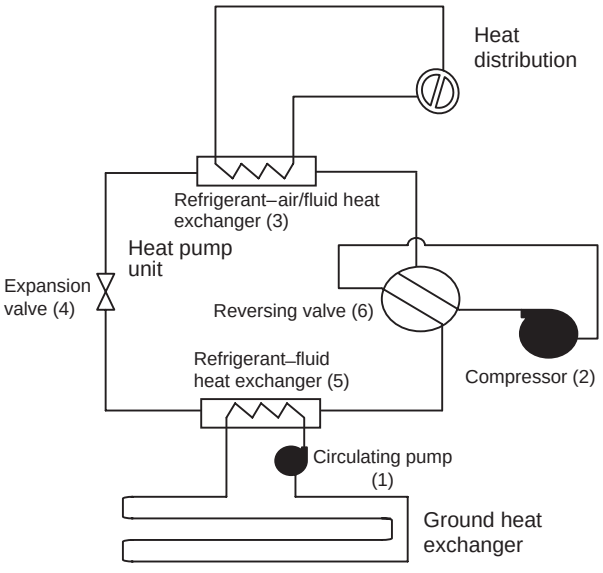

FIGURE 3 A schematic of a ground-source heat pump system, showing stages 1 through 6 (see text for discussion).

4. DESIGN TYPES OF GROUND HEAT EXCHANGERS

The type of GHE used will affect heat pump system performance (therefore, the heat pump energy consumption), auxiliary pumping energy requirements, and installation costs. Choice of the most appropriate type of GHE for a site is usually a function of specific geography, available land area, and life cycle cost economics. Primarily, only two types of GHE designs are used, vertical and horizontal.

4.1 Vertical Ground Heat Exchangers

The vertical ground heat exchanger (VGHE), illustrated in Fig. 1A, is generally considered when land surface is limited. The VGHE consists mainly of two small-diameter high-density polyethylene (PE) tubes that have been placed in a vertical borehole that is subsequently filled with a solid medium. The tubes are thermally fused at the bottom of the bore to a close-return U-bend. Vertical tubes range from 0.75 to 1.5 inches in nominal diameter, and bore depths vary from 15.2 to 183 m (50 to 600 ft), depending on local drilling conditions and available equipment. Multiple wells are typically required, with well spacing not less than 4.6 m (15 ft) in northern climates and not less than 6.1 m (20 ft) in southern climates to achieve the total heat transfer requirements. A minimum base separation distance of 6.1 m

(20 ft) is recommended when loops are placed in a grid pattern. This distance may be reduced when the bores are placed in a single row, when the annual heating load is much greater than the annual cooling load, or when vertical water movement mitigates the effect of heat buildup in the loop field.

4.2 Horizontal Ground Heat Exchangers

Horizontal ground heat exchangers, illustrated in Fig. 1B, are most often used for small installations where space is not a premium. Pipes are buried in trenches, typically at a depth of 1.2–3.0 m (4–10 ft). Depending on the specific design, as many as six pipes may be installed in each trench, with about a foot separating the pipes, and trenches typically being 3.7–4.6 m (12–15 ft) apart. The "slinky," a spiral loop comprising overlapping coils of pipe, can be used to maximize the number of feet of pipe buried per foot of trench, but slinkys require more feet of pipe per ton of thermal energy needed, compared to conventional horizontal systems.

Another variation of the spiral-loop system involves placing the loops upright in narrow vertical trenches. The spiral-loop configuration generally requires more piping, typically 43.3–86.6 m/kW per system cooling ton (500–1000 ft), but less total trenching as compared to the multiple horizontal-loop systems just described. For the horizontal spiral-loop layout, trenches are generally 0.9–1.8 m (3–6 ft) wide; multiple trenches are typically spaced about 3.7 m (12 ft) apart. For the vertical spiral-loop layout, trenches are generally 15.2 cm (6 inches) wide; the pipe loops stand vertically in the narrow trenches. In cases in which trenching is a large component of the overall installation costs, spiral-loop systems are a means of reducing the installation cost. As noted with horizontal systems, slinky systems are also generally associated with lower tonnage systems when land area requirements are not a limiting factor.

The key issue that makes GSHPs unique is the design of the GHE system. Most operational problems with GSHPs stem from the performance of the GHE system. There are several ways of sizing a GHE:

1. Using rules-of-thumb. In the residential sector, many systems have been designed using rules-of-thumb and local experience, but for commercial-scale systems, such practices are ill advised. For this purpose, heat extraction/rejection rates obtained from experience are used. For all but the most northern climates, commercial-scale buildings will have significantly more heat rejection than extraction. This imbalance in heat rejection/extraction can cause heat buildup in the ground to the point where heat pump performance is adversely affected and hence system efficiency and possibly occupant comfort suffer.
2. Short method 1. This method uses the building-block load, estimates of average equivalent full-load operating hours, average values of the equipment energy efficiency ratio (EER) and coefficient of performance (COP), and some values to estimate the temperature penalty due to long-term heat exchange in the GHE. Besides this, this computation also requires obtaining ground thermal properties and thermal resistances.
3. Short method 2. Besides the energy parameters for the heat pump (heating and cooling loads, and run time), the highest supply water temperature acceptable for cooling mode and the lowest temperature acceptable for heating mode must be known. These values, along with local ground temperature, establish the design temperatures for sizing a GHE. Using three simple tables and heat transfer equations, the required calculation may be easily done.
4. Using design software. The abbreviated computation described in short methods 1 and 2 is still very time consuming. More importantly, it is difficult to evaluate the impact of design alternatives, because most of the calculations have to be repeated. The procedure lends itself well to computer-aided design.

Proper design for commercial-scale systems almost always benefits from the use of design software. Today, software tools are available to support the design of any GHE system that meets the needs of designers and installers. Software for commercial-scale GSHP system design should consider the interaction of adjacent loops and predict the potential for long-term heat buildup in the soil. These tools are available from several sources, including the International Ground-Source Heat Pump Association (IGSHPA). In addition, several manufacturers have designed their own proprietary tools, and these are more closely tuned to particular system requirements.

5. SOIL CHARACTERISTICS

Soil characteristics are an important concern for any GHE design. The operation of the heat exchanger

induces a simultaneous heat and moisture flow in the surrounding soil. The transfer of heat between the GHE and adjoining soil is primarily by heat conduction and to a certain degree by moisture migration. Therefore, transfer depends strongly on the soil type, temperature, and moisture gradients. With horizontal GHEs, the soil type can be more easily determined because the excavated soil can be inspected and tested.

The soil thermal diffusivity (α_s) is a defined property and is the ratio of the thermal conductivity (k_s) and the heat capacity ($\rho_s C_s$). Therefore, the three soil properties, k_s, ρ_s, and C_s, must be known or estimated to predict the thermal behavior of GHEs. Obtaining accurate values for thermal properties of the soil requires a detailed site survey. In order to estimate the thermal properties of granular soils (sand, clay, silt) it is necessary to determine the sand and clay content, dry density, and moisture content. The following analytical equations are used to calculate the thermal properties of the soil based on soil dry density and moisture content.

The thermal conductivity of the soil, k, in watts/meter degree Kelvin, may be calculated from Eqs. (1) and (2):

$$k_s = 0.14423(0.9 \log \omega - 0.2)10^{0.000624\rho_{sd}} \quad (1)$$

for silt and clay soils

$$k_s = 0.14423(0.7 \log \omega + 0.4)10^{0.000624\rho_{sd}} \quad (2)$$

for sand soils where ω is moisture content in percentage by weight and ρ_{sd} is dry density in kilograms/cubic meter.

Thermal diffusivity is sensitive to moisture content because the specific heat of water (4.1868 kJ/kg K) is far greater compared to the typical values for soils and rock (0.84 to 1.05 kJ/kg K). Both the dry specific heat and the dry density of soil, C_{psd} and ρ_{sd}, must be corrected in order to determine α_s as follows:

$$\alpha_s = \frac{k_s}{C_{psc}\,\rho_{sc}} \quad (3)$$

with

$$C_{psc} = \left[\omega C_{pw} + (100 - \omega)C_{psd}\right]/100 \quad (4)$$

and

$$\rho_{sc} = \left[\omega \rho_{pw} + (100 - \omega)\rho_{sd}\right]/100 \quad (5)$$

where C_{psc} is the corrected specific heat of soil, ρ_{sc} is the corrected density of soil, C_{pw} is the specific heat of water (4.1868 kJ/kg K), and ρ_{pw} is the density of water (1000 kg/m^3).

6. GROUNDWATER HEAT PUMPS

Groundwater heat pump (open-loop) systems are the oldest and most well established of the GSHP systems, with the first examples of large commercial applications installed in the late 1940s. Common design variations include direct (groundwater used directly in the heat pump units), indirect (building loop isolated with a plate heat exchanger), and standing column (water produced and returned to the same well), as shown in Fig. 2A. Direct systems are typically limited to the smallest applications. Standing-column systems are employed in hard-rock geology sites where it is not possible to produce sufficient water for a conventional system.

Although seemingly simple in nature, these systems require careful consideration of well design, groundwater flow, heat exchanger selection, and disposal, even for very small commercial applications. The direct groundwater system is very susceptible to problems induced by poor water quality, the most common of which is scaling of the refrigerant-to-water heat exchangers. This design is recommended in only the smallest applications when practicality or economics precludes the use of an isolation heat exchanger and/or when groundwater quality is excellent (the determination of which requires extensive testing). The standing-column system has been installed in many locations in the northeast portion of the United States. Like the direct groundwater system, it, too, is subject to problems induced by poor water quality. In general, water quality in the area where most of the systems have been installed is extremely good, with low pH and low hardness (little scaling potential). Standing-column systems are used in locations underlain by hard-rock geology, where wells do not produce sufficient water for conventional open-loop systems and where water quality is excellent. Well depths are often in the range of 304.8 to 457.2 m (1000 to 1500 ft) and the systems operate at temperatures between those of open- and closed-loop systems.

In most commercial applications, the optimum design dictates a flow of 0.045–0.054 liters/sec per kW, or 2.5–3.0 gallons per minute (gpm)/ton, on the building-loop side of the exchanger and 0.018–0.045 liters/sec per kW (1–2.5 gpm/ton) on the groundwater side. As a result of this, the approach, or minimum, temperature difference between the two flows occurs at the building-loop return (heat pump "leaving" water) and groundwater leaving end of the exchanger. Groundwater below 60°F may be circulated directly through hydronic coils in series or in parallel with heat pumps.

There are two basic options for water disposal from an open-loop system: surface and injection. Both options are subject to regulatory oversight and permitting. Surface disposal, the most common method used in the past, is less expensive, but requires that the receiving body be capable of accepting the water over a long period. Injection is more complex and costly but offers the certainty that the groundwater aquifer will not be adversely affected (aquifer decline) by the operation of the system over the long term, because the water is "recycled." For surface disposal, it may be advisable to place a pressure-sustaining valve on the end of the system to maintain full piping when the pump is not operating. Some designers prefer simply to place a motorized valve at this point in the system and interlock it with the pump (through an end switch).

The optimum design of the groundwater heat pump (GWHP) is to realize optimal cooperation for all components, and to consider the running costs and first investment simultaneously under present technical and economic conditions.

7. SURFACE WATER HEAT PUMPS

Surface water heat pump (SWHP) systems can be either closed-loop systems similar to GCHPs or open-loop systems similar to GWHPs (Fig. 2B). However, the thermal characteristics of surface water bodies may be quite different from those of the ground or groundwater. Some unique applications are possible, but special precautions may be warranted.

Closed loops of pipe can be positioned at the bottom of a body of water at sites where the water is deep enough and has significant flow. Such sites utilize the circulating fluids to effect excellent heat exchange with the surrounding water, and limit the need for excavation. SWHP systems are a viable and relatively low-cost GSHP option. Lakes, streams, and bays can be very good heat sources and sinks for these systems, if properly utilized. Many successful systems are currently in operation.

Open systems are restricted for use in warmer climates or for buildings in colder climates with cooling-only applications (or very small heating loads). In colder climates, lake temperatures may range from 38° to 40°F. Pumping at a rate of 0.054 liters/sec per nominal kilowatt (3 gpm/nominal ton) will result in an outlet temperature 3.3°C (6°F) below the heat pump inlet. Even in warmer climates, caution is necessary to ensure that pumping rates are adequate and that the reservoir is large and deep enough to prevent the water temperature from falling below 5.6°C (42°F).

8. HYBRID GROUND-SOURCE HEAT PUMP SYSTEMS

Ground-source heat pump systems offer an attractive alternative for both residential and commercial heating and cooling applications due to their higher energy efficiency compared to conventional systems, but their higher first cost has been a significant drawback to wider acceptance of the technology. This is especially true in commercial and institutional applications, where the vertical GHE is commonly preferred. These types of buildings are generally cooling dominated and therefore reject more heat to the ground than they extract on an annual basis (Fig. 4). As a result, the required GHE length is significantly greater than the required length if the annual loads were balanced. One option to reduce the size of the GHE, and therefore the first cost of the system, is to balance the ground thermal loads by incorporating a supplemental heat rejecter into the system. GSHP systems that incorporate a supplemental heat rejecter have been referred to as hybrid GSHP systems.

Supplemental heat rejection can be accomplished with a cooling tower, fluid cooler, cooling pond, or pavement heating system. Currently suggested design methods for hybrid GSHP systems attempt to size the GHE based on the annual heating load and then size

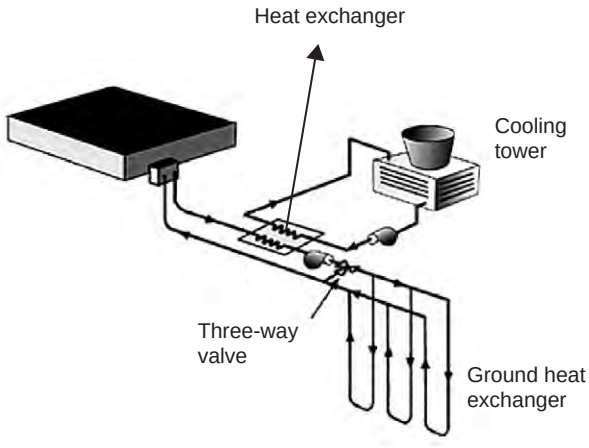

FIGURE 4 Cooling-tower supplemental for cooling-dominated loads.

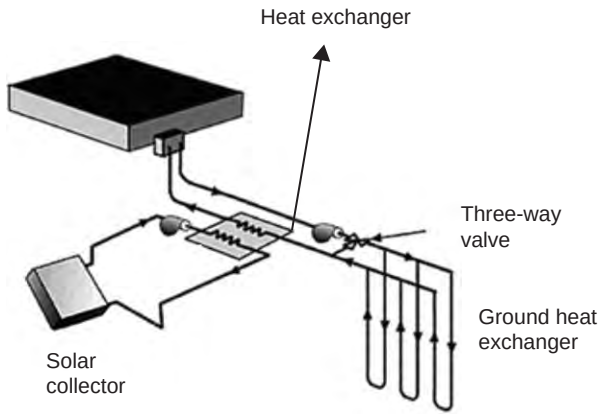

FIGURE 5 Solar-assisted system for heating-dominated loads.

the supplemental heat rejecter to balance the annual ground loads. However, the design of the system components also depends on the strategy used to control the supplemental heat rejecter. A smaller supplemental heat rejecter operated for more time may reject the same amount of heat as a larger supplemental heat rejecter operated for less time. Hence, a balance between the size of GHE, the size of the supplemental heat rejecter, and the control strategy is required to achieve the best economic alternative.

In northern climates, where the heating load is the driving design factor, supplementing the system with solar heat can reduce the required size of a closed-loop ground-coupling system. Solar panels, designed to heat water, can be installed into the ground-coupled loop (by means of a heat exchanger or directly), as illustrated in Fig. 5. The panels provide additional heat to the heat transfer fluid. This type of variation can reduce the required size of the ground-coupled system and increase heat pump efficiency by providing a higher temperature heat transfer fluid.

9. PERFORMANCE EVALUATION OF GROUND-SOURCE HEAT PUMPS

The energy performance of a GSHP system is influenced by three primary factors: the heat pump unit, the circulating pump or well pumps, and the GHE. Designers often devote more energy and resources to the GHE because it is a novel component to most heating, ventilating, and air-conditioning (HVAC) engineers. When the GHEs are correctly designed and installed and high-efficiency extended range heat pump units are specified, GSHPs are extremely efficient. Thus, the high demand and energy use of pumps that may result from unnecessary oversizing, restrictive piping, and poor control are especially noticeable.

9.1 Heat Pump Unit

The heat pump is the largest single energy consumer in the system. Its performance is a function of the efficiency of the machine and the water temperature produced by the GHE or well (either in the heating or cooling mode). The most important strategy is to start with an efficient heat pump. It is difficult and expensive to enlarge a GHE to improve the performance of an inefficient heat pump.

The purpose of rating the efficiency of a heat pump unit is to indicate the relative amount of energy needed to provide a specific heating/cooling output. The more efficient the equipment, the less energy will be used to do the same job. Many of the terms used in the heating, air-conditioning, and refrigeration industry convey performance and efficiency. Among these, four terms, the coefficient of performance, the energy efficiency ratio, the seasonal energy efficiency ratio (SEER), and the heating seasonal performance factor (HSPF), are widely used for these purposes in the United States and are currently rated by the American Refrigeration Institute (ARI). Although codes and standards identify minimum efficiencies, they do not fully communicate the energy efficiency that is achieved by today's heat pumps. A review of manufacturers' literature on commercially available equipment indicates that cooling efficiencies (EERs) of 12.0 to 16.8 Btu/Wh and heating efficiencies (COPs) of 3.0 to 4.3 are readily available (to convert the EER rating to the COP, divide the EER rating by 3.413). In the United States, heat pumps are rated on tonnage (i.e., 1 ton of cooling power produced by 1 ton of ice is equal to 12,000 Btu/hour, or about 3.51 kW).

When comparing equipment efficiencies, it is important to make an appropriate comparison. The efficiency of any heating and cooling equipment varies with application, load, and related heat-source and heat-sink temperatures. Furthermore, standard ratings are for specific conditions and operating conditions. It is highly recommended that the ratings systems be used only to compare one type of equipment to another. The performance of equipment rated in one standard should not be compared with the performance of units rated in another standard. The ratings of water-to-air heat pumps

should not be compared with equipment rated by the air-source heat pump standard, which is much more complex and optimistic.

The actual performance of the equipment is a function of the water temperature produced by the GHE, which is a function of the ground temperature, the pumping energy, and the design of the GHE. In other words, the entering water temperature (EWT) of the heat pump unit is perhaps the single most representative parameter of the GSH effectiveness and heat pump loading. For example, in a region where the local ground temperature is 16°C and the GHE is designed for the customary 11–14°C above ground temperature, a heat pump rated at an EER of 16.8 would actually operate at an EER of 14.2 under peak load conditions. A poorly designed GHE that forces the unit to operate at 17°C above ground temperature would reduce the value to less than 13.0. These are for the cooling operation, which is the dominant load in commercial applications. However, the same relationship holds for heating operations. Besides this, systems with inadequate GHE capacity will have excessively high EWTs in summer and excessively low EWTs in winter.

9.2 Circulating Pump

The energy performance of the system is also influenced by the pumping energy required to circulate the fluid through the heat pump and the GHP. In the design of GSHP systems, the benchmarks given in Table II are proposed for pumping power for commercial GCHP systems. These benchmarks are for judging the effectiveness of a pumping and piping system design for a minimum of 0.162 m^3/kWh of cooling, with optimum pumping flow rates ranging from 0.162 to 0.192 m^3/kWh of cooling. Higher rates require excessive pump power, and lower rates limit the heat pump. In addition, pumping energy should range between 6 and 7% of the total system energy used.

TABLE II

Benchmarks for GSHP System Pumping Efficiency[a]

Watts (input)		Performance	
Per ton	Per kilowatt	Efficiency	Grade
≤50	≤14	Efficient systems	A: Excellent
50–75	14–21	Acceptable systems	B: Good
75–100	21–28	Acceptable systems	C: Mediate
100–150	28–42	Inefficient systems	D: Poor
>150	>42	Inefficient systems	E: Bad

[a] Required pump power to achieve cooling capacity.

To put the values given in Table II into perspective, consider an office building with a 175-kW cooling load and heat pump units selected to operate at an EER of 14 under peak conditions. With an efficient circulating pump design (10 W/kW), the energy demand of the circulating pump would amount to 175 kW × 10 W/kW = 1750 W. Combining the heat pump demand with the heat pump unit demand results in a system EER of 13.5. The same building and equipment coupled to a poorly designed pumping system consuming 34 W/kW would yield a system EER of only 12.2, thus compromising the premium paid for the higher efficiency equipment.

9.3 Ground Heat Exchanger

The design of GHEs is complicated by the variety of geological formations and properties that affect thermal performance. Proper identification of materials, moisture content, and water movement is important. Careful consideration of the interaction between these three components and their impact on system performance is necessary in order to minimize operating costs for the building owner.

The key parameter for GHE layout is the specific performance, i.e., the heat extraction rate during the heating season or the heat rejection rate during the cooling season in watts per meter of borehole (or meter of borehole per kilowatt) for vertical GHEs (or length of buried pipe loop for horizontal GHEs). The heat rejection rate ranges from 40 to 100 W/m, with a typical average of 55–70 W/m in mid-European countries. Based on a study that covered the 22 GSHP systems in the United States, for closed-loop systems, the GHE pipe length ranged from 20.5 to 52.0 m/kW_t, with an average of 39.3 m/kW_t. Of those with vertical bores, the range is 14.4–17.7 m of bore per kW_t.

The impact soil type and moisture content on the performance of GSHPs has recently been reported by some investigators. The length of a GHE can be reduced by using sand or thermally improved bentonite grout instead of standard bentonite grout. It can be concluded that using thermally enhanced materials instead of standard ones decreases the required GHE length by 15–20%. For applications in combination with other heat sources, the specific performance may differ considerably. Therefore, it is

essential to obtain a second parameter, i.e., the specific heat extraction per meter of borehole length for a year. This value ranges between 50 and 200 kWh/m per year for mid-European facilities.

GHEs and associated components have significantly different characteristics compared to other types of HVAC heat exchangers; these differences impact the selection of flow rates, allowable head losses, and piping materials. GSHP piping design may be affected by the following special factors:

1. The ground provides by far the greatest resistance to heat flow; thus, highly conductive pipe materials, extended surfaces, and high internal fluid velocities are of little value.
2. Because the fluid must travel through both the building and GHE, rust inhibitor solutions must be acceptable for in-ground use. Thus, a material that does not require toxic inhibitors is necessary.
3. When design guides are followed, high fluid velocities are unnecessary for good heat transfer in the GHE and head losses through the ground coils can be relatively small [<6 ft (2 m) of water].
4. Because high fluid velocities are unnecessary for good heat transfer in the GHE, moderate flow imbalances will have little impact on overall heat exchange.
5. High-efficiency, extended-range water-to-air heat pumps do not require precise water flow control (or high head loss) to operate near maximum efficiency. A $\pm 33\%$ change in water flow rate results in less than a $\pm 2\%$ change in cooling capacity.
6. Because the water coils of extended-range, high-efficiency heat pumps are much larger than water-loop heat pump coils, head loss is relatively small [<12 ft (4 m) of water].
7. Because the combined head losses in the ground coil and heat pump are small [<18 ft (5.5 m) of water], the lengths of the headers, control valve losses, and fitting restrictions have a significant impact on overall system head loss.
8. Because the cost of the recommended piping material (thermally fused high-density polyethylene) is low relative to labor costs, low friction losses can be economically justified as a method of minimizing pump head.
9. Corrosion- and leak-resistant piping material with a minimal number of in-ground joints is critical to high system reliability and life.

Glossary

desert pavement Natural residual concentration of wind-segregated and closely packed pebbles and other rock fragments mantling a desert surface.

Gulf War The international military campaign of "coalition forces" led by the United States to liberate Kuwait, during January–November 1991, from the occupation by Iraq's forces that began in August 1990. "Gulf" refers to the Arabian Gulf, which is also known as the Persian Gulf.

Landsat A series of U.S. satellites designed to obtain and transmit images of the surface of the earth up to 15 m in resolution (detail).

sabkha Flat, low area covered by clay, silt, and sand and often encrusted with salt; it forms in restricted coastal areas of arid and semiarid environments.

sand dune An accumulation of loose sand heaped up by the wind, where there is an abundant source of sand and constant wind.

sand sheet A large plain of wind-blown sand lacking the discernible sides or faces that distinguish sand dunes.

Systeme pour L'Observation de la Terre (SPOT) A French satellite that obtains and transmits images of the earth up to 5 m in resolution (detail).

tarcrete A hardened surface layer composed of surface sand, gravel, and other rock fragments cemented together by petroleum droplets and soot from the plumes of oil well fires (in Kuwait).

Thematic Mapper An advanced imaging system of Landsat 4, 5, and 7 that collects surface radiation in multispectral bands up to 30 m in resolution (detail) and panchromatic (black-and-white) bands of 15-m resolution.

The Gulf War of 1990–1991 resulted in severe environmental effects, which were analyzed using satellite images followed by field observations. Major disturbances were caused by the disruption of the "desert pavement," a layer of pebbles and gravel that protects the fine-grained soil beneath. The disruption was caused by the activities of military personnel including the digging of trenches and pits, building of berms and sand walls, and the traffic of heavy military vehicles. The exposure of fine-grained soil caused the increase of dust storms and the formation of numerous sand dunes that encroached on roads, installations, and farms. In addition, the explosion of over 600 oil wells caused other major environmental hazards. These included the formation of 240 oil lakes in topographically low areas. Also, plumes from the well fires deposited oil droplets and soot, which hardened on the desert surface as a layer of "tarcrete," affecting desert animals and natural vegetation. Nearly one-third of the land surface of Kuwait was impacted by the war. Although some remediation was performed, long-term monitoring is required to fully understand and ameliorate the impacts on the desert environment.

1. DEFINITION OF WAR IMPACTS

Iraq invaded Kuwait on August 2, 1990. On January 17, 1991, international coalition forces led by the United States began a military campaign for the liberation of Kuwait that became known as the Gulf War. These events resulted in numerous environmental impacts on the desert surface of Kuwait. The impacts were identified based on the study and

 © 2004 Elsevier Inc. All rights reserved.

analysis of satellite images. The most significant of these impacts were the results of exploding the oil wells, most of which caught fire. Plumes of smoke and oil droplets were carried by the southward wind and deposited on the desert surface. The resulting layer of hardened tarcrete disrupted natural vegetation. Some of the exploded oil wells did not catch fire and the oil seeped to form vast lakes. The oil-soaked lake beds continue to be an environmental hazard more than a decade later.

In addition to oilfield-related environmental impacts, the desert surface was disrupted by military troop actions. Disruption of the surface layer occurred due to the passage of heavy military vehicles, digging of trenches, building of berms, etc. All these activities exposed fine-grained material from below the protective layer of pebbles known as desert pavement. Exposure of the fine-grained soil to wind increased dust storms as well as the number and size of sand dunes.

An understanding of the nature of the desert surface in Kuwait is necessary to appreciate these environmental impacts. For this reason, a description of the general setting of Kuwait and the characteristics of its surface is given, followed by an assessment of the prewar conditions based on comparisons of satellite images obtained before and after the Gulf War. The major impacts are described with this background in mind. Recommendations are given for monitoring the changes and remediation of the environmental problems.

2. GENERAL SETTING

Kuwait is an arid country that lies along the northwestern corner of the Arabian (Persian) Gulf, bordering Saudi Arabia to the south, Iraq to the north and west, and the Gulf to the east (Fig. 1). The surface topography of its 17,818 km is marked by flat to undulating gravel-covered plains that slope gently eastward from a maximum elevation of 284 m (above mean sea level) in the west.

During the past three decades, rainfall ranged from less than 25 mm in 1964 to 375 mm in 1972, with an average of 115 mm per year. The precipitation infiltrates rapidly, leaving no permanent surface water, although some wadis fill temporarily with water from winter rains. The largest of these is Wadi Al-Batin, which is 5 km in width at the western border

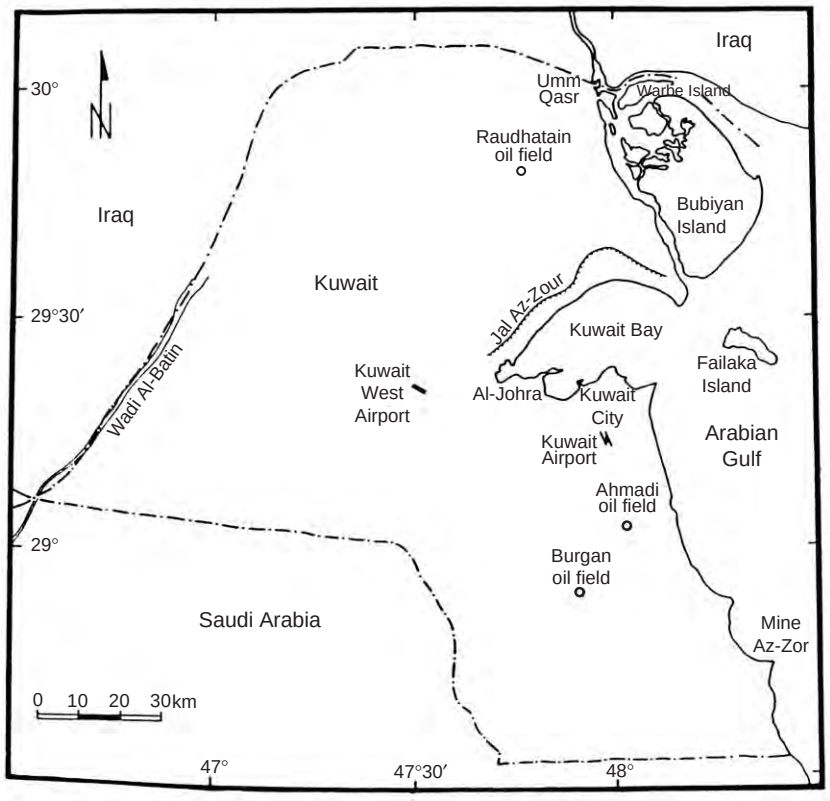

FIGURE 1 Sketch map of Kuwait showing its major features.

of the country. This wadi is part of a partially buried, water-dug channel whose tributaries drain part of the Hijaz Mountains 850 km to the southwest in Saudi Arabia. It was proposed to name the complete channel the Arabia River, whose delta deposits form much of the land surface of Kuwait (Fig. 2).

As mapped by the U.S. Geological Survey, Kuwait consists of flat-lying Tertiary rocks overlying gently folded Cretaceous and Jurassic formations. Exposed rock types include the Eocene Dammam formation, a white, fine-grained cherty limestone that shows some karst development at its contact with the overlying Miocene and Pliocene age Fars and Ghar formations, which are primarily calcareous sandstones, sandy limestones, clay, and sand. Completing the section above the Fars and Ghar formations is the Dibdiba formation, which is composed of sandstone. Quaternary deposits include lag gravels that blanket much of the interior of Kuwait and coastal deposits including unconsolidated marine sands, mudflats, and supratidal sabkha surfaces.

Structurally, Kuwait lies on the Arabian Shield, an area noted for its stability since Cambrian times. The Shield tilts slightly to the northeast, giving rise to sedimentation of the Arabian Shelf consisting of a sequence of laterally extensive but thin limestones, marls, shales, sandstones, and evaporites. North–south trending anticlinal structures, developed with gentle warping and uplift, serve as traps for Kuwait's oil reserves. In addition to this warping, there is evidence of salt diapirs with magnetic low signatures on the anticlinal structures.

Topographically, Kuwait is a flat sandy desert that may be divided into two parts. The north is a vegetated stone desert with shallow depressions and low hills running northeast to southwest and ending near an area of underground water storage. The principal hills in the north are Jal Az-Zor (145 m) and the Liyah Ridge. The southern region is a bare plain covered by sand; the Ahmadi Hill (125 m) is the sole exception to the flat terrain. In addition to Wadi Al-Batin, the only other valley of note is Ash-Shaqq, a portion of which lies within the southern part of the country and the rest in Saudi Arabia.

Morphologically, east of Wadi Al-Batin (along the borders between Kuwait and Saudi Arabia; Fig. 1) the desert surface is composed of a calcretic plain. This unit is composed of rock debris surrounding hills and gravel ridges. Often, parts of the unit are covered with a crust of saline or alkaline soils. The largest morphological unit of Kuwait lies east of the calcrete unit and northeast of Wadi Al-Batin. In this unit, the

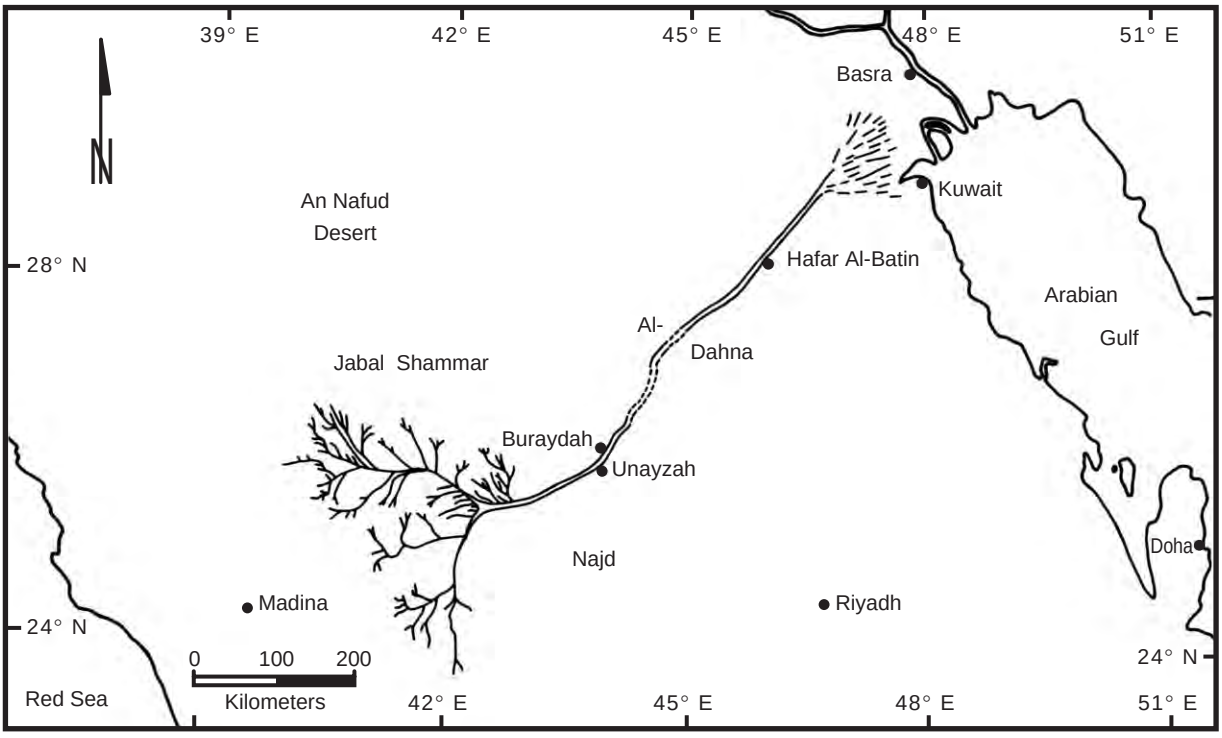

FIGURE 2 Schematic illustration of the tributaries and partly sand-buried channel of the "Arabian River." Note that western Kuwait is part of the ancient delta of the river.

terrain is rugged and composed mainly of a vegetated sand sheet, locally referred to as the Al-Huwaimliyah plain. The ruggedness is caused by the accumulation of sand in the lee of the wind behind desert shrubs. Spaces between the sand piles are composed of a thick bed of wind-blown sand. Therefore, destruction of the vegetation by extended droughts, overgrazing, or vehicular overuse results in the mobilization of sand in the otherwise stable sand sheet.

Northern Kuwait is covered by a vast plain with particles ranging in size from 4 to 10 mm in diameter. This unit is considered a desert pavement of lag gravels, which are fragments of rock too large to be moved by the wind and therefore "lag" behind the finer particles that move with the wind. Their concentration varies from scattered pebbles to densely packed accumulations of pebbles and granules. The predominance of the unit in northern Kuwait is largely attributed, in the literature, to the occurrence of the gravelly Dibdiba formation, which outcrops in northern Kuwait and southern Iraq. However, I propose that the gravel originated in western Saudi Arabia and was transported through the channel of the Arabia River through Wadi Al-Batin (Fig. 2). This is largely based on an apparent provenance of the gravel; rocks from which the gravel may have originated abound in the Higaz Mountains of western Arabia (Fig. 2).

From the characteristics of the desert pavement of Kuwait, it is clear that gravels were first moved by water currents and deposited in a sheet together with finer fractions, which were later blown away by deflation. As a result of the continuous deflation, pebbles and granules were concentrated on the surface until a deflation armor or desert pavement was acquired. The gravel ridges were formed by reversed topography as a result of the preferential deflation of flood plains dissected by fluvial channels in the fan-shaped delta of Wadi Al-Batin.

The coastal zone of Kuwait is composed mainly of sabkha deposits. These are flat areas of clay, silt, and sand that are often encrusted with salt. Along the coasts of Warba and Bubiyan islands, the supratidal flats are covered by thin laminae of sandy mud encrusted by a thin lithified crust. Large areas of sabkha are composed of extensive sheets of mud with almost no relief and flourishing mangroves.

3. PREINVASION CONDITIONS

During the two decades before 1990, developing land for agriculture had increased dramatically in Kuwait. This increase in agricultural activity resulted in the disruption of the desert pavement in developed areas and the exposure of soil to wind action. This, in turn, increased the amount of dust in the air and the movement of sand and its accumulation in mobile dunes. In addition, increases in dust and sand storms in the northern Gulf region were noticed in the 1970s due to major agricultural expansion in the Western Desert of Iraq. Satellite images clearly show that dust storms in southwestern Iraq spread over the eastern part of the Arabian Peninsula.

Similarly, growth of urban communities results in the disturbance of the stable desert surface. Most of the environmental effects of urbanization occur during digging, when soils are exposed to eolian erosion. Such efforts were particularly obvious during the expansion of Al-Jahrah, a community west of Kuwait City (Fig. 1).

Farther inland, disruption of the desert surface from the oil industry resulted from exploration and development activities, including geophysical surveys, drilling operations, building of roads, and laying of pipelines. These activities usually require a large number of vehicles, which criss-cross the desert surface affecting both the desert pavement and the scant desert vegetation.

For example, the aforementioned morphological unit of Al-Huwaimliyah plain, the vegetated sand sheet, extended into the Burgan oil field in south central Kuwait (Fig. 1). This area was badly degraded due to excessive vehicular activities and the desert surface was disturbed. Because disturbances of this type mobilize the sand, vehicular traffic in the open desert in Burgan field had been prohibited during the 6 years prior to the invasion of 1990. Due to this prohibition, vegetation began to flourish and the sand sheet was once again stabilized.

Military installations in the open desert also had some impact on the environment of Kuwait's desert prior to the Gulf War. Military bases have greatly suffered from the effects of destabilizing the desert surface in terms of having to constantly alleviate the effects of sand accumulations around buildings and their entrances. The study of sand deposits within Ali Al-Salem and Ahmad Al-Jabir bases provided insights into accumulations on roads. Three cases of pavement profiles on a slightly raised bed were considered: a flat pavement, one in which the underlying bed was slightly elevated on the upwind side of the road, and another with the elevation on the downwind side of the road (Fig. 3).

In all three cases, sand accumulated on either side of the raised roadbed; regardless of its slight elevation, a roadbed represents a topographic

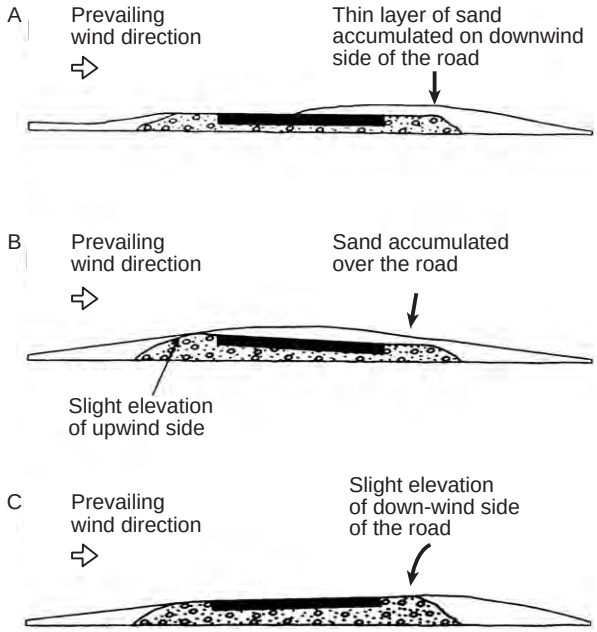

FIGURE 3 Deposition of sand along a road with a horizontal profile (A), an upwind elevation (B), and a downwind elevation (C). Modified from Fikry Khalaf.

impediment to the wind. In the case of the flat roadbed and pavement, sand accumulated on the downwind side of the road. The road with a slight elevation upwind was completely covered by sand because vorticity of the wind as it was confronted by the raised roadbed caused deposition of its sand load. In the case of the slight elevation of the roadbed and pavement on the downwind side, the road remained free of sand. In this case, the wind energy was increased as it moved upslope and carried the sand with it across the road to be deposited beyond the downwind elevation of the roadbed.

In the future, similar precautions and protective measures will have to be taken to safeguard installations in the open desert, such as roads, airport runways, helicopter pads, oil wells and storage tanks, checkpoints, and residential sites in the oil fields of Kuwait. Each site will have to be considered separately because remedies may differ due to local topographic characteristics, the nature of the desert surface, and the potential of particle transport by the wind.

4. POSTWAR EFFECTS

The physical effects of the Gulf War on the desert surface of Kuwait are numerous. Satellite images were used to identify these effects and to quantify their extent. NASA's Landsat Thematic Mapper images with a 30-m resolution were used in conjunction with Systeme pour L'Observation de la Terre (SPOT) images at 10-m resolution.

The variety and extent of environmental damage due to the Gulf War were characterized mainly through "change detection." In this process, an image of a specific area is compared to another image of the same area taken at a different time; the change from one image to another is computed. In this case, four Landsat images of Kuwait obtained in 1989 (prior to the invasion) were compared to four taken in 1992, upon cessation of the last oil well fire.

Most people are familiar with the horrific images of burning oil wells, which resulted from the wanton explosion of Kuwait's 700 oil wells by the Iraqi troops prior to their withdrawal. Naturally, this tragedy resulted in severe environmental effects, particularly spewing smoke and oil particles in the atmosphere for nearly 1 year. There were numerous other environmental effects, which are discussed in the following sections.

4.1 Vehicle Tracks

The movement of a great number of tanks and mechanized vehicles on the natural surface of Kuwait adversely impacted the desert pavement, particularly in the western part of the country. During the invasion, columns of Iraqi military equipment moved along parallel lines both inside and just west of the border of Kuwait. Such heavy equipment forces the surface cover of pebbles and cobbles deep into the sand and excavates large amounts of soil on either side of the tracks.

The net result of vehicle movement on a naturally packed surface is the decrease in the closeness of packing of sand grains. This phenomenon increases the potential of grain movement by the wind, resulting in the mobilization of previously protected fine particles. The spread of newly exposed soil on either side of the tracks allows for their detection on satellite images, even if the resolution of the images is less than the width of the tracks (Fig. 4).

During occupation, most of the troop movements were along paved roads. However, some areas were trampled by military vehicles, causing damage to the desert pavement. This is particularly true in the southwestern and northwestern parts of the country as Iraqi soldiers raised defensive fortifications. In areas covered by a sand sheet, such as in southeastern Kuwait, the tracks of military vehicles have already been covered by drifting sand. On the other hand, areas covered by a desert pavement remained deeply

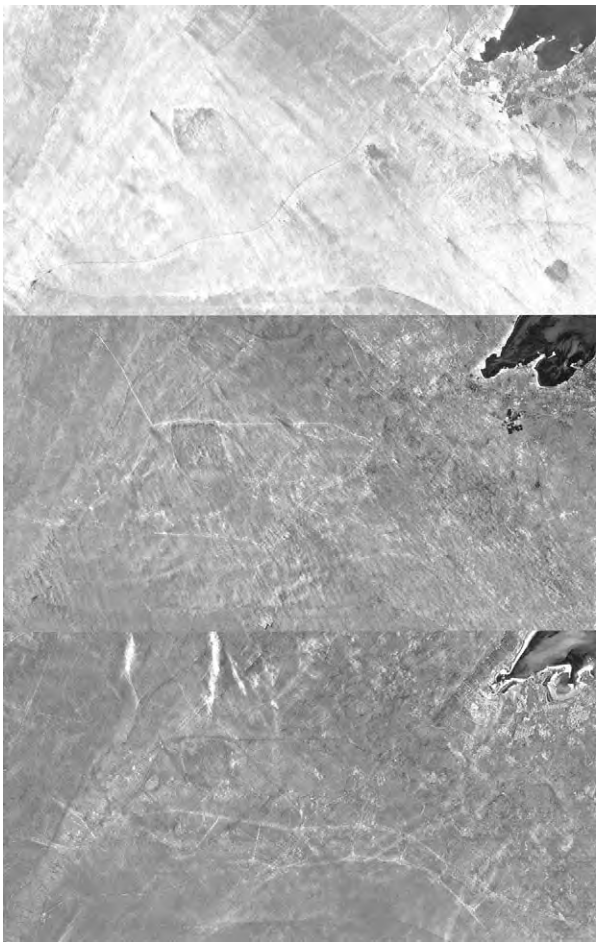

FIGURE 4 Vehicle tracks on the desert surface as depicted on three successive Landsat images of Kuwait's southwestern corner, just east of Wadi Al-Batin. Courtesy of Earthsat Corporation.

scarred, such as north of the Jal Az-Zor escarpment (Fig. 1).

4.2 Trenches and Pits

Iraq's armored forces spent much of their time during the fall of 1990 digging trenches in the desert of Kuwait (Fig. 5). This is particularly true along Kuwait's coastline. Beyond the trenches, pits were dug as hiding places for military equipment and storage areas of ammunition.

After the passage of a windy (shamal) season, most pits and trenches had been filled by drifting sand. The ammunition pits that were covered by sand represent a potential danger in the future. These may be identified by the use of ground-penetrating radar so they can be excavated and destroyed. Such procedures would again mobilize the sand for downwind movement if the dug-up areas are not stabilized, for example, by spreading pebbles on top of the exposed soil.

FIGURE 5 A trench dug in the desert surface north of Jal Az-Zor that was partly filled by sand less than 1 year from the end of the Gulf War.

4.3 Berms and Sand Walls

Berms were built in Kuwait's desert to slow the potential advance of liberation forces. The major berms were constructed in the south along the Saudi border, in the central part (south of the Burgam oil field), and in the northern part of Kuwait (north and west of the Jal Az-Zor escarpment). The berm-building activity continued throughout the occupation phase. Iraqi military strategists knew that the sand walls would be eroded by the consistent wind. Therefore, berms were sprayed with crude oil by pipelines that were laid specifically for this purpose from Kuwait's nearby oil fields. These berms represent a source of shifting sand in the long term. Currently, the soil in these berms is stabilized by the hardened oil crust (Fig. 6). However, this crust will gradually be dismantled by wind erosion and the fine-grained sand will be released regularly.

The effects of such berms on the spread of sand on the desert surface are exemplified by the case of the sand wall in Saudi Arabia just south of its border with Kuwait, which was constructed to stop potential smugglers, mostly of liquor. The berm

is less than 3 m high and a few meters wide at the base. However, its sand was mobilized and spread over such a large area (up to 1 km) so as to make it clearly visible on satellite images of 30-m resolution (Fig. 7).

In addition to the berms built by Iraqi military personnel, an extensive berm was constructed during the summer of 1992 by Kuwait's security forces in the northern part of the country. This berm was intended to stop a wave of smugglers and political agitators from Iraq following the cessations of hostilities. Since wind erodes the fine-grained material of the berm, it is constantly maintained by bulldozers. This berm is a source of drifting sand and must be monitored.

FIGURE 6 An oil-covered berm in northern Kuwait built by Iraqi forces. Crude oil was used to stabilize the sand.

4.4 Mines and Ordnance Detonation

The Iraqi military forces planted between 500,000 and 2.5 million land mines in the desert and coastal areas of Kuwait. The mining was done during the occupation phase to hamper the expected liberation of Kuwait by military action. Numerous defense lines were established particularly along the border of Saudi Arabia and the coastline of the Arabian Gulf. In addition, mines were laid in areas of high troop concentrations, particularly in the triborder area near the western corner of Kuwait.

The laying of land mines is a process that results in the disturbance of stabilized soil and exposure of fine-grained material to the action of wind. This is particularly obvious in a minefield along the northern coast of Kuwait Bay (Fig. 1). In this case, the mines

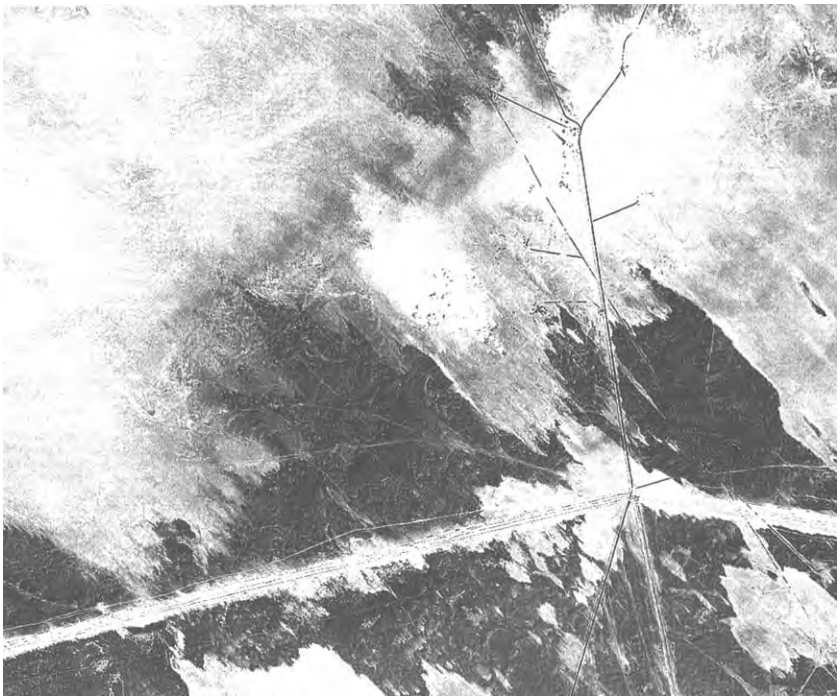

FIGURE 7 Effects of wind erosion on a berm in Saudi Arabia just south of its border with Kuwait. The berm is on the sharp northern edge of the white zone; the wind blowing to the southeast caused the jagged southern boundary due to sand transport downwind. This is part of a SPOT image acquired on May 25, 1992.

were laid in a soil that was stabilized by salt crust. The process of digging the land to plant the mines destroyed the drier crust, resulting in the deflation of the soil layer and exposure of the mines (Fig. 8).

During liberation, several passages were made through the minefield along the southern border of Kuwait. Breakthroughs were made by exploding the mines in groups. This process also disturbed additional stretches of desert pavement. In addition, bombing of Iraqi defensive positions by coalition forces resulted in cratering of the desert surface where bombs missed their targets. Ejecta from the craters exposed much fine-grained soil to the wind. However, because of the accurate targeting these craters are few and far between.

Much of the disruption of the desert surface in the minefields occurred during the postliberation phase as a result of mine detection and detonation. Crews of mine detectors were followed by mine sweepers and/or detonation equipment. The raking of the land and the explosion of mines and undetonated cluster bombs and other ordnance further disturbed the desert surface by exposing fine-grained soil to the wind.

4.5 Oil Crust

As shown in Fig. 9, deposits of oil and soot particles from the plumes of oil well fires were clearly visible in satellite images. When observed in the field, this deposit formed a hardened crust on top of the desert surface. It varied in thickness, with an average of 6 cm; the closer to the center of the deposit, the thicker the crust. Minor variations in the exact orientation of shamal winds caused the spread of the oil rain downwind of the well fires. Naturally, the thicker the deposit, the darker the surface. Minor variations in the spectral reflectance of such deposits were easily depicted on Landsat Thematic Mapper images, and it was possible to correlate the reflectance values to the thickness of the oil crust. Because it represented a new rock formation, this deposit was named tarcrete and defined as a conglomerate consisting of surface sand and gravel cemented together into a hard mass by petroleum droplets and soot.

The total surface area of Kuwait covered by tarcrete was approximately 943 km^2. Particulates in this area had been basically stabilized. Petroleum sprays had been used in the past to stabilize dune sands. Thus, from the standpoint of sand mobility, the tarcrete had a positive impact.

The effects of the tarcrete on plant life must be considered separately. Some plants died from the oil spray. Other species flourished but were not palatable to grazing animals. Furthermore, the salinity of the soil in areas covered by the tarcrete may change with time as sulfur compounds react with moisture to increase soil acidity. For this reason, monitoring of the pH values and other soil characteristics is recommended.

FIGURE 8 Mines exposed by wind erosion of sand along the coast of Kuwait. The minefield was supposed to prevent a marine landing of coalition forces (photograph by Jassim Al-Hassan).

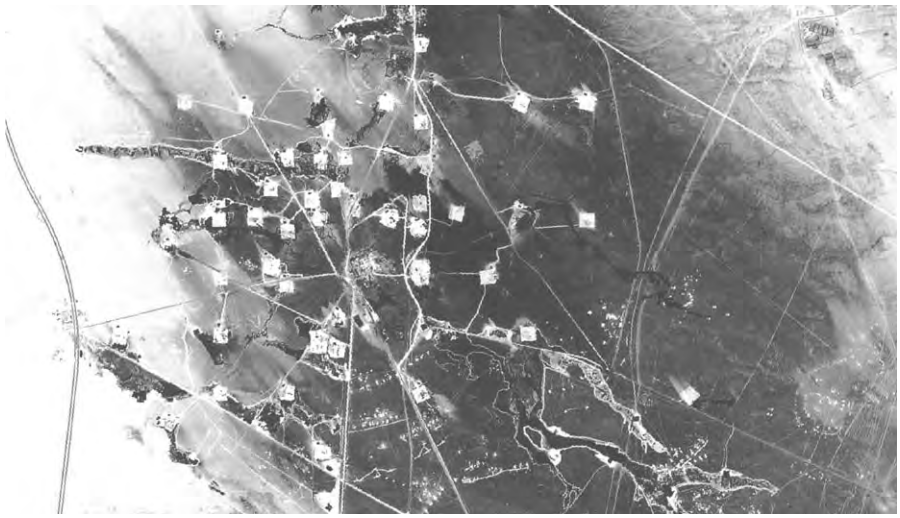

FIGURE 9 Part of a SPOT image acquired on March 25, 1992, of the Raudhatain oil field showing the new dirt roads (white lines) and sand pits around well heads (white squares) that were created during the firefighting operations. Note the oil lakes, which are oriented roughly east–west, within and along the western edge of the darkened surface.

4.6 Oil Lakes

Some of the exploded oil wells did not catch fire, and the seeped oil accumulated in low areas forming lakes (Fig. 9). Smaller oil lakes were also created during the firefighting phase. These lakes were identified using satellite images. The production of accurate maps of oil lakes necessitated the study of Kuwait by both Landsat Thematic Mapper and SPOT as well as maps that were based on field observations. Change detection techniques were used to study the characteristics of oil lakes in Thematic Mapper images. Also, geographic information system correlations of all data sets allowed their accuracy to be checked and the mapped lake boundaries to be confirmed. It was concluded that after a full understanding of the spectral characteristics of the oil lakes in Thematic Mapper images, their accurate mapping could be improved by using the higher resolution SPOT data.

Disregarding patches smaller than $1\,km^2$, the surface area covered by oil lakes in the desert of Kuwait was $35.4\,km^2$ in the fall of 1991, as mapped by the Kuwait Institute for Scientific Research. The total area of oil lakes was $27.5\,km^2$ as mapped from SPOT images obtained on March 25, 1992. The difference between the two measurements is easily ascribed to the shrinkage of the lakes due to the evaporation of aromatic compounds and the seepage of some of the oil into the underlying soil during the intervening months. The larger figure must be used in the estimation of remediation needs because all oil-saturated soil must be treated or removed, replaced, and stabilized.

5. REMEDIATION APPROACHES

It is clear from the previous discussion that the Gulf War has had severe short- and long-term effects on the desert surface of Kuwait and neighboring areas. Short term effects included the following:

1. Evaporation of aromatic compounds such as benzine from the surfaces of the oil lakes created a hazard to humans, animals, and plants.
2. Increased dust storm activity due to the release of fine silt and clay in areas previously protected by course desert pavement increased hazards to aviation in the whole Gulf region. In addition, mineral aerosols in the air constituted a hazard to humans if lodged in the throat, lungs, and eyes.
3. Movement of sand and its accumulation over minefields and ordnance pits hampered the detection of mines and unexploded bombs. In early 1992, several explosions caused severe injury to people and death to grazing animals.
4. The movements of heavy military vehicles as well as the oil and soot from the well fireplumes severely reduced plant cover in the open desert.

Long-term effects include the following:

1. An increase in sand storm activity due to the mobilization of sand-sized particles. Such storms

interfere with all modes of transportation and cause traffic accidents.

2. The formation and movement of sand dunes, which encroach on roads, farms, oil installations, and settlements in the desert. Once a dune is formed, it continues to move as long as the wind blows. For this reason, sand dune encroachment represents a longest term impact on the desert surface of Kuwait.

3. An increase in soil acidity due to the interaction of moisture with remnants of the oil on the desert surface. This increase hampers the rejuvenation of some natural plants.

4. Potential pollution of the groundwater resources from seepage, through fractures, of oil from the stagnating pools of crude petroleum. This represents a long-term impact particularly since agriculture in Kuwait depends solely on groundwater reservoirs.

For these reasons, mitigation of the effects of the Gulf War on the desert surface of Kuwait will require decades for remediation and monitoring of its effects. Remediation approaches include the following:

1. Filling of empty trenches using recently mobilized sand to limit the exposure of sand-sized particles to the action of wind.

2. Leveling of berms and other sand barriers and walls because these structures represent a source of sand for future activation and mobilization by wind.

3. Stabilizing the flattened surface either by increasing desert plant cover or, more efficiently, by spreading gravel on top of the soil to mimic the natural desert pavement.

4. Removing the oil-saturated soil from areas covered by oil lakes to limit potential long-term effects on soil acidity or groundwater pollution.

5. Replacing the removed soil with clean sand to return the land to the original flat contours.

6. Stabilizing the new surfaces by spreading gravel to form the armor against the erosive action of wind.

7. Seeding of areas of the desert that lost vegetation cover using, as much as possible, seeds of natural plants.

6. FUTURE MONITORING

The sources of environmental impacts on the desert surface due to the Gulf War are related to the invasion of Kuwait by Iraqi forces, the activities that persisted during the occupation phase, the initiation of liberating Kuwait by coalition forces and the events that accompanied the retreat of Iraqi troops, and the environmental impact of fighting the oil well fires and the spread of the oil lakes on the desert surface of Kuwait.

Some remediation of the environmental effects of the Gulf War was accomplished during the past decade. This is particularly true in the case of oil lakes. Most of the oil was pumped and bioremediation of the soil was accomplished. However, the more subtle impacts, such as those of sand movement and plant growth, have not been given equal priority. Therefore, the need exists for a long-term effort to monitor these factors and study the best ways to limit their impact on the natural environment.

These impacts can be monitored by use of satellite images, including National Oceanic and Atmospheric Administration satellites to monitor the initiation of dust storms, Landsat Thematic Mapper and SPOT images to monitor sand accumulation and movement, and higher resolution (1 m) satellite images to monitor changes to the topsoil. Interpretations of satellite image data need to be checked and confirmed in the field at specific field stations. At these stations, instruments should be installed to measure the activities discussed in the following sections.

6.1 Dust Storms

The exposure of vast amounts of soil to the action of wind causes an increase in the frequency and ferocity of dust storms. These hamper visibility on roads and at airports and cause respiratory ailments. The need exists to monitor the initiation of dust storms upwind for advance warning of the impending danger.

6.2 Sand Accumulation

The wind carries enormous amounts of sand in the flat terrain of Kuwait. The sand begins to accumulate where the wind regime is affected by topographic impediments. Such accumulations hamper transport and operations in the oil fields and other installations in the desert. Thus, a monitoring system should be established to alleviate the impact of encroaching sand dunes by stabilizing the moving sand with desert vegetation.

6.3 Soil Rejuvenation

The oil rain has caused much damage to the natural desert soils in Kuwait. It is feared that additional harm to the soil might be caused by an increase in acidity. A program needs to be instituted to monitor

soil conditions and characteristics so that a remedy to the potential problem can be carried out in a sustained manner. This can be accomplished by monitoring soil acidity and its treatment wherever pH levels require it.

6.4 Plant Growth

Degradation of the soil has caused much damage to natural desert plants in Kuwait. Some plants have died in areas covered by the oil soot and droplets, and other species have appeared that are not palatable to grazing animals. The growth of plants should be monitored in view of the drastic changes in the desert environment.

Glossary

asphaltenes The part precipitated by addition of a low-boiling paraffin solvent such as normal pentane and benzene-soluble fraction, derived from carbonaceous sources such as petroleum, coal, or oil shale.

boiler slag A black granular material that is coarser than conventional fly ash.

BTEX The BTEX chemicals (benzene, toluene, ethylbenzene, and xylenes) are volatile monoaromatic hydrocarbons that are commonly used in crude petroleum and petroleum products.

characteristic hazardous waste Waste solids, liquids, or containerized gases that exhibit ignitability, corrosivity, reactivity, or toxicity characteristics.

coal bottom ash The coarse, granular, incombustible by-product that is collected from the bottom of furnaces that burn coal.

coal combustion by-products (CCBs) Fly ash, bottom ash, boiler slag, and flue gas emission that are produced when coal is burned.

drilling mud Waste stream associated with drilling operations, including oil-based mud (OBM), synthetic-based mud (SBM), and water-based mud (WBM).

drilling wastes Wastes that are associated with oil exploration and production (E&P).

exploration wastes Wastes that are primarily related to drilling and well completion.

fly ash The fine powder formed from the mineral matter in coal, consisting of the noncombustible matter in coal plus a small amount of carbon that remains from incomplete combustion.

flue gas desulfurization (FGD) gypsum Also known as scrubber gypsum; it is the by-product of an air pollution control system that removes sulfur from the flue gas in calcium-based scrubbing systems.

fossil fuels The biomass that produces coal, gas, oil, and tar sands.

heavy crude Crude oil that contains a relatively high portion of residuum.

listed hazardous wastes Wastes from nonspecific sources and wastes from specific sources and discarded commercial chemicals.

methyl tertiary-butyl ether (MTBE) MTBE is a gasoline additive and is highly water soluble.

naphtha The petroleum fraction ranging from low-boiling C_4 hydrocarbons to those boiling as high as approximately 220°C.

polycyclic aromatic hydrocarbons (PAHs) Often referred to polynuclear aromatics (PNA); they are a class of very stable organic molecules composed of only carbon and hydrogen.

produced water Water produced in association with crude oil.

proppants/frac sand wastes Semisolid sludge consisting of aluminum silicate beads and formation sand.

residuum The petroleum fraction boiling above 343°C.

Superfund A commonly used name for the federal Comprehensive Environmental Response, Compensation and Liability Act (CERCLA).

 © 2004 Elsevier Inc. All rights reserved.

tank bottom wastes Sediment that accumulates in the bottom of oil field vessels and pipelines when fluid turbulence is low.

waste oil Oil arising as a waste product of the use of oils in a wide range of industrial and commercial activities.

workover and completion wastes Wastes from operations in which an oil well's head is partially open to the atmosphere and is filled with a water-base fluid that maintains pressure on the formation to prevent blowout.

The world uses two basic fossil fuels for everyday life. Coal production is used mainly for the production of electricity and petroleum products are mainly used for transportation. The population of the United States uses an amount of fossil fuel in one year that took nature approximately one million years to produce! There are major environmental problems involved with the production, transportation, and consumption of these fossil fuels. Petroleum production has environmental problems at every stage of production, transportation, and consumption. During production, the waste products include drilling mud, drill cuttings, chemical additives, and produced water. In fact, there are 7.5 barrels of produced water for one barrel of oil. The main environmental problem of petroleum refining and storage include oil process wastes and leakage of the storage tanks. Pipeline leaks are also among major environmental issues for transportation of petroleum products. The production of coal requires mining operations. The initial mining virtually ravages the land. The processing of the coal leaves large amounts of tailings and other by-products. Additionally, the use of coal causes major problems with air quality. The fact that the United States uses one billion tons of coal annually for electricity alone is an extremely large environmental problem.

1. OVERVIEW OF THE FOSSIL FUEL CYCLE

Energy fosters human activities and is a necessity for modern life. Energy heats and cools buildings, powers industries, fuels transportation system, etc. All energy on Earth comes from the sun, which contributes to the formation of biomass. The biomass produces decay, which becomes buried in sediments, thereby produces coal, gas, oil, and tar sands. These are called fossil fuels. Figure 1 illustrates a detailed fossil fuel cycle. Fossil fuels are nonrenewable. In 1 year, mankind expends an amount of fossil fuel that took nature approximately 1 million years to produce.

Energy production from fossil fuels can create major environmental problems at every stage of production, transportation, and consumption. Fossil fuels pose risks to the environment. In this article, we discuss the wastes that are associated with fossil fuel in its production, transportation, and consumption.

2. WASTES ASSOCIATED WITH PETROLEUM AND ITS PRODUCTS

Petroleum is derived from Latin *petra*, meaning rock or stone, and Latin *oleum*, meaning oil. Crude oil is a natural occurring material extracted from formations beneath the earth via established drilling production processes. Crude oil refining operations involve extracting useful petroleum products that include naphtha, middle distillate, and residuum. The petroleum fraction ranging from low-boiling C_4 hydrocarbons to those boiling as high as approximately 220°C is called naphtha, which is used primarily in gasoline production. The petroleum fraction boiling from approximately 150 to 343°C is called middle distillate and is used for jet fuel, diesel fuel, and home and commercial heating oils. The petroleum fraction boiling above 343°C is called residuum. The portion that boils from approximately 343 to approximately 566°C is called vacuum gas oil and has no natural market. Material boiling above 566°C is called vacuum residuum, which is a heavy and tarry substance containing a heavier asphaltene fraction.

If crude oil contains a relatively high portion of residuum, it is called heavy crude. Residuum is burned as an industrial fuel in power plants and in ship boilers or is asphalted to make road material. Since gasoline is in great demand, petroleum processes convert lighter fractions (reforming processes) and heavier fractions (cracking processes) to gasoline-range products.

The petroleum industry produces a large percentage of the United State's hazardous waste sites. Various wastes are generated during petroleum exploration, production, and refining. During exploration and production, large quantities of low-toxicity solid waste and wastewater are produced.

In the United States, petroleum production and transportation result in the leakage of approximately 280 million barrels of petroleum (crude oil) each, creating serious environmental problems. Petroleum refinery wastes result from processes designed to

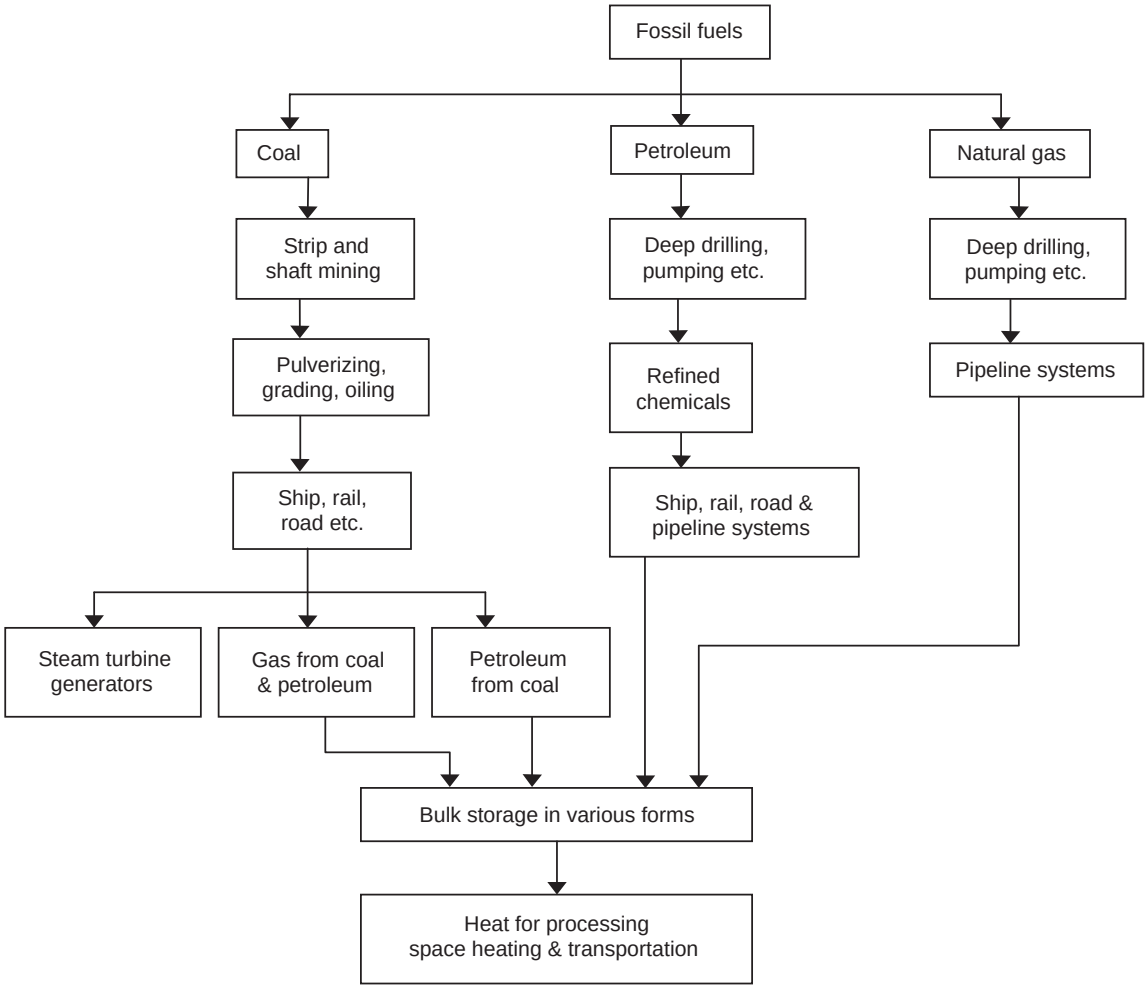

FIGURE 1 Detail of the fossil fuel cycle.

remove naturally occurring contaminants in the crude oil, including water, sulfur, nitrogen, and heavy metals. The waste streams from refineries are smaller but are considerably more toxic, containing listed hazardous waste and characteristic hazardous waste. In addition, poor housekeeping practices during exploration, production, and refining can produce excessive waste.

2.1 Waste from Exploration, Production, and Refining

Oil exploration and production (E&P) operations generate large volumes of drilling waste every year.

2.1.1 Waste from Petroleum Exploration

Exploration wastes are primarily related to drilling and well completion. Table I lists oil production, drilling, and exploration waste streams. Between 1986 and 1995, an average of 313 wells were drilled each year. Drilling operations generate more than 1000 tons of drilling waste per well. This means that more than 300,000 tons of drill cuttings may be produced each year. In addition, the American Petroleum Institute (API) survey of onshore and coastal operators in the United States estimates that approximately 149 million barrels (bbl) of drilling waste (17.9 million bbl of produced water and 20.6 million bbl of other associated wastes) were generated from E&P operations in 1995. The API has also estimated that the average volume of produced water was approximately 7.5 barrels of water per barrel of oil in 1995.

Drilling wastes include drilling mud, drill cuttings, wash water, and chemical additives (Table I). Drilling mud comprises the largest waste stream associated with drilling operation. There are three types of

TABLE I

Oil Production, Drilling, and Exploration Waste Streams[a]

Produced water	
Benzene	Hydrocarbons
Toluene	Radioactive pollutants Ra^{226} and Ra^{228}
Miscellaneous surface water	
Snowmelt and precipitation	Engine coolant
Runoff from cleaning vehicles and shops	Unused cement slurry
Rigwash	
Drilling mud	
Heavy metals	Chlorides (including potassium chloride, sodium chloride, calcium chloride, and magnesium chloride)
Polynuclear aromatic hydrocarbon components (OBM only)	
Barium, gypsum, barites	Clays (bentonite, kaolinities)
	Additives (biocides, scale inhibitors, corrosion inhibitors)
Drill cuttings	
Pieces of rocks and sand	Soil and wet sludge containing oil and water
Workover and completion waste	
Well completion, treatment and stimulation fluids	Fracturing media
Surfactants	Used filters
Weighting agents/viscosifiers	Biocides
Thinners	Packing fluids
Muds (WBM or OBM associated with workovers)	Detergents
Produced water (associated with workovers)	Defoamers
Crude oil	Paraffin
Acidizing agents	Sludges
Corrosion inhibitors	Pieces of downhole equipments
Gels	Intermaterial from downhole mechanical repair (produced sands, formation or pipe scale, cement cutting, and slurries)
Solvents	
Paraffin solvents and dispersants	
Proppants/frac sand	
Semisolid sludge containing the aluminum silicate beads along with formation sand	
Bottom waste	
Solids	Accumulated heavy hydrocarbons (asphaltic or paraffin)
Sands	Drilling mud
Emulsions	Semisolid waste
Pigging wastes	
Produced water	
Oily debris, spent filters, and spent filter media	
Rags	Sand
Sorbent materials	Diatomaceous earth
Water with surfactant (backwash)	Particulates
Oil	Socks
Coal	Cartridges
Gravel	Canisters
Hydrocarbon wastes	
Dirty diesel	Organic halides
Hydrocarbon-bearing soil	Hydrocarbon solids
Camp wastes	
Surplus paints	Wood cribbing supporting temporary pipelines
Batteries	Thread protectors from pipe ends
Light bulbs	Drums for chemical storage

continues

Table I continued

Radioactive smoke detector elements	Oil and air filters on vehicles
Wood pallets	Vehicle lube oil
Fabric pit liners	
Ozone-depleting chlorofluorocarbon	
Halons	Freon
Naturally occuring radioactive materials	
Spent filters	Produced water
Contaminated soil	Completion waste
Camp waste	Hydrocarbon waste

[a] Abbreviations used: OBM, oil-based mud; WBM, water-based mud.

drilling mud: oil-based mud (OBM), synthetic-based mud (SBM), and water-based mud (WBM). Most onshore wells are drilled with WBM or OBM. The key constituents of OBM, SBM, and WBM contaminated cuttings are summarized in Table I. The leachability, runoff, and seepage of heavy metals, chlorides, and the total polyaromatic hydrocarbons degrade the soil and contaminate groundwater, fish, and shellfish. Through the consumption of contaminated fish and shellfish, they can also endanger human health.

2.1.2 Waste from Petroleum Production

Production operations generate massive quantities of produced water. Produced water—water produced in association with crude oil—is by far the largest waste stream in most oil fields. The volume of produced water far exceeds the volume of drilling wastes (approximately 60 times more). The produced water is discharged into surface waters, injected underground, or transported to a commercial oil field waste disposal facility. The majority of produced water is disposed of underground through injection wells, which is allowed by the U.S. Environmental Protection Agency (EPA).

Produced water and drilling fluids could damage agricultural land, crops, ephemeral streams, and livestock and threaten endangered species, fish, and other aquatic and bird life. Metals and polycyclic aromatic hydrocarbon (PAH) discharge cause contamination of aquatic and bird life. Also, improper functioning of injection wells can degrade groundwater. In addition, oil field waste disposal facilities pose significant risk to migratory birds and other wildlife.

Workover and completion wastes result from operations in which an oil well's head is partially open to the atmosphere and is filled with a water-based fluid that maintains pressure on the formation to prevent blowout. Excluding the fluids that were disposed via on-site underground injection, the API calculates that U.S operators generated approximately 5.6 million bbl of completion and workover fluids in 1985. More current data are not available.

The environmental impact related to injection of workover and completion fluids is the potential migration of wastes to underground drinking water sources. Also, seepage of native brines from improperly plugged, unplugged, and abandoned wells could damage groundwater, agricultural land, and domestic and irrigation water.

Tank bottom wastes are a type of sediment that accumulates in the bottom of oil field vessels and pipelines when fluid turbulence is low. Tank bottom wastes are generated continuously at nearly all oil production operations. Oily debris saturated with crude oil comes from oil spill cleanups (minor and major) and spent filter and filter media waste comes from filtering crude oil. According to the API, U.S operators generated a total of 1.5 million bbl of bottom tank wastes and oily debris in 1985. From this total, 1,232,000 bbl (42 U.S. gallons per barrel) were bottom tank wastes and 1,261,000 bbl oily debris.

Potential environmental impact of tank bottom wastes and oily debris may come from landspreading, roadspreading, on-site pits, and on-site burial. The potential impact of landspreading and roadspreading may be a risk of off-site migration of constituents of concern due to surface water run-on and runoff. In addition, off-site transportation could result in high oil and grease concentration wastes to soil and/or vegetation. Also, on-site pits and on-site burial could potentially impact groundwater due to downward migration of constituents of concern and also surface water and soils.

Proppants/frac sand wastes are related to the aluminum silicate beads that are injected into wells to hold formation fractures open, along with formation sand, that together form a semisolid sludge. Hydrocarbon wastes such as dirty diesel fuel are contaminated from pressure testing pipelines. Camp wastes are equivalent in quantity to those of small municipalities.

Ozone-depleting chlorofluorocarbons (CFCs) are used in oil and gas production as a fire and explosion suppressant. Naturally occurring radioactive material is produced in solution with oil field brines and deposited as scale on the inside of oil field vessels and piping. Its radioactivity (rated as "low specific activity" by the Nuclear Regulatory Commission) poses a hazard if it is inhaled as a dry dust during vessel and pipe cleaning or repair.

2.1.3 Waste from Petroleum Refining

Table II shows the waste generation data for petroleum refineries as given by the API survey of U.S. refineries. The major sources of wastewater in petroleum refinery are cooling tower blowdown, boiler blowdown, oily wastes, and other process wastes. Solid wastes from refineries are also a significant problem.

In 1976, Congress enacted the Resource Conservation and Recovery Act (RCRA) for reduction of hazardous waste. This early hazardous waste legislation imposed "cradle to grave" liability on waste generators for the waste that they produce and dispose of. In 1984, Congress passed the Hazardous and Solid Waste Amendments (HSWA), which amended RCRA in an attempt to reduce groundwater contamination by banning or regulating landfill disposal of specific listed hazardous wastes. The refining sector of the petroleum industry generates both HSWA listed and other hazardous wastes. Five refinery solid waste streams are listed hazardous wastes by the EPA and subject to HSWA regulations: dissolved-air-flotation floating solids (K048), slop-oil-emulsion solids (K049), heat-exchanger-bundle cleaning solids (K050), API separator sludge (K051), and leaded-gasoline-tank bottoms (K052).

TABLE II

Refining Residual Stream

Oily sludge and other organic residuals	
American Petroleum Institute separator sludge	Primary sludge (F037)
Dissolved-air-flotation unit float	Primary sludge (F038)
Slop oil emulsion solids	Nonleaded tank bottoms
Leaded tank bottom	Waste oils/spent solvents
	Other oily sludge/organic residuals
Pond sediments	
Contaminated soils and solids	
Heat exchanger bundle cleaning sludge	Residual/waste sulfur
Contaminated soils/solids	Other contaminated solids
Residual coke/carbon/ charcoal	
Spent catalysts	
Fluid cracking catalyst or equivalent	Other spent catalyst
Hydroprocessing catalyst	
Aqueous residuals	
Biomass	Spent stretford solution
Oil-contaminated water (not wastewater)	Treatment, storage and disposal leachate (F039)
High-Ph/low-Ph waters	Other aqueous residuals
Spent sulfide solution	
Chemicals and inorganic residuals	
Spent caustics	Residual amines
Spend acids	Other inorganic residuals
Other residuals	

Several refinery, petrochemical, waste treatment, recycling, and disposal sites have been listed as Superfund sites. An example of a refinery and petrochemical Superfund site is the Sikes Disposal Pits Superfund site. According to the EPA, numerous refineries and petrochemical companies have disposed of chemical and oil-based wastes at the Sikes site. Other examples are the Baldwin Waste Oil site and the Falcon Refinery site, also known as the National Oil Recovery Corporation. The R&H Oil Company site, also known as the Eldorado Refining and Marketing, Inc. site and Tropicana Energy site, and the Dubose Oil Products Company Superfund site, which is a waste treatment, recycling, and disposal facility, are other examples of Superfund sites.

A major portion of refining sector hazardous wastes are not HSWA listed but are characterized as hazardous waste because testing has shown that they have one or more characteristics of hazardous waste (i.e., toxicity, ignitability, reactivity, and corrosivity). These wastes include primary treatment plant sludge, secondary treatment plant sludge, biological treatment sludge, cooling tower sludge, ion exchange regenerant, fluidized catalytic cracking catalysts, and hydrocracking catalysts.

Direct releases from a refinery, especially air emission, can pose significant risk to public, employee, and environmental health. These releases may involve process, storage, transport, fugitive, and secondary emissions.

2.2 Waste from Petroleum Products and Petroleum Storage

Oils originating from petroleum crude can be processed, blended, and formulated to produce numerous products for many applications. Users of

oils and oil products include not only industrial and commercial interests but also the individual citizen through the use of gasoline, lubricants, and fuel oils. These users of petroleum products produce large quantities of waste. Waste oils, due to the nature of their use, contain various contaminants, including heavy metals, combustion by-products, and substances arising from the original use (e.g., PCBs).

The principal uses of oils are as fuels, lubricants, hydraulic and transmission fluids, heat transfer fluids, and insulants. As fuels, oils cover a wider spectrum from light, highly mobile liquids to heavy fuel oils of such low viscosity at ambient temperatures that they must be heated to enable their use. The transportation industry is a major user of oil as a fuel for aircraft, shipping, and many land-based transport systems.

Petroleum products (gasoline, diesel fuel, crankcase oil, and waste oil) are a complex mixture of hundreds of chemicals with individual toxic effects. Those that are most often measured are referred to as BTEX (benzene, toluene, ethylbenzene, and xylenes). The BTEX chemicals are volatile monoaromatic hydrocarbons that are commonly found together in crude petroleum and petroleum products. They are considered one of the major causes of environmental pollution because of widespread occurrences of leakage from underground petroleum storage tanks and spills at petroleum production wells, refineries, pipelines, and distribution terminals. It has been estimated that 35% of the 1.4 million gasoline storage tanks in the United States are leaking. Contamination of groundwater with the BTEX compounds is difficult to remedy because these compounds are relatively soluble in water and can diffuse rapidly once introduced into an aquifer.

Some of the petroleum waste products are gasoline, oil, lubricants, machining or cutting oils, leakage from storage tanks, aqueous waste, sulfur dioxide, and PAHs.

2.2.1 Gasoline

When gasoline or another petroleum product is released into the environment, primary concerns generally include the possibility of contaminating soil and ground- and surface water. Gasoline spill and leaking underground storage tank contaminants are known to be a source of groundwater contamination. The United States uses approximately 16 million bbl of oil and oil by-products, such as gasoline, each day (245 billion gallons per year). Much of this material is stored in tanks at some point during transport from source to point of use. There are approximately 6 million tanks in the United States for storing petroleum, petroleum by-products, and petroleum-related chemicals. Many of the storage tanks are underground. According to the EPA, approximately 1 out of every 4 underground storage tanks may be leaking. Even a small gasoline leak of one drop per second can result in the release of approximately 400 gallons of gasoline into the groundwater in 1 year. A few quarts of gasoline in the groundwater may be enough to severely pollute a farmstead's drinking water.

As gasoline seeps through the soil and encounters groundwater, some components will dissolve and travel with the groundwater. After seeping underground, the petroleum products remain near the top of the water table because they are lighter than water. When wells draw water from the upper portions of the water table, they collect the contaminants during periods of low water availability and high consumption.

A plume of gasoline contaminants has been found in groundwater due to spills and leaking underground storage tanks. Petroleum fuels contain a number of potentially toxic compounds, including common solvents, such as benzene, toluene, and xylene, and additives, such as methyl tertiary-butyl ether (MTBE), ethylene dibromide (EDB), and organic lead compounds. The gasoline additive MTBE has contaminated many thousands of drinking water supplies and wells. MTBE causes widespread groundwater contamination due to its high water solubility and other unique properties. The strong, terpene-like odor of MTBE makes its presence easy to detect, even in minute quantities.

These contaminants (petroleum fuel toxic compounds) are all confirmed or potential carcinogens and could pose a significantly increased cancer risk. MTBE may cause cancer and myriad other health problems, such as asthma and respiratory illnesses. EDB and benzene are also considered carcinogens (cancer-causing).

2.2.2 Crude Oil (Petroleum)

Oils are not especially toxic, but contaminants such as additives, breakdown products, and other substances that may have become mixed with oils during their legitimate use may be much more so. Oils, however, do have considerable potential to cause environmental damage by virtue of their persistence and their ability to spread over large areas of land or water. Films or coverings of oil substances may reduce or prevent air from reaching life-forms of all types within an area of land or sea and can rapidly result in significant degradation of environmental quality in those media. Waste acid sludge arising

from the acid/clay process, a common method of recycling waste oils, represents a serious environmental threat.

2.2.3 Lubricants

Lubricants embrace an even wider spectrum of products with many different viscosities and viscosity ranges and the extensive use of performance-enhancing additives. A major source of waste oils is from lubrication. Lubricating oils need replacing at intervals, and although improved designs of engines and better oil grades may reduce the frequency of change, there is little prospect of the need for oil changes being avoided altogether. Major contributors to this market are cars, commercial vehicles, aircraft, railway locomotives, and other large pieces of machinery. Oils from these sources usually contain not only contamination from their use but also a variety of additives intended to improve performance. For example, lubricants are used for propulsion engines. Motor vehicles of modern design have several different non-fuel oil applications, such as engine crankshaft lubrication, gearbox lubrication, and hydraulic fluids for brake systems. Motor vehicles and their use impinge on most aspects of life.

2.2.4 Machining or Cutting Oils

Machining or cutting oils are used extensively for metal cutting, machining of components on lathes, and general engineering activities. In many instances, depending on the metal being machined, oils for this purpose are used as an emulsion in water with detergents, biocides, chlorinated paraffins, halogenated and nonhalogenated additives, and additives included to improve performance. The waste, which can be substantial in volume, comprises an emulsion of typically 2–5% oil in water. The waste may also contain metal dusts and similar contaminates.

Unintentional releases of process fluid from equipment are another source of waste. Any equipment that can potentially leak (e.g., pump, valve, and flanges) is a source of pollution. An oil refinery may have 250,000 such pieces of equipment.

2.2.5 Storage Tanks

Another source of pollution is leakage from storage tanks. At refineries and other oil/product handling facilities, there are many aboveground crude oil and refined product storage tanks in service. API Standard 653 requires tanks to be taken out of service periodically and to be visually inspected for leaks. However, this standard is often ignored since inspection can be very costly. Buried pipelines within refinery boundaries represent another source of leaks, and according to the API they have caused more groundwater contamination than the more visible storage tanks.

Tank washings and sludge from storage tanks and refineries, including those from the cleaning of oil storage tanks, can be a source of contamination since they contain breakdown products. In addition, tank washings can generate substantial volumes of waste, usually with medium to low oil contents. Typical sources are oily bilge water, oily ballast water, water from the jetting and cleaning of tanks both onboard ships and at land-based installations, and true tank-cleaning residues. The range of oils encountered in the generation of these wastes can be broad and can include accumulated oil sludge and sediment, tank scale, and even grit from grit blasting and related cleaning work.

2.2.6 Aqueous Waste

Many oil wastes are highly aqueous in nature and must first be subject to treatment to separate the waste into an oil-rich fraction that may be usable in some way and an aqueous waste stream that may require further treatment prior to final disposal. Processes of this type usually yield sludges that, along with other oil waste-based sludges, have no beneficial use and will require final disposal. Aqueous wastes are unlikely to be entirely free from oil and may need further treatment. Refining processes such as coking sulfur recovery, steam cracking, hydrocracking, and crude desalting create large volumes of oily wastewater. Wastewater facilities in particular are considered to be a source of significant atmospheric hydrocarbon emissions. Wastewaters constitute more than 80% of total hazardous waste mass at refineries. Also, aqueous wastes may contain other contaminants, depending on the original process, including surfactants, solvents, and toxic metals. PAHs are of particular concern because of their carcinogenic properties.

2.2.7 Sulfur Dioxide

All fossil fuels, including crude oil, contain organic sulfur compounds. When the fuels are burned, sulfur oxides are emitted. Sulfur oxides can cause respiratory problems, but emissions of these compounds are a concern primarily because they react in the atmosphere, forming acids. Over time, deposition of these acids through precipitation and diffusion can increase the acidity of natural bodies of water and change local ecosystems. Crude oil contains materials

such as soils, metals, and sulfur- and nitrogen-containing compounds. Removing these materials during refining results in large volumes of waste.

2.2.8 Polycyclic Aromatic Hydrocarbons

Polycyclic aromatic hydrocarbons, often referred to as polynuclear aromatics, are a class of very stable organic molecules composed of only carbon and hydrogen. These molecules are flat, with each carbon having three neighboring atoms, much like graphite. PAHs are released into the atmosphere as gases or particles during the incomplete combustion of organic material. PAHs have a number of sources, including cars, trucks, ships, and aircraft; industrial-power generation; oil refining and waste incineration; and primarily domestic combustion for heating and cooking, especially solid fuel heaters using wood and coal.

Of the 1410 hazardous waste sites listed on the National Priorities List (NPL) (Superfund or NPL sites), 352 have been contaminated by PAHs found in soil, groundwater, and sediment. Exposure to PAHs usually occurs by breathing air contaminated by wildfires or coal tar or by eating foods that have been grilled. The Department of Health and Human Services has determined that some PAHs may reasonably be expected to be carcinogens.

The smallest member of the PAH group is naphthalene, a two-ring compound that is a gas at normal temperatures. Three- to five-ring PAHs occur as either gases or particles in air. PAHs with five or more rings tend to be solids that attach to the surface of other particulate matter in the atmosphere.

2.3 Pipeline Leaks

Pipelines have historically been a primary source of oil spills both offshore and onshore. Pipeline leaks are not a rare occurrence. When they do occur somewhere within the 160,000 miles of liquid fuel-carrying pipelines that criss-cross the nation, they can have disastrous consequences. In 2000, gasoline leaking from an Olympic Pipe Line Company line in Bellingham, Washington, caused an explosion that killed three people. During the 1990s, major reportable spills, those involving at least 2100 gallons, occurred approximately four times a week and totaled approximately 6 million gallons per year. In 1996, a rupture in a 36-in. Colonial pipeline released more than 1 million gallons of diesel fuel into the Reedy River near Fork Shoals, South Carolina, creating a slick that spread for more than three-fourths of a mile down the waterway. A 1993 leak from a Colonial pipeline in Virginia dumped more than 300,000 gallons of oil into a tributary of the Potomac, forcing Fairfax to temporarily switch to an alternate water supply. A 1991 leak from a Colonial pipeline near Spartanburg, South Carolina, spewed an estimated 562,000 gallons of oil into a tributary of the Enoree River, forcing two towns to close their water-treatment plants. they Tables III and IV summarize the sources and causes of oil spills from the inland transportation and distribution system.

TABLE III

Sources of Oil Spills from Inland Transportation and Distribution System, 1987–1995

Inland source	No. of spills	Volume spilled (millions of gallons)	% of total volume spilled
Fixed facility	43,188	79.5	62
Pipeline	13,771	33.7	26
Highway transport	13,280	6.2	5
Rail transport	2483	3.7	3
Above ground storage tank	921	4.4	3
Underground storage tank	795	0.5	<1
Total	74,438	128	100

TABLE IV

Causes of Oil Spills from Inland Transportation and Distribution System, 1987–1995

Cause	No. of spills	Volume spilled (millions of gallons)	% of total volume spilled
Equipment failure	11,476	22.8	50
Operator error	4235	4.3	9
Transportation accident	3187	3.0	7
Natural causes	583	1.7	4
Dumping	2250	1.0	2
Other	2584	2.3	5
Unknown	934	10.4	23
Total	25,249	45.5	100

2.4 Noise Contamination

Noise in refineries originates from rotating machinery, such as cooler fans, turbines, compressors, engines, and motors. High-velocity flow of fluids

through valves, nozzles, and piping also contributes to the general noise level.

3. WASTE ASSOCIATED WITH COAL AND ITS PRODUCTION

Coal waste products are similar to those produced during petroleum exploration, production, refining, and use. Coal is a solid with a complex hydrocarbon structure and a higher carbon-to-hydrogen ratio than petroleum. Coal is the world's most plentiful fossil fuel energy resource, and its use is likely to quadruple by 2020. Coal has a wide range of moisture content (2–40%), sulfur content (0.2–8%), and ash content (5–40%), causing environmental problems from its use. Burning of coal creates approximately 60% of soot-creating sulfur dioxide emission in the United State. It is also a major source of smog-forming nitrogen oxide pollution, mercury contamination, and carbon dioxide, releasing more than 51 tons of mercury and 2 billion tons of carbon dioxide into the air every year. Sulfur dioxide and nitrogen oxide pollution also creates fine particles, which can cause significant increases in acute and chronic respiratory diseases. At every stage of production, transportation, and consumption, coal poses risks to the environment.

Coal is dirty fossil fuel: Mining it can ravage the land, and burning it can generate a large amount of carbon dioxide and other pollutants. The mining/cleaning of coal creates a significant amount of waste. Wastes that are associated with mine extraction (i.e., surface mining, open-pit mining, and underground mining) and processes of coal include liquid effluents (mine tailings containing fine materials that are discharged as slurry to impoundment areas), solid wastes (coarse materials typically >0.5 mm), and coal dust. According to a survey conducted by the U.S. Department of Energy, approximately 2.5–3 billion tons of fine coal has been deposited in tailing impoundments that typically have a life of up to 20 years.

Mining of coal has left large volumes of mining overburden throughout the United States. Mine overburden and waste soils (commonly referred to as mine tailings) are the waste products generated during mining and milling operations. Mine overburden is any material, consolidated or unconsolidated, excluding topsoil, that lies above a natural deposit of coal. It is also the material after removal from its natural state in the process of surface coal mining.

A complex set of chemical and biological reactions and conditions occur over time in mine overburden. Surface deposition of overburden waste products results in atmospheric exposure and subsequent weathering of sulfide minerals present in the rock, precipitation, and ground- or surface water. Oxidation of sulfide minerals by chemical and microbial processes produces sulfuric acid and heavy metal ions that find their way into surface and groundwaters. The release of these components into natural waters is a widespread and persistent problem in areas of the country that have a long history of coal or precious metal mining. Many of these tailings are causing problems with water quality and revegetation.

Mine overburden piles have acid-producing potential as well as acid-neutralization potential. Generally, the rate of acid production exceeds the rate of acid neutralization. Degradation of water quality of surface and groundwaters in contact with acid-producing mine tailings piles is the major environmental problem associated with acid mine drainage. The pH of the water is lowered due to the introduction of sulfuric acid as a result of sulfide mineral weathering. Acidic mine drainage laden with heavy metals and the precipitation of "yellow boy" has a devastating effect on the ecology of freshwater streams.

Heavy metal ions are released into the water as a result of mineral weathering. Depending on the composition of the mine overburden, the pollutants released into surface and groundwaters typically include any of the following heavy metal ions: iron, zinc, aluminum, manganese, cobalt, nickel, copper, arsenic, selenium, cadmium, and lead.

Mine overburden piles also contain *Thiobacillus ferrooxidans*. *Thiobacillus ferrooxidans* is responsible for the oxidation of iron and inorganic sulfur compounds in mine overburden areas. *Thiobacillus ferrooxidans* is acidophilic (acid loving, capable of surviving at low pH) and has a physiology that is well suited for growth in an inorganic mining environment. It obtains carbon by fixing atmospheric carbon dioxide and is strictly autotrophic. *Thiobacillus ferrooxidans* catalyzes the acid and heavy metal and produces reactions that occur in mine tailings resulting in the degradation of water quality downstream of mining operations.

Approximately 1 billion tons of coal is burned annually to generate electricity in the United States; as a result, more than 97 million tons of coal combustion by-products (CCBs) are produced. CCBs are considered a product by the American Coal Ash Association and are referred to as coal combustion products (CCPs). In 1998, CCPs ranked as the third largest nonfuel mineral commodity produced in the United States. Only one-fourth of these are utilized,

whereas the rest (80% CCBs) are disposed of mainly in landfills and surface impoundments (Table V).

With shrinking landfill space and increasing amounts of ash generation, there is an urgent need to utilize these materials in an environmentally safe manner. One potential use of these materials is waste stabilization. Intrinsic properties of these products allow immobilization of hazardous nuclear, organic, and toxic metal wastes for safe and effective environmental disposal. Additionally, coal ash contains plant nutrients and can be used to amend highly acidic soils.

CCBs produced during coal-fired electric power production are fly ash, bottom ash, boiler slag, and flue gas desulfurization (FGD) material. The physical characteristics and trace element composition of fly ash, bottom ash, boiler ash, and FGD are given in the Tables VI and VII, respectively.

3.1 Fly Ash

Fly ash is the finest of coal ash particles. It is called fly ash because it is transported from the combustion chamber by exhaust gases. Fly ash is the fine powder formed from the mineral matter in coal, consisting of the noncombustible matter in coal and a small amount of carbon that remains from incomplete combustion. Fly ash is generally light tan in color and consists mostly of silt-sized and clay-sized glassy spheres. Properties of fly ash vary significantly with coal composition and plant operating conditions. In the United States, approximately 50 million tons of fly ash is reused annually.

Fly ash is referred to as either cementations or pozzolanic. A cementations material is one that hardens when mixed with water. A pozzolanic material will also harden with water but only after activation with an alkaline substance such as lime. These cementations and pozzolanic properties make some fly ashes useful for cement replacement in concrete and many other building applications. Fly ash is used in concrete and cement products, road base, oil stabilizer, clean fill, filler in asphalt, metal recovery, and mineral filler.

TABLE V

Amount of Coal Combustion By-products (CCBs) Produced in the United States

Material	Metric tons $\times 10^6$
Crushed stone	1500
Sand and gravel	1020
CCBs	97.7
Cement	85.5
Iron ore	62

3.2 Coal Bottom Ash

Coal bottom ash and fly ash are quite different physically, mineralogically, and chemically. Bottom ash is a coarse, granular, incombustible by-product collected from the bottom of furnaces that burn coal for the generation of steam, the production of electric power, or both. Bottom ash is coarser than fly ash, with grain sizes ranging from that of fine sand to that of fine gravel. The type of by-product produced depends on the type of furnace used to burn the coal. Bottom ash is used as construction and railroad fill material, abrasive blasting grit, granules on asphalt roofing shingles, aggregate for concrete and masonry blocks, substitute for sand for traction on icy roadways, and soil amendment to increase permeability.

TABLE VI

Summary of Physical Characteristics and Engineering Properties of Coal Combustion By-products

			Flue gas desulfurization material	
Physical characteristic	Fly ash	Bottom ash/boiler ash	Wet	Dry
Particle size (mm)	0.001–0.1	0.1–10.0	0.001–0.05	0.002–0.074
Compressibility (%)	1.8	1.4		
Dry density (lb/ft^3)	40–90	40–100	56–106	64–87
Permeability (cm/s)	10^6–10^4	10^{-3}–10^{-1}	10^{-6}–10^{-4}	10^{-7}–10^{-6}
Shear strength	0–170	0		
Cohesion (psi)	24–45	24–45		
Angle of internal friction (°)				
Unconfined compressive strength (psi)			0–1600	41–2250

TABLE VII

Trace Element Composition of Coal Combustion By-products

	Fly ash							
	Mechanical		Esp/baghouse		Bottom ash/boiler slag		Dry flue gas desulfurization material	
Element (mg/kg)	Range	Median	Range	Median	Range	Median	Range	Median
Arsenic	3.3–160	25.2	2.3–279	56.7	0.50–168	4.45	44.1–186	86.5
Boron	205–714	258	10–1300	371	41.9–513	161	145–418	318

Fluorine	2.50–83.3	41.8	0.4–320	29.0	2.5–104	50.0	—	—
Mercury	0.008–3.0	0.073	0.005–2.5	0.10	0.005–4.2	0.023	—	—
Manganese	123–430	191	24.5–750	250	56.7–769	297	127–207	167
Lead	5.2–101	13.0	3.10–252	66.5	0.4–90.6	7.1	11.3–59.2	36.9
Selenium	0.13–11.8	5.52	0.6–19.0	9.97	0.08–14	0.610	3.6–15.2	10.0
Silver	0.08–4.0	0.70	0.04–8.0	0.501	0.1–0.51	0.20	—	—
Strontium	396–2430	931	30–3855	775	170–1800	800	308–565	432
Vanadium	100–377	251	11.9–570	248	12.0–377	141	—	—
Zinc	56.7–215	155	14–2300	210	4.0–798	99.6	108–208	141

3.3 Boiler Slag

Boiler slag is coarser than conventional fly ash and is formed in cyclone boilers, which produce a molten ash that is cooled with water. Boiler slag is generally a black granular material with numerous engineering uses.

3.4 FGD Gypsum

FGD gypsum is also known as scrubber gypsum. FGD gypsum is the by-product of an air pollution control system that removes sulfur from the flue gas in calcium-based scrubbing systems. It is produced by employing forced oxidation in the scrubber and is composed mostly of calcium sulfate. FGD gypsum is most commonly used for agricultural purposes and for wallboard production.

4. SUMMARY

Worldwide energy demand increases even as knowledge of how fossil fuel use threatens the global environment grows. Environmental impacts arise at all stages in the life cycle of fossil fuel sources. These impacts are as follows:

- Fossil fuel extraction: coal mining and oil extraction
- Fossil fuel distribution: transport of fuels by road, rail, water, and pipelines; transmission of electricity
- Fossil fuel processing: petroleum refining and coal preparation
- Fossil fuel combustion in the domestic, commercial, industrial, and transport sectors
- Waste and residue management: coal ash and refinery residues

The environmental burdens associated with these activities are many and varied, including:

- Emissions of pollutants to air, mainly from fossil fuel combustion but also from methane leakage from coal and oil extraction and distribution
- Discharges of pollutants to rivers, estuaries, and seas from coal mining and oil extraction
- Groundwater pollution from coal mining
- Visual intrusion, noise, and loss of wildlife habitat

Glossary

albedo (a) For a flat surface, albedo is generally defined as hemisphere- and wavelength-integrated reflectivity. Thus, whereas reflectivity is the ratio of the amount of reflected to total incident radiation at a particular wavelength, albedo can, by definition, encompass a range of wavelengths of interest. In this article, the interest is in solar albedo with an integral over the portion of the solar spectrum between approximately 0.28 and 2.8 μm. Effective albedo is the albedo resulting from geometrical effects (e.g., multiple reflections) in addition to the effects of the surface albedo. Of course, the definition of albedo is not restricted to surfaces.

boundary layer (BL) (e.g., planetary BL and canopy BL) A layer in the fluid (e.g., air) whose momentum, mass, or heat characteristics are affected or dictated by the fluxes of respective quantities at the underlying surface. Thus, generically, a BL is a layer in which the effects of the surface are "felt."

Bowen ratio (β) The ratio of sensible heat flux (H) to latent heat flux (λe) from a surface or plane, land cover, or region of interest: $\beta = H/\lambda e$. The definition can be applied to any scale.

cost of conserved energy (CCE) In this article, CCE is defined as the compounded additional cost per saved kWh that must be invested in order to implement an energy-saving strategy or feature. The CCE of interest is that of increased roof or urban albedo. $\mathrm{CCE} = [\Delta I/\Delta E] \times [i/\{1-(1+i)^{-n}\}$, where ΔI is additional investment ($), ΔE is the annual energy savings (kWh/year), i is interest or compounding rate (e.g., 6%), and n is the number of years.

degree-days (DD) A measure of the magnitude and duration of temperature deviation from a certain given threshold over a certain period of time (e.g., annual, seasonal, and monthly). Thus, for example, $\mathrm{DD} = \Sigma(T_{\mathrm{avg}} - T_{\mathrm{t}})$, where T_{t} is any threshold (reference) temperature [e.g., 18.3°C (65°F)], and T_{avg} is the 24-h average temperature. The summation can be taken over any period of interest (e.g., 1 year).

efficiency Coefficient of performance (COP), energy efficiency ratio (EER), and seasonal energy efficiency ratio (SEER) are measures of the ratio of work provided by a system (e.g., cooling or heating) to the power input to that system. COP is dimensionless, but EER and SEER typically have units of Btu/h W^{-1}.

evaporative cooling The process of cooling the air by evaporation of water, in which case the heat of vaporization is taken from the air. Thus, evaporative cooling is a constant enthalpy process.

view factor (e.g., sky view factor) The ratio of the amount of radiation (e.g., long-wave flux) leaving a surface (e.g., street level) through the sky aperture "seen" by the surface to the radiation leaving the surface in all directions (e.g., to the hemisphere). The view factor is thus a purely geometrical definition and can be qualitatively defined as the ratio of sky area or aperture (solid angle) seen from a certain surface (or point) to the area (solid angle) of the entire hemisphere (or sphere) seen by that same surface (or point).

Weather conditions and local meteorology, e.g., urban climates, have significant impacts on regional and local energy use intensities and patterns. An important phenomenon of urban climates, which has direct bearings on energy use, is the urban heat island (UHI). The UHI itself is partly a result of energy use in urban areas. When a UHI is present, air temperature can be several degrees higher than in the surrounds and in summer the urban-scale peak electric demand for cooling can increase by up to 10%.

1. INTRODUCTION

Urban heat islands (UHIs) and energy are interrelated in two complementary ways. First, energy

 © 2004 Elsevier Inc. All rights reserved.

conversion and use can contribute to creating UHIs via increased anthropogenic heating of ambient air by machinery, equipment, air conditioners, cooling towers, motor vehicles, and other sources of heat (e.g., combustion). Although this is only one of many UHI causative factors, it can be significant in urban areas, where such sources are highly concentrated. Energy use and conversion can also result in increased emissions of air pollutants, CO_2, nitrous oxide (N_2O), and water vapor (motor exhausts, refineries, chimneys, electricity generators, etc.), which can enhance local (e.g., urban) greenhouse effects. From a relatively more extreme point of view, it can also be argued that passive and active energy conversion systems (e.g., solar and, to a much lesser extent, wind systems) can also add to the UHI. This would occur, for example, if a vast array of photovoltaic cells were installed in an urban area such that the effective urban albedo is decreased and heat transfer from the cells to the air becomes larger. However, this effect is small since photovoltaics and other solar equipment (e.g., solar water heaters) are sparse and cover a small surface area. Thus, although the albedo of a photovoltaic cell may be approximately 0.05, the impact on overall urban albedo is very small. Also, most high-concentration solar energy conversion facilities (e.g., solar power plants and wind farms) are usually located in desert and rural areas, not in urban regions. Thus, they do not contribute to UHIs directly.

Second, UHIs directly affect energy use in buildings; heating, ventilating, and air-conditioning (HVAC) systems and equipment; motor vehicles; industrial processes; and so on. In buildings, more cooling and less heating are generally needed when UHIs are present. In addition, equipment efficiencies (coefficient of performance, energy efficiency ratio, and seasonal energy efficiency ratio) of HVAC, industrial, and other equipment are to a certain extent functions of ambient temperature and thus are affected by UHIs, even if only by small amounts.

2. DEFINITION OF HEAT ISLANDS

A heat island is simply an area, volume, or region in which the temperature is higher than that of the surroundings. This very general definition can obviously apply to any scale and environment, from micrometers to thousands of kilometers. That is, a heat island can exist on a scale of a few millimeters, as a bubble of hot air surrounded by colder air, or on a scale of thousands of kilometers, such as a high-pressure weather system moving across a relatively cooler air mass. It can also be thought of as a more global or universal phenomenon. Obviously, we would like to put some bounds on this definition (for the purpose of this article) and speak only of the UHI. Thus, a UHI is the difference between the temperature in a certain urban location and that at a given reference point in a nonurban location (e.g., an upwind rural location). Obviously, the choice of urban and reference points or a collection of points can affect the magnitude and the characteristics of a reported UHI.

Keeping the urban scale in mind, there can be a surface temperature heat island and an air temperature heat island (Fig. 1). The latter can be further broken down using various scales and criteria, but some common classifications include canopy-layer heat islands and the more generic boundary-layer heat islands. The former generally occur below effective roof level (quite qualitatively) and the latter extend up to the boundaries of the urban heat plume.

Figure 1 is a conceptual diagram of a 3.5°C UHI. In reality, UHI attributes are very site specific and meteorology dependent. Figure 1 shows a hypothetical temperature-difference profile (difference from a rural reference temperature), indicated with a thick dashed line. Of course, the intensity of the UHI (0–3.5°C) is purely for illustration purposes. Note the downwind displacement (advection) of the location of peak air temperature difference (i.e., the location of maximum UHI, denoted by "max").

3. CAUSES AND EFFECTS OF URBAN HEAT ISLANDS

In the simplest situations, air temperature is dictated by energy balance at the underlying surface. The following is the basic form of a surface energy balance equation:

$$\alpha_s Q + \alpha_s q + \alpha_1 L + Q_f = \varepsilon\sigma T_o^4 + h_c(T_o - T_a) + kdT_o/dz|_{z=0} + \lambda e,$$

where α_s and α_l are the absorptivities for short- and long-wave radiation, respectively; Q and q are the direct and diffuse short-wave radiative fluxes, respectively; L is incoming long-wave flux; Q_f is anthropogenic heat flux; ε is emissivity; σ is the Stefan–Boltzmann constant; T_o and T_a are surface and air temperatures, respectively; h_c is the convective heat transfer coefficient; k is thermal conductivity; λ is latent heat of vaporization; and e is

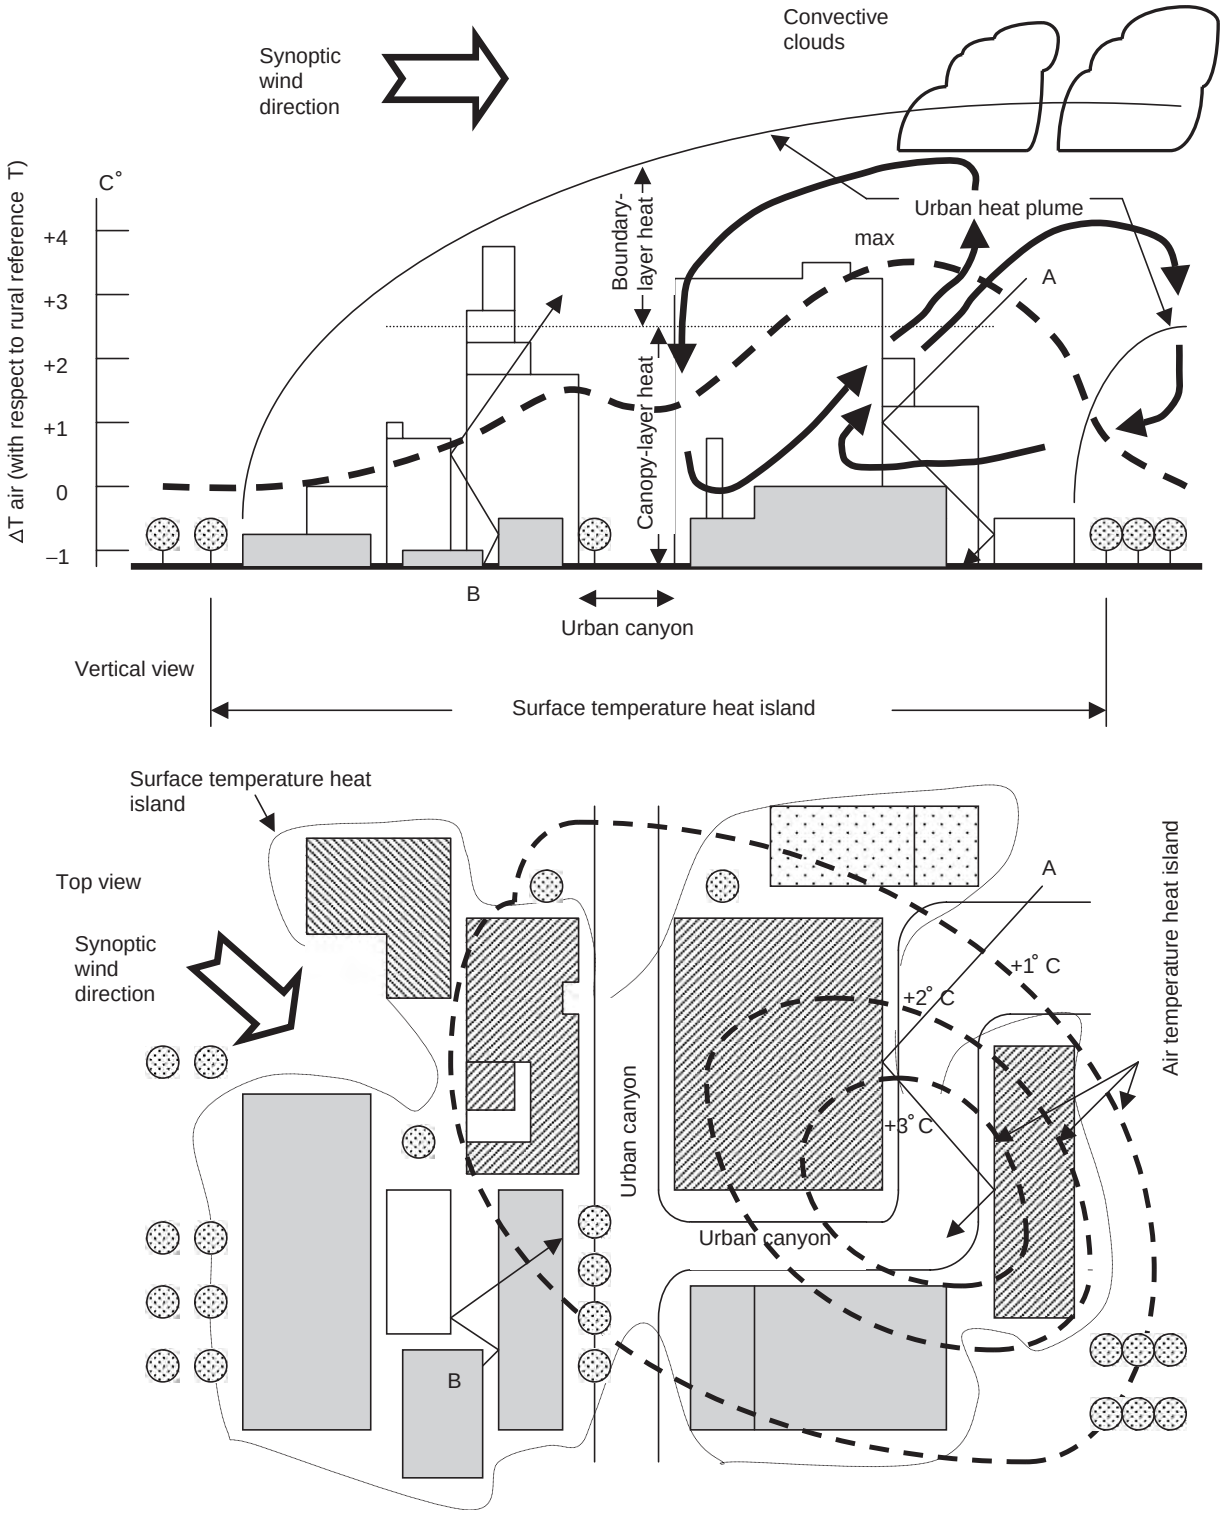

FIGURE 1 Schematic of an urban heat island: (top) vertical view (cross section); (bottom) corresponding projection top view. The thick broken lines show the air temperature UHI intensity read off the scale (°C) at left in the vertical view. The thick arrows show a UHI convective cell advected downwind of the urban center by the synoptic wind. The boundaries of an urban heat plume (also advected downwind) are shown. Other aspects shown are the boundaries of the surface temperature UHI, canopy and boundary layer UHI, convective clouds, incoming and outgoing radiative beams (A and B), and urban canyon.

evaporation rate (mass flux). Thus, the first and second terms on the left side represent the total absorbed short-wave (e.g., solar) radiation flux at the surface (both direct and diffuse), and the third term is the absorbed long-wave (e.g., near infrared) flux. The fourth term on the left is the anthropogenic heat flux (e.g., from motor vehicles, building equipment, and other heat sources) into the surface or near-surface atmospheric layer. On the right side of the equation, the first term represents long-wave radiative flux from the surface, the second term is the sensible heat flux, the third term is ground heat flux (heat conduction through the surface), and the last term is latent heat flux. Some of the terms in this equation are discussed directly or indirectly in the following sections.

3.1 Causes of UHIs

When the energy balance of an urban area is altered so that there is slower cooling relative to that in rural areas (e.g., after sunset), a classic nighttime UHI results. However, when there is significant heat storage in the urban canopy layer, or any additional sources of heat (e.g., anthropogenic), a UHI can arise at any time. Heat islands can appear as a result of a single causative factor or, more likely, a combination of several factors. The following are the main causative factors of the UHI:

Thermal capacity and urban geometry: Urban areas in general are abundant in materials that have high thermal capacity (e.g., concrete, brick, stone, pavements, and asphalt). In addition, urban regions have much more total surface area (exposed to the sun) per horizontal area than do rural regions [surface-to-area ratio (SAR)]. Rural areas tend to have a SAR close to 1. In residential neighborhoods, the SAR is on the order of 2 or 3, whereas in urban cores it is approximately 5 or higher. In cities such as Manhattan, the SAR can easily reach 10 or higher. As a result of the combination of these two factors (increased thermal capacity and increased SAR), solar radiation is captured and stored more efficiently in urban areas. The release of this extra heat, stored in all types of urban structures and materials, contributes directly to warming the air and the creation of a UHI. For example, see beams A and B in Fig. 1.

Sky view factor (SVF): The smaller SVF in urban areas, relative to that in open surrounds, helps create a UHI, especially the nighttime type. This is because radiative cooling of the urban surfaces (and canopy-layer air) to the cooler sky is hindered by the obstructions in urban areas (walls, structures, etc.). In Fig. 1, the beam at point B undergoes multiple reflections that decrease its intensity and warm the surfaces and air in contact with them. The number of reflections may increase when the urban "canyon" is surrounded by taller structures. As a result, a UHI is created due to the differential in cooling rates between the urban area and that of the rural surrounds.

Albedo and effective albedo: The albedo of building materials, pavements, and other urban structures may be lower than that of vegetation or barren land (which is abundant in rural areas). However, in some cases, the reverse is true. For example, low-altitude aircraft measurements have shown that urban albedo can reach 0.20 when the rural vegetated surroundings have an albedo of 0.15. In general, a UHI can arise when urban albedo is lower than that of the rural surrounding areas. In addition to the fact that many urban surfaces (roofs, walls, pavements, streets, structures, etc.) have low albedos, urban areas also create a lower effective albedo compared to that of rural or surrounding areas. The effect of geometry (i.e., urban canyons) is to increase multiple reflections of incident solar radiation and therefore increase the probability that a photon will be absorbed by the canyon surfaces (instead of escaping back), thus resulting in lower effective albedo. This can be seen by the simplified path of beam A in Fig. 1. After several reflections, the beam is less intense and some photons never make it to the canyon floor.

Bowen ratio: As a result of a relatively less dense vegetation cover in urban areas, the partitioning of incoming solar radiation into sensible and latent heat fluxes (among others) is altered. Thus, in urban areas, the Bowen ratio (β) is larger and this results in higher air temperatures. In rural areas or suburbs in which there is typically more vegetation, evaporation, and evaporative cooling, β is smaller, which can help keep air temperatures relatively lower. Typical values for β are approximately 4 or 5 in urban areas and approximately 0.8–1.5 in vegetative canopies. By comparison, β is approximately 0.1 for oceans and in the tropical forests it is approximately 0.2.

Anthropogenic heating: Urban areas alter the energy balance not only "passively," such as through effects of urban geometry, thermal capacity, decreased effective albedo, and lack of vegetation, but also "actively" via injection of heat directly into the air and, to a smaller extent, into the surface. This is typically referred to as furnace heat, anthropogenic heat, or man-made heat. Typical sources of

anthropogenic heat include motor vehicles, stacks and chimneys, HVAC in motor vehicles and buildings, industry, refineries and processing plants, and power plants. Because it is difficult to directly measure anthropogenic heat flux, it is usually indirectly estimated or derived from energy use profiles at sources or in areas of interest. Typical values of anthropogenic heat flux density in residential areas are on the order of 10–20 $W m^{-2}$ and in dense urban cores in the range of 50–100 $W m^{-2}$. Flux densities larger than 100 $W m^{-2}$ are thought to occur at certain times in extremely dense urban cores, such as Lower Manhattan (approximately 120–150 $W m^{-2}$). In Japan, flux densities of up to 500 $W m^{-2}$ have been reported, although this is highly uncommon. For comparison, the maximum incoming solar radiation flux density at street level on a cloudless summer day can range between 800 and 1000 $W m^{-2}$ around solar noon. Outside of the atmosphere, the incoming solar radiation flux density (solar constant) is approximately 1350 $W m^{-2}$.

Of course, a UHI can be caused by any one of the previously discussed causative factors or, most commonly, by a varying degree of combinations of such. As a result, the characters of UHIs and their extents can be very diverse and different from one location or time to another.

3.2 Effects of UHIs

UHIs can alter the meteorology, air pollutant emission rates, pollutant transport, and photochemistry in the area in which they exist. Of course, they also affect energy use. Briefly, the nonenergy effects of UHIs are

Creation of a wind pattern or circulation, which is typically a convective cell located in the UHI vicinity: Depending on the strength of the background winds (e.g., synoptic) relative to that of the UHI winds, the convective cell can be asymmetrical and be advected downwind (see, for example, the thick arrows in Fig. 1). In general, the larger and denser a city (larger population), the stronger its UHI circulation.

Increased cloudiness and rainfall as a result of enhanced convective activity within the heat plume associated with UHIs (see hypothetical clouds in Fig. 1, downwind of the UHI maximum and near the location of divergence of the UHI circulation): Of course, UHIs produce increased convective clouds or precipitation only when the right conditions are met (e.g., temperature, winds, moisture, and condensation nuclei). Long-term observations suggest that UHIs can cause up to an 8% increase in cloudiness, 14% more rainfall, and 15% more thunderstorms near urban areas compared to their surroundings.

Increased ambient temperatures, the most obvious effect of UHIs: On average, typical UHIs are on the order of 2°C, but extremes as high as 8°C have been recorded. Figure 1 shows a hypothetical UHI of 3.5°C downwind of the highest urban concentration. It is obvious that the choice of urban and rural reference points can dictate the "observed" UHI intensity.

Increased mixing of pollutants in the boundary layer (BL): Depending on stability, depth of the BL, and convective activity and strength, pollutants emitted into the urban atmosphere can be well mixed and dispersed within the BL, resulting in lower apparent concentrations compared to a situation in which the BL is shallower and pollutant mixing is inhibited.

Increased temperature-dependent emissions of air pollutants: For example, the emission of biogenic hydrocarbons (e.g., isoprene from vegetation) is highly temperature dependent. It can double or triple for every 6–10°C increase in air temperature in the range of 25–37°C. In addition, most fugitive emissions of hydrocarbons (e.g., from fuel storage tanks, on-road motor vehicles, motor engines hot-soak, and evaporative losses) are temperature dependent. Direct emissions of particulate matter (e.g., of interest PM_{10} and $PM_{2.5}$) are also temperature dependent to a certain extent. Increased precursor emissions generally lead to an increased rate of smog formation, decreased visibility, and poorer air quality.

Photochemical production of smog generally positively correlated with temperature: This is true at least for some of the most influential photochemical reactions. Thus, a UHI can act as a catalyst for accelerating the formation of tropospheric/urban ozone, which poses a significant health problem in major urban areas. Because higher temperatures can exacerbate ozone formation while at the same time increase the mixing of pollutants in the BL, there may appear to be a competing effect. However, most data and observations suggest that the net effect of a UHI in terms of ozone concentrations is a negative impact on air quality.

4. TYPICAL MAGNITUDES OF UHIs

Because UHIs form as a result of several factors that differ in space, time, location, geography, and with combinations of such, it is obvious that their

intensities differ not only in absolute terms but also in location, time, duration, and an array of spatio-temporal characteristics. For example, some UHIs peak at night (most common), others during the day, and others have multiple diurnal peaks. In infrequent cases, a UHI can also be roughly constant during a 24-h period. In addition to hourly and subhourly fluctuation in intensity, UHIs also have diurnal and seasonal fluctuation components.

Thus, it is difficult to generalize and characterize UHI intensities with one or two indicators. However, there may be some observed upper bounds and common (frequently observed) intensities. The upper bounds seem to be related to city size (population) in some ways. Urban heat islands of 1 or 2°C are typical of the North American continent (the United States and Canada), where they can peak up to 4°C or more. Observations and numerical simulations of a number of U.S. metropolitan areas suggest that UHIs on the order of 2°C are typical in Los Angeles, Chicago, Atlanta, Washington, DC, Philadelphia, and New York. UHIs of 1–1.5°C are found in Houston, Dallas, Phoenix, and Miami. In Japan and China, UHIs on the order of 3°C have been frequently reported. Larger UHIs have been reported in Brazil (as high as 8°C in Sao Paolo) and Britain (as high as 6 or 7°C in London). In Mexico, similar UHIs have been observed. As discussed later, a UHI of 1 or 2°C is a significant factor in energy use.

5. IMPACTS OF UHIs ON ENERGY

The impacts of UHI on energy can be seen on regional, urban, and building scales. In terms of energy supply, conversion, and use, these scales roughly correspond to utility service territory and power plants, city-scale grids, and building scales. Of course, urban and building energy use are not the only contributors to utility-scale loads, but most often they are a major component. As previously mentioned, a UHI can cause several meteorological perturbations, but perhaps the most relevant from an energy perspective is that of increased ambient air temperature. Temperature can also be thought of as a surrogate (implicit indicator) for other local weather parameters, such as available sunshine, cloudiness, precipitation, and winds.

The typical energy impact of UHIs is to increase cooling loads in summer and decrease heating loads in winter. The net effect, of course, depends on the characteristics of a region's climate (summer dominated, winter dominated, both, or none) and general meteorological features (e.g., wind patterns, available sunshine, precipitation, and topographically induced flows and phenomena). It also depends on local energy-specific aspects, such as population density, dominant sectors of energy use, types of buildings, age, distribution, general building envelope characteristics, saturation of HVAC equipment, and local cost of fuel and electricity rates. However, in general, a UHI has relatively larger impacts on (increasing) cooling loads than on (decreasing) heating loads. Also, the former is an unwanted effect, whereas the latter is generally a welcomed one. Thus, the remainder of this section focuses more on the cooling energy impacts of UHIs than on their heating energy implications.

A first estimate of the effects of UHIs on energy (e.g., heating and cooling loads) would involve quantifying their impacts on heating and cooling degree-days (HDD and CDD, respectively). If a certain reference temperature is selected [e.g., 18.3°C (65°F)], we find that most urban areas in the United States see a typical increase in CDD of 15–35% as a result of UHIs, with some extremes as high as 90%. A typical decrease in HDD is approximately 5–14%, with extremes as high as approximately 30%. Table I shows the impact of UHIs on HDD and CDD in selected regions.

However, one CDD is not equivalent to one HDD when converted to energy costs, for example, if cooling is done with electricity and heating mainly with natural gas. Thus, in addition to the fact that electricity and gas costs are different, the HDD/CDD weight also depends on how cooling and heating are achieved locally (i.e., HVAC systems, primary and secondary systems, power plants, and overall system

TABLE I

Impacts of UHI on Annual HDD and CDD in Selected Cities (Base 18.3°C)[a]

City	Impact of UHI on HDD (%)	Impact of UHI on CDD (%)
Los Angeles	−30	+90
Washington, DC	−5	+20
St. Louis	−5	+10
New York	−5	+25
Baltimore	−15	+35
Seattle	−15	+55
Detroit	−5	+15
Chicago	−5	+25
Denver	−10	+20

[a] Rounded to the nearest 5%.

efficiencies). Thus, the conversion from HDD/CDD to energy use and costs depends on local factors and energy rates. In the United States, the average electricity cost is approximately \$0.08/kWh and for gas approximately \$0.65/therm (1 therm = 10^5 Btu), but deviations from these averages (by geographical location and time/season) can be quite significant. Thus, the HDD/CDD data given in Table I are for qualitative comparison purposes.

At the building scale, the energy impacts of UHIs are rather straightforward to understand, even though building characteristics, thermal integrity, occupancy schedules, and thermal comfort preferences may be complicating factors. In general, residential or small nonresidential buildings are significantly affected by the UHI. In larger buildings, in which internal loads (heat gain from occupants, lighting, machinery, and equipment) are larger than the heat gain or loss through the envelope, the sensitivity to air temperature (UHI) is relatively smaller. Table II gives some orders of magnitudes for expected peak cooling electric demand change with temperature in North America. These ranges are for illustration purposes and not exact numbers.

Thus, for example, the effect of a 3°C UHI would be to increase peak demand for cooling on a summer afternoon by approximately 5% of the daily average demand in large office buildings (relative to whole-building electricity consumption). For small offices, the increase would correspond to approximately 10% and for residential buildings to approximately 15%.

The impacts of UHIs on building energy use have also been studied and analyzed with numerical simulations in an attempt to isolate the effect of UHIs from other factors. Computer modeling is needed in such sensitivity studies since it is nearly impossible in the real world to find exactly identical buildings some within and others outside of a UHI with everything else similar so that the impacts of UHIs can be isolated. Advanced computer simulations show that in terms of system cooling peak, UHIs can cause increases in the range of 5–40% depending on weather, location, and building type. In terms of heating peaks, the UHIs can cause a decrease on the order of 4 or 5%. The simulations also show that in some regions and climates, the effect of UHIs is small or negligible. In addition to HVAC-related energy use, there are other aspects in buildings that are indirectly related to UHIs, such as indoor thermal comfort, indoor environmental quality, natural ventilation, and the performance of passive energy systems.

TABLE II

Magnitudes for Typical Temperature Sensitivity of Peak Electric Demand for Cooling at the Building Scale

	Total floor area ($\times 1000\,m^2$)	$kW°C^{-1}$	Total electricity usage ($kWh\,m^{-2}\,year^{-1}$)
Large office buildings	50–100	50–110	100–130
Small commercial buildings	1–1.8	1.2–3	70–120
Residential buildings	0.1–0.4	0.2–0.35	50–100

At the urban scale, data suggest a sensitivity in the peak electric demand of 2–5%/°C in the United States. Values of 2.5–3%/°C are common in cities such as Los Angeles, Chicago, Washington, DC, and New York. Values of approximately 5%/°C are found in cities with relatively hotter climates, such as Atlanta, Houston, Dallas, Phoenix, and Miami. The increase in electric demand occurs when the daily maximum temperature is above a certain threshold (e.g., 20°C in summer). In terms of absolute values, these percentages translate into a range of effects. In areas such as the Los Angeles basin, this corresponds to approximately 130 MW/°C, whereas in hotter regions, such as California's Central Valley or the state of Texas, this is equivalent to approximately 300 MW/°C. Thus, depending on the UHI and the regional climate, the actual increase in demand can be significant. On the other hand, in some cold-weather regions, the sensitivity of the electric demand may be negative, indicating savings (rather than penalties) with increased air temperatures as a result of decreased electricity use for heating. This occurs in the northeastern United States and along the Canadian border.

For the purpose of this discussion, it is possible to identify four climate groups in the United States that correspond to certain ranges in the sensitivity of the peak electric demand to temperature. Such climate types are cold, moderate, warm, and hot, as shown in Table III.

According to various numerical and observational studies, UHIs are typically in the range of 1–3°C in North America. Thus, in Los Angeles, Chicago, Washington, DC, New York, and Phoenix, approximately 5% of the peak electric demand is a result of UHIs. In Houston and Dallas, this is approximately

TABLE III

Sensitivities of Peak Electric Demand by Climate Types in the United States

Climate	Sensitivity of peak (%/°C)	States
Cold	−1	Maine, Vermont, Montana
Moderate	1	Massachusetts, Virginia, the Dakotas, Michigan
Warm	2–3	Alabama, Tennessee, California
Hot	3–5	Florida, Louisiana, Texas, Arizona

8%, in Atlanta it is approximately 11%, whereas in Philadelphia it is approximately 3%. In general, it is estimated that 5–10% of the urban peak electric demand in summer-dominated large U.S. urban areas is a result of the UHI effect. Of course, the higher temperatures associated with a UHI not only increase the demand for cooling but also decrease the efficiency of the air-conditioning/cooling systems in meeting the loads.

Finally, UHIs also indirectly affect other aspects of energy use. Warmer conditions, for example, induce an increase in watering needs (e.g., for urban vegetation, nearby crops, and parks) and thus an increased need for pumping water and distributing it. Higher air temperatures also cause an increased need for air-conditioning use in motor vehicles. The additional air-conditioner load requires more energy (increased fuel consumption). For motor vehicle air-conditioner compressors, the "on time" fraction increases by approximately 5%/°C (i.e., the compressor is on 5% longer for every 1°C increase in ambient air temperature above a certain threshold). Another aspect of UHI is health and thermal comfort, which entail indirect use of energy as well. Heat waves, for example, can be exacerbated with UHIs and thus heat-related hospital admissions increase and health care becomes a serious concern during the summertime. Although difficult to quantify, these aspects involve increased energy usage in health facilities.

6. MITIGATION OF UHI EFFECTS TO SAVE ENERGY

Just as the UHI imparts effects on energy at various scales (e.g., building and urban scales), its mitigation (reversing or compensating for its effects) can also be addressed at such scales.

Thus, at the building scale, the goal is to cool the building envelope or cool the ambient air in the immediate vicinity or both. More accurately, the goal is to prevent the envelope and ambient air from heating up as much as they would without UHI control. The current thinking is that cooling the building envelope should be done using high-albedo (reflective) materials so that the amount of solar radiative flux absorbed, and hence the heat conducted through the structure, is reduced. Typical building materials (e.g., roofing materials) have albedos in the range of 0.08–0.25. For example, the majority of asphalt shingles typically have an albedo of 0.10–0.15. Roofing membranes, such as black single-ply roofing, have a typical albedo of 0.06 and gravel roofs between 0.12 and 0.34, depending on the color of the gravel, but most tend to be approximately 0.15.

A hypothetical example of conventional roofing materials with an albedo of 0.25 is shown by the lower (thick) line in Fig. 2. Roof albedos can be increased rather easily with high-albedo (reflective) materials or coatings so that the new albedos attain the range of 0.4–0.6 after accounting for effects of weathering, aging, and soiling. Some reflective materials have an initial albedo of up to 0.85 or higher but require maintenance to keep it at that high value. A hypothetical example of a high-albedo, light-colored material (with an albedo of 0.70) is shown by the upper (thin) line in Fig. 2. However, high-albedo materials need not be lightly colored or white. For example, a hypothetical material shown by the middle line (thick dashed) in Fig. 2 has an albedo of 0.5, but it will appear dark to the human eye because of its low reflectivity in the visible range.

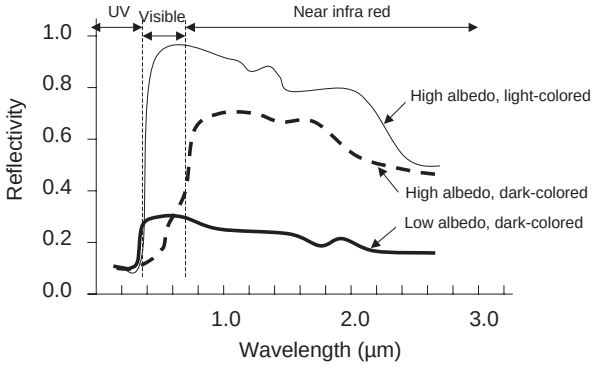

FIGURE 2 Hypothetical spectral reflectivities (albedo) of various materials. These hypothetical materials have albedos of 0.25, 0.50, and 0.70, respectively, from bottom to top.

Materials for increasing roof albedo exist in a variety of colors and textures. In the United States, their incremental cost over traditional roofing materials is \$0–2/m^2. Incremental cost is defined here as the extra costs incurred as a result of selecting a reflective roof instead of a traditional one. Of course, if the selection is done at the time of maintenance reroofing or during the initial construction phases, there may be no incremental costs. The implementation of high-albedo roofs can offset or more than offset the local effects of UHIs on energy use in buildings. Roof surfaces with higher albedo are typically 5–15°C (up to 30°C) cooler than their low-albedo counterparts. Reflective roofs warm up at approximately one-third the rate of more conventional roofs. Thus, whereas conventional roofs can be as much as 40–45°C warmer than the overlying air, high-albedo roofs are typically 10–15°C warmer than the air, assuming similar underlying construction and materials. During certain times, the surface temperature of reflective roofs can be very close to that of ambient air.

To cool the ambient air around a building, the current thinking is to increase vegetative cover so as to promote evaporative cooling. The tree canopy also has the beneficial effect of shading the building structure, thus significantly decreasing solar heat gain by the envelope. Another energy benefit of increased urban vegetation, particularly of the evergreen type, is wind shielding. Although this is only indirectly related to heat islands, it has a significant energy effect. In winter, for example, trees shield buildings from the cold winds, reducing the infiltration of colder air to the indoor spaces and thus helping to reduce heating energy needs, especially at higher latitudes. Of course, this effect is important only for one or two-storied buildings, for which trees can shield the wind from the structures. Upper floors in taller buildings do not benefit from ground-level tree canopies. Urban vegetation has other benefits, such as improving air quality by trapping and depositing pollutants from the air. It also has aesthetics values and qualities.

At the urban scale, the main concept is to implement high-albedo materials not only on buildings (e.g., roofs) but also on pavements, roadways, parking lots, sidewalks, and other built-up surfaces. The strategy would also include a reforestation program in which a large number of trees are planted throughout urban areas. The effects of such large-scale implementation of urban albedo and reforestation programs would be to reduce the urban heat island, completely offset it, or sometimes more than offset it. Simulations show that regional air temperature can be decreased by 4°C or more at certain locations and times as a result of increased urban albedo. These modeling studies also show that increasing vegetative canopy cover by 30% can potentially decrease air temperature by 3°C or more. However, a reduction in air temperature in urban areas of 1 or 2°C is more typical according to mesoscale meteorological modeling work. Thus, in most cities discussed previously, the UHI can be offset by large-scale implementation of high-albedo materials and urban forest. In terms of utility-scale impacts of such strategies, a decrease of 2°C in the UHI would be equivalent to savings of 4–10% from the afternoon peak electric demand in summer.

Extrapolation of numerical simulation results to regional and national scales suggests that the savings from implementing an aggressive reflective roof and pavement program can be significant, even after accounting for the wintertime heating energy penalties that can inadvertently result from increased reflectivity to incoming solar radiation. Typically, however, the heating penalties are smaller than the cooling benefits because in wintertime, solar radiation flux density is smaller (lower sun altitude angle), cloud cover is larger, overcast events are more frequent, and snow and rain can cover building and built-up surfaces (e.g., pavements and parking lots). Thus, the impacts of increased albedo is minimal under such conditions.

Table IV provides some simulation results obtained at the Lawrence Berkeley National Laboratory. The first row gives estimated net energy savings (in millions of dollars per year) from high-albedo roofs for each city. These results were based on the assumptions that residential reflective roofs have an albedo of 0.5 and that nonresidential reflective roofs have an albedo of 0.7 (both having an initial albedo of 0.2).

Table IV also gives the CDD and HDD (base 18.3°C) to show the climate traits for each region. Obviously, the regionwide savings also relate to city size and urban population density, not just to climate type. In addition, savings in cooling electricity and increases in natural gas needs for heating are given per 100 m^2 per year for these selected cities. The savings and penalties are given for both residential and nonresidential buildings and the net effect, integrated over the region, is shown. Extrapolating these results to nationwide scale, the net savings from an aggressive high-albedo roofs program in the United States is estimated to be on the order of \$700 million per year.

TABLE IV

Energy Savings from Complete Implementation of High-Albedo Roofs

	City							
	Los Angeles	Phoenix	Dallas	New Orleans	Atlanta	Miami	WDC/Baltimore	New York
\$M year^{-1} (net savings)	35	37	20	9	9	20	8	16
CDD, base 18.3°C (65°F)	940	3815	2415	2620	4920	4130	1045	1000
HDD, base 18.3°C (65°F)	1300	1155	2305	1680	3020	140	5235	5090
kWh year^{-1} 100 m^{-2}, residential	−182	−314	−166	−199	−153	−259	−137	−104
Therms year^{-1} 100 m^{-2}, residential	+4	+1	+3	+3	+4	0	+6	+10
kWh year^{-1} 100 m^{-2}, nonresidential	−350	−409	−224	−287	−239	−340	−221	−211
Therms year^{-1} 100 m^{-2}, nonresidential	+3	+2	+4	+2	+6	0	+9	+9

The cost of conserved energy (CCE) has been calculated for a range of building types, roof types, insulation levels, roof life spans, various levels of increased albedo, and a range of weather conditions. The target, of course, is to keep the CCE under \$0.08/kWh, which is the U.S. national average cost for electricity. To achieve this target, the incremental cost for reflective roofs should be kept under \$0.6 m^{-2} if it is assumed that the life spans of reflective and nonreflective roofs are equal. This is not true, however, since the life span of reflective roofs can be double that of nonreflective roofs, and if the cost of replacement for nonreflective roofs is factored in, then the cutoff incremental cost for reflective roofs can be much larger (to keep CCE under \$0.08/kWh). This is quite significant since other benefits of reflective roofs are not factored in (e.g., air quality and health benefits).

Increased vegetative cover cools the ambient air within and under a moist, evaporating canopy by up to 3°C. For example, parks are typically 0.5–1.5°C cooler than surrounding areas in higher latitudes. Observations in Canada show that urban parks can be 2.5°C cooler than their immediate built-up surroundings. In relatively lower latitudes (e.g., the southwestern United States), they have been observed to be 1–3°C cooler. Measurements in California's Central Valley show that orchards can be up to 6°C cooler than surrounding nonvegetated land but are typically only 2°C cooler. Studies in Japan show urban parks to be 1.5°C cooler than their surroundings in the summertime. However, it has also been shown that trees can sometimes increase air temperature within or above the canopy, especially if they are drier. The increase can be on the order of 1°C. Thus, the net effects of urban reforestation can be more complex to quantify than the effects of increased urban albedo, which are relatively more straightforward to understand.

For vegetation, the costs vary widely depending on tree species, age, size, planting location, etc. In the United States, trees can cost less than \$5 when small and young. However, some 5-m trees cost \$500 or more if purchased individually. Labor (planting) and maintenance (watering, pruning, and trimming) costs should also be factored in for an accurate analysis.

Glossary

blackbody A body absorbing all the thermal radiation impinging on it.
boundary The geometric contour dividing the thermodynamic system from the exterior.
conservation equations Equations expressing the balance of a prescribed quantity (e.g., mass, momentum, and energy).
convection Heat transfer at the boundary between a solid wall and a moving fluid.
exterior The part of space external to the thermodynamic system.
first law of thermodynamics The physical principle relating heat transfer to mechanical work.
Fourier equation Basic constitutive equation of heat conduction relating heat transfer to temperature gradient.
heat conduction Heat transfer in a substance, solid, liquid, or gas without macroscopic movements of the matter (not involving electromagnetic waves).
heat transfer Energy exchange across the boundary of a thermodynamic system due to a temperature difference.
Newton equation Basic constitutive equation of a fluid relating shear stress to velocity gradient.
non-Fourier equation Constitutive equation of heat conduction for special phenomena (e.g., low temperatures).
non-Newtonian equation Constitutive equation for shear stress of special fluids.
scale of temperature In the International System, the unit of measurement of the temperature is the degree Kelvin (K), which is 1/273.16 of the temperature of the triple point of water, and the dimension is $[\theta]$.
second law of thermodynamics The physical principle establishing a limit in the conversion of heat into work.
temperature The fundamental quantity measured by a thermometer.
thermal radiation Heat transfer connected to electromagnetic waves.
thermodynamic system Part of space under investigation.

Heat transfer is the energy interaction between a thermodynamic system and the exterior, due to a temperature difference, across the boundary. Heat transfer is measured, according to the first law of thermodynamics, as the work exchanged by a closed system in a cyclic process. The unit of heat transfer is Joule (J) (i.e., equal to the work unit), and the dimensions are $[M L^2 T^{-2}]$. No instrument can directly measure heat transfer, and only the thermometer can measure temperature.

1. HISTORICAL SURVEY

Experiments on heat transfer were done in ancient times and several kinds of heat machines have been invented. The first proposal to use a thermoscope to measure temperature is attributed to Galileo Galilei. The Galileo scientific heritage was continued by the Cimento Academy, founded in Florence in 1657 by the Granduke Ferdinand II and Prince Leopold of Medici. The Academy promoted experiments that allowed modern science to make the jump from the heat transfer empiricism of the past to the modern heat transfer scientific design. The most significant scientific contributions of the Cimento Academy, in its 10 years of existence, were the proposal to use several instruments to measure temperature and experiments in barometry and vacuum, which allowed other physical quantities to be defined, such as pressure, which plays a significant role in heat transfer.

2. MODALITY OF HEAT TRANSFER

There are three modalities of heat transfer: heat conduction, thermal radiation, and convection. Heat conduction is the kind of heat transfer, associated with the internal energy of matter, that occurs within a substance (gas, liquid, or solid) without macroscopic movement of its parts. No heat conduction is present in vacuum. Thermal radiation is the kind of heat transfer that is present also in vacuum. Convection is a combined type of heat transfer, occurring in a fluid (liquid or gas), which includes heat conduction and fluid motion.

2.1 Heat Conduction

This kind of heat transfer is present within a substance and is associated with the energy of the molecules, atoms, and their components. Heat conduction is related to the microscopic behavior of the matter. On the other hand, the basic, or constitutive, equation of heat conduction is related to the temperature gradient. The fundamental law of heat conduction must be consistent with the second law of thermodynamics—that is, heat must be exchanged between parts of a body or bodies at different temperatures. In contrast, no heat transfer is present between parts at the same temperature. The first law of thermodynamics, or the energy conservation equation, states that energy is conserved in the absence of heat sources and sinks. In general, the temperature at a certain point on the matter is a function of the space coordinate and time. An isothermal surface is a geometric surface on which temperature is the same throughout. If the temperature along this surface is constant in time, the isotherm can be said to be in steady state. Assume two isothermal surfaces with a temperature difference equal to dT distant in space dn, where dn is measured perpendicularly to the isothermal surface. The heat conduction per unit time and area, Q/A, has been proposed by J. B. Fourier to be proportional to a macroscopic physical property of the substance k according to the equation

$$q = Q/A = -k\ dT/dn = -k\nabla T. \tag{1}$$

The property k, called thermal conductivity of the substance, is defined by Eq. (1) and has been found to be a physical property (i.e., it is a function of temperature and pressure). The units of k are W/m K and the dimensions are $[M\ L\ T^{-2}\ \theta^{-1}]$. The thermal conductivity can be related to the microscopic behavior of the substance. The coupling of the Fourier equation, also called the constitutive equation for heat conduction, with the first law of thermodynamics, or the energy conservation equation, allows one to write a differential equation, in a three-dimensional rectangular domain, in unsteady state as

$$\rho c\ \partial T/\partial t = \partial/\partial x(k\ \partial T/\partial x) + \partial/\partial y\ (k\ \partial T/\partial y) + \partial/\partial z\ (k\ \partial T/\partial z) + q_g, \tag{2}$$

where q_g is the heat generated per unit time and volume, $k = f(x, y, z, t)$, $\rho = f(x, y, z, t)$, and $c = f(x, y, z, t)$. Equation (2) is valid for isotropic, heterogeneous media. The assumption of constant thermal conductivity allows Eq. (2) to be written as

$$\begin{aligned}&\partial T/\partial t\\ &= k(\rho c)\ (\partial^2 T/\partial x^2 + \partial^2 T/\partial\, y^2 + \partial^2 T/\partial\, z^2) + q_g/(\rho c)\\ &= \alpha\nabla^2 T + q_g/(\rho c).\end{aligned} \tag{3}$$

The new physical property of the substance, $\alpha = k/\rho c$, called thermal diffusivity, has been introduced because of the unsteady state; it has the units (m^2/s) and the dimensions $[L^2\ T^{-1}]$. Equation (3) has a parabolic form, which implies an infinite velocity of propagation of the effect or, in other words, that the effects of a thermal disturbance propagate instantaneously to an infinite distance from the source. Equation (3) has been verified for phenomena at ambient and high temperatures, and experimental results have been found to be in agreement with the theory. For very low-temperature phenomena, Eq. (1) has been modified and the following is one of the proposals:

$$\alpha/C^2\ \partial q/\partial t + q = -k\nabla T, \tag{4}$$

and the corresponding conservation equation becomes

$$1/C^2\partial^2 T/\partial^2 t + 1/\alpha\ \partial T/\partial t = \nabla^2 T, \tag{5}$$

where C is the velocity of propagation of heat transfer, given by $C^2 = \alpha/t_o$, and t_o is a relaxation time. The heat transfer with finite propagation velocity has been confirmed experimentally at liquid helium II temperatures. A similar effect of the liquid helium II has been found in materials of great purity and at low temperatures. Equation (5) is a hyperbolic equation.

2.2 Thermal Radiation

Thermal radiation is energy transfer in the form of electromagnetic waves. The microscopic mechanism can be related to the energy transport by photons

released from molecules and atoms. The physical parameters that describe thermal radiation are the photon or wave velocity, c, the wavelength, λ, and the frequency, ν. The photon energy is given by the relation

$$E = h\nu, \tag{6}$$

where h is the Planck constant, $h = 6.6256 \times 10^{-34}$ Js. Frequency and wavelength are related by

$$\lambda\nu = c. \tag{7}$$

The thermal radiation velocity in vacuum is equal to $c_0 = 2.997925 \times 10^8$ m/s. The wave velocity c in a medium is connected to c_0 by the relation

$$n_0 = c_0/c, \tag{8}$$

where n_0 is the refraction index of the medium traveled by the electromagnetic waves. Electromagnetic waves are classified by the wavelength λ, which is usually measured on the scale of 10^{-6} m $= 1\,\mu$m. Visible light is in the range 0.4–0.7 μm. The wavelengths generated by heated bodies are in the range 0.3–10 μm and are the thermal radiations of common interest. Radiation with a wavelength larger than the visible one is called infrared, whereas that with a wavelength smaller than the visible is called ultraviolet. In all energy applications except cryogenics, the characteristic dimensions of the system are large compared to the wavelengths of the thermal radiation. In cryogenics, because of the low temperatures, the radiation wavelengths are large. In the following, it is assumed that the energy transfer by radiation occurs along straight lines, excluding scattering or refraction. The radiant energy flux per unit time, $d\Phi$, can be evaluated for an area element dA along a direction with an angle β toward the surface normal. The radiant energy flux $d\Phi$ contained in a solid angle $d\omega$ within the frequency range $d\nu$ is given by

$$d\Phi = K_\nu \cos\beta\, dA\, d\omega\, d\nu = K_\lambda \cos\beta\, dA\, d\omega\, d\lambda, \tag{9}$$

where K_ν and K_λ are the monochromatic intensities of the radiant flux. In a nonemitting and nonabsorbing medium the intensity K_ν is constant along a ray, whereas it varies if it emits or absorbs radiation, and the radiant energy flux increase $d^2\Phi_e$, which is an order of magnitude smaller than $d\Phi$, is

$$d^2\Phi_e = j_\nu\, \rho dV\, d\omega\, d\nu, \tag{10}$$

where j_ν is the energy emitted per unit time and unit mass into a unit solid angle and within a unit frequency range. The energy flux absorbed along a path length ds is

$$d^2\Phi_a = \chi_\nu\, \rho ds\, d\Phi, \tag{11}$$

where χ_ν is the coefficient of absorption. The decrease in the radiant energy flux due to scattering is

$$d^2\Phi_s = -\sigma_\nu\, \rho ds\, d\Phi, \tag{12}$$

where σ_ν is the coefficient of scattering. Thermal radiation is present when there is local thermodynamic equilibrium in a medium. Application of the laws of thermodynamics to media in thermodynamic equilibrium allows the following conclusions:

The monochromatic intensity emitted, $K_{\nu e}$, is given by $K_{\nu e} = j_\nu/\chi_\nu$.

A radiation beam, traveling toward the interface between two media, with an angle β toward the surface normal is partly reflected with the same angle, with a ratio given by the reflectance or reflectivity, ρ_ν, and it partly penetrates, with an angle β' according to the law $\sin\beta'/\sin\beta = c'/c$.

The assumption of constant velocities, c' and c, allows one to find the final relation: $j_\nu c^2/\chi_\nu = j'_\nu c'^2/\chi'_\nu =$ constant, or a universal function, independent of the medium.

The absorbance of a medium, α_ν, is the ratio between the radiant energy flux absorbed and that approaching the interface.

The intensity of the radiation emitted by a medium to another medium, $i_{\nu e}$, is found in relation to the previous parameters as $i_{\nu e} = \alpha_\nu K_{\nu e}$.

A medium with $\alpha_\nu = 1$ is a blackbody, and no radiation impinging on that body is reflected or transmitted but is only absorbed. For a blackbody, the intensity $i_{\nu b}$ becomes $i_{\nu b} = K_{\nu e}$.

One of the conclusions of the electromagnetic theory of Maxwell was that the radiation reflected from an interface between two media exerts a pressure on that surface. The radiation pressure, which the solar radiation exerts on the surface of Earth, is very small (4×10^{-6} N/m^2). An important application of radiation pressure is associated with space flight, for which it has been proposed as a means of propelling space vehicles. The monochromatic intensity has been derived by Planck from the quantum theory as

$$i_{\nu b} = 2h\nu^3/(c_0^2(\exp(h\nu/\mathbf{k}T) - 1)), \tag{13}$$

where $k = 1.38054 \times 10^{-23}$ J K, the Boltzmann constant is universal. From Eq. (7), written in vacuum, it is found that

$$i_{\nu b} = 2C_1/[\lambda^5(\exp(C_2/\mathbf{k}T) - 1)], \tag{14}$$

where $C_1 = 0.59548 \times 10^{-16}$ W m^2 and $C_2 = 1.43879$ cm K. The maximum of $i_{\nu b}$ occurs according to the relation

$$\lambda_{\max} T = C_3, \tag{15}$$

where $C_3 = 0.28978$ cm K. The total heat radiated by a blackbody, into a unit solid angle, in the wavelength range from 0 to ∞ is

$$i_b = \int_0^\infty i_{\lambda b} d\lambda = \sigma T^4/\pi. \tag{16}$$

The emissive power e_b is found by integration over the whole hemispherical space (i.e., the solid angle ω),

$$e_b = i_b \int \cos\beta d\omega = \pi i_b = \sigma T^4, \tag{17}$$

where $\sigma = 5.6697 \times 10^{-8}\,\mathrm{W/m^2\,K^4}$. The previous equation is a good approximation of the behavior of the radiation emitted from a blackbody into a gas.

2.3 Heat Transfer by Convection

Convection occurs in a fluid during its flow at the boundary with a solid wall. The temperature of the fluid distant from the wall can be assumed to be constant and the gradient of temperature is mainly concentrated in a relatively narrow layer, δ, of fluid, close to the wall. A thin film of fluid adheres to the wall and temperature variation takes place across the layer δ. The temperature is constant outside the layer δ due to mixing of the fluid. In the layer δ of fluid, the heat is transferred by pure conduction as in a solid body. In the oversimplified case of a linear temperature variation across the layer, it is possible to write

$$Q = k_f A(T_f - T_w)/\delta, \tag{18}$$

where k_f is the thermal conductivity of the fluid, A is the surface involved in the heat transfer, T_f is the fluid temperature, and T_w is the wall temperature. The layer δ depends on the velocity of the fluid, the shape and the structure of the surface, and other factors. In the practical application, the ratio k_f/δ is substituted by a new coefficient h, the convective heat transfer coefficient, such that Eq. (18) becomes

$$Q = hA(T_f - T_w). \tag{19}$$

The coefficient h is not a property of the fluid, as is k in the constitutive equation of heat conduction, but it depends on the fluid dynamics conditions established in the fluid flow. It is important to use this coefficient in heat conduction problems as thermal boundary conditions. Later, the link between the heat transfer coefficient and the fluid flow is discussed. In convective studies, the concept of boundary layer, shear layer, and turbulence must be introduced. Several forces are involved in the movement of a fluid: body forces (e.g., gravity), electric or magnetic forces, centrifugal or Coriolis force, surface forces due to the influence of the surrounding fluid, and tensile and shear (or viscous) forces. The surface forces per unit area are the stresses. In a fluid, the tensile and shear stresses are related to the time rate of the deformation, and at rest only the tensile stress (i.e., pressure) is present. The shear stress must be related to the rate of deformation. For a simple flow situation in which the velocities, variation is only in the direction y, normal to the velocity, Newton proposed the proportional relation between the shear stress τ, in the flow direction, to the velocity gradient

$$\tau = \mu du/dy, \tag{20}$$

where the property μ is the dynamic viscosity, with units in kg/m s and dimensions $[M\ L^{-1}\ T^{-1}]$. The kinematic viscosity, ν, also called momentum diffusivity, is defined as

$$\nu = \mu/\rho, \tag{21}$$

with units $\mathrm{m^2/s}$ and the dimensions $[L^2\,T^{-1}]$. If the fluid obeys Eq. (20), it is Newtonian; otherwise, it is non-Newtonian. Several equations have been proposed for non-Newtonian fluids, but only some of them are shown here:

$$\text{Ostwald–de Waele fluid}: \ \tau = m(du/dy)^n, \tag{22}$$

where m is the consistency of the fluid and n is the index.

$$\text{Eyring fluid}: \ \tau = A \sin h^{-1}(du/dy\ 1/B), \tag{23}$$

where A and B are constants.

$$\text{Bingham plastic}: \ \tau = \mu du/dy + \tau_o \quad \text{if } \tau > \tau_o \text{ and } du/dy = 0 \text{ if } \tau < \tau_o. \tag{24}$$

Fluid particles in contact with a surface at rest have zero velocity, but velocity increases rapidly in the thin layer of thickness δ, called the boundary layer. The Reynolds experiment demonstrated the existence of two forms of flow—laminar and turbulent. In laminar flow, the individual streamlines run orderly side by side, whereas in turbulent flow they are interwoven with each other in an irregular manner. The motion of fluid particles in turbulent flow fluctuates around some mean flow path, and vortices of different size and orientation occur. The measurement of the velocity component, u, in turbulent flow at a location versus time results in the sum of a time-averaged value, $\bar{u}$, and an instantaneous value, u', of the timewise fluctuation. Assuming that the mean velocity is only in the x direction of u and that $\bar{v}$ and $\bar{w}$ are zero, the turbulent

intensity J is defined as

$$J = \sqrt{1/3(\bar{u}'^2 + \bar{v}'^2 + \bar{w}'^2)}/\bar{u}, \tag{25}$$

where each of the three terms is the time mean of the square of the velocity fluctuations. Heat transfer is influenced by the nature of the turbulence, as described by the length scale of the turbulent fluctuations and the vortices. A measure of the length scale of the turbulent fluctuations and vortices is given by the length L,

$$L = \int_0^\infty R(y)dy, \tag{26}$$

where the parameter R, given by

$$R = (\bar{u}_1' u_2')/\sqrt{\overline{u_1}'^2}\sqrt{\overline{u_2}'^2} \tag{27}$$

is obtained by hot-wire measurements, which determine the instantaneous velocity fluctuations simultaneously but at a varying distance y. Heat transfer by convection is enhanced by turbulent flow compared to the laminar one.

2.4 Heat Transfer Applications

There are many applications of heat transfer. The main applications are discussed here. Heat transfer is important in many practical applications relating to different branches of engineering but with opposite goals. Indeed, for mechanical and civil engineering, when energy must be conserved, and heat transfer to the exterior must be reduced, e.g., heat transfer losses in buildings during the winter. Energy savings from a building's heating and cooling systems can be obtained with the use of heating networks and cogeneration plants. One very important application is for very low-temperature situations such as cryogenics, which uses superconducting systems, in which heat transfer control with the exterior is crucial. On the other hand, in electrical and electronic engineering, because of the Joule effect, heat transfer to the exterior must be increased to maintain a constant temperature or to decrease the temperature of the system.

The problem of dissipating heat is an important issue in many electrical and electronic applications, such as in electrical wires and cables. Increased heat dissipation can be obtained with finned surfaces, which are of great importance in many energy systems, such as economizers in steam power plants, convectors for steam and hot water heating systems, electric transformers, and aircraft engines. In electrical machines, dissipation of electric energy requires an appropriate design, which is also required for chemical and nuclear fields in which heat sources are present. Heat transfer with change of phase is important in melting and solidification processes, combustion, frost penetration into the ground, and in aerodynamic ablation phenomena such as the protective devices of atmospheric reentry vehicles. The presence of a moving heat source or sinks in heat conduction is important in arc welding, surface hardening, continuous casting, or quenching. Radiation heat transfer phenomena are important in conventional, nuclear, and fusion power plants; gas turbines; and propulsion devices for aircraft, missiles, satellites, and space vehicles. Radiation pressure, in connection with space flight, has been proposed as a means of propelling space vehicles. Energy exchange by radiation is important in the calculation of heat transfer between surfaces in enclosures, as applied to satellites or space probes, moving in vacuum. The correct evaluation of the shape factor is important in several engineering applications, such as the radiation cooling surfaces in the furnace of a steam boiler or the tungsten spiral in an electric light bulb. Gas radiation is important in the heat transfer evaluation of furnaces and steam boilers. It is also important in plasma technology and the reentry phase of satellites or space vehicles through the atmosphere, when the gas is at very high temperatures. Flame radiation is important in the evaluation of heat transfer within tube bundles of water-tube boilers. Heat transfer analysis is useful for evaluating the temperature of a fluid flowing in a tube if the fluid temperature differs greatly from the ambient temperature. An additional systematic error in the temperature measurement is due to the heat exchange by radiation with the surrounding solid surfaces. Solar radiation evaluation is another important application of heat transfer because it can be employed for house heating and cooling.

3. HEAT CONDUCTION

3.1 Steady State

3.1.1 Composite Plane Wall

Consider a composite wall with three layers of different materials with thermal conductivities k_1–k_3, thickness x_1–x_3, and temperatures at the two extremes equal to T_{w1} and T_{w2}. The solution to Eq. (2), using the one-dimensional assumption

and steady state, gives the heat flux through the surface A:

$$Q/A = (T_{w1} - T_{w2})/(x_1/k_1 + x_2/k_2 + x_3/k_3). \quad (28)$$

The temperature variation within the layers is linear if the thermal conductivity is constant versus the temperature. If the boundary conditions at the two extreme walls are not given with assumed values of temperature but are defined according to Eq. (19) (i.e., the heat flux is specified in the form of the two convective heat transfer coefficients, h_i and h_e), and the two temperatures of the fluids are known as T_e and T_i, the heat flux is given by

$$\frac{Q}{A} = \frac{(T_i - T_e)}{(1/h_i + x_1/k_1 + x_2/k_2 + x_3/k_3 + 1/h_e)}. \quad (29)$$

3.1.2 Composite Cylindrical Wall

Consider a metallic tube with internal radius R_1, external radius R_m, and thermal conductivity k_m covered by an insulating material with external radius R_i and thermal conductivity k_i. Assume the internal wall of the metallic tube is T_{w1} and the external wall of the insulating material is T_{w2}. The solution to the conservation equation, obtained using the one-dimensional cylindrical assumption and the steady state, gives the heat transfer per unit length L of the cylinder:

$$\frac{Q}{L} = \frac{(T_{w1} - T_{w2})}{[\ln(R_m/R_1)/(2\pi k_m) + \ln(R_i/R_m)/2\pi k_i)]}. \quad (30)$$

If the boundary conditions are of specified heat fluxes, with the convective heat transfer coefficients h_i and h_e and the two fluid temperatures (the internal T_i and the external T_e), then the heat transfer is

$$Q/L = (T_i - T_e)/(1/(2\pi R_1 h_i) + \ln(R_m/R_1)/(2\pi k_m) + \ln(R_i/R_m)/(2\pi k_i) + 1/(2\pi R_i h_e)). \quad (31)$$

For a large radius of the insulation, R_i, the previous equation shows a decrease in heat transfer with the increase in the radius R_i. In the case of small values of R_i the previous equation presents a maximum depending on R_i. The radius of the maximum heat transfer is equal to

$$R_{crit} = k_i/h_e. \quad (32)$$

The practical application is for the insulation of electrical wires, where the objective is to provide an electric insulation and the maximum heat transfer for wire cooling.

3.1.3 Extended Surfaces

Assume that a solid body needs to dissipate more heat and the temperature of the cooling fluid cannot be modified. The only possibility is to increase the surface of heat transfer between the solid body and fluid. The simplest case is that of a thin rod with constant cross section A, perimeter C, and length L that is exchanging heat with a fluid of temperature T_f. With the assumptions that the temperature of the rod is only dependent on the distance from the body, is equal to T_0 at the base of the rod near the wall, is constant across the section A, and is in steady state, Eq. (3) can be solved to give the following temperature variation along the rod:

$$\frac{[T(x) - T_f]}{[T_0 - T_f]} = \frac{[\cosh(m(L-x) + (h_2/(mk))\sinh(m(L-x))]}{[\cosh(mL) + (h_2/(mk))\sinh(mL)]}, \quad (33)$$

and the heat flux at the boundary between rod and body is

$$\frac{Q}{A} = \frac{mk(T_0 - T_f)[h_2/(mk) + \tanh(mL)]}{[1 + (h_2/(mk))\tanh(mL)]}, \quad (34)$$

where $m^2 = hC/(kA)$, h is the convective heat transfer along the perimeter and h_2 at the final section of the rod, and k is the thermal conductivity of the metal rod. If the temperature of a fluid flowing in a tube is measured by a thermometer located in a well welded into the tube wall, and the tube wall has a lower temperature than the fluid, heat will be exchanged by conduction from the well to the tube wall and the indicated temperature will not be the true fluid temperature. The error can be calculated using the previous equations. Finned surfaces are of great importance in many energy systems, such as economizers in steam power plants, convectors for steam and hot water heating systems, electric transformers, and in aircraft engines. Practical finned surfaces differ from the thin rod, and the problem becomes more complicated from a mathematical standpoint. The finned surfaces of practical interest are rectangular fins, straight fins of triangular profile, and circumferential fins, for which the problems are the minimum weight, the fin effectiveness, and the fin arrangement.

3.1.4 Walls with Heat Sources

When heat sources are present in heat conducting bodies, it is necessary to calculate the temperature distribution within the bodies. In electrical machines and apparatus, the dissipation of electric energy

requires an appropriate design. In the chemical and nuclear fields, similar heat sources are present. In a plane wall $2L$ wide, with heat sources surrounded by a fluid at temperature T_e, Eq. (2) becomes, in steady state

$$d^2(T - T_e)/dx^2 + q_g/k = 0, \tag{35}$$

and the solution is

$$(T - T_e) = -q_g x^2/(2k) + C_1 x + C_2, \tag{36}$$

where the two constants C_1 and C_2 can be calculated by the boundary conditions imposed on the surfaces. With the convective heat transfer boundary condition at the two walls, and the convective heat transfer coefficient given by h, the final solution is

$$(T - T_e) = q_g(L^2 - x^2)/(2k) + q_g L/h. \tag{37}$$

The temperature distribution along the plane wall is parabolic with the maximum on the middle of the plane.

3.2 Unsteady State

The temperature of a body exchanging heat with a fluid of constant temperature is variable with time in unsteady state. Assume that the body has a large thermal conductivity compared to that of the fluid and the temperature difference is low in the body compared to that of the fluid. In this case, the first law of thermodynamics allows one to write the equivalence between the body internal energy variation (per unit time) and the heat transfer by convection with the fluid:

$$\rho c V dT/dt = hA(T_f - T), \tag{38}$$

where V is the volume and A is the surface of the body. With the initial condition of the body temperature, T_0, the following solution is found:

$$\begin{aligned}(T - T_f)/(T_0 - T_f) &= \exp - (hA/\rho c V t) \\ &= \exp - [(hL/k)(\alpha t/L^2)],\end{aligned} \tag{39}$$

where $L = V/A$ is a characteristic dimension that depends on the form of the body. The group of variables hL/k is called the Biot number and is represented by B_i. The group of variables $\alpha t/L^2$ is called the Fourier number and is represented by F_o.

3.3 Moving Boundaries

In many engineering heat transfer problems, there is a change of phase in the conducting medium. Examples include melting and solidification processes, combustion, frost penetration into the ground, and aerodynamic ablation applications such as in the protective devices of atmospheric reentry vehicles. The interface between the two regions of different physical properties moves as a function of time and latent heat is rejected or absorbed at its boundary. The formation of ice in water at 0°C is a problem that allows an exact solution, neglecting the heat capacity in the ice. The ice layer at time t is $x(t)$, the temperature in the liquid phase is equal to the phase change temperature T_{cp} and is constant throughout the liquid layer, and the solid phase temperature changes from the phase change value T_{cp} to that of the external surface T_s. The latent heat of fusion, Q_L, released by the change of phase of a layer dx has to be removed by conduction through the solid layer according to the following equation:

$$\rho Q_L dx/dt = k(T_{cp} - T_s)/x, \tag{40}$$

where ρ and k are relative to the solid. Imposing the boundary condition that the ice layer is zero at the beginning time, the analytical solution is

$$x = \sqrt{2k(T_{cp} - T_s)t/(\rho Q_L)}. \tag{41}$$

Consider the solidification of a liquid that has a temperature T_2 at a long distance from the surface. Heat is removed from the surface, which is maintained at the constant temperature T_1. In addition to the latent heat of fusion, solidification can take into account that the thermal conductivities, specific heats, and densities are different for the two phases. With the method developed by Neumann, it is found that the two temperatures, T_S and T_L, respectively in the solid (ice) and liquid (water) phases, are given by

$$\frac{(T_{cp} - T_L)}{(T_{cp} - T_1)} = 1 - \frac{\operatorname{erf}(x/2\sqrt{\alpha_1 t})}{\operatorname{erf}(K\beta/2)\sqrt{\alpha_1}} \tag{42}$$

$$\frac{(T_{cp} - T_s)}{(T_{cp} - T_2)} = 1 - \frac{\operatorname{erfc}(x/2\sqrt{\alpha_2 t})}{\operatorname{erfc}(K/2\sqrt{\alpha_2})}. \tag{43}$$

The interfaces move according to the laws

$$X_1 = K\beta\sqrt{t} \tag{44}$$

$$X_2 = K\sqrt{t}, \tag{45}$$

where $\beta = \rho_2/\rho_1$ takes into account the density decrease of ice and K is a constant to be determined numerically. In the water–ice system, an adequate approximation of K is

$$K_0 = \sqrt{2(T_{cp} - T_1)k_1/(Q_L\rho_1)} \quad \text{for } \beta = 1 \tag{46}$$

$$K_\beta = \sqrt{2(T_{cp} - T_1)k_1/(Q_L\rho_1\beta^2)} \quad \text{for } \beta > 1. \tag{47}$$

In the process of ablation, the melting fluid can be assumed to be completely removed by aerodynamic forces, the surface recedes with time, the surface temperature remains constant at the phase change temperature, and a temperature distribution exists only in the remaining solid.

Assuming the semiinfinite solid is heated by a constant heat flux, q_0, at the surface $x = 0$, the melted material is removed, the boundary of the solid and melt line is located at $X(t)$, the temperature distribution in the solid penetrates to a depth $\delta(t)$, and the temperature for $x > \delta(t)$ is constant and equal to T_S. The variation of the melt line X with time t is represented parametrically by

$$\Omega = -1/3[\zeta - 2 + 2(1+v)\ 1n\{(2(1+v) - \zeta)/(2v)\}], \tag{48}$$

where $\Omega = q_0^2 t/(\rho Q_L k \theta_P)$, $v = Q_L/(c\theta_P)$, $\zeta = q_0(\delta - X)/(\theta_P k)$, and $\theta_P = T_{cp} - T_S$, and also by

$$\lambda = -1/3[\zeta - 2 + 2v\ 1n\{(2(1+v)\text{-}\zeta)/(2v)\}], \tag{49}$$

where $\lambda = q_0 X/(K\theta_P)$.

The presence of a moving heat source or sinks in heat conduction is important in arc welding, surface hardening, continuous casting, or quenching. If a point source moves at velocity U in x direction in an infinite medium, with temperature T_f and a heat generated by the point source equal to q_g, the temperature distribution is given by

$$T - T_f = q_g \exp(-(U/(2\alpha))\ (r + \xi))/(4\pi k r), \tag{50}$$

where $r = \sqrt{(\xi^2 + y^2 + z^2)}$ and $\xi = x - Ut$.

4. THERMAL RADIATION

Several processes occur at high temperatures in engineering, and the proper knowledge of the radiation heat transfer phenomena is important for the correct design of equipment. Applications are relate to conventional, nuclear, and fusion power plants; gas turbines; and propulsion devices for aircraft, missiles, satellites, and space vehicles.

4.1 Radiation of Strongly Absorbing Media

For strongly absorbing media, the parameters can be related to the surface conditions neglecting the differences in the thermodynamic state within the thin layer, which contributes to absorption or emission. A new term, monochromatic emittance ε_λ, is introduced by the equation

$$\varepsilon_\lambda = i_\lambda / i_{\lambda b} = \alpha_\lambda, \tag{51}$$

which shows that the monochromatic absorptance is equal to the monochromatic emittance. A radiant beam, incident on a medium, can be absorbed in the medium, transmitted through it, or reflected. Reflectance, ρ_λ, is the ratio of the reflected to the incident energy; absorbance, α_λ, is the ratio of the absorbed to the incident energy, and transmittance, τ_λ, is the ratio of the transmitted to the incident energy. According to energy conservation, the following relation can be written:

$$\rho_\lambda + \alpha_\lambda + \tau_\lambda = 1, \tag{52}$$

which for a strongly absorbing medium, in which the transmitted energy is small, becomes

$$\rho_\lambda + \alpha_\lambda = 1. \tag{53}$$

Most solids absorb radiation very strongly and all the incident radiation is absorbed in a very thin layer of the surface. Exceptions are a few solid substances like glass, quartz, rock salt, and most liquids in the visible and near-infrared range. However, all the mentioned substances and liquids absorb very strongly in the bulk of the infrared.

4.1.1 Enclosures with a Nonparticipating Medium

Energy exchange calculations between surfaces in an enclosure with a nonparticipating medium can be applied to satellites or space probes moving in vacuum. The surfaces of the enclosure are assumed to be strongly absorbing media. The surfaces emit with an intensity independent of direction and with perfectly diffuse or specular reflection. The shape factor determines the influence of the local arrangement of the surfaces involved. Considering two area elements, dA_1 and dA_2, with dimensions small compared to the distance, s, between them, the shape factor of dA_1 toward dA_2, $dF_{dA_1 - dA_2}$, is given by the ratio between the heat flux incident on dA_2 to the heat flux leaving dA_1 as

$$dF_{dA_1 - dA_2} = \cos\beta_1 \cos\beta_2\ dA_2/(\pi s^2). \tag{54}$$

The shape factor depends only on the angular relationship describing the mutual position of the two area elements. It can be shown that

$$dA_1 dF_{dA_1 - dA_2} = dA_2 dF_{dA_2 - dA_1}, \tag{55}$$

which is called the reciprocity relation. The shape factor for a finite area A_2 is finally given by

$$F_{dA_1 - A_2} = \int_{A_2} (\cos\beta_1 \cos\beta_2\ dA_2/(\pi s^2)) \tag{56}$$

and the reciprocity relation for finite areas is

$$A_1 F_{A_1-A_2} = A_2 F_{A_2-A_1}. \quad (57)$$

The shape factor is 1 for two surfaces infinite in extent and for a surface inside an enclosure. For other configurations, the integral must be solved. For a surface A_i, completely surrounded by n surfaces, A_k, the following relation holds:

$$\sum_k F_{A_i-A_k} = 1. \quad (58)$$

The correct evaluation of the shape factor is important in several engineering applications, such as the radiation cooling surfaces in the furnace of a steam boiler or the tungsten spiral in an electric light bulb.

4.1.2 Enclosures with Black Surfaces

The radiation energy flux leaving the surface i, with A_i, is $A_i e_{bi}$, where $e_{bi} = \sigma T_i^4$. The radiation energy flux leaving a surface k in the direction toward surface i is $A_k F_{k-i} e_{bk}$; it arrives at surface i and is absorbed by it. The total energy flux absorbed by the surface i is $\sum_k A_k F_{k-i} e_{bk}$, and the net heat flux, exchanged per unit time, is

$$Q_i = A_i e_{bi} - \sum_k A_k F_{k-i} e_{bk} \quad (59)$$

Using the reciprocity law and Eq. (54), we obtain

$$Q_i = A_i \sum_k F_{i-k}(e_{bi} - e_{bk}), \quad (60)$$

and this equation can be written for each surface. The system of equations can be solved once the boundary conditions are prescribed, usually knowing the temperature, the emissive power, and the shape factor. Rapid solution of these equations can be carried out with analogy to the electric networks.

4.1.3 Enclosures with Gray Surfaces

Surfaces that emit radiation with an intensity independent of direction and that are perfect diffuse reflectors allow the introduction of radiosity, B, as the total heat flux leaving the surface per unit area and time. Radiosity is then independent of whether radiation is generated by emission or reflection. Irradiance, H, is the heat flux arriving at a surface per unit area and time. The surfaces are also assumed as gray and non-transparent, with $\alpha_i = \varepsilon_i$ and $\rho_i + \alpha_i = 1$. The heat loss of the surface by radiation is

$$Q_i = (B_i - H_i) A_i. \quad (61)$$

The heat flux H_i arriving from the surrounding surfaces is

$$H_i = \sum_k F_{i-k} B_k. \quad (62)$$

The radiosity B_i, due to emission and reflection, is given by

$$B_i = \varepsilon_i e_{bi} + \rho_i H_i. \quad (63)$$

The term H_i can be eliminated from the previous equations, with the assumption $\rho_i = 1 - \varepsilon_i$, giving

$$Q_i = \sum_k A_i F_{i-k}(B_i - B_k) \quad (64)$$

$$Q_i = A_i(e_{bi} - B_i)\varepsilon_i/(1 - \varepsilon_i). \quad (65)$$

Similar equations can be solved for each surface with the same boundary conditions as those for the enclosure with black surfaces, and the similar electrical analogy can be carried on. An additional resistance has been introduced into each connection of a node without influence on the potential of this node. In other words, the temperature of an adiabatic wall is independent of the absorption of the wall. The application of the procedure to two parallel gray surfaces of very large extent gives the heat transfer

$$Q_1/A_1 = (e_{b1} - e_{b2})/(1/\varepsilon_1 + 1/\varepsilon_2 - 1), \quad (66)$$

whereas for a surface A_1, enclosed in A_2, it gives

$$Q_1/A_1 = (e_{b1} - e_{b2})/(1/\varepsilon_1 + A_1/A_2(1/\varepsilon_2 - 1)). \quad (67)$$

If the surface 2 is much larger than 1, Eq. (67) becomes

$$Q_1/A_1 = (e_{b1} - e_{b2})\varepsilon_1. \quad (68)$$

4.2 Radiation of Weakly Absorbing Media (Gases)

Scattering is neglected in gases. Knowledge of the coefficient of absorption χ_λ is sufficient for the analysis because of the Kirchhoff equation,

$$j_\lambda = \chi_\lambda K_{\lambda e} = \chi_\lambda i_{\lambda b}. \quad (69)$$

The coefficient of absorption χ_λ can be measured from emission and absorption measurements in a medium of dimension S using the simplified equation of the monochromatic emissivity, ε_λ:

$$\varepsilon_\lambda = 1 - \exp(-\rho\chi_\lambda S) = \alpha_\lambda = 1 - \tau_\lambda. \quad (70)$$

Heat transfer by radiation can be calculated in an enclosure filled with an absorbing and emitting gas,

with the assumptions that the intensity of the walls of the enclosure are independent of direction and that they are diffuse reflectors and gray surfaces. The gas filling the enclosure is gray. The radiation heat flux leaving the surface k to the surface i is $A_iF_{i-k}B_k$, and the part arriving on surface i is $A_iF_{i-k}(1-\alpha_{i-k,g})B_k$, where $\alpha_{i-k,g}$ is the average absorbance between surfaces i and k. The radiation heat flux arriving at surface i is $A_i\varepsilon_{i,g}e_{bg}$, where $\varepsilon_{i,g}$ is the emissivity of the gas. The radiation heat flux leaving i is A_iB_i, and the net radiation heat loss of the surface i is

$$\begin{aligned} Q_i &= A_i[B_i - \sum_k F_{i-k}(1-\alpha_{i-k,g})B_k - \varepsilon_{i,g}e_{bg}] \\ &= A_i\varepsilon_{i,g}(B_i - e_{bg}) \\ &\quad + \sum_k A_iF_{i-k}(1-\alpha_{i-k,g})\,(B_i - B_k), \end{aligned} \tag{71}$$

and the net heat loss of the gas due to the radiation heat is

$$Q_g = \sum_i A_i\varepsilon_{i,g}(e_{bg} - B_i). \tag{72}$$

The last three equations are sufficient to calculate the heat loss for surfaces with known temperature, the temperature for adiabatic surfaces, and the heat loss of the gas in the enclosure. Gas radiation is important in the heat transfer evaluation of furnaces and steam boilers. It is also important in plasma technology and in the reentry phase of satellites or space vehicles through the atmosphere when gases are at very high temperatures. In this condition, radiation has its largest contribution from visible or near-ultraviolet wavelength range. Flame radiation is important in the evaluation of heat transfer within the convective surfaces of tube bundles in water-tube boilers.

5. HEAT TRANSFER BY CONVECTION

5.1 Conservation Equations

The conservation equations are written for a volume of fluid, in a system of Cartesian coordinates, of dimensions dx, dy, dz. The mass conservation for a fluid system without chemical reactions is

$$\partial\rho/\partial t + \partial(\rho u)/\partial x + \partial(\rho v)/\partial y + \partial(\rho w)/\partial z = 0, \tag{73}$$

and introducing the notation

$$D/dt = \partial/\partial t + u\partial/\partial x + v\partial/\partial y + w\partial/\partial z \tag{74}$$

it can be written as

$$D\rho/dt + \rho(\partial u/\partial x + \partial v/\partial y + \partial w/\partial z) = 0. \tag{75}$$

The conservation of momentum for the control volume states that the sum of all the forces acting on the mass must equal the time derivative of the momentum of the fluid mass. The fluid momentum changes due to the momentum flux, both out of and in the control volume, or due to the time change of the momentum of mass of the control volume. The surface forces per unit area, or the stresses, represent the action of the surrounding fluid on the control volume fluid. The stresses have two indices, as, for example, p_{xy} and p_{xz}. The first index indicates the direction normal to the surface and the second the direction of the stress component. The shear stresses are, for example, p_{xy} and p_{xz}. The normal stress $(p_{xx}-p)$ is composed of a viscous stress p_{xx}, which is a tensile stress that vanishes when the velocity becomes zero, and the fluid pressure p. The minus sign for the pressure takes into account the fact that it is assumed positive when it is compression stress (i.e., it acts from outside). The momentum conservation in the x direction is

$$\begin{aligned} &\partial(\rho u^2)/\partial x + \partial(\rho vu)/\partial y + \partial(\rho wu)/\partial z + \partial(\rho u)/\partial t \\ &= \partial(p_{xx} - p)/\partial x + \partial p_{yx}/\partial y + \partial p_{zx}/\partial z + \rho g_x. \end{aligned} \tag{76}$$

Using the mass conservation equation, it becomes

$$\begin{aligned} &\rho u\partial u/\partial x + \rho v\partial u/\partial y + \rho w\partial u/\partial z + \rho\partial u/\partial t \\ &= -\partial p/\partial x + \partial p_{xx}/\partial x + \partial p_{yx}/\partial y + \partial p_{zx}/\partial z + \rho g_x, \end{aligned} \tag{77}$$

and with notation similar to that of the mass conservation equation, that is,

$$Du/dt = \partial u/\partial t + u\partial u/\partial x + v\partial u/\partial y + w\partial u/\partial z, \tag{78}$$

it becomes

$$\begin{aligned} \rho Du/dt = &- \partial p/\partial x + \partial p_{xx}/\partial x \\ &+ \partial p_{yx}/\partial y + \partial p_{zx}/\partial z + \rho g_x. \end{aligned} \tag{79}$$

It is similarly obtained in the other two directions:

$$\begin{aligned} \rho Dv/dt = &- \partial p/\partial y + \partial p_{xy}/\partial x \\ &+ \partial p_{yy}/\partial y + \partial p_{zy}/\partial z + \rho g_y \end{aligned} \tag{80}$$

$$\begin{aligned} \rho Dw/dt = &- \partial p/\partial z + \partial p_{xz}/\partial x + \partial p_{yz}/\partial y \\ &+ \partial p_{zz}/\partial z + \rho g_z. \end{aligned} \tag{81}$$

At this point, the empirical relations connecting the stresses with the deformation of the fluid volume, also called constitutive equations, must be introduced, but only for Newtonian fluids. The shear

stresses for a Newtonian fluid have been derived by Stokes and are the following

$$p_{xx} = 2\mu\partial u/\partial x - \mu'(\partial u/\partial x + \partial v/\partial y + \partial w/\partial z) \quad (82)$$

$$p_{yx} = p_{xy} = \mu(\partial v/\partial x + \partial u/\partial y) \quad (83)$$

for the x direction and similarly for the other directions. The viscosity μ' has the value of $2\mu/3$ for monoatomic molecules and is the only one considered here. Introducing the previously mentioned constitutive equations, the three momentum conservation equations become

$$\begin{aligned}\rho Du/dt = &-\partial p/\partial x + 2\partial(\mu\partial u/\partial x)/\partial x \\ &+ \partial[\mu(\partial v/\partial x + \partial u/\partial y)]/\partial y \\ &+ \partial[\mu(\partial u/\partial z + \partial w/\partial x)/\partial z \\ &- \partial[\mu'(\partial u/\partial x + \partial v/\partial y + \partial w/\partial z)]/\partial x \\ &+ \rho g_x \end{aligned} \quad (84)$$

$$\begin{aligned}\rho Dv/dt = &-\partial p/\partial y + 2\partial(\mu\partial v/\partial y)/\partial y \\ &+ \partial[\mu(\partial v/\partial z + \partial w/\partial y)]/\partial z \\ &+ \partial[\mu(\partial v/\partial x + \partial u/\partial y)]/\partial x \\ &- \partial[\mu'(\partial u/\partial x + \partial v/\partial y + \partial w/\partial z)]/\partial y \\ &+ \rho g_y \end{aligned} \quad (85)$$

$$\begin{aligned}\rho Dw/dt = &-\partial p/\partial z + 2\partial(\mu\partial w/\partial z)/\partial z \\ &+ \partial[\mu(\partial w/\partial x + \partial u/\partial z)]/\partial x \\ &+ \partial[\mu(\partial w/\partial y) + \partial v/\partial z)]/dy \\ &- \partial[\mu'(\partial u/\partial x + \partial v/\partial y + \partial w/\partial z)]/\partial z \\ &+ \rho g_z. \end{aligned} \quad (86)$$

These equations are referred to as Navier–Stokes equations. The energy conservation equation is derived on the basis of the first law of thermodynamics applied to the fluid contained in the control volume. The time variation of the total energy contained in the control volume, $e_t = u + V^2/2$, which is the sum of the internal and kinetic energy, $dE_t/dt = d(e_tM)/dt$, is equal to the sum of the work transfer per unit time, dW/dt, of the energy exchange by convection, dE_c/dt, of the energy transfer by molecular movements, dE_m/dt (i.e., heat conduction) but also by diffusion:

$$dE_t/dt = d(e_tM)/dt = dW/dt + dE_c/dt + dE_m/dt. \quad (87)$$

For the control volume of dimensions dx, dy, dz, the total energy becomes

$$d(e_tM)/dt = \partial[(\rho e_t)dxdydz]\partial t. \quad (88)$$

The work exchanged in the x direction is positive when the force is acting in the flow direction and negative in the opposite direction and is

$$\begin{aligned}dW/dt = &[\partial(up)/\partial x - \partial(up_{xx})/\partial x - \partial(up_{yx})/\partial y \\ &- \partial(up_{zx})/\partial z]dxdydz + \rho ug_x dxdydz. \end{aligned} \quad (89)$$

The energy flux by convection in the x direction is

$$dE_c/dt = -\partial[\rho ue_c dxdydz]/\partial x. \quad (90)$$

The energy transfer by molecular movements in the x direction is

$$dE_m/dt = -\partial[e_{mx}dxdydz]/\partial x. \quad (91)$$

Using similar expressions for the other two directions, with the help of the mass conservation equation and the substantial derivative of the total energy, the total energy conservation equation is obtained as follows:

$$\begin{aligned}&\rho De_t/dt + \partial(up)/\partial x + \partial(vp)/\partial y + \partial(wp)/\partial z \\ &+ \partial(e_{mx})/\partial x + \partial(e_{my})/\partial y + \partial(e_{mz})/\partial z \\ &= \partial(up_{xx})/\partial x + \partial(up_{yx})/\partial y + \partial(up_{zx})/\partial z \\ &+ \partial(vp_{xy})/\partial x + \partial(vp_{yy})/dy + \partial(vp_{zy})/\partial z \\ &+ \partial(wp_{xz})/\partial x + \partial(wp_{yz})/\partial y + \partial(wp_{zz})/\partial z \\ &+ \rho ug_x + \rho vg_y + \rho wg_z. \end{aligned} \quad (92)$$

For a one-component fluid, the energy flux e_m is due to the Fourier equation.

5.2 Forced Convection

5.2.1 Laminar Flow

In a two-dimensional steady-state flow, the previous equations, restricted to the boundary layer, reduce to

$$\partial u/\partial x + \partial v/\partial y = 0 \quad (93)$$

$$\rho(u\partial u/\partial x + v\partial u/\partial y) = -\partial p/\partial y + \mu\partial^2 u/\partial y^2 \quad (94)$$

$$\partial p/\partial y = 0 \quad (95)$$

$$\rho c_p(u\partial T/\partial x + v\partial T/\partial y) = k\partial^2 T/\partial y^2, \quad (96)$$

considering negligible the influence of the gravitational body forces and assuming a fluid with constant properties.

5.2.2 Turbulent Flow

Considering a constant-property fluid in a two-dimensional flow and dividing the turbulent flow in a time-averaged value, $\bar{v}$ and a fluctuating value, v', for each variable, $u = \bar{u} + u'$, $v = \bar{v} + v'$, $p = \bar{p} + p'$, $T = \bar{T} + T'$, using the time average rules it is possible to obtain the following equations for the conservation of mass and momentum:

$$\partial\bar{u}/\partial x + \partial\bar{v}/\partial y = 0 \quad (97)$$

$$\rho(\partial\bar{u}/\partial t+\bar{u}\partial\bar{u}/\partial x+\bar{v}\partial\bar{u}/\partial y+\partial\overline{u'^2}/\partial x+\partial\,\overline{u'v'}/\partial y = -\partial\bar{p}/\partial x+\mu\partial^2\bar{u}/\partial y^2 \quad (98)$$

$$\rho\partial\,\overline{v'^2}/\partial y = -\partial\,\bar{p}/\partial y. \quad (99)$$

Integration of Eq. (99) gives $p_s = \bar{p} + \rho\overline{v'^2}$, which simplifies Eq. (98) giving the following equations, including the energy conservation equation:

$$\partial\bar{u}/\partial x + \partial\bar{v}/\partial y = 0 \quad (100)$$

$$\rho(\partial\bar{u}/\partial t + \bar{u}\partial\bar{u}/\partial x + \bar{v}\partial\bar{u}/\partial y) = -\partial p_s/\partial x + \mu\partial^2\bar{u}/\partial y^2 - \rho\partial\overline{u'v'}/\partial y \quad (101)$$

$$\rho c_p(\partial\bar{T}/\partial t + \bar{u}\partial\bar{T}/\partial x + \bar{v}\partial\bar{T}/\partial y) = k\partial^2\bar{T}/\partial y^2 - \rho c_p\partial\overline{T'v'}/\partial y. \quad (102)$$

The momentum equation differs from the laminar counterpart for the term containing the fluctuating quantities, which can be interpreted as resulting from turbulent stresses. The turbulent–boundary-layer equations contain too many unknowns and it is necessary to relate the turbulent stresses to the mean time values. Boussinesq first proposed the following:

$$\tau_t = -\rho\,\overline{u'}\,\overline{v'} = \rho\varepsilon_m\partial\,\bar{u}/\partial y, \quad (103)$$

where ε_m is the turbulent diffusivity of momentum. Similarly, the corresponding term of the energy equation has been proposed as given by

$$-\rho c_p\,\overline{T'}\,\overline{v'} = \rho c_p\varepsilon_h\partial\,\bar{T}/\partial y, \quad (104)$$

which introduces ε_h, the turbulent diffusivity of heat. The ratio of the two turbulent diffusivities has been defined as the turbulent Prandtl number:

$$Pr_t = \varepsilon_m/\varepsilon_h. \quad (105)$$

5.3 Natural Convection

The laminar boundary-layer equations under body force due to gravitational acceleration in low-velocity conditions, when the effect of viscous dissipation can be neglected, can be written for plane flow as well as for steady rotationally symmetric flow, as

$$\partial(\rho u r_0^n)/\partial s + \partial(\rho v r_0^n)/\partial y = 0 \quad (106)$$

$$\rho(u\partial u/\partial s + v\partial u/\partial y) = -dp/ds + \partial(\mu\partial u/\partial y)/\partial y + \rho g_s \quad (107)$$

$$\rho c_p(u\partial T/\partial s + v\partial T/\partial y = \partial(k\partial T/\partial y)/\partial y, \quad (108)$$

where s is the coordinate along the curved surface and y is normal to it. The exponent n is zero for two-dimensional flow and 1 for rotationally symmetric flow. Outside the boundary layer, the viscous effects are negligible and the momentum equation reduces to

$$dp/ds = \rho_e g_s - \rho_e u_e du_e/ds, \quad (109)$$

where e refers to the conditions outside the boundary layer. The momentum equation becomes

$$\rho(u\partial u/\partial s + v\partial u/\partial y) = g_s(\rho - \rho_e) + \rho_e u_e du_e/ds + \partial(\mu\partial\,u/\partial y)/\partial y, \quad (110)$$

and introducing the thermal expansion coefficient

$$\beta = 1/v(\partial v/\partial t)_p = -1/\rho(\partial\rho/\partial t)_p, \quad (111)$$

the following equation is obtained:

$$\rho(u\partial u/\partial s + v\partial u/\partial y) = -\beta\rho g_s(T - T_e) + \rho u_e du_e/ds + \partial(\mu\partial u/\partial y)/\partial y. \quad (112)$$

6. DIMENSIONAL ANALYSIS

For some heat transfer phenomena, the basic understanding of the physical processes is not enough to permit the writing of the fundamental equations. The alternative is to perform experiments and to generalize the results by dimensional analysis. For other heat transfer applications, an approximate knowledge of the equations is possible, and this allows one to start with these equations and make them dimensionless. One example of this approach is the case of flow separation on cylinders. The writing of the basic Navier–Stokes equations allows the conclusion that the velocity fields and pressure fields around cylinders are physically similar, provided the Reynolds number has the same value for all the considered cases. If the cylinder is kept at a temperature T_w and the fluid is at T_0, the Navier–Stokes equations can be written dimensionless and the dimensionless temperature can be found as

$$\theta^* = (T - T_0)/(T_w - T_0) = f(x/d,\ \mathrm{Re},\ Pr,\ Ec), \quad (113)$$

where x is the Cartesian coordinate and d is the cylinder diameter. The Reynolds number, Re, is defined as

$$\mathrm{Re} = \rho u_0 d/\mu, \quad (114)$$

where u_0 is the fluid velocity outside the boundary layer. The Prandtl number, Pr, is defined as

$$\mathrm{Pr} = \mu c_p/k. \quad (115)$$

The Eckert number, Ec, is defined as

$$\mathrm{Ec} = u_0^2/c_\mathrm{p}\theta_\mathrm{w}. \tag{116}$$

The convective heat transfer coefficient at the wall between fluid and cylinder, h, can be put in dimensionless form by introducing the Nusselt number, Nu, which is defined as

$$\mathrm{Nu} = hd/k = (\partial\theta^*/\partial(x/d)). \tag{117}$$

Considering also a fluid with variable properties, T_w/T_0, the final relation of the average Nusselt number on the total surface is

$$\mathrm{Nu}_\mathrm{average} = f(\mathrm{Re},\ \mathrm{Pr},\ \mathrm{Ma},\ T_\mathrm{w}/T_0, \alpha, \gamma), \tag{118}$$

where the Mach number, Ma, is defined as

$$\mathrm{Ma} = u_0/a_0, \tag{119}$$

where u_0 is the velocity of the fluid outside the boundary layer and a_0 is the velocity of sound for a gas with c_p, $\gamma = c_\mathrm{p}/c_\mathrm{v}$, $k = C_k T^\alpha$, and $\mu = C_\mu T^\alpha$:

$$a_0 = \sqrt{(\gamma - 1)c_\mathrm{p}T_0} = \sqrt{\gamma R\ T}. \tag{120}$$

The following relation holds between Mach and Eckert numbers:

$$\mathrm{Ec} = (\gamma - 1)\mathrm{Ma}^2/(T_\mathrm{w}/T_0 - 1). \tag{121}$$

In the practical applications, Eq. (118) is usually stated as the sum of exponential terms of the form

$$X = C_1 + C_2 Y^a Z^b W^c, \tag{122}$$

where the values of C_1, C_2, a, b, and c have to be found by specific experiments. The effect due to the rarefaction of gas is taken into account by the dimensionless Knudsen number, Kn, which is defined as

$$\mathrm{Kn} = \lambda/L = \mathrm{Ma}/\mathrm{Re}\sqrt{\gamma\pi/2}\ , \tag{123}$$

where λ is the mean free molecular path and L is a body dimension characteristic in the flow field. In natural or free convection flow (i.e., when the flow and heat transfer are present because of a constant body force due to the gravitational effect, g) two additional dimensionless numbers are defined: the Grashof number, Gr, and the Rayleigh number, Ra, defined as

$$\mathrm{Gr} = \beta g(T_w - T_0)L^3/\nu^2 \tag{124}$$

$$\mathrm{Ra} = \mathrm{GrPr}. \tag{125}$$

Another dimensionless number that is often defined in heat transfer problems is the Stanton number, St, defined as

$$\mathrm{St} = \mathrm{Nu}/(\mathrm{RePr}). \tag{126}$$

Glossary

anaerobic metabolism Cellular production of energy-containing adenosine triphosphate in the absence of oxygen.
basal metabolic rate The lowest rate of heat production by an adult mammal or bird (endothermic or "warm-blooded" animal), measured when body temperature is normal and costs for activity, temperature regulation, digestion, and other expenses are low or zero.
chemical potential energy Energy that is contained in the foodstuffs and that is released as heat or as other forms of chemical energy (e.g., adenosine triphosphate) during cellular oxidative or anaerobic metabolism.
efficiency The portion of energy used or converted out of the total energy input, usually expressed as a ratio (out/in) or as a percentage (100 * out/in).
feeding rate The amount of food, usually in grams of dry matter of the diet, that an animal eats each day.
field metabolic rate The rate of heat production by an animal living undisturbed in its natural habitat.
homeostasis Regarding energy flow, the maintenance over time of energy balance, where in = out and energy storage is zero (none accumulated or depleted over time).
oxidative metabolism Cellular production of energy-containing adenosine triphosphate from foodstuffs via an oxygen-using process.
production The synthesis of new biochemicals that contain chemical potential energy and their accumulation as stored fatty tissue, new body tissue (growth), or reproductive tissues (e.g., embryos, eggs, milk).
standard metabolic rate The lowest rate of heat production by a reptile, amphibian, fish, or invertebrate (ectothermic or "cold-blooded" animal) measured at a specified body temperature and when costs for activity, temperature regulation, digestion, and other expenses are low or zero.

Autotrophic organisms, including most plants and some micro-organisms, "eat" energy in the form of photons (radiant energy as sunlight) or as energy-containing bonds in inorganic chemicals. Heterotrophs eat autotrophs, thereby obtaining their energy in the form of organic chemicals (carbohydrates, fats, and proteins). Nearly all animals are strict heterotrophs, dining either on plants, other animals, or the remains of these organisms. Thus, life on earth depends on the flow of energy, primarily from the sun, through plants, through herbivores, through carnivores, and finally through detritivores.

1. IMPORTANCE OF HETEROTROPHIC ENERGY FLOW

1.1 Money Analogy

Energy is intimately involved in living processes at every level of biological organization, from the organelles in cells to ecosystems. The central importance of energy as a common currency for individual animals and within ecosystems is somewhat analogous to the importance of money in human societies. The main goal of working each day is to obtain this resource (food or money) in sufficient quantities to meet the needs of living that day. Daily needs are not fixed but rather vary with lifestyle and especially with behavior. If income exceeds daily needs, the excess can be stored or used for growth or reproduction. Too little of this resource can be fatal.

1.2 Competition for Food, Selection, and Adaptation

Thomas Malthus observed that populations reproduce faster than their food supply, and Charles

 © 2004 Elsevier Inc. All rights reserved.

Darwin realized that this should cause intense competition for food within a species. The critical component of the food is presumed to be its energy. Hence, energy availability should limit population density. It follows that there should be intense selection favoring individuals that manage their energy budgets more effectively. Effective management may involve (1) getting more energy from the environment each day, (2) digesting food more thoroughly, (3) reducing daily metabolic expenditures, and/or (4) increasing the "efficiency" of reproduction by producing more successful offspring from the same energy intake. If energy is the principal limiting resource for wild animals, selection pressure on biological properties that are directly concerned with energy metabolism should be more intense than selection pressure on other properties of animals. Thus, energy should be evolutionarily paramount, and most of the important features of living animals should be understandable from the perspective of energetics.

Unfortunately, studies indicate that this paradigm may be too simplistic an explanation of the biology of wild animals given that only rarely can food supply be shown to be an important limiting resource. When food energy is in excess, there is no pressure to conserve energy. If food is abundant, animals can simply eat more and overcome any shortcomings of energy management or inefficiencies within their bodies. Food shortages probably do limit populations at times, but such bottlenecks may be decades or centuries apart, making them difficult to study. During intervals between energy bottlenecks, other causes of mortality, such as predation, may predominate. Nevertheless, the energy bottlenecks are probably quite severe when they occur and should have a large selective effect on the characteristics of subsequent generations. Thus, animals may display phenotypes that reflect adaptations to energy limitations even though energy might not be limiting at the time. If so, knowledge of the energetics of a species should yield a better understanding of its biology, ecology, and evolution in general.

1.3 Energy Costs of Living

Living animal cells are chemically different from their environment, which is the extracellular fluid within the animal. These differences across the cell membrane tend to disappear due to passive diffusion down concentration gradients, and maintenance of constant intracellular conditions requires a continuous expenditure of energy by the cells. Additional energy is used by groups of differentiated cells (organs and organ systems) in carrying out the higher level functions they perform within animals. At the level of the whole animal, more energy is used for integrated actions such as social interchanges, predator avoidance, and food acquisition. Population energy flow is the sum of energy use by individuals, and community energy flow incorporates the effects of interactions among species of producers, consumers, and detritivores. Whole animals also must spend extra energy, beyond that spent by their cells on intracellular maintenance, to maintain internal chemical homeostasis in their extracellular fluids. Additional energy is needed for animals to move, obtain and digest their food, interact socially, grow, and reproduce. A complete energy budget for an animal would include all of the avenues of heat gain and loss and chemical potential energy gain and loss. Such a budget could be given in units of daily energy intake, loss, and storage in kilojoules per day (kJ/day). These units are rates reflecting the dynamic nature of animal energetics. This article focuses on chemical potential energy intake as food and follows the fate of that food energy.

2. ENERGY BUDGET OF AN ANIMAL

Animals fall into two main metabolic categories: endotherms (primarily mammals and birds that are sometimes termed "warm-blooded") and ectotherms (fish, amphibians, reptiles, and invertebrates). Endotherms use their high metabolic rates to produce the internal heat that allows them to maintain relatively high and constant body temperatures compared with their surroundings. Ectotherms have quite low rates of metabolic heat production, too low to warm their bodies much at all. However, some species of ectotherms, especially lizards, can achieve and maintain high body temperatures for hours by using external heat sources such as sunlight and sun-warmed rocks. Endotherms have much more metabolic machinery (enzymes) in their cells, and this makes their cellular operating costs much higher than those of ectotherms. The ability of endotherms to keep themselves warm allows them to occupy colder habitats such as those at high latitudes and altitudes. Ectotherms, which have good fasting endurance due to their low energy needs, can persist in habitats such as deserts and the ocean's depths, where food may be scarce periodically or continuously.

The only source of chemical potential energy for most animals is their food. The food can be taken in by mouth, or nutrients can be absorbed across body walls as in some parasites and marine organisms. Some of the food energy is digested and absorbed (assimilated energy), and the indigestible food residues are voided by the animals as feces. Feces actually contain additional substances such as bacteria from the hindgut that grow and feed on the undigested dietary residues as well as sloughed off gut cells and proteins (e.g., mucus) that contain energy that was assimilated earlier but escaped redigestion and reassimilation. Thus, the term "apparent assimilation efficiency" (AE) is used to describe the following ratio: (food energy in) – (fecal energy out)/(food energy in). Some assimilated chemical potential energy leaves animals as urine, and this energy is also not available for metabolism. Most of the urinary energy is in nitrogen waste products (e.g., urea, uric acid), but some is in mucus. The difference between energy ingested as food and that excreted as urine and feces is called metabolizable energy, and "apparent metabolizable energy efficiency" (MEE) is used to describe the following ratio: (food energy in) – (feces and urinary energy out)/(food energy in) (Fig. 1).

Metabolizable energy is used primarily for oxidative metabolism in most animals, and all of this energy ultimately leaves the animal as heat (Fig. 1). If any metabolizable energy is left over after paying the energetic costs of the essential physiological processes, it can be used for production (growth, storage, or reproduction). The essential energetic costs of living include the minimum (idling) cost, called basal metabolic rate (BMR) in endothermic animals and standard metabolic rate (SMR) in ectotherms, along with the additional costs of obtaining, ingesting, digesting, absorbing, and biochemically processing food as well as the costs of being alert, interacting socially, maintaining body temperature, being active (e.g., locomoting), and responding to diseases or parasites. Energy savings resulting from reduced oxidative metabolism may occur in endotherms that can lower their body temperatures for hours or days (torpor) or weeks (hibernation). Total metabolic cost also may be lower than the sum of its (separately determined) components if an animal can substitute heat produced from one process (e.g., activity cost, digestion cost) for simultaneous requirements for heat needed for maintenance of body temperature (thermoregulation cost).

When an animal eats just enough food to provide the metabolizable energy it burns in oxidative metabolism each day, it is maintaining energy balance. The chemical potential energy content of its body will not be changing from day to day, although during a given day it will have a positive energy budget when absorbing its food and a negative energy budget when the assimilation rate

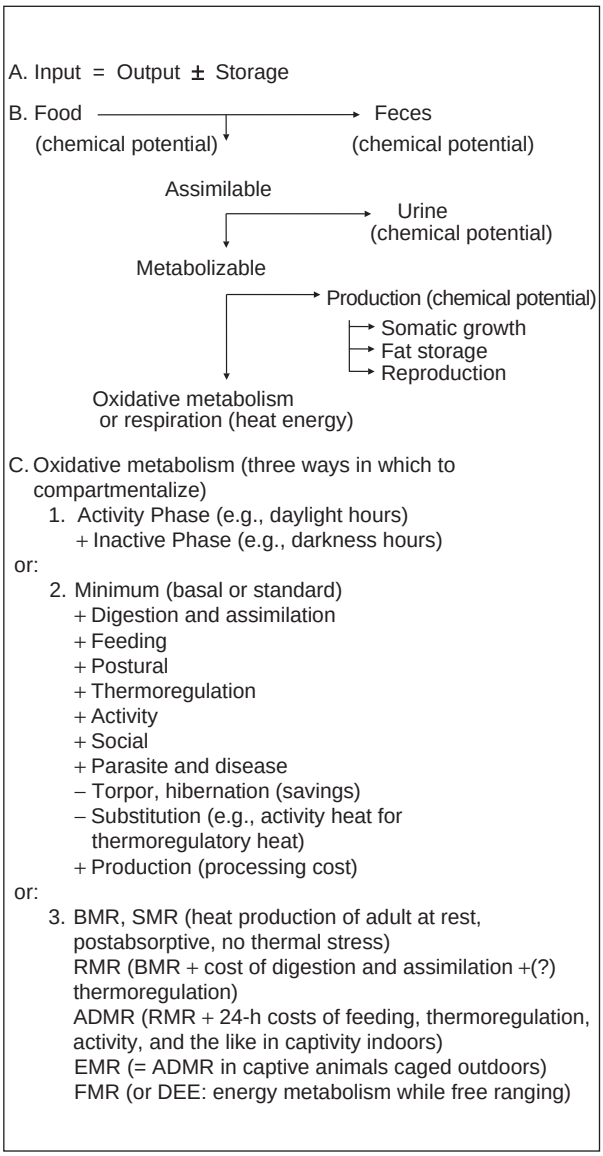

FIGURE 1 Three versions of a daily energy budget. Version A is in the form of a simple equation, and Version B accounts for the substances (food, feces, and urine) that move in and out of an animal. Version C shows three ways of subdividing the daily metabolic rate (daily heat production) portion of the energy budget of an animal, reflecting the different ways of measuring component parts. BMR, basal metabolic rate; SMR, standard metabolic rate; RMR, resting metabolic rate; ADMR, average daily metabolic rate; EMR, existence metabolic rate; FMR, field metabolic rate; DEE, daily energy expenditure.

declines below its metabolic rate. When an animal consumes more or less metabolizable energy than it burns in a day, its body will store the excess or contribute the deficit from body stores of energy. Most animals must have balanced energy budgets over relatively short periods of time (days, weeks, or even just hours for small endotherms such as some shrews and hummingbirds) to maintain life.

There are several ways in which to subdivide, or "itemize," an energy budget (Fig. 1). In theory, the various costs of living can be identified and listed as separate entries in the budget. Such a theoretical budget has intellectual value and appeal, but the practical difficulties of measuring each component of such a budget usually lead to its modification. For example, a theoretical budget might include the energetic expenses of hunting for and obtaining food (foraging cost), looking for and courting a mate (reproductive cost), and watching for and avoiding predators (antipredation cost). Using a rodent such as a desert kangaroo rat as an example, let us assume that it is in its burrow for 22 h and out of the burrow and active for 2 h each day. Let us also assume that we were able to measure the rat's daily metabolic expenditure and its metabolism only while it was in its burrow and that the difference between these expenditures (45 kJ/24 h–31 kJ/22 h) is 14 kJ/2 h active. The first problem in partitioning these 14 kJ into their theoretical budget categories is deciding whether basal metabolism, thermoregulatory and digestion costs, and the like, which the rat is also paying while it is outside its burrow doing other things, should be subtracted off to determine the pure cost of foraging, antipredation, and the like. This correction requires assumptions about energy allocation in active animals that have not yet been verified. The second problem is deciding, say from detailed observations of the animal's behavior while it was above ground, what portion of those 2 h the rat spent foraging, looking for mates, and avoiding predators and then subdividing the 14 kJ appropriately. This requires reading the mind of the kangaroo rat to determine whether it was looking for food, predators, or mates while it was sitting still in an alert, eyes-open posture during much of its time above ground. In fact, active animals probably do all three things simultaneously. The conservative choice is to label the 14 kJ simply as "metabolic cost while above ground." Creative experimentation will be required to increase the resolution of energy metabolism measurements of wild animals to evaluate the components of theoretical energy budgets. For now, researchers are settling for budget categories that reflect measurable parameters such as active and inactive periods of the day or basal (BMR), resting (RMR), average daily (ADMR), existence (EMR), and field (FMR) metabolic rates (Fig. 1).

Metabolizable energy that is not burned is available for production (synthesis of new biomass). Excess energy can simply be converted to fat and stored somewhere in the body, where it can be used for somatic growth (mostly as the protein and lipids needed for cell division and development) or for reproduction (growth of eggs or embryos as well as production of milk by mammals). Production involves formation of new biomass from foodstuffs. There are metabolic costs involved in these biochemical processes that add to the total rate of oxidative metabolism (heat production) of an animal producing new biomass. Animals are using energy continuously, and it is important to view energetics as an assemblage of processes, each having its own rate that varies through time. A useful analogy is that of a leaky bucket under an intermittently opened faucet. Various holes in the bucket can represent the components of oxidative metabolism that drain water (energy) out, lowering the water level. The intermittent faucet represents feeding events that add water (energy) to the bucket periodically. If more water is added than drains out each day, the volume of water in the bucket will increase (grow) over time. However, unlike the holes in the bucket, animals can influence the rates at which they use energy for various purposes, and they also influence their rate of energy intake (feeding rate).

We are accustomed to thinking about energy as packets, such as food items, that are measured in units of calories or joules. These are static units that do not represent rates of energy flow. The ratio of energy units to time units (joules/day or watts) does represent flow, and it is used herein. It is also important to pay attention to the time unit in discussions of animal energetics. Animals can spend energy very quickly over short time intervals (seconds or minutes, as during sprinting), and their maximum rates of energy expenditure can be far higher than their maximum rates of energy intake. However, over the course of a day, they may achieve energy balance by interspersing periods of activity with periods of resting, so that total energy expenditures do not exceed income. Likewise, some seasons may be difficult for animals and other seasons may be benevolent to animals, but over a whole year, the animals may achieve energy balance or even a positive energy budget that allows for growth or reproduction.

3. ENERGY INTAKE

The rate of metabolizable ("usable") energy intake that an animal achieves depends on many factors, including food availability in the habitat, feeding rate, diet composition and digestibility, capacities of the digestive tract, and appetite.

3.1 Food Availability

The availability of food in a habitat is different from food present in a habitat. Some of the potential food items are not available for a variety of reasons. For example, chemical potential energy in plant tissues might not be available to herbivorous animals because it is unreachable (underground or high on a shrub or tree), inedible (woody trunk of a tree or spine-covered stem or leaf), distasteful (containing antifeedant chemicals), toxic (containing poisons), or nutritionally inadequate (poor balance of nutrients or full of protein digestion inhibitors such as tannins). Some plant parts may be nutritionally poor or even toxic by themselves but can be edible and nutritious when eaten along with other plant parts that counteract toxins or make up for nutritional deficiencies. Similarly, plant items that are nutritious for an animal species having certain detoxification or digestive capabilities may be detrimental to another animal species that does not have those capabilities. Moreover, food availability also includes effects of patchy food distribution in space and time, and the ability of various animal species to exploit a given patch depends on the characteristics of the animals (e.g., small vs large, ability to catch insects). Thus, "food availability" must be defined from the perspective of the animal of concern and not simply as a fixed property of a habitat.

3.2 Food Composition and Digestibility

The chemical composition of diets that animals choose varies greatly. The plant matter in the diets of herbivores can consist largely of cell wall components that include cellulose, hemicellulose, and lignins. The chemical potential energy in these substances (collectively called "fiber") is generally unavailable to many herbivorous animals because they do not have the enzymes needed to digest fiber. Thus, less than half of the potential energy in the food may be available to these herbivores. On the other hand, animals that eat other animals are ingesting a food that has a chemical composition very similar to that of their own bodies, and most of those chemicals are digestible.

Diet digestibility, or digestive efficiency (DE), refers to the percentage of the dry matter (not energy, which is called assimilation efficiency or AE) of food that is digested and absorbed across the gut: DE = 100 * [(dry matter in) – (dry matter out as feces)/(dry matter in)]. DE varies greatly among different animals and diets. DE can be as low as 0.5% in earthworms (detritivores) eating soil with little organic matter in it (Table I) or as high as essentially 100% in hummingbirds or butterflies eating nectar, which is pure sugar dissolved in water. Herbivorous animals fall into two main categories: fermenters and nonfermenters. The most specialized fermenters are the ruminant mammals (e.g., cattle, antelope, sheep), which have a four-chambered stomach that contains an ecosystem of micro-organisms capable of digesting plant cell walls. The fiber is broken down by cellulases produced by microbes and is fermented by those microbes into volatile fatty acids that can be used by the animals for energy. The microbes use fiber fermentation and most of the soluble chemicals in the food (e.g., sugars, starch, proteins, lipids from the plant cells) for their own metabolism

TABLE I

Average Digestibilities and Energy Yields for Some Representative Diet/Consumer Combinations

Dietary category	Example species	Apparent dry matter digestibility (percentage)	Energy yield (metabolizable kJ/g dry matter)
Herbivore, monogastric	Gopher, jackrabbit	30–75	7–13
Herbivore, fermenter	Sheep, antelope	60–75	10–13
Carnivore	Insectivorous lizard	70–85	16–19
Granivore	Seed-eating rodent	90	16.9
Nectarivore	Hummingbird, butterfly	100	18
Soil eater	Earthworm	0.5–5.0	0.7

and production. Then, the microbes are digested and absorbed later in the digestive tract (beginning in the fourth stomach chamber, which is acidic). Thus, ruminants "cultivate" and "eat" microbes (mainly bacteria) and also eat plants. Nonruminant vertebrate herbivores ("monogastrics") have the standard acidic stomach and are able to digest only the soluble components in plant matter in their stomachs and small intestine. Thus, they obtain much less of the total energy in the diet than do fermenters (Table I), although in the field monogastrics often compensate by selecting young vegetation that has more soluble and less fiber components. However, many species of monogastric herbivores have some fermentation occurring somewhere in their gut, either in a somewhat modified portion of the stomach (e.g., macropod kangaroos, some primates) or in the large intestine (e.g., horses, many primates), and these species gain some of the energy locked up in plant fiber. Rabbits and some herbivorous rodents ingest their own feces (coprophagy) and thereby derive nutrition from the fermentative microbes bodies, as do ruminants. Carnivores digest most of the dry matter in their food (Table I). Granivores and nectarivores have the highest gain of energy from their food. They eat products of plants with which they have coevolved, wherein the plant benefits from pollination or seed dispersal and the animals benefit by obtaining food of high energetic quality. It is not surprising to find large benefits to consumers in circumstances where those producers that favor consumption have a selective advantage.

3.3 Stomach Capacity

Daily food consumption may be influenced by maximum stomach capacity. If predation or competitive pressures are high, animals that can obtain more food during a single foraging trip should have greater fitness. However, the information needed to test this hypothesis is largely unavailable. Early attempts to measure stomach volume by removing stomachs during autopsy, filling them with water, and weighing them are of questionable relevance to the situation in a live animal. In general, the capacities (volumes) of organs increase as a constant percentage of body mass as body size increases, but there is much room for interspecific differences. This is a topic for future research to address.

3.4 Appetite

Appetite is a major factor influencing energy intake rates, but little is known about appetite in wild animals. There is much literature on laboratory rats and mice, as well as on humans in relation to obesity and control of body mass, in both the physiological and psychological arenas. The scanty information on wild animals comes from measurements of feeding rate under various conditions rather than from measurements of hunger or satiation, which are the components of appetite, probably because of the difficulties in evaluating hunger and satiation directly in wild animals. Nutrient deprivation and hormone manipulation experiments indicate that food consumption rates of wild animals are determined primarily by energy needs rather than by needs for specific nutrients such as certain amino acids, fatty acids, vitamins, minerals, and/or carbohydrates or by needs for protein, carbohydrates, lipids, and/or vitamins in general. Animals eating diets deficient in specific vitamins, minerals, or amino acids generally do not increase food consumption beyond that needed to satisfy their energy requirements, but new foods become more attractive to them. However, animals deprived of water do develop an appetite for water (thirst), and sodium deprivation leads to "salt hunger" in some species. In general, appetite is influenced primarily by the energy requirements of the animal. This is also an area where research is needed.

3.5 Rates of Feeding

Feeding rates that are actually achieved in the field are influenced not only by intrinsic factors, such as endothermy or ectothermy, activity level, reproductive status, and digestive physiology, but also by extrinsic factors, such as season, food availability, competitive and social interactions with other individuals of the same or other species, and reduction of feeding opportunities due to the presence of predators or inclement environmental conditions (e.g., excessive midday heat, darkness, rainstorms). Over a period of several days or weeks, animals are usually able to compensate for short-term difficulties in getting food and are able to obtain approximately enough food to maintain energy balance. Body size is the most important determinant of feeding rate; bigger animals eat more food than do smaller animals. However, this is not a one-to-one relationship. An animal weighing 10 times more than another animal does not eat 10 times more food each day; rather, it eats only approximately 5 to 6 times more, in accordance with the scaling of metabolic rate. When differences in body mass are accounted for, feeding rates still vary by more than 25 times among species during their activity seasons. For example, a

representative insectivorous lizard that weighs 100 g consumes about 0.7 g of food (dry matter intake [DMI]) per day, whereas a typical 100-g bird living in a marine habitat consumes about 18 g of dry matter per day (Table II). Both may be living in the same seashore habitat, eating a similar diet (arthropods), and maintaining the same body temperature during the day, but the lizard's metabolic energy expenditures over a 24-h period are only about 4% those of the bird, so the lizard's food needs are proportionately lower as well. Within various groups of endothermic vertebrates, there is a 230% variation in feeding rates among same-sized animals. Desert-dwelling mammals and birds have relatively low feeding rates, and marine birds have relatively high feeding rates. Desert mammals and birds are known to have lower metabolic rates (basal and field) than do related species living in other habitats, so their food requirements should be correspondingly lower. The high feeding rates of herbivorous mammals, relative to other mammals, most likely result in part from their low MEE (Table I), meaning that relatively more plant food must be eaten to obtain a given daily rate of metabolizable energy intake.

TABLE II

Feeding Rates of Wild Vertebrates, Summarized in Allometric Equations Derived from Field Measurements of Energy Metabolism, for Various Groups of Mammals, Birds, and Reptiles

Animal group	*a*	*b*	Expected feeding rate (g dry matter/day) for a 100-g animal
Eutherian mammals (58 species)	0.299	0.767	10.2
Marsupial mammals (20 species)	0.483	0.666	10.4
Herbivorous mammals (26 species)	0.859	0.628	15.5
Desert mammals (25 species)	0.192	0.806	7.9
Birds (95 species)	0.638	0.685	15.0
Passerine birds (39 species)	0.630	0.683	14.6
Desert birds (15 species)	0.407	0.681	9.4
Marine birds (36 species)	0.880	0.658	18.2
Reptiles (55 species)	0.011	0.920	0.77
Herbivorous reptiles (9 species)	0.033	0.717	0.91
Insectivorous lizards (27 species)	0.011	0.914	0.73

Note. The equations have the following form: $y = ax^b$, where y = feeding rate (in grams dry matter consumed per day), x = body mass (in grams), a is the intercept at body mass = 1 g, and b is the allometric slope.

4. ENERGY USE

4.1 Metabolic Rate

Oxidative metabolism is the avenue of energy use that powers the daily costs of living (analogous to the overhead of human financial budgets such as housing, food, and transportation). This portion of the energy budget, also known as respiratory metabolism or metabolic rate, ultimately ends up as heat, which is produced primarily inside the animal during biochemical reactions or by friction of moving parts but also outside the animal, mainly by friction with, and work done on, the environment. Although most animals are capable of fueling these energy expenditures by anaerobic metabolism for short periods, either because of a lack of oxygen during breath holding (e.g., forced diving) or because the muscles are called on to spend adenosine triphosphate (ATP) energy faster than it can be produced by oxidative processes, the "oxygen debt" that is built up is paid off ultimately by aerobic processes. However, a few animals live most or all of their lives in anaerobic conditions (e.g., worms in anoxic mud and unstirred water in swampy areas, some intestinal parasites), and anaerobic metabolism is their main source of ATP energy. Nevertheless, most animals have access to oxygen and produce ATP primarily by oxidative metabolism.

Energy needs for oxidative metabolism apparently get the highest priority for metabolizable energy. When an animal is eating extra food, it will either store fat, grow in mass, or reproduce with the extra metabolizable energy (Fig. 2). However, as the feeding rate is diminished, these productive processes decline to zero while the metabolic rate remains nearly constant. At feeding levels below those needed for energy balance (where the rate of metabolizable energy intake = the rate of oxidative metabolic expenditure), production is "negative" in that the animal draws on chemical potential energy stored in its body to make up the deficit between intake from food and metabolic expenses (Fig. 2) and body mass declines. An animal's rate of oxidative metabolism does not remain exactly constant over a range of feeding rates. Metabolic rate increases as food intake increases above the weight maintenance level of intake, apparently due to greater costs of digestion and assimilation and to added

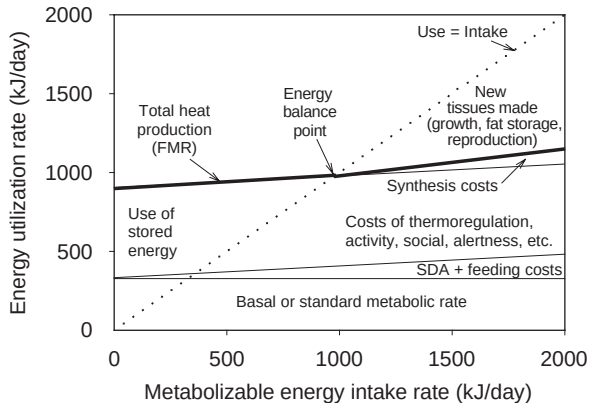

FIGURE 2 Fate of metabolizable energy input at various feeding rates in a representative 1-kg mammal. As daily feeding rate increases, metabolizable energy intake (dotted line) increases to a point where intake rate = utilization rate (energy balance point), and stored energy (e.g., fat) in the body is no longer used to make up the deficit (deficit indicated by the triangular space between dotted line [intake rate] and heavy solid line [metabolic rate] to the left of the energy balance point). At higher intake rates, extra energy intake (indicated by the triangular space above the heavy solid line to the right of the energy balance point) ends up in new biomass (production) either as fat, new somatic tissues, or reproductive tissues. Specific dynamic action (SDA, the cost of digesting food) and feeding costs increase as more food is consumed in a day, and costs of synthesizing new tissues increase as food consumption exceeds the energy balance point.

biosynthesis costs for production. The decline in metabolic rate as the food intake rate drops farther below the maintenance level is due to reduced digestion costs and probably to changes in behavior (reduced activity) and physiology (e.g., lower peripheral and even core body temperatures) that often accompany various degrees of starvation.

Rates of energy metabolism in free-living wild vertebrates are known as field metabolic rates (FMRs) or as daily energy expenditures (DEEs) and are expressed in units of kilojoules per day. There is much variation in FMRs of different animals, with measured values ranging from 0.2 kJ/day ($\sim$2.5 mW given that 1 W = 86.4 kJ/day) in a small African gecko to 67,700 kJ/d (784 W) in a male elephant seal weighing half a metric ton. This difference of nearly six orders of magnitude (10^6) in FMR is due largely to differences in body mass; bigger animals need more energy each day to pay their daily costs of living. FMRs increase exponentially (rather than linearly) with body mass, as do many other physiological and morphological variables. The slopes of the log–log (allometric) relationships for FMRs in various taxonomic, dietary, and habitat groupings of vertebrates range from 0.5 to near 1.0 and average approximately 0.7 (Table III). A slope of

TABLE III

Field Metabolic Rates of Wild Vertebrates, Summarized in Allometric Equations Derived from Field Measurements of Energy Metabolism, for Various Groups of Mammals, Birds, and Reptiles

Animal group	*a*	*b*	Expected FMR (kJ/day) for a 100-g animal
Eutherian mammals (58 species)	4.21	0.772	147
Marsupial mammals (20 species)	10.1	0.590	153
Rodents (30 species)	5.48	0.712	145
Desert rodents (15 species)	9.68	0.487	91
Herbivorous mammals (26 species)	7.94	0.646	156
Birds (95 species)	10.5	0.681	242
Passerine birds (40 species)	10.4	0.680	238
Marine birds (36 species)	14.25	0.659	296
Desert birds (15 species)	6.35	0.671	140
Reptiles (55 species)	0.196	0.889	11.8
Desert lizards (16 species)	0.177	0.935	13.1
Herbivorous reptiles (8 species)	0.232	0.813	9.8

Note. The equations have the following form: $y = ax^b$, where y = feeding rate (in grams dry matter consumed per day), x = body mass (in grams), a is the intercept at body mass = 1 g, and b is the allometric slope.

0.7 indicates that an animal that is 10 times larger than another animal will have an FMR approximately five times greater.

By solving the allometric equations in Table III for a 100-g animal, we can adjust FMRs for body size effects and then compare the FMRs of various taxa. It is obvious that birds and mammals are "high-energy" machines in comparison with reptiles. The endotherms need 15 to 25 times more energy per day to pay their costs of living (overhead) as do lizards of the same body mass. This enormous difference in the daily cost of living is due in part to the much higher concentrations and activities of metabolic enzymes, higher mitochondrial densities and cellular membrane surface areas, and higher thyroid activities in endotherms. It is also due to metabolic responses to the daily body temperature regimes of the two groups. Lizards become cool at night and their metabolism decreases, but endotherms stay warm and their metabolism may increase rather than

decrease at night to provide the needed heat. Among the endotherms, daily costs are similar for eutherian mammals and marsupial mammals but are higher for birds. One group of birds, those that live in marine habitats, has a very high cost of living, being about twice that of similar-sized mammals. As a group, desert-dwelling mammals and birds have relatively low FMRs, and this may benefit them in their sparsely provisioned habitat. FMRs also change with seasons, as indicated by the doubling in FMRs of desert kangaroo rats from summer to winter (Fig. 3A). This is probably related to the higher thermoregulatory costs during the cooler months (Fig. 3B). To the contrary, FMRs of desert tortoises decline during winter because the cold weather inhibits activity in these ectothermic animals and they hibernate during winter (Fig. 3).

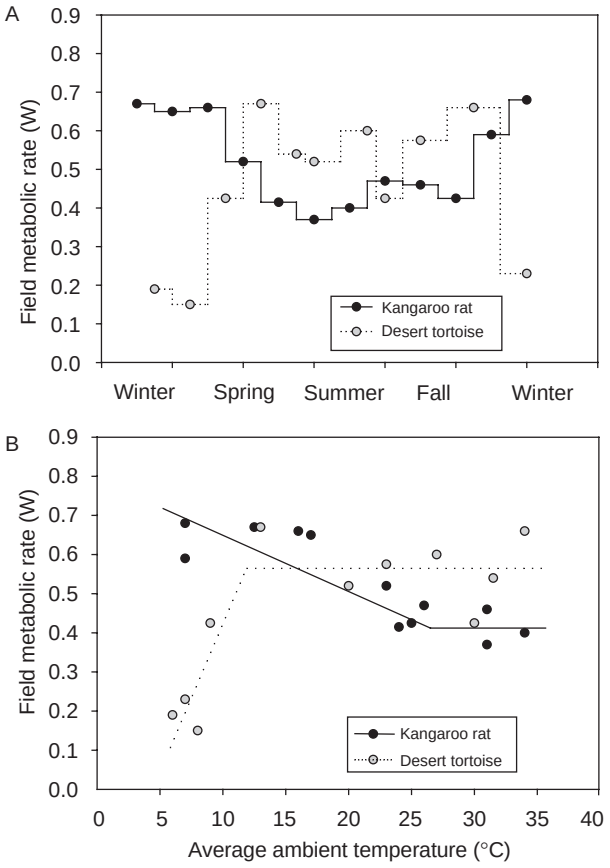

FIGURE 3 Field metabolic rates throughout a year in two desert animals: the kangaroo rat (*Dipodomys merriami*) and the desert tortoise (*Gopherus agassizii*). (A) The endotherm (rat) had higher metabolic rates during the cold seasons than during the warm seasons, but the reverse was true for the ectotherm (tortoise), which had higher FMRs during the warm seasons. (B) The ambient temperature effects are more easily seen when the FMR data are replotted versus average ambient air temperature. Interestingly, the annual energy expenditures of the two species are similar because the tortoise, a "low-energy" ectotherm, is about 30 times larger than the kangaroo rat, a "high-energy" endotherm. Thus, one individual of either species will have a similar impact on the food resources in its habitat.

What determines FMRs? Itemizing daily field energy expenses can reveal the mechanisms underlying daily costs of living and can provide explanations for differences in FMRs.

4.2 Production

Metabolizable energy consumed in excess of that required by oxidative metabolism can be used to create new biomass in the form of somatic growth, storage, or reproduction—or even two or all three simultaneously (Fig. 2). There are two issues here. The first concerns the conditions under which an animal consumes more energy than it needs to maintain energy balance, and the second concerns how extra ingested energy will be allocated. Both issues depend on species of the animal, its age, its sex, its endocrinological status, and the food supply in its habitat, among other things.

Many animal species (e.g., most reptiles, many invertebrates) seem to eat whenever food is available to them even though they may have already eaten enough to meet their immediate metabolic needs. These species have indeterminate growth and continue to increase in size throughout life via somatic growth. Although the extra energy is allocated mainly to growth, fat may be accumulated during times of great food abundance. For example, some snakes have greater fat contents just before winter begins as well as during occasional rodent population explosions, and filter-feeding bivalve mollusks have high fat contents during autumn as well as during algal blooms that may occur in some years and not others. These species do accumulate fat at certain times of the year, usually before seasons of low food availability, but the regulation of mode of production is poorly understood in many species. Some indeterminate growers, such as marine crustaceans, bivalves, and coelenterates, are able to reverse the growth process and become smaller while oxidizing their own somatic tissues during periods of food shortage.

Determinate growers, such as birds and many insects and mammals, have a fixed adult size range, and individuals do not grow much after reaching adult size. In fact, most birds reach adult size before they fledge and leave the nest. For adults of these species, appetite usually limits food intake to just that needed for oxidative metabolism even though food may be abundant in the habitat. In general, wild

vertebrates do not become obese, in contrast to some species of domestic animals and humans. Adults of species having determinate growth tend to have similar body fat contents in the field during a given season, and very fat individuals are rare. Many of these species are capable of increasing appetite and accumulating much adipose tissue, but they do not get fat until just before the period of need (e.g., winter hibernation, migration). One could speculate that obese animals would be quite attractive to predators due to their high energetic reward as well as to their lowered agility and consequent increased vulnerability. If so, selection would act to restrict periods of obesity to times of need only.

During the breeding season, both indeterminate and determinate growers allocate energy-containing chemicals to reproductive tissues. In many species, the males' energy investment in reproductive tissues (testes and accessory gland enlargement and sperm production) is minor compared with that of females. (An exception is found in male crickets and other insect species where males pass a large spermatheca to females, which use some of the chemical energy in the spermatheca to produce eggs.) Depending on species and body size, females may synthesize reproductive tissues (e.g., eggs, embryos, placentas, milk) at very high rates, and their feeding rates may double or even triple (in some species of small rodents) during some phases of the breeding period. For example, a female deer mouse may produce a litter that, at weaning time, may weigh several times her own body mass—all accomplished in a few weeks.

The chemicals needed for synthesizing the new biomass apparently are taken from the pool of substrates circulating in the blood. Hormones (i.e., growth hormone and thyroid hormones in the case of somatic growth, reproductive hormones in the case of reproductive tissues) trigger anabolic metabolism in certain tissues, and this apparently depletes blood substrates. This is presumably detected by the liver and other organs, which then add substrates to the blood to restore homeostasis. On the other hand, fat deposition appears to be a consequence of higher than normal blood levels of nutrients, favoring production and storage of lipids in adipose tissue. This process is influenced by the pancreatic hormones insulin and glucagon. It is not clear whether increased appetite or hormonal stimulation of fat deposition is the primary stimulus for the rapid deposition of fat in some small mammals just before they hibernate and in some birds just before they migrate.

It is possible for both "negative" and "positive" production to occur simultaneously in an animal. For example, lactating female mammals may draw on their own tissues to produce milk for their babies when food intake is inadequate. Similarly, female desert tortoises use protein and fats from their own soma, along with newly consumed foodstuffs, to synthesize eggs during spring.

It is important to recognize that neither food energy supply nor energy intake is the primary determinant of production in many animals. Food supply may be high, but that does not necessarily mean that an animal will consume more and then grow or reproduce. Although fat deposition may occur as a result of a high food intake in response to high food availability, somatic growth (in determinate growers) and reproduction are usually triggered by factors other than energetics, and it is these factors that increase appetite. Appetite seems to be determined largely by hormonal conditions in the animal that are responding to factors such as season, photoperiod, and age and sex of the animal as well as by energetic parameters in the animal and its environment.

In the field, an animal that is producing new biomass is paying not only additional energy for biosynthesis costs but also the extra costs associated with getting the additional food needed for growth. These costs include the extra activity involved in foraging longer, avoiding predators longer, thermoregulating longer, and interacting socially longer while getting the extra food as well as the higher specific dynamic action required to process the extra food. These added costs should also be considered as costs of production.

5. EFFICIENCY

Not all of the chemical potential energy in the food can be used by animals because some is indigestible and is lost as feces, and some that is digested and absorbed leaves the body as urinary wastes (which in some animals is mixed inseparably with feces when voided). The fraction of the food's energy that is absorbed across the gut and not lost in feces is called assimilated energy, and the percentage of dietary energy that this amounts to is the apparent AE. Apparent MEE, or the percentage of dietary energy that is usable for metabolism or production, is assimilated energy corrected for urinary energy losses. Production efficiency can be expressed in a variety of ways. Here, it is given as net production efficiency (NPE), which is the percentage of metabolizable energy that appears as chemical potential energy in new biomass (e.g., fat, growth, eggs, embryos, milk).

TABLE IV

Typical Energetic Efficiencies (Percentages) in Animals Having Various Diet

Diet type	Assimilation efficiency	Metabolizable energy efficiency	Net production efficiency
Herbivore, monogastric	30–77	22–73	20–55
Herbivore, ruminant	60–75	50–70	23
Herbivore, hindgut fermenter	60–72	55–68	23
Granivore	77–90	74–81	22–24
Carnivore	70–88	62–81	30–58
Omnivore	80	74	23–58
Lactivore	95	87	45
Detritivore	12–44	12–42	53
Parasites	77–100	71–95	50

Note. AE (assimilation efficiency) = [(I−L) / I]100; MEE (metabolizable energy efficiency) = [(I−L−U)/I)]100; NPE (net production efficiency) = [P/(I−L−U)]100; I, food energy intake; L, feces energy loss; U, urinary energy loss, P, energy allocated to production of biomass.

AE and MEE vary greatly among diets (Table IV). This variation is due mainly to the relatively indigestible organic components of the various diets: cellulose in plants, keratin in vertebrates, and chitin in arthropods. Within the herbivores, the type of digestive system an animal has also influences AE. For a given diet, herbivores that ferment foods, either at the beginning of the gut in specialized stomachs (e.g., ruminants) or at the end of the gut (cecum or colon fermenters), can digest and assimilate more of that food's energy. These fermenters obtain some of the energy in cellulose, which is broken down by cellulases produced by anaerobic microbes in their fore- or hindgut. This allows ruminants to live on lower quality plant foods, such as dry grasses (straw), and reduces competition for food among herbivore types. Monogastric herbivores often choose high-quality foods (e.g., young leaves, flowers, buds) when available, and they may attain high AE and MEE (up to 73–77% [Table IV]) by diet selection, thereby avoiding the low AE (22–30%) they would have if they ate dry grasses.

Young suckling mammals (lactivores), parasites, and animals that eat seeds (granivores), nectar (nectarivores), or other animals (carnivores) all have relatively high AE and MEE. Coevolution of plants along with the animals that pollinate their flowers and disperse their seeds probably has favored their cooperation and the ready satisfaction of those animals' energy needs from those plants' products. On the other hand, herbivores are essentially predators on plants, and evolution has favored plants that developed defenses against herbivory such as spines, woody tissues, poisons, crystalline inclusions (silica spines), and antifeedant chemicals (secondary plant compounds). Moreover, plant foods often are unbalanced in regard to the nutrient proportions (e.g., energy, protein, minerals, vitamins) required by the consumer. Thus, some herbivores have extraordinary modifications of their feeding and digestive apparati that improve their ability to survive on vegetation (e.g., plant toxin avoidance or resistance by some caterpillars and beetles, coprophagy by rabbits, rumination by sheep and antelope). Animals that eat other animals (carnivores and parasites) do not face the problems of food quality that the herbivores face because the composition of these animals' food is essentially the same as their own. However, carnivores often are challenged by problems of food quantity in that their prey may be hard to obtain.

Production efficiency can be measured only when an animal is producing new biomass, and this may be a fleeting event in the lives of some wild animals, especially birds and many mammals and insects. The values for NPE in Table IV are mainly from domestic, farm, or captive wild animals, and they represent near maximum efficiencies that occur during peak production periods. Efficiencies will be lower in animals that forage for their own food because extra energy is required to obtain the extra food needed to support growth. Nevertheless, some generalizations seem warranted from studies on domesticated animals. Ectotherms generally have higher peak NPE than do endotherms, apparently due to the higher metabolic expenditures for oxidative metabolism paid by endotherms. Where a range of values for NPE is given in Table IV, the highest efficiencies are for ectotherms and the lowest are for endotherms. Diet type has a large effect on NPE, with high-protein foods having lower efficiencies than high-fat

and high-starch diets. Finally, the type of production occurring influences NPE, with milk production and somatic growth having efficiencies substantially higher than those for fattening. There is still controversy about whether NPE declines at higher rates of food intake, so the "law of diminishing returns," derived from experiments on adding increasing amounts of fertilizer to crops, might not be applicable to animal energetics.

Studies on five species of farm animals, selected for good production capabilities, show a modest and surprisingly uniform maximum rate of food energy consumption (maximum ME intake = 4.4–5.7 BMR). A subsequent evaluation of maximum observed feeding rates in domestic and wild mammals (8 species) and birds (11 species) indicates that maximum ME intake ranges from three to six times BMR. Thus, animals may limit their food intake to rates that their guts can deal with effectively. The role of appetite is clearly critically important but still poorly understood for wild animals.

Energetic efficiency values are useful for evaluating the quality of various foods and for identifying feeding and digestive adaptations of animals eating a variety of food types. It is tempting to hypothesize that animals should be selected for having higher efficiencies, but this is unlikely for three reasons. First, efficiency is a ratio of two rate processes, and there is no evidence that natural selection responds to such an abstract derived variable as a ratio. Second, some important efficiencies are already near the maximum of 100%, leaving little variation on which selection might operate. Third, an animal can increase its daily rate of metabolizable energy intake much more easily and dramatically by eating more food and keeping AE constant than by keeping feeding rate constant and improving its digestive physiology enough to increase MEE substantially.

6. REGULATION OF ENERGY METABOLISM

Most physiological processes and systems are closely regulated, so it is reasonable to ask whether and how oxidative metabolism of animals is regulated. Metabolic rates of marine and aquatic invertebrates and water-breathing vertebrates may be regulated by oxygen availability in their environments. Metabolism of terrestrial and aquatic invertebrates and ectothermic vertebrates that live in cold climates may be reduced dramatically when these animals freeze during winter. For air-breathing vertebrates (birds, mammals, reptiles, and most amphibians), current knowledge indicates that aspects of energy budgets (e.g., thermoregulation, reproductive output) are regulated but that overall daily energy expenditure (FMR) itself is probably not directly controlled. Instead, the FMR appears to be a consequence of its component parts. For example, an ectothermic vertebrate has a total daily expense for its resting metabolic costs that will be determined by its daily body temperature excursion, which is most likely determined by the animal's minute-by-minute decisions to hide, forage, bask, display, or escape predators and not by some metabolic control center in its central nervous system. This animal may spend additional energy for activity associated with basking, feeding, interacting, and escaping. These costs are also consequences of other phenomena, as are the added costs of digesting and processing food, producing new biomass, and remaining alert and responsive while above ground. Thus, the total daily expense (FMR) seems to be the sum of costs incurred for tasks not directly related to energy metabolism. The situation for an endotherm is similar except that its minimum metabolic rate (BMR) is fixed and its thermoregulatory costs are determined by ambient temperatures.

Animals do some things that may reflect a crude ability to regulate (mainly reduce) FMRs. Ectotherms may choose to remain inactive in cool retreats for days, especially during periods of environmental stress (e.g., drought, low food availability), and this behavior reduces the daily use of energy and other nutrients. Similarly, some small endotherms may use torpor or hibernate, and their low body temperatures reduce FMRs greatly, but this also renders them relatively unresponsive and vulnerable to predation. However, for normally active animals, there is no known mechanism that might sense the rate of energy expenditure or the accumulated daily total energy expenditure and then limit the amount allocated to thermoregulation, activity, digestion, and the like during the rest of the day (regulate output). Instead, it seems that animals spend whatever energy is called for to get through the day and then regulate intake, by means of altered appetite, to achieve energy balance. Similarly, energy allocation to growth and reproduction appears to be a consequence of hormonal changes associated with regulation of those processes, with appetite being the "cart" following the "horses" of growth and reproduction.

Even though the rate of oxidative metabolism might not be under direct physiological control, there are upper limits that constrain energy expenditures.

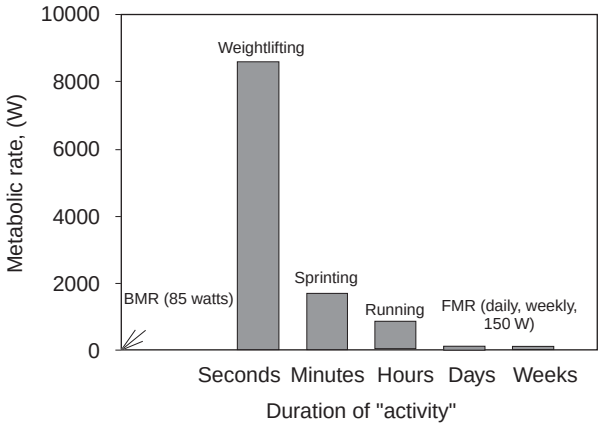

FIGURE 4 Rates of energy expenditure achieved by human athletes during bouts of activity of various kinds. Weightlifters can use ATP very quickly during a lift (100 times their BMR), but this cannot be sustained for very long due to buildup of oxygen debt. Sprinters also use anaerobic sources of ATP and cannot sustain sprinting for longer than a few minutes. Runners (at 20 times BMR) sustain their activity aerobically but are not maintaining energy balance while running because their intake is zero. Maximum sustainable metabolic rates, where humans are in energy balance, are only 5 times BMR. Typical FMRs of nonathlete humans are 1.5 to 2.5 times BMR.

The level of these limits depends on the amount of time involved in the determination of the limit. For example, a champion weightlifter can put out power during a lift that is more than 100 times his BMR, but this effort draws on and uses up energy-containing chemicals and oxygen stored in muscles, so it cannot be sustained for more than a few seconds (Fig. 4). Similarly, sprinters use aerobic as well as anaerobic metabolism to power their running, so sprinting cannot be sustained for more than a few minutes, but sprinters can run faster (use energy faster) than can long-distance runners, who are entirely aerobic. However, continuous running is not a sustainable activity either due to the needs to eat and sleep periodically. The highest sustainable FMR measured in humans is approximately 480 W (in Tour de France cyclists) or approximately 5.6 times BMR. Maximums measured in wild animals are approximately 6.9 times BMR in a small marsupial mammal, 5.0 times BMR in a rodent (eutherian mammal), 6.7 times BMR in a breeding seabird, and 4.6 times estimated field SMR in a small reptile.

7. SUMMARY

Chemical potential energy, in the form of food, is a centrally important resource for animals (heterotrophs) and has been termed the "primary currency of life." Knowledge of the ways in which animals gain, use, and store energy, and of their rates or "flows," may reveal much about the biology of various species, and such knowledge is essential in understanding energy flows in populations and through communities. The input side of a chemical potential energy budget is simple, being made up only of food intake. Energy outputs, corrected for loss of chemical energy in excreta, include heat resulting from oxidative metabolism and biomass (production of new tissues in the form of adipose tissue [fat storage], somatic growth, and reproductive tissues [sperm, embryos, eggs, placentas, and milk]). Different kinds of foods yield widely different amounts of energy; soil and detritus contain the least, plant tissues are intermediate, animal matter is higher, and seeds and nectar are highest. However, the availability of these food types in the field is not uniform in space or time. Endothermic animals require much more (15–25 times more) energy each day than do same-sized ectothermic animals. Large animals need more food energy than do small animals, but the increased food requirement is only about half that expected from the difference in body masses (a 10-fold mass increase requires only a 5- to 6-fold food intake increase). Most or all of the available food energy (metabolizable energy) is used for oxidative metabolism (metabolic rate), which has highest priority. Excess metabolizable energy can be used for production, but many animals do not consume excess food, despite its availability, except during certain seasons (e.g., breeding, premigratory, prehibernation). Daily energy needs appear to be influenced mainly by energy use for resting costs, temperature regulation, and activity. Although there appear to be upper and lower limits to rates of energy expenditure and food intake, actual daily energy needs seem to be determined more by lifestyle, season, and local circumstances than by precise regulation of energetic parameters themselves. Digestibility, AE, and MEE are determined mainly by diet type, although there is much variation among digestive capabilities of different herbivores. Net production efficiency is usually higher in ectotherms than in endotherms. Although daily energy expenditures by animals have operational upper and lower limits, actual expenditures do not seem to be regulated directly; rather, they are subservient to other aspects of the animals' biology such as thermoregulation needs, foraging expenses, reproductive and migration costs, and costs of interactions with other organisms (e.g., conspecifics, predators) in

their surroundings. Appetite, a poorly understood factor in wild animals, apparently matches income with expenditures, so that most animals are approximately in energy balance much of the time. The evolution and success of birds and mammals, which have extraordinarily high costs of living compared with those of ectotherms, still needs a compelling explanation.

Glossary

aerobic respiration (metabolism) Energy producing reactions that require oxygen (O_2).
basal metabolic rate (BMR) The minimum level of energy required to sustain basic biological function of the body.
body mass index (BMI) A weight-for-height index used to assess physical nutritional health, calculated as weight(kg)/height(meters)^2.
calorimetry The measurement of heat transfer.
kilocalorie (kcal) The amount of heat required to raise the temperature of 1 kilogram (or 1 liter) of water by 1°C. This is the unit most commonly used to measure the energy content of food and human energy requirements.
macronutrient Chemical components of food that are used as sources of energy. These include carbohydrates, fats, and proteins.
physical activity level (PAL) The ratio of total daily energy expenditure to basal metabolic rate (TDEE:BMR).
total daily energy expenditure (TDEE) The total energy requirements of a person over the course of an entire day.

The dynamic relationship between energy intake and expenditure has important consequences for human health, survival, and reproduction. Human energy requirements are determined by a variety of factors, including age, sex, body size, and activity levels. Energy availability, on the other hand, is strongly shaped by one's social, economic, and physical environments. Worldwide variation in nutritional health directly reflects differences in long-term energy balance. Among rural populations of the developing world, conditions of negative energy balance and undernutrition are common due to high levels of daily energy expenditure and marginal food availability. Conversely, in the industrialized world rates of obesity and chronic metabolic diseases are increasing at an alarming rate due to the abundance of dietary energy and increasingly sedentary lifestyles.

1. INTRODUCTION

Sufficient dietary energy is essential to the survival and health of all animals. From the perspective of human biology and health, energy is particularly important for a number of reasons. First, food and energy represent critical points of interaction between humans and their environment. The environments in which we live determine the range of food resources that are available and how much energy and effort are necessary to procure those resources. Indeed, the dynamic between energy intake and energy expenditure is quite different for a subsistence farmer of Latin America than it is for an urban executive living in the United States. Beyond differences in the physical environment, social, cultural, and economic variations also shape aspects of energy balance. Social and cultural norms are important for shaping food preferences, whereas differences in subsistence behavior and socioeconomic status strongly influence food availability and the effort required to obtain food.

Additionally, the balance between energy expenditure and energy acquired has important adaptive consequences for both survival and reproduction. Obtaining sufficient food energy has been an important stressor throughout human evolutionary history, and it continues to strongly shape the biology of traditional human populations.

This article examines aspects of energy expenditure and energy intake in humans. First it explores the principles of calorimetry, the methods used to measure energy expenditure in humans and other animals. The discussion then examines sources of energy in our diets, the macronutrients—carbohydrates, fats, and proteins. Next, the of the physiological basis of variation in human energy requirements is evaluated, specifically the different factors that determine how much energy a person must consume to sustain himself of herself. Finally, the discussion considers patterns of variation in energy expenditure and intake among modern human populations, highlighting the different strategies that humans use to fulfill their dietary energy needs and the health consequences associated with the increasingly sedentary lifeways of modern society.

2. CALORIMETRY

The study of energy relies on the principle of calorimetry, the measurement of heat transfer. In food and nutrition, energy is most often measured in kilocalories (kcal). One kilocalorie is the amount of heat required to raise the temperature of 1 kilogram (or 1 liter) of water, 1°C. Thus, a food item containing 150 kcal (two pieces of bread, for example) contains enough stored chemical energy to increase the temperature of 150 liters of water by 1°C. Another common unit for measuring energy is the joule or the kilojoule [1 kilojoule (kJ) = 1000 joules]. The conversion between calories and joules is 1 kcal is equal to 4.184 kilojoules.

Techniques for measuring energy expenditure involve either measuring heat loss directly (direct calorimetry) or measuring a proxy of heat loss such as oxygen consumption (O_2) or carbon dioxide (CO_2) production (indirect calorimetry). Direct calorimetry is done under controlled laboratory conditions in insulated chambers that measure changes in air temperature associated with the heat being released by a subject. Although quite accurate, direct calorimetry is not widely used because of its expense and technical difficulty.

Thus, methods of indirect calorimetry are more commonly used to quantify human energy expenditure. The most widely used of these techniques involve measuring oxygen consumption. Because the body's energy production is dependent on oxygen (aerobic respiration), O_2 consumption provides an accurate indirect way of measuring a person's energy expenditure. Every liter of O_2 consumed by the body is equivalent to energy cost of approximately 5 kcal. Consequently, by measuring O_2 use while a person is performing a particular task (for example, standing, walking, running on a treadmill), the energy cost of the task can be determined.

Figures 1 and 2 show alternative methods for measuring of oxygen consumption. Figure 1 shows the classic Douglas bag method for measuring O_2 uptake. With this technique, subjects breathe through a valve that allows them to inhale room air and exhale into a large collection bag. The volume and the O_2 and CO_2 contents of the collected air sample are then measured to determine the total amount of oxygen consumed by the subject. Recent advances in computer technology allow for the

FIGURE 1 Measurement of resting energy expenditure using the Douglas Bag method of indirect calorimetry. The subject breathes into the collection bag for a specified amount of time. The volume of the collected air sample and its oxygen and carbon dioxide content will then be measured to determine the amount of energy the subject has used.

FIGURE 2 Measurement of energy expenditure using a computerized metabolic system (Aerosport TEEM 100). As with the Douglas bag method, this system measures the volume of expired air along with its oxygen and carbon dioxide contents to determine rates of energy expenditure.

determination of O_2 consumption more quickly without directly collecting the expired air samples. Figure 2 shows an example of a computerized system for measuring oxygen consumption. As with the Douglas bag method, this system determines energy costs by measuring the volume and the O_2 and CO_2 concentrations of expired air samples.

The most recently developed method of indirect calorimetry is the doubly labeled water (DLW) technique that involves the use of stable isotopes. With the DLW method, subjects drink a small amount of water that has been enriched with isotopes of both hydrogen (^2H, deuterium) and oxygen (^{18}O). After the labeled water has been consumed, subjects then provide urine samples for the subsequent 10 to 14 days. Over this period, the concentrations of both the ^2H and ^{18}O isotopes decrease, because they are being lost in the products of aerobic respiration, H_2O and CO_2. The concentration of ^{18}O in the body decreases more rapidly than that of ^2H, because the oxygen is contained in both metabolic waste products (H_2O and CO_2), whereas hydrogen is contained in only one (H_2O). Figure 3 shows a graph of the rates of decline (washout rates) of the two isotopes over a 14-day period. The differences in the washout rates provide an accurate measurement of CO_2 production and O_2 consumption over the period of study. These estimates of CO_2 production and O_2 consumption are then converted to kilocalories to provide a measure of total energy expenditure of the subject over the entire study period.

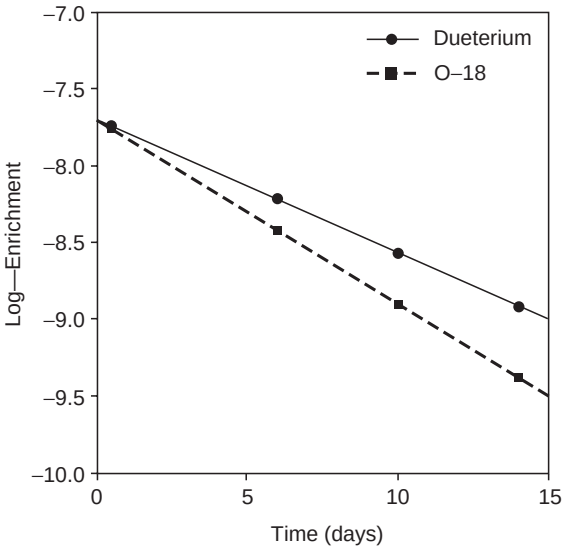

FIGURE 3 Graph showing the rates of decline (washout rates) in the two key isotopes (^{18}O and ^2H [deuterium]) used to measure daily energy expenditure in the "doubly labeled water" method. The difference in the washout rates of the two isotopes provides a measure of carbon dioxide (CO_2) production, which allows for the determination of energy expenditure.

Validation studies of the DLW method against direct calorimetry have shown that the technique is quite accurate (± 2 to 3% error for individuals). Hence, since the late 1980s, DLW has become the most accurate technique for measuring human energy expenditure in real-world (i.e., nonlaboratory) situations. The main limitations of the technique remain its expense, about $800 to $1000 per subject.

3. SOURCES OF FOOD ENERGY

The main chemical sources of energy in our foods are carbohydrates, protein, and fats. Collectively these three energy sources are known as macronutrients. Vitamins and minerals (micronutrients) are required in much smaller amounts and are important for regulating many aspects of biological function.

Carbohydrates and proteins have similar energy contents; each provides ~ 4 kilocalories of metabolic energy per gram. In contrast, fat is more calorically dense; each gram provides about 9 to 10 kilocalories. Alcohol, although not a required nutrient, also can be used as an energy source, contributing ~ 7 kcal/g. Regardless of the source, excess dietary energy can be stored by the body as glycogen (a carbohydrate) or as fat. Humans have relatively limited glycogen stores (about 375 to 475 grams), in the liver and muscles. Fat, however, represents a much large source of stored energy, accounting for approximately 13 to 20% of body weight in men and 25 to 28% in women.

3.1 Carbohydrates

The largest source of dietary energy for most humans is carbohydrates (~ 45 to 50% of calories in the typical American diet). The three types of carbohydrates are monosaccharides, disaccharides, and polysaccharides. Monosaccharides, or simple sugars, include glucose, the body's primary metabolic fuel; fructose (fruit sugar); and galactose. Disaccharides, as the name implies, are sugars formed by a combination of two monosaccharides. Sucrose (glucose and fructose), the most common disaccharide, is found in sugar, honey, and maple syrup. Lactose, the sugar found in milk, is composed of glucose and galactose. Maltose (glucose and glucose), the least common of the disaccharides, is found in malt products and germinating cereals. Polysaccharides,

or complex carbohydrates, are composed of three or more simple sugar molecules. Glycogen is the polysaccharide used for storing carbohydrates in animal tissues. In plants, the two most common polysaccharides are starch and cellulose. Starch is found in a wide variety of foods, such as grains, cereals, and breads, and provides an important source of dietary energy. In contrast, cellulose—the fibrous, structural parts of plant material—is not digestible to humans and passes through the gastrointestinal tract as fiber.

3.2 Fats

Fats provide the largest store of potential energy for biological work in the body. They are divided into three main groups: simple, compound, and derived. The simple, or neutral fats, consist primarily of triglycerides. A triglyceride consists of two component molecules: glycerol and fatty acid. Fatty acid molecules, in turn, are divided into two broad groups: saturated and unsaturated. These categories reflect the chemical bonding pattern between the carbon atoms of the fatty acid molecule. Saturated fatty acids have no double bonds between carbons, thus allowing for the maximum number of hydrogen atoms to be bound to the carbon (that is, the carbons are saturated with hydrogen atoms). In contrast, unsaturated fatty acids have one (monounsaturated) or more (polyunsaturated) double bonds. Saturated fats are abundant in animal products, whereas unsaturated fats predominate in vegetable oils.

Compound fats consist of a neutral fat in combination with some other chemical substance (for example, a sugar or a protein). Examples of compound fats include phospholipids and lipoproteins. Phospholipids are important in blood clotting and insulating nerve fibers, whereas lipoproteins are the main form of transport for fat in the bloodstream.

Derived fats are substances synthesized from simple and compound fats. The best known derived fat is cholesterol. Cholesterol is present in all human cells and may be derived from foods (exogenous) or synthesized by the body (endogenous). Cholesterol is necessary for normal development and function because it is critical for the synthesis of such hormones as estradiol, progesterone, and testosterone.

3.3 Proteins

Proteins, in addition to providing an energy source, are also critical for the growth and replacement of living tissues. They are composed of nitrogen-containing compounds known as amino acids. Of the 20 different amino acids required by the body, 9 (leucine, isoleucine, valine, lysine, threonine, methionine, phenylalanine, tryptophan, and histidine) are known as essential because they cannot be synthesized by the body and thus must be derived from food. Two others, cystine and tyrosine, are synthesized in the body from methionine and phenylalanine, respectively. The remaining amino acids are called nonessential because they can be produced by the body and need not be derived from the diet.

4. DETERMINANTS OF DAILY ENERGY NEEDS

A person's daily energy requirements are determined by several different factors. The major components of an individual's energy budget are associated with resting or basal metabolism, activity, growth, and reproduction. Basal metabolic rate (BMR) represents the minimum amount of energy necessary to keep a person alive. Basal metabolism is measured under controlled conditions while a subject is lying in a relaxed and fasted state.

In addition to basal requirements, energy is expended to perform various types of work, such as daily activities and exercise, digestion and transport of food, and regulating body temperature. The energy costs associated with food handling (that is, the thermic effect of food) make up a relatively small proportion of daily energy expenditure and are influenced by amount consumed and the composition of the diet (for example, high-protein meals elevate dietary thermogenesis). In addition, at extreme temperatures, energy must be spent to heat or cool the body. Humans (unclothed) have a thermoneutral range of 25 to 27°C (77 to 81°F). Within this temperature range, the minimum amount of metabolic energy is spent to maintain body temperature. Finally, during one's lifetime, additional energy is required for physical growth and for reproduction (for example, pregnancy, lactation).

In 1985, the World Health Organization (WHO) presented recommendations for assessing human energy requirements. The procedure used for determining energy needs involves first estimating BMR from body weight on the basis of predictive equations developed by the WHO. These equations are presented in Table I. After estimating BMR, the total daily energy expenditure (TDEE) for adults (18

TABLE I

Equations for Predicting Basal Metabolic Rate (BMR) Based on Body Weight (Wt, in Kilograms)

	BMR (kcal/day)	
Age (years)	Males	Females
0–2.9	60.9 (Wt)−54	61.0 (Wt)−51
3.0–9.9	27.7 (Wt)+495	22.5 (Wt)+499
10.0–17.9	17.5 (Wt)+651	12.2 (Wt)+746
18.0–29.9	15.3 (Wt)+679	14.7 (Wt)+496
30.0–59.9	11.6 (Wt)+879	8.7 (Wt)+829

TABLE II

Physical Activity Levels (PALs) Associated with Different Types of Occupational Work Among Adults (18 Years and Older)

	PAL			
Sex	Minimal	Light	Moderate	Heavy
Male	1.40	1.55	1.78	2.10
Female	1.40	1.56	1.64	1.82

Source. FAO/WHO/UNU (1985).

years old and older) is determined as a multiple of BMR, based on the individual's activity level. This multiplier, known as the physical activity level (PAL) index, reflects the proportion of energy above basal requirements that an individual spends over the course of a normal day. The PALs associated with different occupational work levels for adult men and women are presented in Table II. The WHO recommends that minimal daily activities such as dressing, washing, and eating are commensurate with a PAL of 1.4 for both men and women. Sedentary lifestyles (for example, office work) require PALs of 1.55 for men and 1.56 for women. At higher work levels, however, the sex differences are greater. Moderate work is associated with a PAL of 1.78 in men and 1.64 in women, whereas heavy work levels (for example, manual labor, traditional agriculture) necessitate PALs of 2.10 and 1.82 for men and women, respectively.

In addition to the costs of daily activity and work, energy costs for reproduction also must be considered. The WHO recommends an additional 285 kcal/day for women who are pregnant and an additional 500 kcal/day for those who are lactating.

TABLE III

Energy Constants and PALs Recommended for Estimating Daily Energy Requirements for Individuals Under the Age of 18 Years Old

Age (years)	Males	Females
	Energy constant (kcal/kg body weight)

17.0–17.9	1.60	1.52

Source. FAO/WHO/UNU (1985); James and Schofield (1990).

Energy requirements for children and adolescents are estimated differently because extra energy is necessary for growth and because relatively less is known about variation in their activity patterns. For children and adolescents between 10 and 18 years old, the WHO recommends the use of age- and sex-specific PALs. In contrast, energy requirements for children under 10 years old are determined by multiplying the child's weight by an age- and sex-specific constant. The reference values for boys and girls under 18 years old are presented in Table III.

5. HUMAN VARIATION IN ENERGY DYNAMICS

5.1 Energy Consumption

Compared to most other mammals, humans are able to survive and flourish eating a remarkably wide range of foods. Human diets range from completely vegetarian (as observed in many populations of South Asia) to ones based almost entirely on meat

and animal foods (for example, traditional Eskimo/Inuit populations of the Arctic). Thus, over the course of our evolutionary history, humans have developed a high degree of dietary plasticity. This ability to utilize a diverse array of plant and animal resources for food is one of the features that allowed humans to spread and colonize ecosystems all over the world.

Table IV presents information on the percentage of energy derived from plant and animal foods for subsistence-level (that is, food producing) and industrial human societies. The relative contribution of animal foods varies considerably, ranging from $<10\%$ of dietary energy in traditional farming communities of tropical South America, to more than 95% among traditionally living Inuit hunters of the Canadian Arctic.

Subsistence-level agricultural populations, as a group, have the lowest consumption of animal foods. Among hunting and gathering populations, the contribution of animal foods to the diet is variable, partly reflecting the environments in which these populations reside. For example, the !Kung San, who live in arid desert environments of southern Africa, have among the lowest levels of animal food consumption among hunter-gatherers. In contrast, hunters of the arctic rely almost entirely on animal foods for their daily energy. Foragers living in forest and grassland regions of the tropics (for example, the Ache and the Hiwi) have intermediate levels of animal consumption.

The amount of energy that humans consume also varies widely. Table V shows per capita energy consumption (kcal/person/day) for selected countries around the world. Daily energy intakes in the United States (3699 kcal) and France (3518 kcal) are more than double those found in Afghanistan (1745 kcal). Overall, individuals from industrialized countries consume about 55% more energy per day than their counterparts from the developing world (3311 versus 2140 kcal/day).

These broad worldwide differences in daily energy consumption are mirrored in differences in under- and over-nutrition. As discussed Section 5.3, under-nutrition remains a persistent problem among populations in the developing world, despite the fact that worldwide food production is sufficient to meet the energy needs of all people. In contrast, populations of the industrialized world, most

notably the United States, are now heavier and fatter than ever before. Just as there is a dramatic economic divide between rich and poor populations around the world, there is also a stark nutritional divide.

5.2 Energy Expenditure

Humans also show considerable variation in levels of energy expenditure. Recent comparative analyses indicate that daily energy expenditure in human groups typically ranges from 1.2 to 5.0 x BMR (that is, PAL = 1.2–5.0). The lowest levels of physical activity, PALs of 1.20 to 1.25, are observed among hospitalized, and nonambulatory populations. In contrast, the highest levels of physical activity (PALs of 2.5 to 5.0) have been observed among elite athletes and soldiers in combat training. Within this group, Tour de France cyclists have the highest recorded daily energy demands of 8050 kcal/day (a PAL = 4.68)!

Table VI presents data on body weight, total daily energy expenditure, and PALs of adult men and women from selected humans groups. Men of the subsistence-level populations (that is, foragers, herders, and agriculturalists) are, on average, 20 kilograms (45 pounds) lighter than their counterparts from the industrialized world and yet have similar levels of daily energy expenditure (2897 versus 2859 kcal/day). The same pattern is true for

TABLE VI

women; those from subsistence-level populations are 12.5 kilograms (~28 pounds) lighter than women of industrialized societies but have higher levels of daily energy expenditure (2227 versus 2146 kcal/day).

Thus, when we express daily energy needs relative to BMR, we find that adults living a modern lifestyle in the industrialized world have significantly lower physical activity levels than those living more traditional lives. Among men, PALs in the industrialized societies average 1.67 (range = 1.53 to 1.84), as compared to 1.90 (range = 1.58 to 2.38) among the subsistence-level groups. Physical activity levels among women average 1.63 in the industrialized world (range = 1.48 to 1.69) and 1.78 (range = 1.56 to 2.03) among the subsistence-level societies.

The differences in daily energy demands between subsistence-level and industrialized populations are further highlighted in Fig. 4, which shows daily energy expenditure (kilocalories/day) plotted relative to body weight (in kilograms). The two lines denote the best-fit regressions for both groups. These regressions show us that at the same body weight, adults of the industrialized world have daily energy needs that are 600 to 1000 kilocalories lower than those of people living in subsistence-level societies.

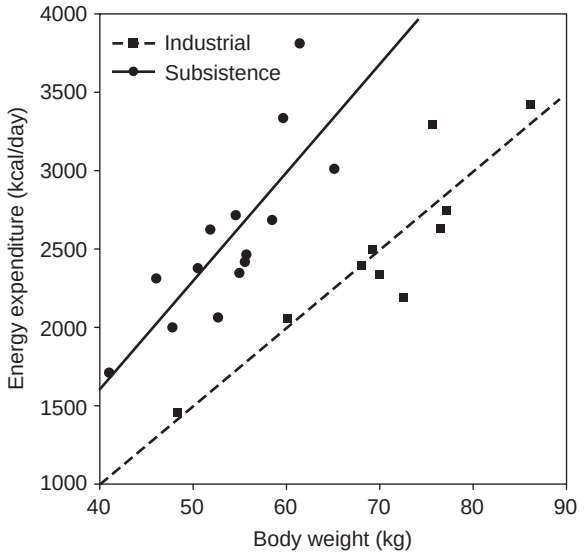

FIGURE 4 Daily energy expenditure (kcal/day) versus body weight (kg) for adult men and women of industrial and subsistence-level populations (from data presented in Table V). At a given body weight, individuals from subsistence-level groups have levels of energy expenditure that are 600 to 1000 kcal greater than those of the industrialized populations.

5.3 Energy Balance and Its Health Consequences

Ultimately, energy balance, the dynamic relationship between energy consumed and expended, is critical for determining nutritional health and well-being. In the industrialized world, low levels of physical activity coupled with relative abundance of food create a net surplus of energy, or a positive energy balance. Conversely, among rural food-producing societies of the developing world, limited energy availability and heavy workloads produce widespread under-nutrition (negative energy balance).

To assess long-term energy balance (physical nutritional status), nutritionists typically measure body weight and composition (i.e., fat and muscle). One of the most widely used measures of physical nutritional status is the body mass index (BMI). The BMI is a weight-for-height measure that is calculated as weight (in kilograms) divided by height (in meters) squared. Because the BMI is strongly correlated with levels of body fatness, it provides good long-term measure of energy balance.

Table VII shows the BMI cutoffs for different levels of nutritional health for adults (individuals 18 years and older). BMIs between 18.5 and 24.9 kg/m^2 are considered healthy because this range is associated with the lowest mortality risks. Individuals with BMIs under 18.5 kg/m^2 are considered to be underweight. Mild and moderate under-nutrition is associated with BMIs of 17.0 to 18.4 and 16.0 to 17.0 kg/m^2, respectively. BMIs of less than 16 kg/m^2 are indicative of starvation conditions (i.e., severe and acute under-nutrition). BMIs of 25 and above are indicative of over-nutrition. Individuals with BMIs between 25.0 and 29.9 kg/m^2 are considered overweight, and those with BMIs of 30.0 kg/m^2 or more are classified as obese.

In the United States, rates of obesity have increased dramatically (see Table VIII). As of 2001, 21% of the

adult American population was considered to be obese, up from ~12% in 1991. Obesity rates are particularly high in minority groups—31% in African Americans and 24% among Hispanics—linked to conditions of poverty, class, and level of education.

These rising rates of obesity in the United States are also associated with increased rates of other cardiovascular problems, including high cholesterol, high blood pressure, and diabetes. This cluster of chronic health problems is referred to as the metabolic syndrome, because all of the individual features reflect a surplus of energy.

In the developing world, under-nutrition has declined; however, it remains a persistent problem. As shown in Table IX, rates of under-nutrition (BMIs <18.5 kg/m^2) are relatively higher in Asia and Africa than in Latin America. In China and India, the levels are 12% and 49%, respectively whereas those in the Sahelian region of Africa fall between 15% and 20%. The prevalence of under-nutrition in Latin American nations is typically less than 10%. These national-level statistics can be misleading in that they mask large urban-rural differences in nutritional health. Sadly, it has generally been the impoverished rural populations of the developing world that have shown the smallest improvements in health and nutritional status.

While under-nutrition remains a severe problem in rural regions of the Third World, increasing rates of obesity are being found among urban populations of the developing world. This trend has been documented in North Africa (e.g., Morocco and Tunisia) and South America (e.g., Brazil and Chile) and is likely attributable to the Westernization of dietary habits and more sedentary lifestyles. As in the United States, diabetes and other cardiovascular diseases have increased as a consequence of the rise in obesity. It thus appears that much of developing world is now undergoing a rapid nutritional transition such that obesity and under-nutrition exist as parallel problems.

Addressing the emerging obesity epidemic in the United States and throughout the world will require changes in consumption patterns as well as broader lifestyle modifications. The wider availability of

inexpensive market foods that are high in fats and simple carbohydrates is certainly a primary cause of the obesity problem. However, the other half of energy balance equation—reduced energy expenditure associated with increasingly sedentary lifestyles—is also a critical and yet often overlooked part of the problem. Consequently, it is not surprising the most effective nutritional interventions are those that promote increased exercise and activity levels as well dietary modifications.

Glossary

collecting A hunter–gatherer strategy in which task groups move out from a residential base to harvest, process, and transport seasonal concentrations of resources for future use.

foraging A hunter–gatherer strategy for exploitation of resources in the vicinity of the residential base, to harvest and consume resources that are continuously available in low concentrations.

Holocene The period of Earth history that began 10,000 years ago, at the end of the last glacial period.

hominid A primate of the order Hominidae, which includes modern humans (*Homo sapiens sapiens*), earlier human subspecies, and their direct ancestors.

logistic mobility The pattern of spatial movements associated with collecting resources from a residential base.

megafauna Mammals, reptiles, and birds that belong to the largest size categories.

optimal foraging theory (OFT) Models of hunter–gatherer behavior that predict the selection of resources, foraging behavior within patches of resources, or the mobility of the residential base. OFT uses microeconomic theory to assess what outcome will be the most efficient for the individual or for society—for example, by maximizing energy gain.

Pleistocene A period of Earth history that began 2.5 million years ago, and characterized by repeated glacial/interglacial fluctuations in climate.

residential mobility The pattern of frequent moves of the residential base made by hunter–gatherer groups that exploit resources by foraging.

sedentism A sedentary settlement pattern, through which hunter–gatherers settle down to live in fixed locations and in more permanent dwellings.

Hunter–gatherer (HG) societies have existed in all continents, and today survive mainly in tropical forests, semidesert areas, boreal forests, the tundra, and the Arctic, all environments where agricultural colonization and other forms of displacement have not yet occurred. These societies are defined principally according to their dependence on nondomesticated resources, accessed through hunting, trapping, fishing, and gathering. In many societies, cultivation or herding coexists with the HG mode, and exchange often provides people with some items not available from local sources. Typically, these societies are small scale, egalitarian, and live at low population densities, although not in all cases. Their patterns of energy flow, including diet, labor use, mobility, and optimizing behavior, have been used as models for understanding past HG societies in areas that are now agricultural, and also to illuminate the behavior of other hominids, because HG subsistence has been dominant for about 90% of the history of *Homo sapiens sapiens* and about 99% of the time since hominids first evolved.

1. INTRODUCTION

Extrapolating data back in time from a few modern HG societies must be done cautiously. The geographical distribution of modern hunter–gatherers is highly skewed; modern groups live in environments marginal for farming or pastoralism and in places remote from colonialism, modernity, and the nation state. Because of the disappearance of megafauna,

 © 2004 Elsevier Inc. All rights reserved.

they exploit a range of resources that are much depleted compared to the Pleistocene norm. Hunter–gatherers encompass such a range of different adaptations, particularly in relation to variations in the seasonality in energy supply and variations in the spatial concentration of food energy, that generalizing from particular case studies is very hazardous. Problems in defining HG societies need first to be addressed (Section 2), before confronting this ecological diversity and achieving a meaningful classification of HG societies (Section 3). Only then is it possible to make valid generalizations about the patterns of energy flow in HG societies (Sections 4 and 5), to generate findings that might be applicable to other times and places.

2. PROBLEMS IN DEFINING HUNTING AND GATHERING

2.1 Origins of the Hunter–Gatherer Concept

The concept of "hunter–gatherer" became necessary when, in the 19th century, Western scholars began to classify the different modes of subsistence that existed in the world. Sedentary agriculturalists were distinguished from pastoralists, people primarily dependent on their herds of domesticated animals. But what of those societies whose food resources were not domesticated, who lived instead by hunting wild animals, fishing, and gathering wild plant foods? Such peoples lived in an immense range of different environments and in rather strongly contrasted societies, in places as remote from each other as African deserts, South American jungles, and the Arctic tundra. Even so, for convenience, all were put in the one category, hunter–gatherer, for reasons that perhaps were partly political. By seeing HG societies as a homogeneous category with a preagricultural and therefore "primitive" technology, it became easier to justify their displacement following the spread of European settlement and colonial expansion.

Despite its unsatisfactory origins, the HG concept became even more firmly established when the long prehistory of the genus *Homo* was demonstrated by comparison with the rather short history of plant and animal domestication. Whereas agriculture was recognized as extending no further back than the Neolithic, perhaps 6000 years ago, the origins of *Homo sapiens* lay a long way back in the Pleistocene. In 1966, a symposium was held in Chicago on the theme "Man the Hunter," at which Richard Lee and Irven DeVore claimed that "cultural man has been on earth for some 2,000,000 years, and for more than 90% of this time he has lived as a hunter–gatherer."

Although modern archaeology would not extend the origins of *H. sapiens sapiens* (anatomically modern humans) beyond about 130,000 years ago, research has also confirmed that no clear evidence exists for full-scale agriculture anywhere until well after the Holocene began 10,000 years ago. Nor is pastoralism any older; indeed, most pastoral societies postdate the formation of settled farming communities, with which they typically exchange products (e.g., cattle for grain). From various perspectives, therefore, it became important for scholars to understand more about the economies, societies, and cosmologies of these preagricultural and prepastoral HG societies, because they were now seen as representing such a large part of the human heritage. Yet we inherit many prejudices and assumptions about such societies. Prejudice in Western thought can be traced back at least to the time of Thomas Hobbes (1651), who typecast hunter–gatherers as not merely the primeval state of humanity, but people who lived lives that he famously described as "solitary, poor, nasty, brutish and short." The influence of this stereotype undoubtedly lingered until the mid-20th century, but it did so alongside another more romantic vision of hunter–gatherers. This alternative view can be traced back to John Dryden, who in 1670 depicted hunter–gatherers as living in a state of grace from which the rest of humanity had fallen, coining the equally famous phrase "the noble savage" to describe them.

The stereotypes of both Hobbes and Dryden influenced Western attitudes and policies towards HG societies during the colonial period, and were not finally dispelled until the 1960s when the results of scientific research became more widely known, including studies of the energy efficiency of hunting and gathering. Ironically, by then most HG societies were disappearing, displaced by colonial genocide and modernity or absorbed by the expansion of neighboring groups and by the nation state.

2.2 Sources of HG Food Energy

Hunter–gatherers are usually identified today by means of a "package" of traits, including economic, ecological, sociocultural, and ideological features, but of these the HG economy is the most important

characteristic. The *Cambridge Encyclopaedia of Hunters and Gatherers* offers the following definition of the HG mode: "Subsistence based on hunting of wild animals, gathering of wild plant foods, and fishing, with no domestication of plants and no domesticated animals except the dog." As well as their food energy, the fuels, fibers, and tools of hunter–gatherers also come from nondomesticated, noncultivated sources, although iron tools, pottery, and a few other items may be acquired by exchange.

In most HG societies, there are five categories of food energy procurement: (1) hunting, involving the active pursuit of mammals, reptiles, or birds; (2) trapping, which is the passive capture of prey (mammals, birds, or fish) by means of prior investments in pitfalls, traps, nets, weirs, and other technical means; (3) fishing, using a wide range of active techniques; and (4) gathering, which involves the acquisition of passive animal prey/products such as shellfish, snails, insect larvae, birds' eggs, and honey, and also plant foods of all kinds. The final category, (5) exchange with neighboring groups, should be added, in almost all modern cases, although the extent to which food energy is traded, rather than other goods, varies a lot.

The relative importance of the various sources of subsistence is highly variable between different HG societies, dependent on environmental opportunities and constraints. However, to prioritize hunting in the definition of such societies is misleading. Only in a minority of cases (for example, in the Arctic, in boreal forests, and in places where fish and sea mammals are especially abundant) do hunting, trapping, and fishing contribute more to the diet than does the gathering of plant foods. Meat is generally the preferred food in all societies, but gathered plant foods are more abundant in a majority of cases and, crucially, are more dependable. "Gatherer–hunters" might, therefore, be a more accurate term.

Other definitions of HG subsistence could be cited, but what they all have in common is the absence of direct human control over the sources of food energy on which people depend, including the reproduction, the distribution, and the abundance of the various plant and animal species. Lack of direct control in HG societies is contrasted to what agriculturalists achieve, including (1) a transformation of ecosystems using energy-intensive means and (2) a partial or total domestication of plants and animals, with either minor or major genetic changes to the various species involved.

2.3 Energy Foraging versus Energy Collecting

For understanding spatial behavior in HG societies, the archaeologist Lewis Binford made an important distinction between foraging and collecting food energy. These represent alternative strategies for solving problems of resource distribution. Foraging takes place where resources are widespread and continuously available, and where frequent residential mobility enables hunter–gatherers to move their camps to the resource they wish to use. In this way, they can forage for what they need by means of immediate return technologies and social practices. The storage of food energy is minimal in such societies, which are typical of HG societies in the semideserts and forests of tropical and midlatitudes (Fig. 1).

In contrast, logistical mobility takes place where collecting of resources is needed for future consumption. From the residential base, task groups are sent out to hunt or gather particular foods, undertake the initial processing, and return to base with a surplus that then provides a future energy store. This alternative has been called by James Woodburn a strategy of delayed return, and it is essential where periods of resource shortage can be anticipated. The northwest coast of North America, for example, was

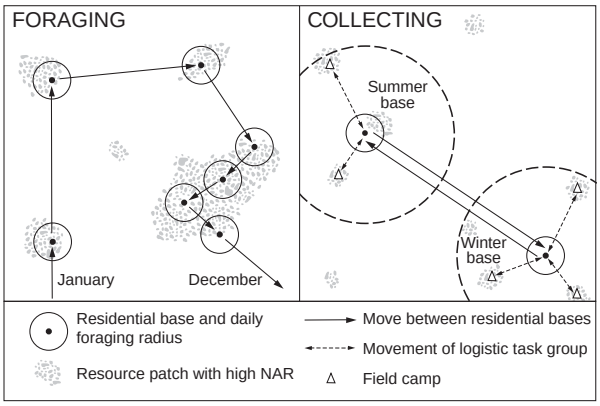

FIGURE 1 Schematic maps contrasting the foraging and the collecting strategies of hunter–gatherers. In both cases, residential bases are located in places with good access to resource patches with high net acquisition rates. A net acquisition rate (NAR) is defined as food energy output divided by work energy input, per hour of foraging/collecting activity. The residential bases of the foragers are each occupied for much shorter periods, compared to those of the collectors. In both cases, virtually no stored food energy is in the possession of the society at the end of the more difficult season of the year, but foragers consume energy on an immediate-return basis in the intervening period, whereas collectors have a delayed-return consumption pattern made possible by their logistic strategy.

an environment where salmon and waterfowl were superabundant in season, and where a single sturgeon, sea lion, or whale could provide enough food for many days or weeks of consumption. However, according to anthropologist Wayne Suttles, "abundance consisted only of certain things at certain times and always with some possibility of failure." To cope with abundance, in a situation where for some foods (e.g., salmon) more effort was needed to store the food than to collect it, complex technologies and social institutions had be developed that could guarantee delayed energy return, and so prevent the society from being destroyed by famine at the end of winter.

Most HG societies need to have a mix of foraging and collecting strategies, being residentially mobile in some seasons (e.g., summer or dry season) but in other seasons (e.g., winter or wet season) operating from fixed base camps by means of logistical mobility. A primary emphasis on delayed-return energy use seems to be associated with the emergence of more stratified ("complex") societies, such as the ranked societies of chiefs, freemen, and slaves that existed on the northwest coast of North America. Ian Hodder has argued that the ideologies associated with delayed-return HG subsistence paved the way for agriculture, but other archaeologists disagree.

Using these concepts, HG societies can be classified according to their adaptations to two critical aspects of their energy resources: (1) seasonal and year-to-year fluctuations, which control the scale of energy storage required, and (2) variations in the spatial concentration of critical resources (food, water, fuel), which permit different degrees of sedentism. The four main categories of HG society are shown in Table I, together with examples. In practice, it is rare today to find societies that depend solely on hunting, fishing, and gathering. For their subsistence, most documented communities engage in a limited amount of cultivation, herding, and/or trading, in addition to their main HG focus.

2.4 Use of Energy Subsidies

Unlike farmers, hunter–gatherers do not depend on energy subsidies (e.g., from fossil fuels), and their impact on the landscape is small-scale apart from localized fuelwood consumption. However, HG societies do exert indirect control over energy flows in the ecosystem, particularly by using fire to assist with hunting and to improve the grazing. In what is today the United States, driving game with fire was practiced almost everywhere in pre-Columbian times. Open areas of grassland found today in the apparent Yosemite wilderness are in fact the legacy of former HG hunting practices. In Australia, the use of fire by HG societies transformed vegetation over a much longer period (perhaps 50,000 years), reducing

TABLE I

A Classification of Hunter–Gatherer Societies[a]

Spatial concentration of main sources of food energy[b]	Different mobility patterns	Example: Seasonal and year-to-year fluctuations in resource abundance[c] — Low	Example: Seasonal and year-to-year fluctuations in resource abundance[c] — High
Low	Residential mobility	Inland Australian Aborigines Kalahari San (e.g., !Kung)	No examples known
Intermediate	Seasonal base camps with logistic mobility	Coastal Australian Aborigines (e.g., Gidjingali)	Sub-Arctic maritime societies (e.g., Coastal Sámi, Varanger Fjord, Norway)
		Arctic tundra (e.g., Tuluaqmiut Inuit, north Alaska)	Boreal forest hunters (e.g., Cree, northern Ontario)
		Sub-Arctic inland (e.g., Mountain Sámi, northern Sweden)	Torres Strait islanders, Australia
High	Sedentism	No examples known	Northwest Coast Indians (e.g., Kwakiutl, Salish, Chinook)

[a] Based on the extent of seasonal and year-to-year fluctuations in available food energy and the extent of spatial concentration in food energy, with ethnographic examples.

[b] Correlates with different mobility patterns.

[c] Correlates with (1) extent of capital investments in storage to safeguard future energy supplies and (2) with institutions for ownership and defense of territories.

evergreen rainforest to small patches and greatly enlarging the open woodlands dominated by *Eucalyptus*. Far from being "natural," *Eucalyptus* woodland is now interpreted as an anthropogenic fire-climax vegetation.

Some anthropologists studying hunting practices in Aboriginal Australia and among North American Indians are so impressed by the importance of fire as an indirect tool for ecosystem management that they use the phrase "firestick farming." In the savannas of northern Australia, for example, in the early part of the dry season when cool nights dampen the ground with dew, the Aborigines use small and controlled bush fires that clear away undergrowth but leave the trees undamaged. The growth of new grass in such areas attracts game and makes hunting much easier. Because the modern state has imposed a ban on firestick farming, infrequent but catastrophic and far more destructive forest fires take place.

2.5 Social Differences in Energy Use

A consequence of the low intensity of management of food energy sources by HG societies is that they live at very low population densities, often in small bands of 25–50 persons, with temporary or seasonal settlements and frequent long-distance mobility. In most respects, these societies are strongly egalitarian, with food sharing and an absence of social stratification and only weak institutions for political control. However, there is a strong gender division of labor, with males doing most of the hunting and females gathering the plant foods. Fishing and the collecting of shellfish and small game may be an activity of both sexes, and children participate in the food quest from an early age.

Hierarchy is most strongly developed in semisedentary HG societies where seasonally abundant resources make possible large-scale food energy storage, as among Northwest Coast Indians such as the Kwakiutl in British Columbia or the Chinook in Washington state. Lee and DeVore, in the classic text *Man The Hunter*, wrote "we make two basic assumptions about hunters and gatherers, (1) they live in small groups, and (2) they move around a lot." Perhaps these "simple," residentially mobile HG societies have always coexisted with more sedentary, more complex, and more hierarchical ones.

As regards their attitudes to energy consumption, these are not societies in which maximizing energy flow finds ideological support. Far more important is maximizing the security of energy supplies, simultaneously minimizing the energy expended in work so that more time is spent enjoying leisure and strengthening social bonds with others—itself, arguably, a useful risk-minimizing strategy.

3. PROBLEMS IN GENERALIZING FROM MODERN HG SOCIETIES

3.1 Can We Extrapolate from HG Societies to Hominids?

There has been much interest in the possibility that studies of energy flow in HG societies can be used to achieve an understanding of our hominid ancestors. As Robert Foley put it, "until very recently being a hominid, being a human and being a hunter–gatherer were very nearly the same thing." Do studies of the energetic efficiency of food-gaining among the !Kung San of the Kalahari, or the energy storage strategies of sub-Arctic maritime hunting/fishing communities, have general implications for the behavior of humans or hominids who are remote from these societies in time and space? Perhaps it is the intentionality of the human subject that distinguishes his or her behavior from the superficially similar food quest of the nonhuman HG groups, as well as the human capacity for a symbolic expression of hunting experiences, as shown in the cave art of the Upper Palaeolithic and the shamanism of modern HG groups.

Remember also that modern HG groups exploit a depleted set of resources compared to their Pleistocene ancestors, because of megafaunal extinctions. The capacity clearly existed in the past for rapid population growth and a relationship with nature that is far removed from the stable and rather harmonious one that HG societies have exhibited in modern times. Moreover, these societies are not a random sample of those that existed on Earth before the spread of agriculture. Not only are they restricted to environments less suited ecologically to agriculture or pastoralism, but also they are no longer "pure" in their HG lifestyle, interacting with farmers or herdsmen when opportunity arises.

3.2 The Skewed Distribution of HG Societies Today

Using ethnographic sources, we can map the distribution of 115 HG societies that existed in the 20th century (Fig. 2). Based on the environments they occupy, five groups can be distinguished:

FIGURE 2 Map of 115 hunter–gatherer societies that were ethnographically documented in the 19th and 20th centuries.

- Hot deserts and tropical savannas (19 societies).
- Tropical rain forests and coral reefs (30 societies).
- Boreal forest and tundra zone (38 societies).
- Cool temperate maritime regions (13 societies).
- Other environments (15 societies).

It is apparent that in modern times HG societies have been absent from almost all environments that are prime farming land. Therefore, those that still survive are a very biased sample of the HG mode of the past. The temperate deciduous forests, for example, have not been the domain of hunter–gatherers in Europe since the Neolithic 5000–6000 years ago. In eastern North America and Chile, such forests were used for a mixed HG/agricultural strategy before being taken over by European colonists some 400 years ago; the same process removed Aboriginal HG societies from the temperate forests of Tasmania in the 19th century. While being careful not to label the environments of modern HG societies as necessarily "marginal," which they are not except from the point of view of agriculture, we should also bear in mind the predominance of hot deserts, jungles, and seasonally frozen environments in the world list.

4. ENERGY FLOW IN CONTRASTING HG ENVIRONMENTS

4.1 Managing the Daily Risks of Energy Shortage

4.1.1 General Principles

In some societies, it might make sense to understand behavior in terms of profit or surplus (i.e., maximizing energy output), but most anthropologists now believe that for HG societies maximizing security (i.e., minimizing risk) makes more sense. Security is increased when the risks of food shortage are successfully managed. From her studies of the San in southern Africa, Polly Wiessner identified four general ways in which risk is reduced: (1) prevention of energy deficit, (2) transfer of deficit, (3) pooling of resources, and (4) storage strategies. To prevent deficits on a daily basis, hunter–gatherers need appropriate tools for killing prey or gathering plants; expert knowledge of the probabilities of success and how it can be achieved; and intragroup cooperation in tracking, processing, and transporting foods. The transfer of deficit is achieved by sharing within the

group and by exchange relationships, whereas the pooling of resources is another social strategy that provides for an individual some insurance against failure in food energy acquisition.

Storage strategies for food and water are also potentially useful, but except in the short term these are difficult to achieve in hot and humid climates. Fuel storage is essential only for HG societies coping with extreme winter conditions. Unless food storage can be achieved effectively, for the hunter or gatherer to maximize short-term gain by producing as much energy as possible is not a sensible strategy. Where energy storage is problematic, the social strategies of sharing, cooperation, and exchange are more effective, but all require some form of investment. Investing in friendships and exchange, activities that require leisure time, might prove to be a better strategy for risk reduction, compared to killing more and more animals.

4.1.2 Example: Anbarra Gidjingali Aborigines

The ways in which risk and productivity can interact are well demonstrated by the example of the Anbarra, a subgroup of about 40 people that are part of the Gidjingali (population 350) of Arnhem Land, northern Australia. The economy of the Anbarra was studied by Rhys Jones and Betty Meehan at a time (early 1970s) when a large part of the Anbarra diet still derived from HG resources. Anbarra territory is at the mouth of the Blyth river, in the subhumid tropical savanna zone. There is seasonal access to the rich resources of open woodlands, grassy plains, freshwater swamps and lagoons, sand dunes, and mangroves, as well as the open sea, using a semisedentary pattern of settlement. In the wet season, people live by the coast and depend largely on fish and shellfish. Later in the year, they range inland to take advantage of cycad fruits, wild yams, and small game, and they move further inland across the grassy plains for wallaby hunting in the latter part of the dry season. The seasonal availability of foods is one obvious constraint over their pattern of energy consumption.

Another important factor, however, is the probability of success in the food-gaining quest. There is an inverse relationship between the productivity of labor and the probability of a successful trip. Activities such as wallaby hunting provide on average a high yield of food energy per unit of time invested, but are also the most risky activities, with a 75% chance of complete failure of a hunting trip. At the other end of the spectrum are plant-gathering activities, for which success is virtually guaranteed but the returns to labor are considerably less attractive. The Anbarra's overall strategy is to combine high-yield, high-risk activities (e.g., wallaby hunting or spear fishing) with low-yield, low-risk tasks (e.g., collecting shellfish and gathering of plant foods such as yams and cycads). Table II shows data for risk and yield for four of the major Anbarra food resources.

A viable long-term strategy for energy acquisition therefore requires a blend of different activities. Hunting is men's work, and to ensure against their failure the women must engage in less rewarding but more secure tasks such as gathering cycads and other plants and collecting shellfish. In this way, Anbarra

TABLE II

The Trade-off between Productivity and Risk in Northern Australia[a]

Hunter–gatherer activity	Sex of persons involved[b]	Gross acquisition rate (MJ)[c]	Risk[d]	Importance[e]
Buffalo hunting	M	8400	0.001	8
Wallaby hunting	M	210	0.25	7
Fishing with spear	M	146	0.4	3
Trapping fish	M	146	0.55	5
Fishing with hook and line	M and F	25	0.65	1
Cycad gathering and processing	F	5.4	1.0	6
Yam gathering	F	5.0	0.9	4
Shellfish gathering	F	4.2	0.9	2

[a] The gross acquisition rate for various Anbarra activities during successful trips, compared to the probability of success per attempted trip. Calculations based on 1972–1973 data from Jones (1981).

[b] M, Male; F, female.

[c] Megajoules of food energy per person-hour on a successful trip.

[d] Probability of success per attempted trip.

[e] Ranked according to percentage of days in the year when the activity was attempted.

society maximizes utility in terms of risk avoidance, secures a balanced diet, and maintains social solidarity and mutual aid between the sexes.

4.2 Managing the Energy Cost of Mobility

4.2.1 General Principles

Rather than managing plants and animals to achieve a spatially focused concentration of food energy, which is the strategy of agriculturalists and pastoralists, hunter–gatherers must depend on the natural distribution patterns in time and space of the resources on which they depend. In circumstances in which there is a natural concentration of resources in time and space, sedentism is encouraged, so that people and their possessions do not have to keep shifting from place to place. Even if temporary, sedentism is likely to be attractive to HG societies for many reasons: (1) it confers many social benefits; (2) it allows long-term storage of food energy to be an option, thereby increasing future security; (3) it reduces the direct energy expenditures involved in walking, carrying infants, and transporting possessions from one residential base to another; and (4) it reduces the indirect costs of high mobility, such as higher infant mortality, less equipment, and smaller energy stores, if all food must be carried. However, unless food energy sources are spatially concentrated, sedentism also reduces the accessible territory to a local area, which is soon likely to become overexploited. In arid areas, water may also become scarce. The HG lifestyle can be seen as the outcome of a perpetual compromise between the various costs of mobility (many of them measurable as energy costs) and the costs of sedentism. The disadvantages of sedentism will become energy costs once carrying capacity is exceeded, because when hunting yields decline and other resources are depleted, labor productivity will fall. As a result, people must work for longer periods, and/or journey times from home base to food source must increase, so as to compensate.

4.2.2 Example: The Dobe!Kung

The Dobe subgroup of the !Kung San were studied by Richard Lee in the 1960s, and provide an example of these interacting constraints. For the Dobe, water is the overriding factor that dictates the location of camps. The camp serves as the home base for 30–40 people, who move out each morning in groups of 2 or 3 to collect plant foods (especially mongongo nuts) or hunt game. All groups must return before evening if they wish to share the common meal. After moving to a new camp, the food resources of the local area (defined by the Dobe as the area within a 2-hour hike) are exploited first. By fanning out in all directions and moving at about 5 km/hour with pauses for rest and work, an area within a 10-km radius can be worked in the space of a 6-hour day.

Once the low-productivity/low-risk resources within this local area have been depleted (i.e., the plant foods and easily collected small game), it is more efficient for the group to move to a new camp than it is for people to spend more and more time walking. A division of labor becomes evident, with younger, more active people making longer trips to mongongo woodlands and the older people and children staying close to the camp and searching for less desirable foods. Any who are not prepared to walk further for the staple mongongo must eat foods such as bitter melons, roots, acacia gum, and the heart of the ivory palm. Richard Lee showed that for mongongo nut foraging, the round-trip distance was the best measurement of the time and energy "cost" of obtaining this desirable food. Camps are moved quite frequently (five or six times in the year), but never very far. A rainy season camp in the mongongo woodland is seldom more than 16–20 km from the previous one, but this is sufficient to shift the spatial focus of exploitation to a new and almost unexploited area.

A 10-km radius is a relatively small territory for hunting the larger game animals, which can move over long distances. Potentially, Dobe hunters must be more mobile than the gatherers and small-game hunters, and the Dobe hunters do sometimes range up to 30 km from a home base using overnight stops, in pursuit of high-yield but high-risk game. However, to do so involves the carrying of much equipment, including water, and the return journey with an animal carcass can be equally arduous. Even for these hunters it is generally more energy efficient to focus on those game available within a 10-km radius.

4.2.3 The Original Affluent Society?

For HG groups, any risk of subsistence crisis will be reduced where (1) food energy derives from a diverse set plant and animals and (2) aggregate food resources are continuously available during the year, even if certain foods are more abundant in certain seasons. If a preferred food such as meat is temporarily scarce, then, through more intensive efforts and high spatial mobility, other less desirable foods (e.g., edible plants) can usually be accessed elsewhere. As a result of these strategies, basic

supplies of food energy can be secured throughout the year, and what is produced is almost immediately shared and consumed.

Both the Anbarra Gidjingali (Section 4.1.2) and the Dobe!Kung San (Section 4.2.2) are examples of HG societies that can exploit such circumstances, but with somewhat different mobility patterns. Dobe campsites must be moved frequently, whereas the Anbarra can be semisedentary, with long-term seasonal residence at the boundary between land and estuary. But even in their arid "desert wasteland" (judged from an agropastoralist standpoint), the Dobe!Kung strategy can be judged as highly efficient in maximizing leisure time. According to Lee's data, they devoted only 12–19 hours per week to food-gaining "work" to achieve a state of subsistence energy balance (nobody hungry, but no storage). The surprisingly low level of energy input resulted in the San (and, by extension, all HG societies) being characterized by Marshall Sahlins as "the original affluent society." Agriculturalists, by contrast, usually have to work harder, enjoy less adequate diets, and sometime suffer harvest failure.

In this situation, there is no urgent reason for an HG society to produce a food surplus even if circumstances permit, and there is also little incentive to invest in techniques for food storage. Such "hand-to-mouth" strategies characterize the relatively non-seasonal environments of tropical forests, midlatitude deserts, and productive high-latitude coasts such as the Aleutian islands, Tierra del Fuego, and Tasmania. HG societies that occupy such environments share a number of features in common. Robin Torrence has demonstrated that the technologies employed by such societies involve relatively few types of tools. Hunting focuses on the most rewarding methods of securing prey, and gathering is equally focused on plant foods with the highest returns per unit of gathering effort. New tools and new techniques are added to the HG repertoire in order to reduce the probability of failure, but this only tends to happen in more uncertain environments where the costs of concentrating efforts on only the "best" (i.e., most rewarding) food sources can be very high.

4.3 Coping with Extreme Seasonality in Energy Resources

4.3.1 General Principles

Higher levels of risk are typical of more seasonally fluctuating environments, especially where winter conditions of darkness and extreme cold make hunting difficult and the option of constant mobility becomes extremely arduous. Midwinter sedentism is virtually obligatory in sub-Arctic and Arctic environments, where food storage is not so technically difficult (stored food will not spoil in the freezing conditions), but where substantial quantities of food energy must be amassed if the group's winter survival is to be safeguarded. HG societies in such environments typically invest much energy in strategies that enable them to cope with extreme seasonality—in particular, mass harvesting and mass storage.

4.3.2 Mass Harvesting

To exploit seasonal gluts of animal food requires first an efficient technology and social organization, so that by a concentration of effort a huge surplus of food energy can be amassed. Hunting wild reindeer/caribou, for example, requires leadership, communal effort, and the creation of decoys, barriers, and pitfall traps covering extensive areas, so that many animals can be killed during the window of opportunity that opens up during the brief period of migration in the fall. At Rondane in central Norway, wild reindeer were hunted on a large scale during the period 1000–1200 AD. On the high plateaus, large trapping systems were designed using 3-km lines of wooden stakes to guide the animals into a steep gully, where they could be slaughtered in a funnel-shaped corral. Ørnulf Vorren has found and mapped the remains of 1700 stakes, each supported on a cairn of stones and requiring timber to be transported from pine forests located at least 10 km away. It was obviously hard work to set up and to maintain this system, and the hunt needed the coordinated efforts of many people, but the reward was a large stockpile of meat and furs. When the snows came, this stockpile could be transported to winter base camps on sledges, using tame reindeer as draft animals.

4.3.3 Mass Storage

The limits to energy storage capacity have often been set less by people's capacity to collect food than by their capacity to store it. For HG groups to take advantage of seasonal runs of fish, for example, they require large investments in weirs, nets, and traps, and these must be in place before harvesting begins. Equally important, however, are the investments in processing, transport, and secure storage of such foods. For groups such as the Chinook, Salish, or Kwakiutl, which occupy the big rivers of the northwest coast of North America, a heavy fall run of

salmon represented a crisis of abundance. How much food could be stored depended mainly on the number of hands available for the work of cutting and skewering the fish, how many drying racks had been prepared in houses, the availability of fuel for smoke, and the number of containers available. Preserving food was largely women's work, and the key role of women was reflected in contested rights over them, high bride prices, and the institution of slavery.

Not all fish keep equally well, and many salmon species cannot be preserved for the winter simply by drying. On the Columbia River, for example, the Chinook dried the filleted salmon and then pulverized it with berries. Tons of this preserved food was then stored in wooden boxes sealed with oil rendered from sea mammal fat. On the Great Plains, buffalo meat was prepared in a similar way with berries and grease to make pemmican, which, if made properly, could be stored for years, although most was consumed within a single year.

Techniques to preserve food energy, such as salting, drying, and smoking, all represent major investments. Like the technology of mass harvesting, these storage technologies represent forms both of stored energy and of social capital to provide the reserves without which winter survival would be impossible. A consequence of the investments in traps and storage is that a form of property is created by the group or individual responsible, and this property and the territories that serve as catchments (pastures, bays, rivers) may also be defended by groups against outsiders. In such circumstances, too, a more stratified and hierarchical HG society tends to emerge.

4.3.4 Example of Mass Harvesting/Storage: The Varanger Sámi

The Coastal Sámi of Varanger fjord in north Norway are today largely assimilated into the modern society and economy of Norway. They are farmers, commercial fishermen, and reindeer herders rather than hunters and gatherers. In the past, however, this large, treeless Arctic fjord, with its hinterland of stunted birch forests and mountain tundra, was the site of one of Europe's last hunter–gatherer societies. Their seasonal pattern of resource use has been reconstructed by the archaeologist Knut Odner (Fig. 3).

Until the 1700s, the main basis for both subsistence and lifestyle was fishing (cod, coalfish, and haddock), hunting wild reindeer, and hunting whales and seals. All of these foods could be plentiful in season, and a range of minor foods such as seabirds and their eggs, grouse, hare, and freshwater salmon

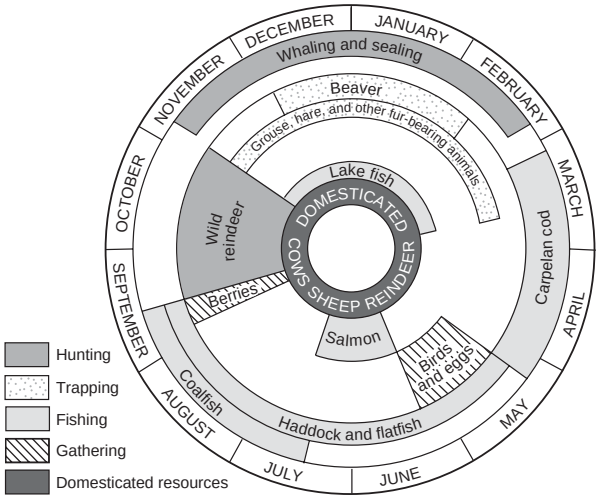

FIGURE 3 Seasonality of the food energy sources available the Varanger Sámi before circa 1700, as reconstructed by Knut Odner.

was also available for brief periods. The problem was to devise effective delayed-return strategies to enable the society to cope with fluctuations, particularly the very sparse resources available in the late-winter season, after the end of whaling and sealing in mid-February and before the arrival of shoals of cod at the end of March.

Of all the various resources, sea fishing for resident species was the most dependable year-round source of energy (low productivity but low risk). Migratory shoals also made possible a storable surplus, particularly the spring cod. On average, a fisherman could expect in one day to land about 100 kg of cod, and he could maintain this level of productivity for about 10 weeks. Each family might therefore expect to be able to dry about 7000 kg of fish in the season. Drying racks, women's labor, and access to boats, fish hooks, and lines were all essential for success. In an environment where fuel energy was scarce, air drying was the main preserving technique in spring, until warmer summer weather caused the fish to become fly-blown.

Until the wild reindeer became extinct, the Varanger Sámi employed various techniques for mass harvesting during their fall migration. The most effective were systems of fences and corrals using stones or poles stuck in the ground, and also lines of pitfalls. The remains of about 5000 hunting pits can be seen around Varanger fjord today. Probably all families contributed hunters to the task group, and the carcasses would have been equally divided. The frozen meat and the skins provided a source of food and clothing for the community in the winter months.

By 1700, growing trade and reindeer domestication made possible an increased sedentism, the animals playing a crucial role in transporting meat and fuel energy from the hinterland. A more sedentary lifestyle in turn made it possible for cattle and sheep to be kept on a small scale, despite the high energy costs that foddering and housing them entailed. The animals and their wool, milk, and cheese made a small but critical contribution to the seasonal energy gap that existed in the late winter, especially after the disappearance of wild reindeer as a significant resource. In these ways, the dependence of the Varanger Sámi on HG energy sources diminished, as they diversified to become semi-agropastoralists.

5. ENERGY FLOW AND OPTIMAL FORAGING THEORY

5.1 Resource Selection
